ISBN 978-1-955917-76-6

Organizing Committee

General Chair

Dan Roth, University of Pennsylvania and AWS AI Labs

Program Chairs

Marine Carpuat, University of Maryland
Marie-Catherine de Marneffe, Ohio State University
Ivan Vladimir Meza Ruiz, National Autonomous University of Mexico

Local Arrangements

Priscilla Rasmussen, ACL
Jennifer Rachford, ACL

Industry Track Chairs

Rashmi Gangadharaiah, Amazon
Anastassia Loukina, Grammarly
Bonan Min, Raytheon BBN Technologies

Advisors for the Industry Track

Owen Rambow, Stony Brook University
Yunyao Li, IBM Research

Tutorial Chairs

Cecilia Alm, Rochester Institute of Technology
Miguel Ballesteros, Amazon
Yulia Tsvetkov, University of Washington

Demonstration Chairs

Hannaneh Hajishirzi, University of Washington
Qiang Ning, Amazon
Avi Sil, IBM Research

Workshops Chairs

Dan Goldwasser, Purdue University
Yunyao Li, IBM Research
Ashish Sabharwal, Allen Institute for AI

Student Research Workshop Chairs

Daphne Ippolito, University of Pennsylvania

Liunian Harold Li, University of California Los Angeles
Maria Leonor Pacheco, Purdue University

Advisors for the Student Research Workshop

Danqi Chen, Princeton University
Nianwen Xue, Brandeis University

Publication Chairs

Ryan Cotterell, ETH Zürich
Danilo Croce, Tor Vergata University of Rome
Jordan Zhang,

Ethics Chairs

Kai-Wei Chang, University of California Los Angeles
Diyi Yang, Georgia Institute of Technology
Dirk Hovy, Bocconi University

Reproducibility Chairs

Niranjan Balasubramanian, Stony Brook University
Jesse Dodge, Allen Institute for AI
Annie Louis, Google
Daniel Deutsch, University of Pennsylvania
Yash Kumar Lal, Stony Brook University

Sponsorship Chair

Byron Wallace, Northeastern University

Diversity and Inclusion Chairs

Diana Galván, Tohoku University
Snigdha Chaturvedi, University of North Carolina Chapel Hill
Yonatan Bisk, Carnegie Mellon University

Advisory for the Diversity and Inclusion Committees

Pranav A, Dayta AI
Luciana Benotti, National University of Córdoba

Volunteers Chair

Daniel Khashabi, Allen Institute for AI

Publicity Chairs

Nanyun (Violet) Peng, Microsoft Research
Emily Sheng, University of North Carolina Chapel Hill

Sameer Singh, University of California Irvine

Virtual Infrastructure Chair

Deepak Ramachandran, Google
Martín Villalba, Saarland University
Rishita Anubhai, Amazon

Website Chairs

Ice Pasupat, Google
Vered Shwartz, University of British Columbia

Program Committee

Computational Social Science and Cultural Analytics

Svitlana Volkova, Pacific Northwest National Laboratory
David Bamman, University of California Berkeley

Dialogue and Interactive systems

Michel Galley, Microsoft
Kallirroi Georgila, University of Southern California
Nina Dethlefs, University of Hull
Heriberto Cuayáhuitl, University of Lincoln

Discourse and Pragmatics

Viviane Moreira, Universidade Federal do Rio Grande do Sul
Nafise Moosavi, University of Sheffield

Ethics Bias and Fairness

Vinodkumar Prabhakaran, Google
Svetlana Kiritchenko, National Research Council Canada

Efficient methods in NLP

Alexandra Luccioni, Hugging Face
Roy Schwartz, Hebrew University Hebrew University of Jerusalem

Language Generation

Michael White, Ohio State University
Snigdha Chaturvedi, Department of Computer Science University of North Carolina Chapel Hill
Shashi Narayan, Google

Information Extraction

Muhao Chen, University of Southern California
Timothy Miller, Harvard University
Deepak Ramachandran, Google
Ruihong Huang, Texas A&M University

Information Retrieval and Text Mining

Sophia Ananiadou, University of Manchester
Luca Soldaini, Allen Institute for Artificial Intelligence

Interpretability and Analysis of Models for NLP

Sebastian Gehrmann, Google Research
Sameer Singh, University of California Irvine

Language Grounding to Vision Robotics and Beyond

Parisa Kordjamshidi, Michigan State University
Peter Anderson, Google

Language Resources and Evaluation

Annemarie Friedrich, Bosch Center for Artificial Intelligence
Sebastian Schuster, New York University
Pradeep Dasigi, Allen Institute for Artificial Intelligence

Linguistic Theories Cognitive Modeling and Psycholinguistics

Allyson Ettinger, University of Chicago
Raquel Fernández, University of Amsterdam

Machine Learning for NLP - Classification and Structured Prediction Models

He He, New York University
Wei Xu, Georgia Institute of Technology

Machine Learning for NLP - Language Modeling and Sequence to Sequence Models

Colin Raffel, Hugging Face
Miguel Ballesteros, Amazon

Machine Translation

Kevin Duh, Johns Hopkins University
Gholamreza Haffari, Monash University
Rachel Bawden, Inria

Multilinguality

Dan Garrette, Google Research
Avirup Sil, International Business Machines

NLP Applications

Vukosi Marivate, University of Pretoria
Helena Gomez Adorno, Instituto de Investigaciones en Matemáticas Aplicadas y en Sistemas - UNAM
Wei Lu, Singapore University of Technology and Design
Dan Goldwasser, Purdue University

Phonology Morphology and Word Segmentation

Micha Elsner, Ohio State University
Reut Tsarfaty, Bar-Ilan University Technion

Question Answering

Mihaela Bornea, IBM International Business Machines
Jordan Boyd-Graber, University of Maryland College Park
Siva Reddy, Mila McGill University

Semantics - Lexical Semantics

Adina Williams, Facebook AI Research (Meta Platforms Inc.)
Mohammad Taher Pilehvar, Tehran Institute for Advanced Studies

Semantics - Sentence-level Semantics and Textual Inference

Xiaodan Zhu, Queen’s University
Eduardo Blanco, Arizona State University
Rachel Rudinger, University of Maryland College Park

Sentiment Analysis and Stylistic Analysis

Davide Buscaldi, Ecole polytechnique
Sara Rosenthal, International Business Machines

Speech

Adam Stiff, Infoscitex Corporation
Rolando Coto Solano, Dartmouth College

Summarization

Greg Durrett, University of Texas Austin
Jackie Cheung, Microsoft

Syntax - Tagging Chunking and Parsing

Marie Candito, Université de Paris
Lilja Øvrelid, Dept. of Informatics University of Oslo

Special Theme

Jeffrey Bigham, Carnegie Mellon University

PubHealthTab: A Public Health Table-based Dataset for Evidence-based Fact Checking

Mubashara Akhtar, Oana Cocarascu and **Elena Simperl**
Department of Informatics, King's College London
`{mubashara.akhtar,oana.cocarascu,elena.simperl}@kcl.ac.uk`

Abstract

Inspired by human fact checkers, who use different types of evidence (e.g. tables, images, audio) in addition to text, several datasets with tabular evidence data have been released in recent years. Whilst the datasets encourage research on table fact-checking, they rely on information from restricted data sources, such as Wikipedia for creating claims and extracting evidence data, making the fact-checking process different from the real-world process used by fact checkers. In this paper, we introduce *PubHealthTab*, a table fact-checking dataset based on real-world public health claims and noisy evidence tables from sources similar to those used by real fact checkers. We outline our approach for collecting evidence data from various websites and present an in-depth analysis of our dataset. Finally, we evaluate state-of-the-art table representation and pre-trained models fine-tuned on our dataset, achieving an overall F_1 score of 0.73.

1 Introduction

Fact-checking is the task of establishing the veracity of factual information, commonly performed manually by journalists. In addition to classifying how truthful claims are, human fact checkers also provide evidence for their judgements. To support this process with computational tools, researchers have compiled several datasets for evidence-based automated fact-checking (AFC), which include information about the sources supporting or refuting the claims alongside veracity labels (Thorne et al., 2018; Chen et al., 2020b; Aly et al., 2021; Schuster et al., 2021; Nørregaard and Derczynski, 2021).

While a large share of the datasets used in evidence-based AFC focus on textual evidence (e.g. (Thorne et al., 2018; Augenstein et al., 2019; Diggelmann et al., 2020; Schuster et al., 2021)), some recent datasets also cover structured data, for instance in the form of web tables (Chen et al., 2020b; Aly et al., 2021). This is useful, as human fact checkers often need to consider a range of data modalities to verify claims. However, two main limitations remain. First, existing table fact-checking datasets consist largely of claims which have been 'artificially' created via online crowdsourcing, starting from randomly selected evidence tables. Second, the datasets use single sources of evidence, for instance Wikipedia; this is different from how human fact checkers go about the task - more often than not, they consult multiple primary sources, including websites, databases, and public reports.

To overcome these limitations, we propose *PubHealthTab*[1], a new table fact-checking dataset, using the *PubHealth* dataset (Kotonya and Toni, 2020) as a seed. PubHealth has a number of advantages. It contains public health claims that human fact-checkers work on. The authors compared the complexity of these claims to real-world political claims, as well as to claims created by crowdworkers (Kotonya and Toni, 2020). As a proxy for complexity, they determined the reading skills needed to understand the claims. They established that public health claims are much more challenging, requiring high school levels of reading of 10 to 12 rather than 6 to 8 for political and crowdsourced claims. PubHealth also includes multiple sources of evidence for the claims, however, the evidence is purely text-based. In our dataset, we include web tables as evidence, extracted from different websites, similar to those used by human fact-checkers.

We designed a hybrid dataset pipeline, which takes PubHealth claims and links them, via Wikipedia articles, to other websites containing potential evidence tables. We used crowdsourcing in three ways: to establish the relevance of the extracted tables; to adjust PubHealth claims to support or refute the tables; and finally to assess the

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1 - 16
July 10-15, 2022

quality of the new claims. The result is a dataset of $1,942$ claim-table pairs about public health, drawing on evidence from more than 300 websites.

We analysed the dataset to spot potential biases in the way we collected the data and compared PubHealthTab with other table-based fact-checking datasets. Moreover, we experimented with several BERT-based models and table representations to understand how our dataset performs on state-of-the-art AFC, achieving an overall F_1 score of 0.73. Both allowed us to identify areas of future improvement, in particular to refute claims against evidence consisting of mostly numerical data or with noisy text headers.

2 Background & Related Work

2.1 Evidence-based Fact-Checking

Evidence-based AFC requires one to predict a veracity label against the evidence. While most datasets focus on textual sources of evidence (Thorne et al., 2018; Jiang et al., 2020; Diggelmann et al., 2020; Schuster et al., 2021), human fact checkers use a wider range of modalities (Nakov et al., 2021). To verify factual information, they commonly ask experts, search in databases, and consult text, tables, and graphics from a multitude of sources, including scholarly literature, public reports, and official statistics.[2]

2.2 Table Fact-Checking Datasets

There is a small number of datasets that consider tables in AFC. However, in all cases, the claims are created by crowdworkers given evidence from Wikipedia. For instance, TabFact (Chen et al., 2020b) contains tables extracted from Wikipedia and considers two classes for the claim veracity: entailment and contradiction. The InfoTabs dataset (Gupta et al., 2020) has claims that can be verified using information from Wikipedia info-boxes, with an additional "neutral" class. In FEVEROUS (Aly et al., 2021), claims are verified using text, tables, and lists from Wikipedia. Finally, the recent Sem-Eval fact-checking challenge, Sem-Tab-Facts (Wang et al., 2021), released a table fact-checking dataset with tables extracted from scientific articles. Claims were created by crowd workers based on sentences in the article describing these tables.

2.3 Tables in Other NLP Tasks

There is an increasing body of literature looking at tables alongside text for NLP tasks such as table question answering (tableQA) or table-to-text natural language generation (NLG). The former aims to find answers to natural language questions in tabular data (Pasupat and Liang, 2015; Zhong et al., 2017; Iyyer et al., 2017) and inspired the first table fact-checking dataset (Chen et al., 2020b). Researchers later introduced variations of the task with additional modalities (Chen et al., 2020c; Hannan et al., 2020) or sub-tasks such as table retrieval (Chen et al., 2021). There are also several table-to-text NLG datasets, for instance numericNLG (Suadaa et al., 2021) with tables extracted from scientific papers, and LogicNLG (Chen et al., 2020a) with Wikipedia tables. We used some of the methods proposed by the numericNLG team (Suadaa et al., 2021) to represent tables in our experiments.

2.4 The PubHealth Dataset

As noted earlier, we used PubHealth (Kotonya and Toni, 2020) as a starting point for creating our table fact-checking dataset. PubHealth consists of real-world claims about public health extracted from fact-checking and news review websites. The authors comment that the majority of fact-checking datasets either concentrate on politics (Wang, 2017; Augenstein et al., 2019) or are built for research purposes (Thorne et al., 2018; Chen et al., 2020b). Each record in the PubHealth dataset consists of a claim, the full text of the fact-checking or news article, which discusses its veracity, and the article summary or a justification for the veracity label.

3 The PubHealthTab Dataset

Figure 1 shows an overview of the data construction pipeline. In the top half, we automatically create pairs of claims and tables. We start from the PubHealth claims, assess them for relevance and then match the remaining ones with web tables (see Section 3.1). In the bottom half, we use crowdsourcing to filter tables, adjust claims to tables, and check for quality (see Section 3.1.2).

3.1 Dataset Construction

3.1.1 Steps 1 to 3: From Claims to Tables

In Step 1 we removed ambiguous and out-of-domain claims from the PubHealth dataset using a

---

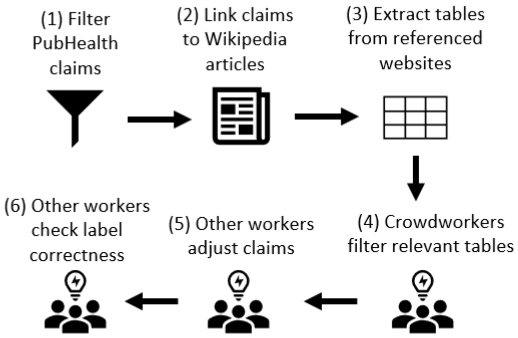

Figure 1: Dataset creation process.

lexicon of 4132 medical terms from: Wikipedia;[3] medical dictionaries from Harvard University,[4] University of Michigan[5], and Schulich School of Medicine and Dentistry[6]; as well as the ConceptNet knowledge graph.[7] We retained the claims that contained at least one token matching the lexicons. For the other claims, we carried out NER to detect medical entities that the lexicons might have missed, using SciSpacy (Neumann et al., 2019). We kept the claims for which we could find an entity in the claim text whose ConceptNet node was liked to a lexicon term via the "hasContext" relation.[8]

In Step 2 we linked the claims from Step 1 to Wikipedia articles using two entity linking services: ELQ (Li et al., 2020) and WAT,[9] for better coverage. We then took the websites referenced by the articles as a source of evidence tables. In Step 3, from all Wikipedia references, we kept those in English that could be scraped and which contained at least one table HTML tag ($\langle table \rangle$). We heuristically removed all tables that were used purely for formatting reasons, and then ranked the remaining tables based on their BM25 similarity to the claim text. The result of this step was a set of 1915 claim-table pairs (1010 claims and 1422 tables from 1196 websites), which was fed to the crowdsourced half of the pipeline.

3.1.2 Steps 4 to 6: Crowdsourcing

We ran three crowdsourcing tasks on Amazon Mechanical Turk (MTurk) in May-June 2021: *table relevance*, *claim adjustment*, and *verification*, loosely following the *"find-fix-verify"* crowdsourcing workflow for text processing by Bernstein et al. (2015). For each of the three tasks, we checked for quality, evaluated worker agreement, and aggregated the results before feeding them to the subsequent task.

Recruitment and training of workers. We allocated each task to three crowdworkers. Only workers with minimum 1000 previously-approved tasks and an approval rate of 95% or above were eligible to work on the tasks. Moreover, all workers had to pass a table literacy qualification test (see appendix). To train the workers, we followed the recommendations from Gadiraju et al. (2015); Doroudi et al. (2016) and included examples of expert-labelled tasks in the instructions, including the rationales for the chosen labels.

Tasks design. The tasks were designed as follows (see appendix for instructions and interfaces):

1. Task 1 - table relevance: We asked crowdworkers if claims and tables were related to each other. This was needed to evaluate the ranked list of tables from Step 3 (Figure 1), where we matched claims to tables using BM25. For each claim-table pair, workers could choose between four options: table *supports*, *refutes*, *is related but more information is needed*, and *is unrelated* to the claim. In addition, we also asked the crowd to name the columns which contributed to their choice. Each task had seven claim-table pairs, of which two were from the gold standard (see quality assurance below). We used majority voting to aggregate the answers.

2. Task 2 - claim adjustment: The input for this task were only the claim-table pairs which were judged as *related but not enough information* in the previous step. We asked crowdworkers to adjust a claim so that they could be supported or refuted by the table. The workers also had to flag whether the table supported or refuted the claim. Each task consisted of five claim-table pairs. As this was an open-

	K-α	F-κ	R-κ
Table relevance	0.26	0.38	0.65
Verification	0.60	0.60	0.67

Table 1: Inter-annotator agreement scores for the *table relevance* task and the *verification* task.

ended task, we evaluated the results in the third crowdsourcing task.

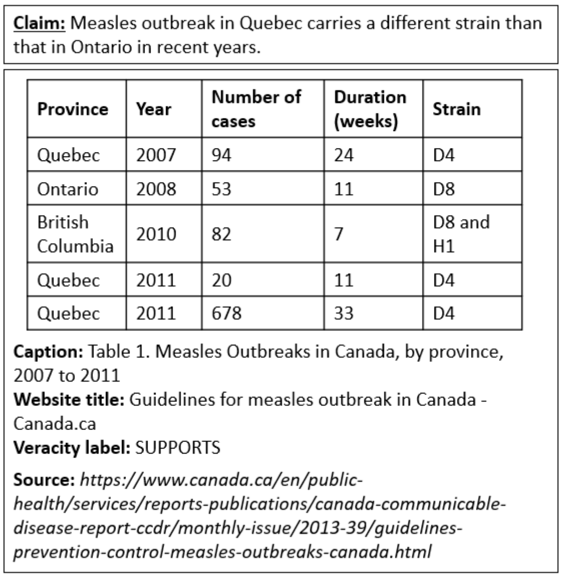
3. Task 3 - verification: We asked crowdworkers to verify the adjusted claims. Again, each task had seven pairs of claims and tables, with two gold pairs. Workers could choose between four labels: *supports*, *refutes*, *related but not enough information*, and *unrelated*. We performed majority voting to aggregate the answers.

For the final dataset (see Section 3.2), we discarded the pairs of adjusted claims and tables labelled as *unrelated* by the majority of workers.

Quality assurance. For each task, we followed best practices to maintain annotation quality and detect malicious behaviour. One of the authors created a gold standard of 30 claim-table pairs for the close-ended tasks (table relevance and verification); we used two gold pairs per task. Workers who failed those two gold pairs could not submit their work. For the remaining submissions, we computed the *inter-annotator agreement*.

Table 1 shows the inter-annotator agreement scores using Krippendorff's alpha (K-α), Fleiss' kappa (F-κ), and Randolph's kappa (R-κ). F-κ is prone to the high agreement but low kappa phenomenon when the dataset is imbalanced (Feinstein and Cicchetti, 1990); this was the case for the table relevance task: after aggregating the answers with majority voting, we had the following distribution: less than 1% *support*, less than 1% *refute*, 22% *related but not enough information*, and 77% *unrelated*. This is why we used R-κ, which yields more accurate results for imbalanced data. For the verification task, the data was more balanced, which is reflected in the similar scores. For both tasks, we obtained a R-κ value of at least 0.65, which indicates substantial agreement according to Landis and Koch (1977).

The claim adjustment task was open-ended. We allowed only submissions which met a set of criteria, for instance by looking at the time spent per task and comparing the original and adjusted claim; the full list of criteria is in the appendix. We also manually inspected the adjusted claims before accepting them. We randomly sampled one claim for each submission and accepted the work if its quality was sufficient. After a first pilot round, we banned workers with malicious behaviour, e.g. workers who did not adjust the claims, but only added or removed one token.



Claim: Measles outbreak in Quebec carries a different strain than that in Ontario in recent years.

Province	Year	Number of cases	Duration (weeks)	Strain
Quebec	2007	94	24	D4
Ontario	2008	53	11	D8
British Columbia	2010	82	7	D8 and H1
Quebec	2011	20	11	D4
Quebec	2011	678	33	D4

Figure 2: A *support* example from PubHealthTab.

3.2 Dataset Statistics

Our PubHealthTab dataset comprises $1,942$ claim-table pairs. A claim is a natural language sentence checked against a table. Each pair is labelled as *support*, *refute*, or *not enough information (NEI)*, following Thorne et al. (2018); Gupta et al. (2020); Diggelmann et al. (2020); Aly et al. (2021). The dataset has $1,019$ supported claims, 462 refuted claims, and 461 NEI claims. Figure 2 shows an example.

The evidence table is organised as a list of n rows. Each row is a list of cells, where m, the number of cells, can vary across rows. If the first row is a header, it is instead saved as "header_horizontal". Similarly, if the first column is a header, it is saved as "header_vertical". For each table, we provide the source website and, if available, the table caption. Moreover, each record also includes the original PubHealth claim text, which was adjusted by crowdworkers in Step 5 (Figure 1).

Table 2 compares the original PubHealth dataset with our dataset, PubHealthTab.

	PubHealthTab	**PubHealth**
Entries	1,942	11,832
Evidence type	Table	Text
Claim length	20 - 194	25 - 400
Veracity labels	{supports, refutes, NEI}	{true, mixture, false, unproven}

Table 2: Comparison between our dataset and PubHealth (Kotonya and Toni, 2020).

4 Dataset Analysis

We analysed the PubHealthTab dataset for biases and correlations, and compared it to other table fact-checking datasets. We applied three methods: (i) correlation analysis of table attributes; (ii) Local Mutual Information (LMI) on adjusted claims; and (iii) claim-only veracity prediction.

4.1 Correlation analysis of table attributes

While correlations between claims and veracity labels in fact-checking datasets have been previously explored (Schuster et al., 2019; Aly et al., 2021; Thorne et al., 2021), such underlying relationships might also be present in the evidence data. Thus, we examined correlations related to tables in the PubHealthTab dataset. We analysed if the veracity labels and the length of adjusted claims were correlated with the following table attributes that were visible to crowdworkers during annotation: table length (i.e. number of rows), availability of table captions, and availability of table headers.

Depending on the type of the attribute analysed, we used: the Pearson correlation coefficient, the χ^2 test, and the Anova F-test and a significance level α of 0.05 to examine correlations. The p-values for all attribute pairs are shown in Table 3. No significant correlations were found between the adjusted claim length and the table attributes' length, caption availability, and header availability. Given p-values $\geq \alpha$, the hypothesis of independence holds for these pairs of variables. Similarly, the veracity labels were not significantly correlated with the table length, caption availability, and adjusted claim length. For the correlation between veracity labels and header availability, we calculated a p-value of 0.03 indicating an underlying relationship between the variables. Examining the attributes in detail, we found that tables with headers were more prominent for supported and refuted claims than for NEI claims in the PubHealthTab dataset.

	Adj. claim length	**Veracity label**
Table length	0.05 (Pearson)	0.35 (F-test)
Adj. claim length	-	0.47 (F-test)
Caption available	0.36 (F-test)	0.05 (χ^2 test)
Header available	0.16 (F-test)	0.03 (χ^2 test)

	for health	398	0.6	5
	to the	365	0.28	18

Table 4: Top LMI-ranked bigrams for support, refute and NEI claims (including probability and count).

4.2 Local Mutual Information

Following Schuster et al. (2019), we analysed the correlation between frequently occurring phrases in adjusted claims and their veracity labels. We computed the Local Mutual Information (LMI) score (Evert, 2005) between a bigram b and the claim's veracity label l: $LMI(b,l) = p(b,l) * log(\frac{p(l|b)}{p(l)})$. Unlike the Point-wise Mutual Information (PMI) score, $PMI = log(\frac{p(l|b)}{p(l)})$, the LMI score avoids over-weighting bigrams with no or low occurrences in the overall dataset by multiplying it with the probability $p(b,l)$, where $p(b,l)$ is approximated by $\frac{count(b,l)}{|B|}$, $|B|$ is the number of all bigrams in the dataset and $count(b,l)$ is the number of times b and l occur together.

Table 4 shows the top LMI-ranked bigrams for PubHealthTab claims. We found similar bigrams in different classes, for example "has a" appears in refuted claims and "had a" in supported claims. Furthermore, no top-ranked bigram of refuted claims contains negation tokens such as "not", "never" or "false". Thus, we conclude that the top-ranked bigrams occurring in claims are not specific to their veracity labels.

4.3 Claim-only Veracity Prediction

We fine-tuned a BERT base model (Devlin et al., 2019) on PubHealthTab claims to predict their veracity labels using only the text as input and ignoring evidence tables. A claim-only model that performs well could indicate underlying correlations between the claims and the veracity labels. A similar approach was used by Schuster et al. (2019) to evaluate claim-only biases in the FEVER dataset (Thorne et al., 2018). Using the fine-tuned claim-only BERT model, we obtain an F_1 score of 0.51 on our test set. Comparing the F_1 score of the claim-only model to the performance of models using evidence data (see Section 5), we conclude that claims alone are not sufficient for the BERT model to predict the veracity labels.

4.4 Table Analysis

We compared PubHealthTab to three fact-checking datasets that use tables, TabFact, InfoTabs, and FEVEROUS (Table 5). Whilst almost all TabFact, InfoTabs and FEVEROUS tables have headers, this is not the case in more than half (56.9%) of PubHealthTab tables. Similarly, all TabFact and InfoTabs tables include captions and approximately only one-fifth of PubHealthTab tables (21%) and FEVEROUS tables (22%) have captions. While captions and headers can be useful for understanding the context of a table, these attributes are not always present in real-world tables.

The average number of characters per cell is 13.4 for PubHealthTab tables, more than the average cell length of TabFact tables (8.6) and less than for InfoTabs (22.6) and FEVEROUS (17.3). Moreover, PubHealthTab tables show the highest ratio of cells with numerical content (59%) and the smallest ratio with text-only content compared to the other datasets. Numerical content can pose a challenge for state-of-the-art NLP models as previous works have shown (Suadaa et al., 2021).

5 Experiments and Results

We experimented with several table representation techniques and state-of-the-art models on PubHealthTab to understand related challenges.

5.1 Table Representation

To assess the impact of different table representation methods on the table fact-checking task, we used five table representation techniques. We also used the BERT-based TAPAS model which extends the BERT model architecture with three additional embeddings to encode table structure. We describe the TAPAS model in more detail when we discuss the modelling approaches in Section 5.2. We describe the table representations in detail below:

Concatenation: transforms the entire content of a table into one flat string ignoring the table structure. The table caption, headers, and content are concatenated and used jointly as input for label prediction.

Template-based concatenation: maps table columns and cell values into a structured form using the following template applied to each row: `row_1: column_1:cell_value, column_2:cell_value, [...]`. The `row` and `column` tokens were replaced by the corresponding vertical header (for row) and horizontal header (for column), if available.

Template-based sentences: We defined a template to convert table content to one sentence per row. For example, given a table with headers "medicine" and "price", and two cells in the first row, we generate the following template-based sentence for this row: *In row one column one (medicine) is Panadol, column two (price) is £15.*

T5 (concatenation): Similarly to Suadaa et al. (2021), we used text from representation *concatenation* as input to the T5 text generation model (Raffel et al., 2020) to generate sentences that describe the tables.

T5 (template): We used text from representation *template-based sentence* as input to the T5 model.

5.2 Modelling Approaches

Based on the previously described table representation methods, we evaluated state-of-the-art NLP models on PubHealthTab. We use models previously applied in table fact-checking (BERT, ALBERT, RoBERTa) (Chen et al., 2020b; Gupta et al., 2020; Aly et al., 2021), as well as domain-specific models (BioBERT, BlueBERT, ClinicalBERT), pretrained on large-scale health datasets. We describe the models below:

BERT: We used the uncased BERT-base (Devlin et al., 2019) model from `huggingface` library[10].

ALBERT: A transformer-based model that extends BERT with a parameter-reduction technique, resulting in lower memory consumption and higher training speed (Lan et al., 2020).

Support	810	106	103	1019
Refute	370	46	46	462
NEI	373	43	45	461
Sum	1553	195	194	1942

Table 6: Class distribution across dataset split.

RoBERTa: We used the RoBERTa-Large model released by Nie et al. (2020). The model was pre-trained on SNLI (Bowman et al., 2015), MNLI (Williams et al., 2018), ANLI (Nie et al., 2020), and FEVER (Thorne et al., 2018).
BioBERT: A domain-specific BERT model, pre-trained on PubMed abstracts and PMC full-text articles (Lee et al., 2020). The model was fine-tuned on two NLI datasets, SNLI and MultiNLI.
BlueBERT: The model was pre-trained on PubMed abstracts and MIMIC-III clinical notes, a database of electronic health records from ICU patients at a Boston hospital (Peng et al., 2019).
ClinicalBERT: A BERT model which was pre-trained on MIMIC-III data (Huang et al., 2019).
TAPAS: An extension to BERT which uses additional, table-specific embeddings (column embeddings, row embeddings, rank embeddings) that capture the table structure (Herzig et al., 2020). We experiment with TAPAS on our dataset as it achieved good performance on the TabFact dataset.

We partitioned the dataset into training (80%), test (10%), and validation (10%) sets. Table 6 shows the class distribution across the dataset split. We performed hyper-parameter search on the validation set and evaluated the following parameters for each model before selecting the best-performing combination: $\{4, 8, 16\}$ for batch size, {1e-3, 1e-5, 1e-7} for learning rate, $\{2, 3, 4, 5\}$ for training epochs, and $\{0.01, 0.001, 0.0001\}$ for weight decay.

Table 7: F_1 (macro) score for different state-of-the-art models and table representations on PubHealthTab.

5.3 Discussion

We evaluated and compared the table representation and modelling approaches, and report the overall (macro) F_1 score and the F_1 scores for each class in Table 7.

Table Representations. The resulting F_1 scores across all models and veracity classes remained overall the same when different methods for table representation were applied. The *template-based*

	Dataset	All	Sup.	Ref.	NEI

Table 8: F_1 score for RoBERTa with different representation methods on various table fact-checking datasets.

sentence approach outperforms other representation techniques in terms of the overall F_1 score for four out of six models (i.e. ALBERT, BioBERT, BlueBERT, and ClinicalBERT). However, for all four models, the difference to the second highest scoring representation was relatively small, between 0.02 and 0.03. Thus, choosing between *concatenation* and *template* did not seem to influence the overall claim classification.

Models. RoBERTa outperformed the other models across all representations, followed by BioBERT. The highest macro F_1 score (0.73) was obtained using RoBERTa with T5 concatenation. The BioBERT model outperformed BERT, ALBERT and all other domain-specific models for all representations except *concatenation* where BERT yielded a slightly higher overall F_1 score. Surprisingly, TAPAS achieved the lowest score. We believe that this is attributed to the small dataset; while TAPAS is one of the best-performing models on TabFact (Eisenschlos et al., 2020), our training set is much smaller, which can pose a challenge to the BERT-based model.

Performance on refuted claims. Across all applied models and table representations, we obtained a noticeable low F_1 score for PubHealthTab refuted claims compared to the two other veracity classes, support and NEI. The F_1 scores ranged from 0 (ClinicalBERT with concatenation) to 0.52 (RoBERTa and T5 concatenation).

To determine if this scenario was specific to our dataset, we compared the F_1 scores we obtained on our dataset using RoBERTa with other table fact-checking datasets. The results are shown in Table 8. While the F_1 score for PubHealthTab refuted claims was between 0.39 and 0.52 using RoBERTa, this value was between 0.65 and 0.87 for refuted claims from TabFact, InfoTabs and FEVEROUS. Whilst the low performance of RoBERTa on FEVEROUS NEI claims can be attributed to the imbalanced class distribution (Aly et al., 2021), this is not the case for PubHealthTab as the three veracity classes $\{$support, refute, NEI$\}$ are present in a ratio of 2:1:1 in our training set. We believe that the comparably low performance of RoBERTa on PubHealthTab *refute* claims is due to the fact that state-of-the-art representation and modelling approaches were previously evaluated on Wikipedia evidence tables. These approaches seem to struggle with noisy web tables: lacking table captions and headers, a higher ratio of numerical content, and a lower ratio of string-only content (see Section 4.4) could pose a challenge for generating table representations and for pre-trained models previously evaluated on tables from single data sources.

The results we obtained using RoBERTa on TabFact are lower compared to the other datasets. Whilst Chen et al. (2020b) do not report the results per class, the overall F_1 score we obtained is comparable to their baseline.

6 Conclusion

We introduced PubHealthTab, a table-based dataset for evidence-based fact checking centred on real-world public health claims. Our dataset comprises $1,942$ claim-table pairs, with tabular evidence data extracted from websites similar to those used by fact checkers. We described the dataset creation process and the steps taken to minimise biases and correlations. We evaluated state-of-the-art representation and modelling approaches and showed that the RoBERTa model achieves the highest performance on PubHealthTab across all representation methods compared to other models. In contrast to previous table-based fact-checking datasets that contain tables from single data sources, state-of-the-art models struggle to correctly classify refute claims from PubHealthTab against evidence consisting of mostly numerical data or with noisy text headers, making PubHealthTab a challenging dataset for table-based fact-checking research.

Ethics Statement

The PubHealthTab dataset can be used for developing and evaluating fact checking systems intended for a real-world context. The labels *supports*, *refutes* and *not enough information* describe a claim's veracity given the evidence table. We do not make any statement on PubHealthTab claims' truthfulness in a real-world context.

We obtained ethical clearance prior to crowdsourcing from the relevant authority in the academic institution. We informed the participants about the data being collected and its purpose. Participants had the opportunity to withdraw at any time and to provide feedback at the end of each task. All workers were from English speaking countries. The payment was above the minimum wage and decided based on the time workers spent on the pilot tasks. For the first and third tasks we paid $0.75 USD$ (2.5 minutes per task on average) and for the second $1.35 USD$ (average 5 minutes per task).

Acknowledgements

The authors acknowledge support from the Distributed AI (DAI) research group at King's College London for creating the dataset.

A Supplementary Materials

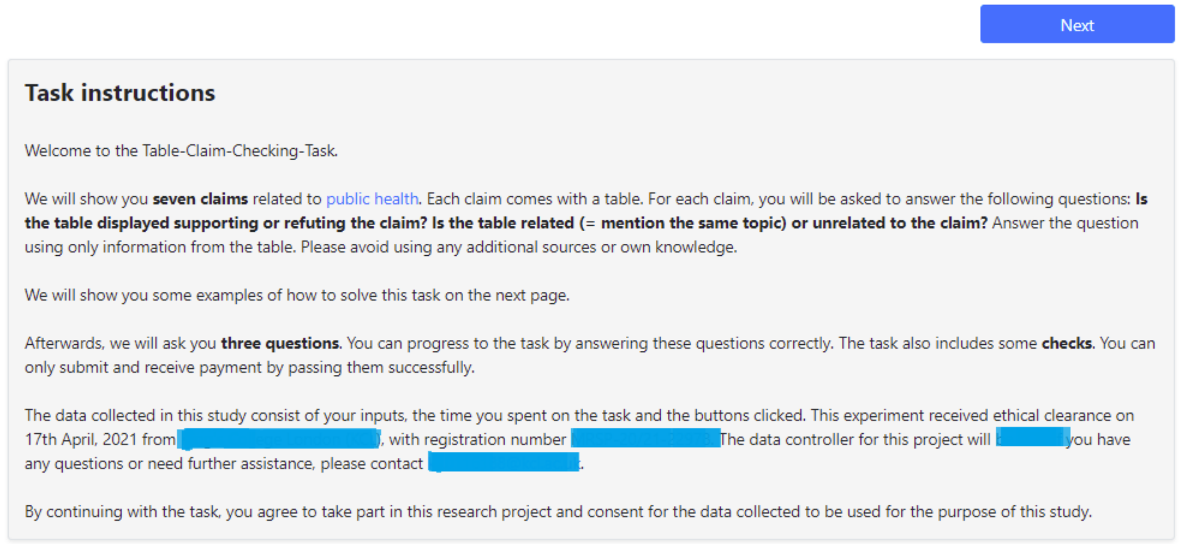
A.1 Dataset Creation

We evaluated the following conditions for the second crowdsourcing task. Workers could only submit their work if all checks were passed:

- A veracity label is selected for the adjusted claim.
- Minimum 2.5 seconds are spend on each HIT page for adjusting the claim.
- Adjusted claim length is between 5 and 30 tokens.
- The adjusted claim is different from the initial claim.
- The adjusted claim text does not contain ambiguous words, i.e. *maybe, probably, mostly, occasionally, frequently, might, many, few, some, several, most of, sometimes*.
- The adjusted claim does not contain negation words, i.e. *not, never, none, nobody*.

A.2 Experiments

After hyperparameter tuning on the validation set, we selected the following parameters for the different modelling approaches displayed in Table 9.



Task instructions

Welcome to the Table-Claim-Checking-Task.

We will show you **seven claims** related to public health. Each claim comes with a table. For each claim, you will be asked to answer the following questions: **Is the table displayed supporting or refuting the claim? Is the table related (= mention the same topic) or unrelated to the claim?** Answer the question using only information from the table. Please avoid using any additional sources or own knowledge.

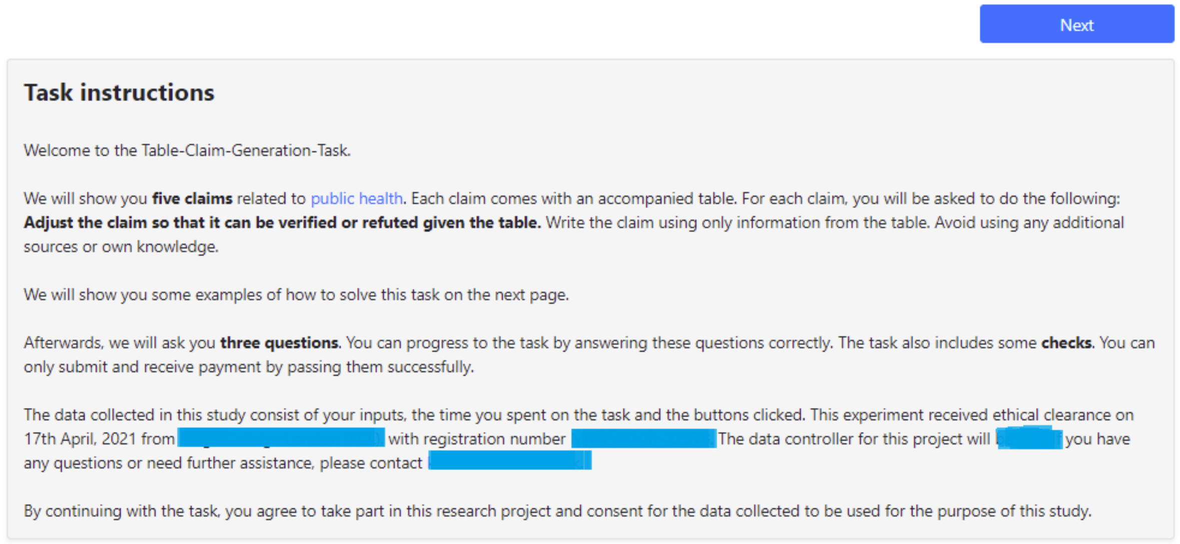
We will show you some examples of how to solve this task on the next page.

Afterwards, we will ask you **three questions**. You can progress to the task by answering these questions correctly. The task also includes some **checks**. You can only submit and receive payment by passing them successfully.

The data collected in this study consist of your inputs, the time you spent on the task and the buttons clicked. This experiment received ethical clearance on 17th April, 2021 from [redacted], with registration number [redacted]The data controller for this project will [redacted]you have any questions or need further assistance, please contact [redacted].

By continuing with the task, you agree to take part in this research project and consent for the data collected to be used for the purpose of this study.

Figure 3: Introduction text for *table relevance* and *verification* task.



Task instructions

Welcome to the Table-Claim-Generation-Task.

We will show you **five claims** related to public health. Each claim comes with an accompanied table. For each claim, you will be asked to do the following: **Adjust the claim so that it can be verified or refuted given the table.** Write the claim using only information from the table. Avoid using any additional sources or own knowledge.

We will show you some examples of how to solve this task on the next page.

Afterwards, we will ask you **three questions**. You can progress to the task by answering these questions correctly. The task also includes some **checks**. You can only submit and receive payment by passing them successfully.

The data collected in this study consist of your inputs, the time you spent on the task and the buttons clicked. This experiment received ethical clearance on 17th April, 2021 from [redacted] with registration number [redacted]The data controller for this project will [redacted] you have any questions or need further assistance, please contact [redacted]

By continuing with the task, you agree to take part in this research project and consent for the data collected to be used for the purpose of this study.

Figure 4: Introduction text for *claim adjustment* task.

Model	TE	BS	LR	WD
BERT	5	4	1e-5	0.001
AlBERT	5	16	1e-5	0.001

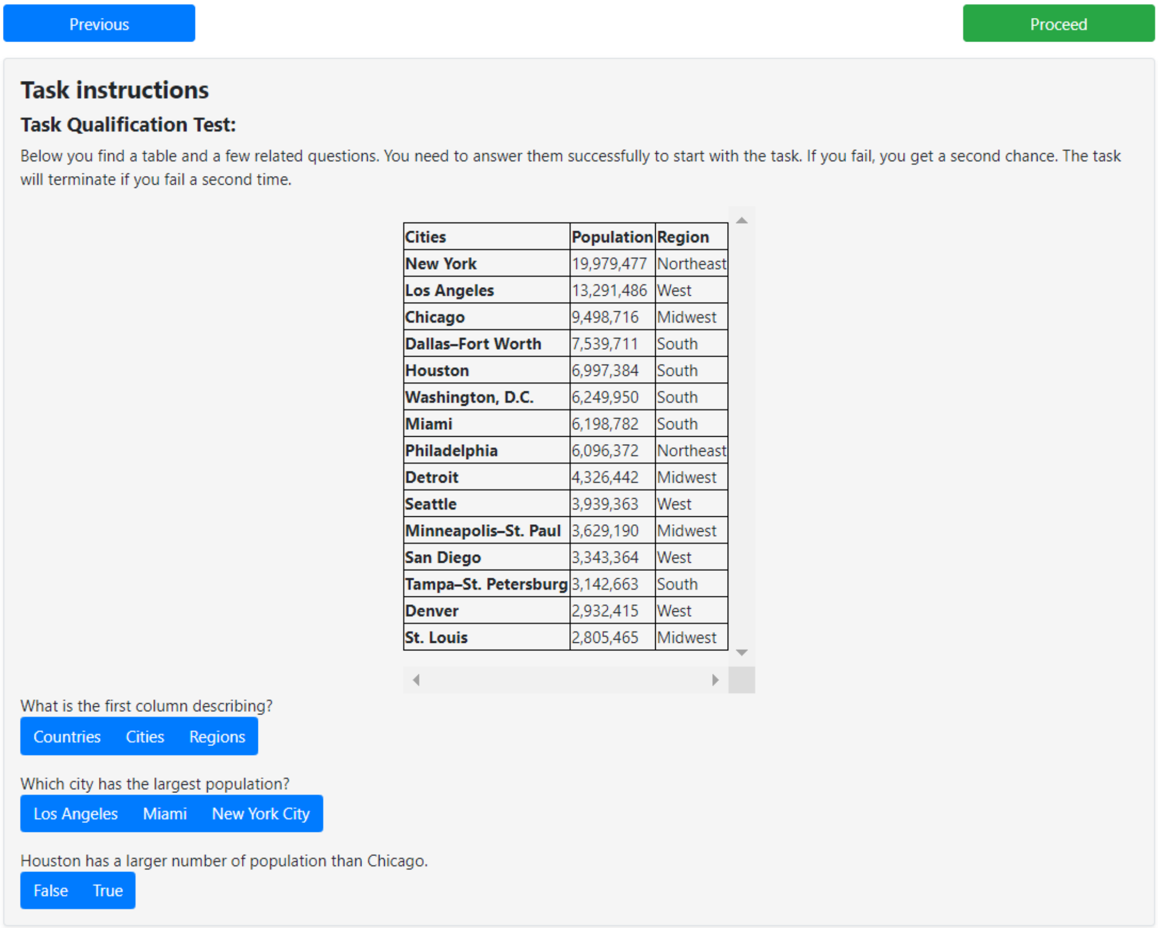
BioBERT	5	4	1e-5	0.001
BlueBERT	5	8	1e-5	0.001
ClinicalBERT	4	4	1e-5	0.01

Table 9: Hyperparameters evaluated on the PubHealthTab dataset: training epochs (TE), batch size (BS), learning rate (LR), weight decay (WD).



Task instructions

Task Qualification Test:

Below you find a table and a few related questions. You need to answer them successfully to start with the task. If you fail, you get a second chance. The task will terminate if you fail a second time.

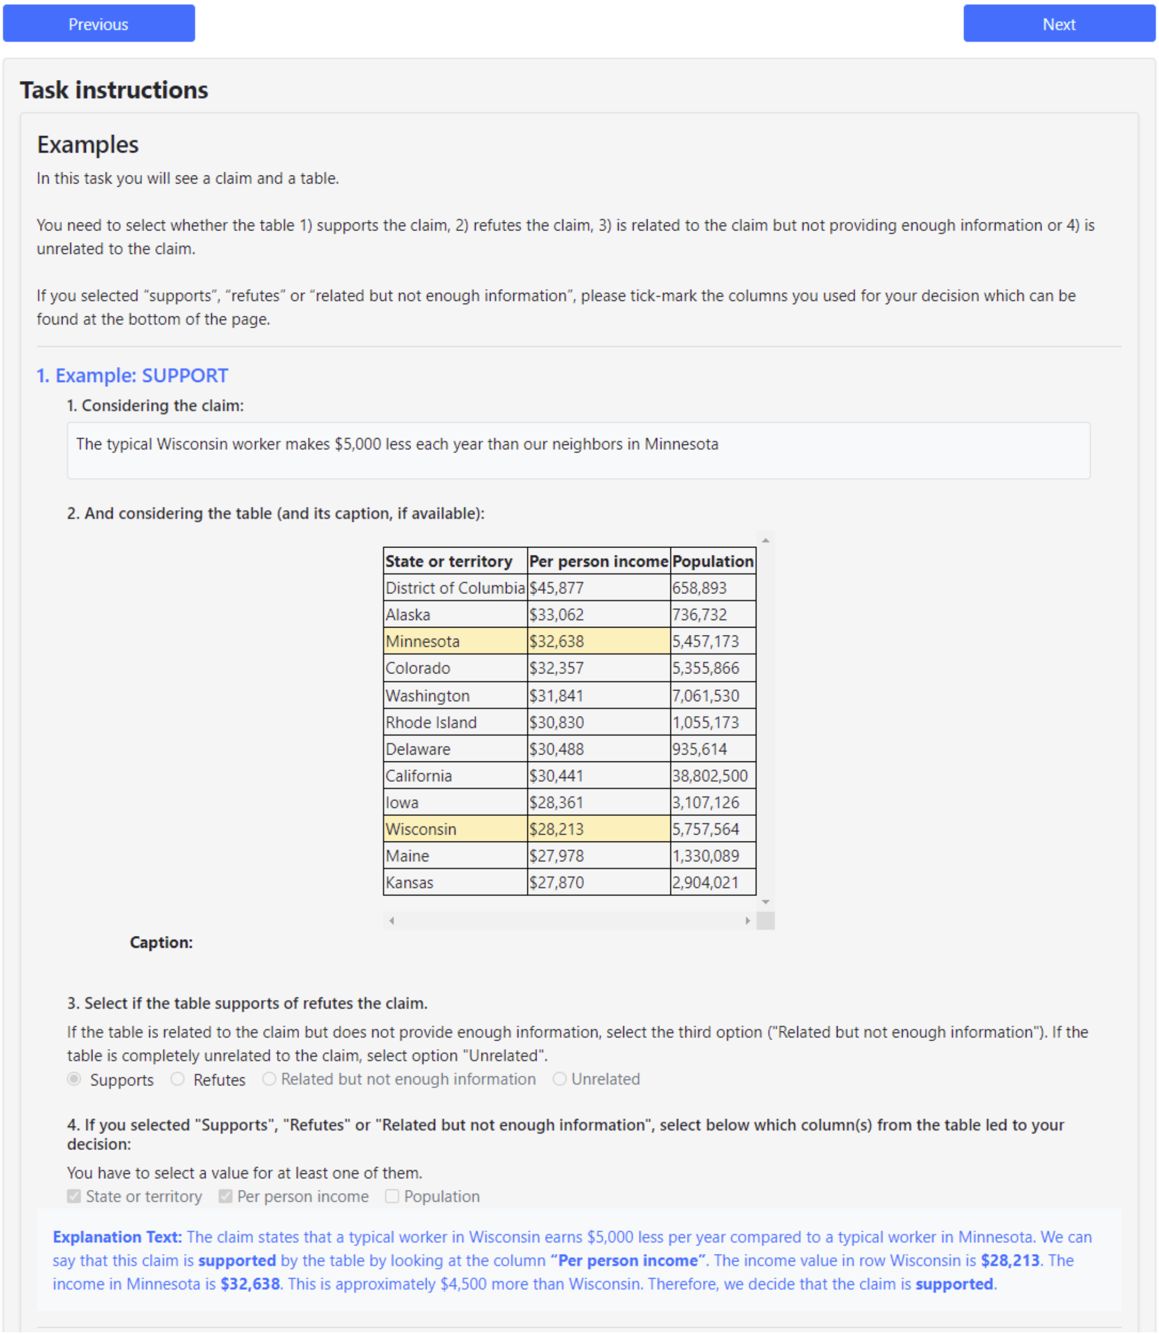
Cities	Population	Region
New York	19,979,477	Northeast
Los Angeles	13,291,486	West
Chicago	9,498,716	Midwest
Dallas–Fort Worth	7,539,711	South
Houston	6,997,384	South
Washington, D.C.	6,249,950	South
Miami	6,198,782	South
Philadelphia	6,096,372	Northeast
Detroit	4,326,442	Midwest
Seattle	3,939,363	West
Minneapolis–St. Paul	3,629,190	Midwest
San Diego	3,343,364	West
Tampa–St. Petersburg	3,142,663	South
Denver	2,932,415	West
St. Louis	2,805,465	Midwest

What is the first column describing?

Which city has the largest population?

Houston has a larger number of population than Chicago.

Figure 5: Crowdsourcing qualification test.



Task instructions

Examples

In this task you will see a claim and a table.

You need to select whether the table 1) supports the claim, 2) refutes the claim, 3) is related to the claim but not providing enough information or 4) is unrelated to the claim.

If you selected "supports", "refutes" or "related but not enough information", please tick-mark the columns you used for your decision which can be found at the bottom of the page.

1. Example: SUPPORT

1. Considering the claim:

The typical Wisconsin worker makes $5,000 less each year than our neighbors in Minnesota

2. And considering the table (and its caption, if available):

State or territory	Per person income	Population
District of Columbia	$45,877	658,893
Alaska	$33,062	736,732
Minnesota	$32,638	5,457,173
Colorado	$32,357	5,355,866
Washington	$31,841	7,061,530
Rhode Island	$30,830	1,055,173
Delaware	$30,488	935,614
California	$30,441	38,802,500
Iowa	$28,361	3,107,126

3. Select if the table supports of refutes the claim.

If the table is related to the claim but does not provide enough information, select the third option ("Related but not enough information"). If the table is completely unrelated to the claim, select option "Unrelated".

● Supports ○ Refutes ○ Related but not enough information ○ Unrelated

4. If you selected "Supports", "Refutes" or "Related but not enough information", select below which column(s) from the table led to your decision:

You have to select a value for at least one of them.

☑ State or territory ☑ Per person income ☐ Population

Explanation Text: The claim states that a typical worker in Wisconsin earns $5,000 less per year compared to a typical worker in Minnesota. We can say that this claim is **supported** by the table by looking at the column **"Per person income"**. The income value in row Wisconsin is **$28,213**. The income in Minnesota is **$32,638**. This is approximately $4,500 more than Wisconsin. Therefore, we decide that the claim is **supported**.

Masked Measurement Prediction:
Learning to Jointly Predict Quantities and Units from Textual Context

Abstract

Physical measurements constitute a large portion of numbers in academic papers, engineering reports, and web tables. Current benchmarks fall short of properly evaluating numeracy of pretrained language models on measurements, hindering research on developing new methods and applying them to numerical tasks. To that end, we introduce a novel task, Masked Measurement Prediction (*MMP*), where a model learns to reconstruct a number together with its associated unit given masked text. *MMP* is useful for both training new numerically informed models as well as evaluating numeracy of existing systems. To address this task, we introduce a new **Ge**nerative **M**asked **M**easurement (*GeMM*) model that jointly learns to predict numbers along with their units. We perform fine-grained analyses comparing our model with various ablations and baselines. We use linear probing of traditional pretrained transformer models (RoBERTa) to show that they significantly underperform jointly trained number-unit models, highlighting the difficulty of this new task and the benefits of our proposed pre-training approach. We hope this framework accelerates progress towards building more robust numerical reasoning systems in the future.[1]

1 Introduction

Many natural language processing tasks require a deep understanding of numbers – for example, reading comprehension (Ran et al., 2019), textual entailment (Sammons et al., 2010; Roy, 2017) and hybrid table tasks such as fact-verification (Chen et al., 2020) or question answering (Chen et al., 2021). Masked number prediction (*MNP*) is a popular pretraining objective to imbue language models with numerical understanding and evaluate existing models for their numerical capacity.

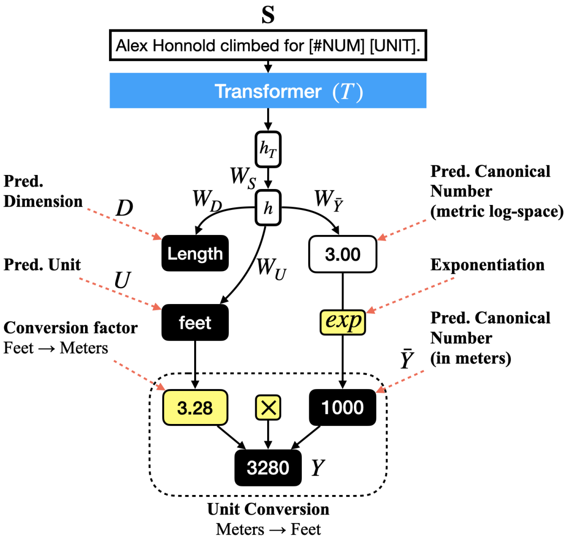

Figure 1: We present the Masked Measurement Prediction (*MMP*) task where the model predicts the dimension, unit and real-valued number. We also show the model architecture of **Ge**nerative **M**asked **M**easurement model (*GeMM*), the model we propose to perform *MMP*. We display the fixed operations used during unit conversion in yellow. In black, we show the different components of the model's prediction.

As an example of *MNP*, given the sentence *"Cats have [#NUM] paws."* a model learns to predict the number *4*. While appropriate for numerical commonsense, *MNP* is deficient when it is used to predict measurements. *Measurements*, such as *2 meters* or *13.2 square miles*, are a special class of particularly common numbers in text that have a well-defined and typed system of *units*. Given a simple question: *"How long did Alex Honnold climb for?"*, a single number alone is an insufficient answer since it is meaningless without the unit. Answers like *1000 meters* or *4 hours* could both suffice.

Current *MNP* systems do not jointly reason about numbers *with* units. It is reasonable to expect that pretrained models like BERT could leverage information of units directly as text without

---

[1] We will release our trained models and data-splits upon acceptance on Github.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 17 - 29
July 10-15, 2022 ©2022 Association for Computational Linguistics

any special treatment. However, in preliminary experiments we find that this yields poor numerical abilities (see Appendix B). Furthermore, including units as text directly raise more questions: should we evaluate using all units (*meters, feet, inches*)? Should we equally weight across the units? Current models have no opinion about which unit is appropriate because they are not required to make unit predictions during training. Together, this indicates that current training objectives do not capture sufficient representations of measurements and that a direct application of *MNP* to evaluate numeracy of measurements is ill-suited.

To address these shortcomings, we propose the more challenging task of Masked Measurement Prediction (*MMP*) along with a new model. In this task, a model must reconstruct both the number together with the correct unit. In Figure 1 we show how in a *MMP* setting our model generates a dimension (“Length”), a number in metric log-space (“3.00”), the unit ("feet") and then uses the conversion factor (“3.28”) to deterministically output the full measurement (“3280 feet”). This example illustrates a key distinction in that our model is flexible and can generate *non-metric measurements* (feet) but evaluates numerical prediction in canonical units (meters).[2]

MMP is useful for two reasons: 1) as a way to *train* models to give them better numeracy 2) as a new kind of *evaluation* that allows for a much more fine-grained analysis of reasoning over numerical quantities. The task of measurement estimation decouples the different aspects of numeracy allowing for a more interpretable and thorough analysis of numerical reasoning. We introduce a new evaluation benchmark for *MMP* based on WikiConvert (*WiCo*) (Thawani et al., 2021a), a large scale dataset of English Wikipedia sentences with ground truth measurement annotations. We compare the performance of our models on their ability to accurately predict the dimension, unit, and value of a measurement. We employ a large pretrained transformer model as our textual encoder and examine the performance of different discriminative, generative, and latent variable models along with several ablations. Our contributions are as follows:

- We introduce a novel challenging task *MMP* for pretraining and evaluating numeracy.

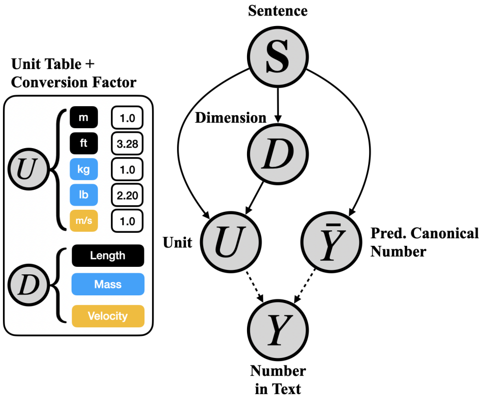

Figure 2: *GeMM* as a graphical model. The broken arrows represent a deterministic unit conversion. Examples of unit values and their corresponding dimension values are also shown.

- We show that linear probing of existing pretrained models on MMP *significantly underperforms* fully finetuned models.
- We train a model that reasons jointly about numbers and units which predicts numbers 8.1 times more accurately than the probed pretrained models.
- We find our best performing generative model outperforms human annotators on two evaluations, achieving 7.4-7.8% better dimension accuracy and 33.5-39.9% better unit accuracy. Furthermore, this model predicts a number **closer** to ground truth than our annotators 66.2-78.8% of the time.

Furthermore there are numerous applications of better measurement prediction and unit reconstruction such as in table to text generation (Moosavi et al., 2021), answering numerical queries (Sarawagi and Chakrabarti, 2014; Ho et al., 2019) or for improving e-commerce product search(Arici et al., 2021). We hope that Masked Measurement Prediction becomes a standard benchmarking tool from which we can gain insight how to best incorporate new numeracy modeling techniques as well as evaluate existing models.

2 Models

2.1 Background + Notation

The International System of Units (SI) defines seven *fundamental dimensions* (Length, Time, Mass, etc.) and seven corresponding *base SI units* (meters, seconds, kilograms, etc.). The SI system is the most widely adopted measurement standard

---

[2] Our metric of choice described in Equation 2 is invariant to the specific choice of canonical unit i.e., *log-mae* in meters is equal to *log-mae* in feet.

and is used internationally in domains such as commerce, finance, logistics, and science. We designate $\mathcal{D}$ to be the set of composite dimensions obtained from (and including) the *fundamental dimensions*. Values of $\mathcal{D}$ include velocity and power. We let $\mathcal{U}$ be the set of all units: the various ways to describe dimensions. For example, units of Length include meters and miles. Each training example consists of a real number y, a dimension $d \in \mathcal{D}$, a unit $u \in \mathcal{U}$, and the remainder of the sentence $\boldsymbol{S}$. In *MMP*, our task is to predict y, d, and u given only $\boldsymbol{S}$. In the next sections we describe our generative model designed for *MMP* followed by the ablations we consider.

2.2 Model

Measurements have complex semantic meanings, shaped by many standards, particular instruments, and natural world phenomena. Consider a text concerning rainfall. From a dimensional analysis perspective, the units *inches per year (in/y)* and *meters per second (m/s)* share the same dimension *velocity*. However, mentioning *in/y* usually implies that the text is discussing total rainfall in a region. Likewise, the use of *m/s* suggests that the text is examining the speed of falling rain droplets. To capture this complexity, we consider a generative model that learns the joint distribution of the number, dimension, and unit.

We now describe the generative process of our full model. To start, conditioned on $\boldsymbol{S}$, our model samples a discrete dimension variable $\boldsymbol{D}$. Then conditioned on the sampled dimension, our model samples a discrete unit variable $\boldsymbol{U}$ compatible with the dimension. For example, conditioned on the dimension *velocity* our model will output a distribution over the units of velocity such as *[miles per hour; meters per second, inches per year]* as opposed to all of $\mathcal{U}$. We then separately predict a distribution on the canonicalized measurement, $\bar{\boldsymbol{Y}}$, which is the numerical quantity represented in a base canonical (metric) unit like meters. During inference time, we use the highest scoring dimension and unit and choose the proper conversion factor to deterministically produce the final number y represented in the predicted unit. We refer to this **Ge**nerative **M**asked **M**easurement model as *GeMM*, where the joint $p(\boldsymbol{D}, \boldsymbol{Y}, \boldsymbol{U}|\boldsymbol{S})$ is given by the following equation:

$$p(\boldsymbol{D}|\boldsymbol{S}) \times p(\boldsymbol{U}|\boldsymbol{D}, \boldsymbol{S}) \times p(\boldsymbol{Y}|\boldsymbol{S})$$

We show the graphical model of *GeMM* in Figure 2. We also consider, *GeMM* U→Y, a slight variant where we have a direct dependence between the unit and number prediction with a joint equal to:

$$p(\boldsymbol{D}|\boldsymbol{S}) \times p(\boldsymbol{U}|\boldsymbol{D}, \boldsymbol{S}) \times p(\boldsymbol{Y}|\boldsymbol{U}, \boldsymbol{S})$$

2.3 Discrete Latent Dimension Model

We also consider an unsupervised generative model which treats the dimension as a discrete latent variable. We use the same number of dimension classes $|\mathcal{D}|$ and train to maximize the log-likelihood of the observed $\boldsymbol{Y}$. We refer to this model as *Lat-Dim* and is characterized by:

$$p(\boldsymbol{Y}|\boldsymbol{S}) = \sum_{\boldsymbol{D}} p(\boldsymbol{D}|\boldsymbol{S}) \times p(\boldsymbol{Y}|\boldsymbol{D}, \boldsymbol{S})$$

To evaluate this model we build a contingency matrix of the predicted classes and using a linear solver find the best mapping between our predicted and true dimensions. We can then apply this mapping to the model predictions and calculate classification metrics for dimension prediction.

2.4 Model Ablations

We also consider several model ablations of *GeMM*. Our first ablation is *GeMM* -Y -U which models $p(\boldsymbol{D}|\boldsymbol{S})$. The second, *GeMM* -Y, learns the distribution $p(\boldsymbol{U}, \boldsymbol{D}|\boldsymbol{S}) = p(\boldsymbol{D}|\boldsymbol{S}) \times p(\boldsymbol{U}|\boldsymbol{D}, \boldsymbol{S})$. The third, *GeMM* -U, models $p(\boldsymbol{Y}, \boldsymbol{D}|\boldsymbol{S}) = p(\boldsymbol{D}|\boldsymbol{S}) \times p(\boldsymbol{Y}|\boldsymbol{D}, \boldsymbol{S})$. Our final ablation is *GeMM* -U -D which learns $P(\boldsymbol{Y}|\boldsymbol{S})$ directly.

2.5 Model Architectures

For our textual encoder, we use the Huggingface Transformers (Wolf et al., 2020; Liu et al., 2019) implementation of RoBERTa, a pretrained 12-layer transformer. We refer to this text encoder as $\boldsymbol{T}$ such that given a sentence $\boldsymbol{S}$, our model outputs a 768-dimensional vector $\boldsymbol{h_T}$. We use a single linear layer, $W_S \in \mathbb{R}^{768 \times M}$, to project $\boldsymbol{h_T}$ to $\boldsymbol{h}$ and treat the dimension M as a hyper-parameter. To form a distribution over the real number line $\mathbb{R}$ we use a *Log-Laplace* model, a competitive model used in the numeracy literature (Spokoyny and Berg-Kirkpatrick, 2020; Thawani et al., 2021a; Zhang et al., 2020). This is equivalent to L_1 regression in log-space and yields the following loss function where $\boldsymbol{Y}$ and $\boldsymbol{Y}^*$ are predicted and ground truth numbers, respectively:

$$\log P(\boldsymbol{Y}|\boldsymbol{S}) = |\log \boldsymbol{Y}^* - \log \boldsymbol{Y}| + \log \left|\frac{1}{\boldsymbol{Y}}\right| \quad (1)$$

Split	Examples	Max #	Min #
All	919,237	5.5E+36	1E-06
Train	728,629	5.5E+36	1E-06
Val	91,110	4.4E+14	1.2E-06
Test	91,092	1.6E+21	1.8E-06

Table 1: Summary statistics for Wiki-Convert. The median number of characters and tokens per example is 106 and 33, respectively.

As shown in Figure 1, we project $\boldsymbol{h}$ with a linear layer $W_{\boldsymbol{D}} \in \mathbb{R}^{M\times|\mathcal{D}|}$ to obtain a distribution over $\boldsymbol{D}$. We then use a separate linear layer, $W_{\boldsymbol{U}} \in \mathbb{R}^{M\times|\mathcal{U}|}$, to project $\boldsymbol{h}$ and obtain a distribution over $\boldsymbol{U}$. To predict $\bar{\boldsymbol{Y}}$, we project $\boldsymbol{h}$ with a linear layer $W_{\boldsymbol{Y}}$. In the case of *GeMM*, we let $W_{\boldsymbol{Y}} \in \mathbb{R}^{M\times|\mathcal{D}|}$ in order to parameterize a mean of a *Log-Laplace* distribution for each dimension in $\boldsymbol{D}$. For *GeMM* U→Y, we set $W_{\boldsymbol{Y}} \in \mathbb{R}^{M\times|\mathcal{U}|}$ to output the mean of a *Log-Laplace* distribution for each unit in $\boldsymbol{U}$ and the remaining models, we set $W_{\boldsymbol{Y}} \in \mathbb{R}^{M\times 1}$ resulting in a single mean of a *Log-Laplace* distribution. For training, we use cross-entropy loss for the dimension and unit distributions, and the loss from the equation above for number prediction.

3 Dataset

We train and evaluate our models on *WiCo* (Thawani et al., 2021a), a dataset of English Wikipedia sentences where the number and unit in each sentence are human-annotated. We canonicalize the units and map each to a single dimension. For example both *feet per second* and *miles per hour* map to *velocity*. We show the distribution of all measurements and *lengths* in Figure 3. The resulting dataset consists of 919,237 sentences with annotated (number, unit, dimension) triples. We provide more details on the data in Appendix A.

4 Experiments

We train all models using a batch size of 200 and use the AdamW (Loshchilov and Hutter, 2019) optimizer with a learning rate of $1e^{-4}$ and a linear warm-up schedule of 500 steps. We use the "❄" symbol to indicate that we freeze the transformer parameters for training. For all frozen models we use a log frequency weighted cross-entropy due to the highly imbalanced classes as well as a higher learning rate of $1e^{-3}$. We employ early stopping with a patience of five epochs on validation score.

Model	10-shot	40-shot	70-shot	100-shot
GeMM -Y -U ❄	15.5	50.0	52.5	53.4
GeMM -Y -U	**42.5**	**51.2**	**57.6**	**60.5**
Majority	14.3	14.3	14.3	14.3

Table 2: Results (measured by F1 ↑) of our few-shot experiment on dimension classification (probing $p(D|S)$). x-shot implies the model is trained on x labeled examples per dimension. *GeMM* -Y -U indicates an ablation of *GeMM* where $\boldsymbol{Y}$ and $\boldsymbol{U}$ are not modeled. ❄ indicates the model's parameters are frozen during training.

Model	10-shot	40-shot	70-shot	100-shot
GeMM -U -D ❄	1.94	1.82	1.72	1.75
GeMM -U -D	**1.70**	**1.56**	**1.43**	**1.41**
Median	1.99	1.99	1.99	1.99

Table 3: Results (*log-mae* ↓) of our few-shot experiment on number prediction (probing $p(Y|S)$).

To evaluate the performance of our models, we report the macro averaged F1 score for dimension and unit prediction and *log-mae* to evaluate number prediction. We define *log-mae* in Equation 2 where $\boldsymbol{Y}$ is the predicted number and $\boldsymbol{Y}^*$ is the ground truth number. As a simple baseline for dimension and unit prediction, we employ majority class voting. For number prediction we use the median of all the numbers in the training set.

$$\textit{log-mae} = \frac{1}{|\mathcal{D}_{\text{test}}|}\sum_{\mathcal{D}_{\text{test}}} |\log_{10}\boldsymbol{Y}^* - \log_{10}\boldsymbol{Y}| \tag{2}$$

4.1 Few-Shot

To study the degree to which current pretrained models capture different aspects of numeracy, we consider the following few-shot experiment. We sample a balanced dataset of dimensions where each class gets 10, 40, 70, or 100 labeled examples. We train *GeMM* -Y -U and *GeMM* -U -D on the few-shot task where the pretrained text encoder $\boldsymbol{T}$ parameters are frozen and compare their performance against full fine-tuning. Due to the high variance of *GeMM* -Y -U, we report the average of three random seeds. In Table 2 and Table 3 we show results of *GeMM* -Y -U and *GeMM* -U -D respectively.

Although performance improves with more data, the frozen models significantly underperform their

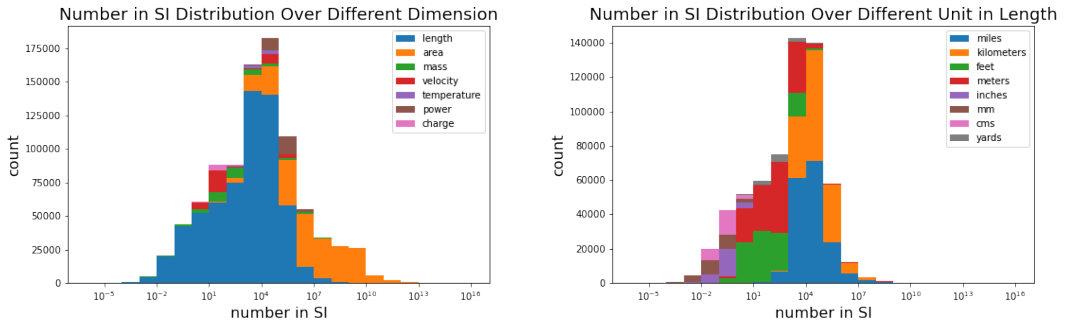

Figure 3: Histograms of *WiCo* numbers binned by base-10 exponent. All numbers are canonicalized to their SI form. **Left:** All numbers labeled by dimension. **Right:** Numbers in the *length* dimension labeled by unit.

Model	**Probing Type**	**Val**	**Test**
Majority	-	33.1	33.1
GeMM❄	$p(\boldsymbol{D}\|\boldsymbol{S})$	69.1	67.5

GeMM	$p(\boldsymbol{U}\|\boldsymbol{D},\boldsymbol{S})$	51.5	**54.9**
GeMM U→Y	$p(\boldsymbol{U}\|\boldsymbol{D},\boldsymbol{S})$	49.3	47.8

Table 6: Results (**F1** ↑) on unit prediction conditioned on the true dimension and text. Ablations are above the double horizontal line.

unfrozen counterparts across all dataset sizes. For example, in the 100-shot dataset, the frozen model shows 7.1 lower F1 and 0.34 higher *log-mae*. These results suggest that current pretrained transformers do not capture numeracy to a large extent.

4.2 Dimension Prediction

We train our models and their ablations on the full dataset and measure their performance on dimension prediction. In Table 4, we show the results of dimension prediction conditioned on $\boldsymbol{S}$. We observe that the performance gap between the frozen and unfrozen *GeMM* grows to 19.5 F1 on the test split despite training on 3 orders of magnitude more training data than the few-shot setting.

By using Bayes' rule, we perform dimension prediction conditioned on both $\boldsymbol{S}$ and $\bar{\boldsymbol{Y}}$ and show our results in Table 5. We observe that both models show improved dimension prediction ability when supplied with the number with *GeMM* U→Y reaching 96.6 F1 score, an effective error rate reduction of 75%.

4.3 Unit Prediction

We show the unit prediction performance of our models in Table 6. The strongest performing model for unit prediction was *GeMM* with a F1 score of 54.9. Again, the frozen *GeMM*❄ produced a 25.1 lower F1 score than its unfrozen counterpart.

We note that even though the F1 scores on unit prediction are much lower than dimension prediction, they are still significantly better than the majority baseline. Although one can freely substitute a unit with one in the same dimensional class, we tend to be more systematic and choose units that allow for more straightforward human readability or reflect the actual instruments used for measure-

Model	Probing Type	Val	Test
Median	-	1.98	1.97
GeMM❄	$p(\bar{\boldsymbol{Y}}\|\boldsymbol{S})$	1.377	1.370
GeMM -U -D	$p(\bar{\boldsymbol{Y}}\|\boldsymbol{S})$	0.529	0.531
GeMM -U	$p(\bar{\boldsymbol{Y}}\|\boldsymbol{D},\boldsymbol{S})$	0.468	0.469
	$p(\bar{\boldsymbol{Y}},\boldsymbol{D}\|\boldsymbol{S})$	0.517	0.518
Lat-Dim	$p(\bar{\boldsymbol{Y}},\boldsymbol{D}\|\boldsymbol{S})$	0.545	0.546
GeMM	$p(\bar{\boldsymbol{Y}}\|\boldsymbol{S})$	0.517	**0.515**
GeMM U→Y	$p(\bar{\boldsymbol{Y}}\|\boldsymbol{U},\boldsymbol{D},\boldsymbol{S})$	0.401	**0.401**
	$p(\bar{\boldsymbol{Y}},\boldsymbol{U},\boldsymbol{D}\|\boldsymbol{S})$	0.526	0.526

Table 7: Results (*log-mae* ↓) for number prediction conditioned on $\boldsymbol{S}$. In the second row of *GeMM* -U, we select the highest scoring $d^* \in \boldsymbol{D}$ and predict y conditioned on d^* and $\boldsymbol{S}$. In the second row of *GeMM* U→Y, we select the highest scoring $u^* \in \boldsymbol{U}$ and $d^* \in \boldsymbol{D}$ and predict y conditioned on u^*, d^*, and $\boldsymbol{S}$. For *Lat-Dim*, we sum over the latent variable $\boldsymbol{D}$ to predict y conditioned on $\boldsymbol{S}$.

ment. As a result, we gravitate towards regularities that models can learn to recognize. The converse of this is also interesting as it suggests that the expressed units imply more semantic meaning than what is captured in the standardized measurement.

4.4 Number Prediction

We show the number prediction performance of our models in Table 7. Consistent with our previous experiments, all models outperform *GeMM*❄. Furthermore, we observe that not modeling $\boldsymbol{U}$ and $\boldsymbol{D}$ (as is the case in *GeMM* -U -D) increases *log-mae*, i.e., results in worse numerical prediction. While competitive with *GeMM* and its variants on number prediction, *Lat-Dim* cannot predict dimensions with the same efficacy (Table 4).

We also experiment with the setting where *GeMM* -U conditionally generates the number for a particular dimension. In this setting, *GeMM* -U improves *log-mae* to 0.469. Extending this setting further, we condition *GeMM* U→Y on both a unit and a dimension to produce the best *log-mae* among our models: 0.401.

We now revisit our original motivating example: *"Alex Honnold climbed for [NUM] [UNIT]"*. Assume we want to know the distance of a climb. To do this, we condition *GeMM* U→Y on $\boldsymbol{D} = \textit{length}$ and $\boldsymbol{U} = \textit{feet}$. If, on the other hand, we want to know the duration of a climb, we change the conditioning to $\boldsymbol{D} = \textit{time}$ and $\boldsymbol{U} = \textit{hours}$. Now, if we want to know the length of Alex Honnold's climbing career, we condition *GeMM* U→Y on $\boldsymbol{D} = \textit{time}$ and $\boldsymbol{U} = \textit{years}$. These examples illustrate the flexibility of *GeMM* U→Y and the importance of jointly modeling numbers, units, and dimensions.

4.5 Quantitative Analysis

4.5.1 Dimensions and Unit

In Figure 4a we visualize a confusion matrix of dimension predictions by *GeMM* U→Y. The low accuracy for electric charge and temperature is attributed to a mislabeling in the dataset.[3] For mass, we find many ambiguous situations where either mass or length are appropriate. See the first row of Table 10 for such an example.

Thus far, we have treated dimensions as distinct classes with no relationships. However, dimensions are compositions of the seven fundamental dimensions. Therefore, dimensions that share fundamental dimensions are more similar than those that do not. To quantify this similarity, we can treat dimensions as a vector where each element represents the exponent of a fundamental dimension. Then to measure the similarity of two dimensions, we take their Manhattan distance. To illustrate, assume there exist only two fundamental dimensions: Length and Time. Let $\textit{speed} = (1, -1)$ and $\textit{length} = (1, 0)$ where the first element represents Length and the second represents Time. The Manhattan distance between $\textit{speed}$ and $\textit{length}$ is equal to one. In Figure 5, we visualize the Manhattan distance between the predictions of *GeMM* U→Y and ground truth. We observe that there is generally an inverse relationship between error count and the distance of the errors. This observation suggests that our model has learned that some dimensions are more similar than others. This suggestion is reinforced by Figure 4a where misclassifications tend to have small distances from the true dimension. For example, velocity is most often misclassified as length. For unit prediction, we find that most mistakes occur substituting units with ones that have similar magnitudes like feet for meters or kilometers for miles.

4.5.2 Numeracy

In Table 8, we show *log-mae* by dimension as predicted by *GeMM* U→Y. We note that errors are not uniform across dimensions, predicting *areas* is 2.2

---

[3] Sentences with mislabeled `Celsius` as `Coulombs`, which may due to wrong annotation between °`C` and `C`. Also observed by Elazar et al. (2019)

(b)

Figure 4: Confusion matrices for predictions by *GeMM* U→Y over the validation split. **Left 4a:** Dimension prediction. Most misclassified dimensions are similar to their ground truth counterparts in terms of Manhattan distance. **Right 4b:** Unit prediction for examples that share the *length* dimension. Most misclassified units of length share similar magnitudes to their ground truth units.

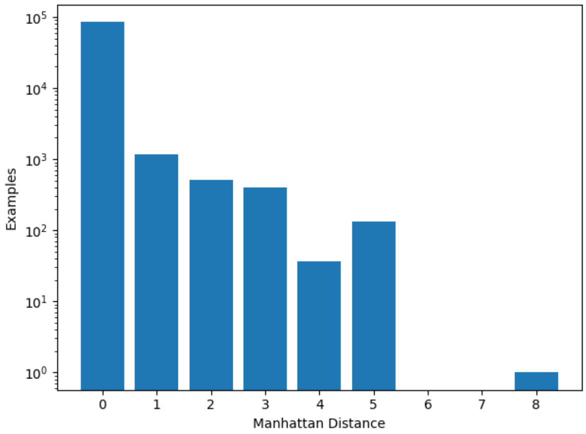

Figure 5: Manhattan distance between true and predicted dimensions by *GeMM* U→Y. We treat dimensions as vectors whose elements are the exponents of the fundamental dimensions that compose a given dimension. Note that the y-axis is in log-scale.

Length	**Area**	**Velocity**	**Mass**	**Power**
0.37	0.54	0.19	0.55	0.27

Table 8: *log-mae* ↓ by dimension. It is harder to predict numbers of Area and Mass than other dimensions.

	Model		**Human**		**Model > Human**
	D	***U***	***D***	***U***	***Y***
Tech Ann.	**96.7**	**86.2**	88.9	46.3	**78.8**
AMT Ann.	**96.7**	**77.0**	89.3	43.5	**66.2**

Table 9: Dimension and unit prediction accuracy of our human evaluation experiment. *GeMM* U→Y outperformed the human annotators in both evaluations. **Tech Ann.** is over a balanced set of 90 sentences labeled by Technical Annotators. **AMT Ann.** is over a balanced set of 2,122 sentences annotated by AMT Annotators. The final column shows the model predicted a number closer to ground truth in 66.2-78.8% of the cases.

times harder *velocities*. We also observe that the magnitudes of errors seem to be positively correlated with the variances observed in Figure 3.

4.5.3 Human Evaluation

We perform two evaluations of *GeMM* U→Y against human annotators. In the first evaluation, we compare against the combined effort of three Technical Annotators on a balanced set of 90 sentences randomly sampled from the test set. The annotators worked together to predict the missing dimensions,

		True			*GeMM* U→Y **Prediction**			**Human Prediction**		
#	**Text**	Dim	Unit	Num	Dim	Unit	Num	Dim	Unit	Num
1	Hope is gaff rigged, 'V'-bottomed and has an [#NUM] [UNIT] centerboard.	Mass	pounds	385.6	Length	feet	2.97	Length	meter	50
2	Some have been running for over 50 years, each covering about [#NUM] [UNIT].	Velocity	$\frac{\text{miles}}{\text{year}}$	0.10	Area	sqkm	2.09E+10	Area	sqmi	2.59E+07
3	Another medium-sized corvid, the [#NUM] [UNIT] Eurasian magpie (Pica pica) is also amongst the most widely reported secondary prey species for goshawks there.	Mass	grams	0.22	**Mass**	**grams**	0.05	**Mass**	**grams**	**0.2**
4	The twin cylinder, liquid-cooled, in-line two-stroke, [#NUM] [UNIT] Rotax 582 has also been used.	Power	horsepower	47725	**Power**	**horsepower**	39248	**Power**	**horsepower**	**45000**
5	Chrysothamnus may grow up to a [#NUM] [UNIT] tall shrub or subshrub, usually with woody stem bases	Length	cms	1.2	**Length**	meters	**1.147**	**Length**	meters	1
6	Kurt Busch was the fastest in the first practice session with a time of 21.372 seconds and a speed of [#NUM] [UNIT].	Velocity	$\frac{\text{miles}}{\text{hour}}$	75.1	**Velocity**	$\frac{\textbf{miles}}{\textbf{hour}}$	**63.584**	**Velocity**	$\frac{\text{meters}}{\text{second}}$	10

Table 10: Instances of the *MMP* task performed during our human evaluation experiment, all numbers are in SI units. In ex. 1, both the model and humans predict the incorrect dimension length instead of mass. The preceding sentence of ex. 2 references "trains" leading both to incorrectly predict area instead of velocity. In ex. 6 the model predicts the speed of the NASCAR driver Kurt Busch's car whereas the humans had mistaken him for a runner.

units, and accurate measurement estimates. Examples of sentences and annotations shown in Table 10.

In the second evaluation, we compare against Amazon Mechanical Turk (AMT) Annotators on a balanced set of 2,122 sentences randomly sampled from the test set. We show the results for both evaluations in Table 9.

In both evaluations, the model outperforms the human annotators on every task. For dimension prediction, the model led by 7.4-7.8 percentage points. Of the sentences where the dimension was correctly annotated, the model led by 33.5-39.9 percentage points on unit prediction. For sentences where both the model and human correctly predicted the dimension, the model predicted a number closer to ground truth 66.2-78.8% of the time.

4.6 Qualitative Analysis

4.6.1 Semantic Head Embeddings

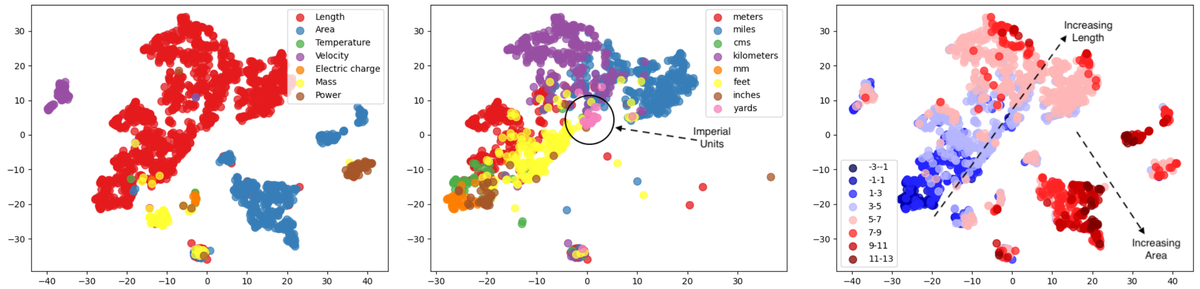
In Figure 6 we plot the t-SNE embeddings of the sentences' $\boldsymbol{h}$, the output of our text encoder. We label each $\boldsymbol{h}$ with the masked measurement's true dimension, unit and exponent of the number. In 6a we observe that most embeddings labeled by their true dimension tend to form tight clusters. In 6b we filter to only show embeddings that share the *Length* dimension and label them by their units. We find that clusters are organized by the relative magnitudes of their units: large (*Kilometers, miles*), medium (*feet, meters*), and small (*millimeters, inches, centimeters*). Further we see that *yards* appear close to other *imperial units* of *feet* and *miles*. Finally, in 6c when embeddings are binned by the exponent of their values we observe that the left to right direction appears to capture the increasing magnitude of a number.

5 Related Work

5.1 Numeracy

Multiple works have probed word embeddings like word2vec, GloVe, FastText (Naik et al., 2019) and contextual embeddings from models like BERT (Wallace et al., 2019; Zhang et al., 2020) or T5 (Pal and Baral, 2021) on a variety of numerical tasks like sorting, numeration, magnitude prediction, and common sense (Lin et al., 2020). Several works have targeted numeracy pretraining using left to right language models (Spithourakis and Riedel, 2018), CNN and RNN based models (Chen et al., 2019), pretrained transformers (Spokoyny and Berg-Kirkpatrick, 2020; Jin et al., 2021), for an overview (Thawani et al., 2021b).

Incorporating synthetic mathematical data augmentations (Geva et al., 2020) has improved question answering while numerical pretraining has been shown to lower masked language modelling perplexity (Thawani et al., 2021a). Either directly or indirectly units have been involved in providing more interpretable explanation of quantities (Chaganty and Liang, 2016), solving Fermi problems (Kalyan et al., 2021) and resolving numeric Fused-Heads (Elazar and Goldberg, 2019).



(a) (b) (c)

Figure 6: t-SNE visualizations of semantic head embeddings labeled by **(left 6a)** dimension, **(middle 6b)** units of *length*, and **(right 6c)** number exponent bin. **Middle**: we observe a clustering of imperial units: feet, yards, miles. **Right**: we show two directions where magnitudes of length and area measurements increase in value.

5.1.1 Numeracy Benchmarks

Several numeracy benchmarks have been proposed like quantitative reasoning in natural language entailment (Ravichander et al., 2019) and synthetic measurement estimation (Jin et al., 2021). The closest benchmark to our work is the Distribution over Quantities dataset (DoQ) introduced by Elazar et al. (2019). A rule-based method was combined with simple heuristics to build DoQ resulting in its high-coverage albeit also higher noise. Although, *WiCo* is smaller, it has much higher fidelity since it utilizes a feature used by editors of Wikipedia to automatically convert quantities into different units. Further, *WiCo* provides the whole sentence as context as opposed to triplets of words. Zhang et al. (2020) use artificial templates to probe models on DoQ and find little difference between numerically pretrained and frozen embeddings such as ELMo. In contrast, our findings show there is a significant gap on *WiCo* between fully finetuned models and their frozen counterparts.

6 Limitations

The pretrained RoBERTa model we use in experiments was likely pretrained on data that included *WiCo*. Thus, it is reasonable to be concerned about inflated test performance. That said, the task we consider is distinct from the self-supervised task used to pretrain RoBERTa (i.e. masked word classification vs. masked number regression). Further, our experiments on directly probing RoBERTa to predict masked numbers and units showed poor performance – indicating, perhaps, that even if RoBERTa's pre-training set did include *WiCo*, RoBERTa did not memorize aspects of our test set relevant to masked number prediction, partially mitigating these concerns.

The human evaluation studies we conducted are a quite limited 'guesstimating' task. The human annotators were not allowed to use any external information from searching the internet or looking up answers in knowledge-bases. Their total average completion time per question was 33 seconds. Furthermore, many annotators may not have strong intuition about measurements with unfamiliar and uncommon unit types. For these reasons it is not surprising that our models outperform the human annotators in this limited experiment. However, these human evaluation studies do help calibrate the difficulty of the *MMP* task on *WiCo*.

7 Conclusion

In this work we propose Masked Measurement Prediction, a new task that requires models to jointly predict masked numbers and units in running text. We motivate this task as an important extension of existing masked number-only prediction tasks that addresses their limitations and allows for better evaluation of numeracy in NLP models. In our study, we show that probing of traditional pretrained transformers exposes a gap in their understanding of contextualized quantities. Through careful quantitative and qualitative analysis of our new model, which directly reasons about underlying units and dimensions, we find that it is possible to learn good representations of measurements. For future work we aim to extend this dataset to cover more existing standardized units from organizations such as UNECE.[4] We hope our *MMP* task encourages research into further development of better numeracy methodologies.

A Dataset

We train and evaluate our models on Wiki-Convert (*WiCo*) (Thawani et al., 2021a), a dataset of English Wikipedia sentences where the number and unit in each sentence are human-annotated. The built-in template in Wikipedia can ensure the text contains numbers and units. For example, `{{convert|2|km|mi}}` displays as `2 kilometres (1.2 mi)`. By searching within Wikipedia articles for the use of this template, the authors of *WiCo* automatically extract human-annotated numbers. To perform unit canonicalization, we use Pint [5] whenever the mapping is unambiguous. In the ambiguous case, we manually inspect the sentence and perform the mapping. For example, we map the unit `sqmi` in *WiCo* to `square miles` to let pint perform unit canonicalization. Table 10 shows examples of the extended dataset. The original dataset contains 924,473 sentence. The median sentence length is 106 characters, with 29,597 sentences has a length shorter than 20 characters. We provide statistics of the data in Table 1. For preprocessing we exclude sentences which have more than 64 tokens to have efficient computing memory or where the number is negative for simplicity. According to Thawani et al. (2021a) *WiCo*, "... has been extracted from Wikipedia dumps, which are licensed under the GNU Free Documentation License (GFDL) and the Creative Commons Attribution-Share-Alike 3.0 License." Thawani et al. (2021a) constructed *WiCo* with the intent that it be used to further numeracy NLP research. Our use of *WiCo* is aligned with its authors' goals.

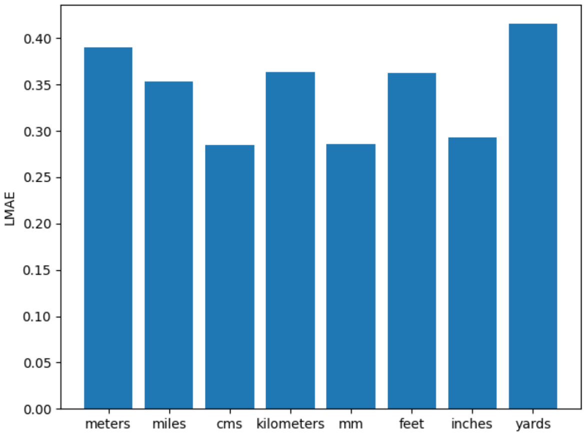

Figure 7: *log-mae* ↓ by units of length. Predicting numbers for small magnitude units is easier than predicting numbers for their larger counterparts.

B MLM Preliminary Unit Probe

We perform a preliminary unit probe shown in Table 11. The model predicts vastly different numbers when conditioned on different units. We observe a mean of 3086.8 and a standard deviation of 5820 for all the converted metric output.

C Experiments

We train our model *GeMM* U→Y on a single Nvidia GeForce RTX 2080 Ti for 4 hours and 14 minutes with a total parameter of 124,696,538.

C.1 Quantitative Analysis

In Figure 7, we show *log-mae* is relatively small for small magnitude units, which means predicting

numbers for small magnitude units is easier than predicting numbers for their larger counterparts.

In Figure 4, we show confusion matrices of dimension and unit predictions by *GeMM* U→Y.

D Human Annotators

D.1 Evaluation 1

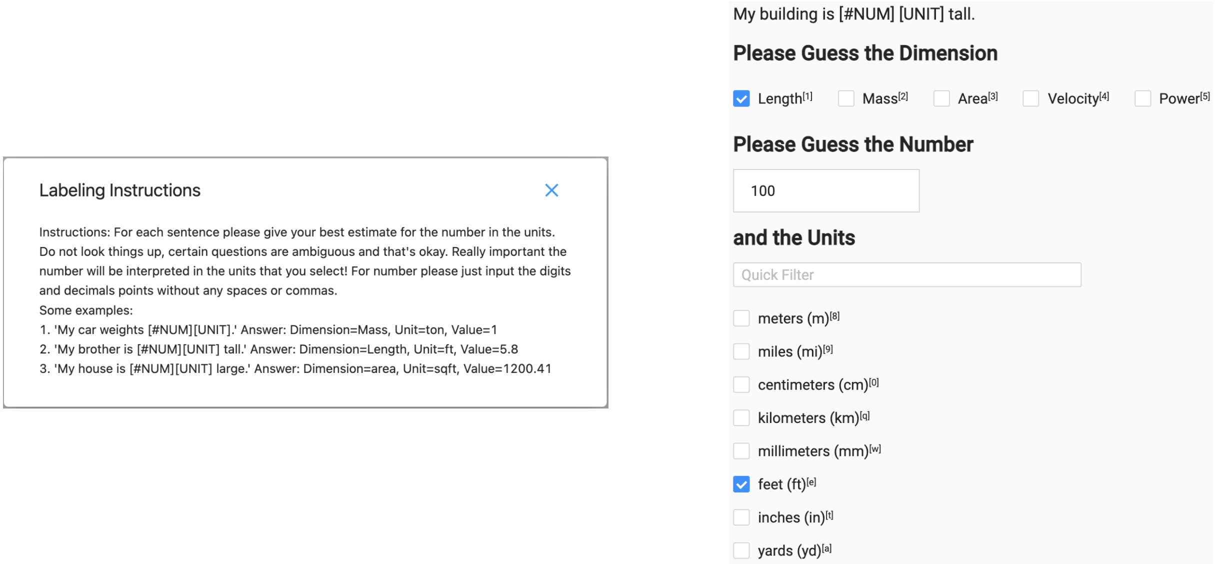
The Technical Annotators have diverse scientific backgrounds ranging from chemistry, earth sciences, and computer science. One annotator is a native Chinese speaker, and two are native English speakers.

D.2 Evaluation 2

In Figure 8 we show the instructions provided along with the interface we designed for our *MMP* task. While the workers' geographic location were not provided to us by Mechanical Turk, we aimed to compensate the workers above the US federal minimum wage of $7.25. We paid workers $0.15 per annotation with an average completion time of 33 seconds. This equates to an hourly rate of $12.80 after Mechanical Turk fees. Other demographic information is only provided by Mechanical Turk for an extra fee.

E Ethical Considerations

Like any system that makes predictions, those made by *GeMM* are not necessarily accurate and may be used by malicious actors to generate fake information to mislead their audience. Additionally, *GeMM* is an extension of RoBERTa and therefore inherits the biases learned during the training of RoBERTa. Our work focuses exclusively on English and Arabic numerals. As noted by Thawani et al. (2021a), the units in *WiCo* are heavily biased towards European and American units as they are over-represented in English Wikipedia.



Labeling Instructions

Instructions: For each sentence please give your best estimate for the number in the units. Do not look things up, certain questions are ambiguous and that's okay. Really important the number will be interpreted in the units that you select! For number please just input the digits and decimals points without any spaces or commas.
Some examples:
1. 'My car weights [#NUM][UNIT].' Answer: Dimension=Mass, Unit=ton, Value=1
2. 'My brother is [#NUM][UNIT] tall.' Answer: Dimension=Length, Unit=ft, Value=5.8
3. 'My house is [#NUM][UNIT] large.' Answer: Dimension=area, Unit=sqft, Value=1200.41

My building is [#NUM] [UNIT] tall.

PromptGen: Automatically Generate Prompts using Generative Models

Yue Zhang, Hongliang Fei, Dingcheng Li, Ping Li

Abstract

Recently, prompt learning has received significant attention, where the downstream tasks are reformulated to the mask-filling task with the help of a textual prompt. The key point of prompt learning is finding the most appropriate prompt. This paper proposes a novel model `PromptGen`, which can automatically generate prompts conditional on the input sentence. `PromptGen` is the first work considering dynamic prompt generation for knowledge probing, based on a pre-trained generative model. To mitigate any label information leaking from the pre-trained generative model, when given a generated prompt, we replace the query input with "None". We pursue that this perturbed context-free prompt cannot trigger the correct label. We evaluate our model on the knowledge probing LAMA benchmark, and show that PromptGen significantly outperforms other baselines.

1 Introduction

Prompt learning (Petroni et al., 2019; Kassner et al., 2021) is a new learning paradigm for utilizing pretrained language models (LM), where downstream tasks are reformulated as a mask filling task with the help of a textual prompt in the original pretrained LM. Recently, prompt learning has been used in applications such as knowledge probing (Petroni et al., 2019; Zhong et al., 2021; Jiang et al., 2021), text classification (Gao et al., 2021; Han et al., 2021; Chen et al., 2021; Chai et al., 2020), natural language inference (Shin et al., 2020; Gao et al., 2021). Furthermore, prompt learning has shown its utility in solving few-shot learning problems (Schick and Schütze, 2021; Gao et al., 2021).

The essence of prompt learning is designing the most appropriate prompts to trigger the correct target text for downstream tasks from an LM. The latest methods to construct prompts include: i) handwritten prompts (Petroni et al., 2019), where users manually create intuitive templates based on human introspection, and ii) automatically searched prompts (Shin et al., 2020; Zhong et al., 2021; Gao et al., 2021; Qin and Eisner, 2021), where researchers search over the space of input tokens or embeddings for prompts that elicit correct predictions in the dev set. Although manually written prompts are interpretable, they are limited by the manual effort, and might not be optimal for eliciting correct predictions. The automated approaches (Shin et al., 2020; Zhong et al., 2021; Gao et al., 2021) can overcome the limitations of manual prompts by training a model, but they learn a universal prompt for each task (e.g., factual probing for one relation), regardless of different inputs. But such a setting may result in sub-optimal prompts. For example in factual probing, different subjects might have a different context when describing the same relation in an open-domain corpus. Similarly, for sentiment analysis, different query sentences might have different syntax or semantics.

We hypothesize that learning different prompts conditioned on inputs can benefit the overall masked filling accuracy in prompt learning. Towards that end, we propose a dynamic prompt generation model, named as `promptGen`, to automatically generate prompts based on inputs by leveraging the pre-trained generative model BART (Lewis et al., 2020). Generally, `PromptGen` consists of an encoder and an autoregressive decoder based on Transformer (Vaswani et al., 2017). We show the overall architecture of `PromptGen` applied on factual probing task in Figure 1. A knowledge fact is defined as a triplet: <sub, rel, obj>. The encoder produces a latent representation from input <sub, rel>, and the decoder autoregressively generates prompt in the form of [sub][D_1]...[MASK]..., [D_{m+n}]. Generated prompts are then passed to a fixed pretrained LM (e.g., BERT) to fill <MASK> as [obj]. A cross-entropy loss will be calculated based on the pre-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 30 - 37
July 10-15, 2022 ©2022 Association for Computational Linguistics

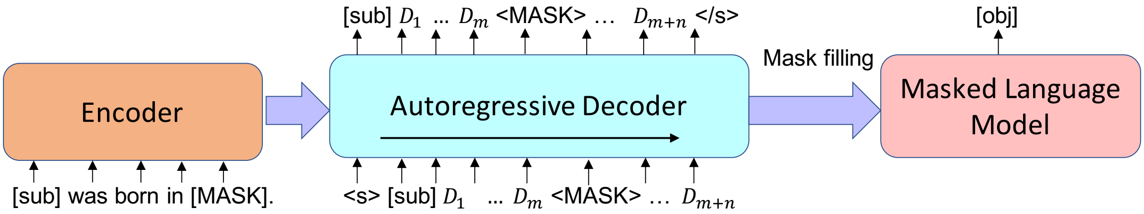

Figure 1: The overall architecture of our model `PromptGen`. `PromptGen` consists of an encoder and an autoregressive decoder. The downstream MLM is fixed and without fine-tuning. We will fine-tune the encoder and decoder to generate optimal prompts. Note that [sub] and <MASK> are directly copied in the decoding stage.

dicted [obj] v.s. ground-truth and backpropagated to update BART's weights. Compared to previous search models, although `PromptGen` has a higher computation cost, we find more appropriate and contextualized prompts, which is especially important for knowledge probing.

However, it is nontrivial to adopt a generative model for prompt generation. First, to make our model end-to-end trainable, at each decoding step, our decoder outputs a multinomial distribution over predefined vocabulary. Hence we finally get a sequence of distributions as our prompt, instead of a sequence of tokens. The token embedding of each $[\mathbf{D}_i]$ is a linear combination of the embedding of all tokens in the vocabulary. We then pass the generated prompts into an LM to fill the mask. Moreover, we should avoid any label information leaking from the pre-trained generative model. With pretraining, generative models can store related knowledge regarding input subjects, but we want to generate context-aware (i.e., <sub, rel>) prompts without leaking label information (i.e., object). Without any constraint, after generative model fine-tuning, the generated prompts could be trivial. For example, for input <Obama, place of birth>, the prompts could be "Obama...Hawaii...[MASK]...". It is trivial since it leaks the object label "Hawaii". To mitigate label leaking, we replace [sub] of a generated prompt with "None" and pass the perturbed prompt to LM. We pursue that the perturbed prompt cannot trigger the corresponding [obj] from a downstream MLM. Such a perturbation strategy was previously used for calibration (Zhao et al., 2021) and robustness improvement (Wang et al., 2021), and we are the first to use this strategy for the prompt generation.

Our contributions are as follows: i) We propose the first generative model based prompt generation method for knowledge probing. Meanwhile, we develop effective strategies to make the whole framework end-to-end trainable and avoid label leaking, ii) We evaluate our model on the factual probing benchmark LAMA (Petroni et al., 2019) and show that our model can significantly outperform other baselines. Detailed comparison and analysis justify our modeling choice.

2 Related Work

Factual Probing The factual probing setting was introduced by the LAMA benchmark (Petroni et al., 2019; Jiang et al., 2020; Shin et al., 2020), where given subject and relation, we want to infer the object by querying a pre-trained MLM. In contrast to previous knowledge graph completion models (Zhang et al., 2022b; Huang et al., 2019; Zhang et al., 2020; Liu et al., 2020; Yu et al., 2021) and information extraction models (Zhang et al., 2021, 2022a), where they need to fine-tune a pre-trained MLM. Here, we convert the knowledge graph completion task into a mask filling task, without MLM fine-tuning.

Pre-trained Generative Models. Our work is based on generative models, hence recent pre-trained generative models are related, including GPT-3 (Brown et al., 2020), BART (Lewis et al., 2020) and T5 (Raffel et al., 2020), all of which are capable of filling in missing spans in the input. Among all prompt search methods, Gao et al. (2021) is the most similar to ours since they used T5 to construct prompts. Compared with our work, Gao et al. (2021) uses T5 without fine-tuning, and they learn one prompt for all inputs. In our work, we learn dynamic prompts conditional on the given input and fine-tune on the generative model.

Instance-level Prompt Learning. Concurrently, couple instance-level prompt learning methods are developed, where given different query input, they utilize different prompts. Jin et al. (2022) learns instance-level prompts through calculating the relevance scores between token embedding in a universal prompt and token embedding in a given query, then the relevance scores are used to map the universal prompt into an instance-level prompt. IDPG (Wu et al., 2022) leans a light-weight generator to generate prompts, which are similar to our PromptGen. However, for downstream tasks, IDPG extracts the representation of [CLS] token to make the final predictions. So, IDPG has to fine-tune the pre-trained MLM, while we keep the downstream MLM frozen.

3 Methodology

We elaborate our method on the application of the LAMA task, in which the downstream MLM is BERT (Devlin et al., 2019). Our generative model adopts pre-trained BART (Lewis et al., 2020).

Given a subject s, relation r, a generated prompt $\mathcal{T}_{<r,s>}$, and an MLM, we can identify the word $\hat{o} \in \mathcal{V}$ to which the MLM assigns the highest probability of $P([\text{MASK}] = \hat{o}|\mathcal{T}_{<r,s>})$, where $\mathcal{T}_{<r,s>}$ represents the generated prompt conditional on relation r and subject s; $\mathcal{V}$ represents the predefined vocabulary. If the MLM can fill in the mask with the correct object, we conclude that the MLM encodes information about the fact. In this work, we will fine-tune BART using our novel approach to generate the optimal prompts.

3.1 Conditionally Generate Prompts

3.1.1 Input and Output Format

The input of our generative model is the manual prompt provided by the LAMA dataset. For instances: for relation "place of birth", our input is "[sub] was born in [MASK]"; for relation "occupation", our input is "[sub] is a [MASK] by profession". Here, [sub] will be replaced by a concrete subject name, e.g., "Obama", "Dante".

The prompt is generated from the decoder. Our prompt is in the following form:

$$\texttt{[sub]}\ [\mathrm{D}]_1\ [\mathrm{D}]_2 \ldots [\mathrm{D}]_{\mathrm{m}}\ \texttt{[MASK]}\ [\mathrm{D}]_{\mathrm{m+1}} \ldots [\mathrm{D}]_{\mathrm{m+n}}$$

where m is pre-defined maximal number of triggers between [sub] and [MASK]; n is the maximal number of triggers after [MASK]; each $[D]_i$ represents a multinomial distribution over vocabulary $\mathcal{V}_{\text{common}}$. Since the vocabulary of the generative model and the vocabulary of MLM could be different, we consider the intersection of their vocabularies, which is represented as $\mathcal{V}_{\text{common}}$.

3.1.2 Generating Procedure

Generative models usually are trained under the sequence-to-sequence framework. While, in our work, the target sequence (i.e., prompt) is unknown, our model will generate the optimal target sequence through exploration. Also, in the classic sequence-to-sequence framework, people consider the teacher forcing training strategy, where during training, the model uses the ground truth as decoder input. Since we have no ground truth target sequence, at each decoding step, we use the model output from a prior time as the current input.

At each decoding step t, our decoder computes the current hidden state h_t and current token distribution D_t, based on the current sequence $[\mathrm{D}_1], \ldots, [\mathrm{D}_{t-1}]$, and the encoding output h_{encode}:

$$\begin{aligned} h_{\text{encode}} &= \texttt{Encoder}(s, r) \\ h_t &= \texttt{Decoder}(h_{\text{encode}}, [\mathrm{D}_1], \ldots, [\mathrm{D}_{t-1}]) \\ \mathrm{D}_t &= \mathrm{Softmax}(h_t) \end{aligned}$$

where, `Encoder` and `Decoder` both adopt Transformer architecture; h_{encode} only needs to be computed once for each input <s, r>; h_t and D_t are calculated recursively from `Decoder`. In the below section, we will elaborate how to compute word embedding for sequence of distributions $[\mathrm{D}_1], \ldots, [\mathrm{D}_{m+n}]$ in Transformer `Decoder`.

Assuming the BART word embedding matrix for tokens in vocabulary $\mathcal{V}_{\text{common}}$ is $\mathcal{E}_V \in \mathcal{R}^{|V| \times d}$, we know that each $[\mathrm{D}_i]$ is a multinomial distribution on $\mathcal{V}_{\text{common}}$, so the embedding vector $\mathcal{E}_{D_i}$ for each $[\mathrm{D}_i]$ is a linear combination on $\mathcal{E}_V$:

$$\mathcal{E}_{D_i} = \mathrm{D}_i^T * \mathcal{E}_V \tag{1}$$

Encoding position embedding for $[\mathrm{D}_i]$ is straightforward, depending on its position in a sequence.

During generating, assuming the current output is D_i, where $i \in [1, m]$, if the highest possibility token is </s> or the sequence reaches the maximal number m, we stop current generation, and start generating $[\mathrm{D}_{m+1}] \ldots [\mathrm{D}_{m+n}]$. The same is for generating $[\mathrm{D}_i]$, where $i \in [m+1, m+n]$.

3.2 Optimization

The generated prompt $\mathcal{T}_{<s,r>}$ is passed forward to a downstream MLM. Following the convention of BERT, we add special tokens [CLS] (or <s>), [SEP] (or </s>) at the first and the last position of the prompt, separately. The calculation of word embedding of $[D_i]$ in the downstream MLM is the same as Equation (1), where $\mathcal{E}_V$ will be from the MLM.

The downstream MLM can be viewed as a blackbox, and it is used as a critic to evaluate the quality of our generated prompts. We fine-tune the parameters of the generative model to minimize the negative log-likelihood of a training set $\Pi = \{<s, r, o>\}$:

$$\mathcal{L}_{\Pi} = -\frac{1}{|\Pi|} \sum_{<s,r,o>\in\Pi} \log P([\text{MASK}] = o | \mathcal{T}_{<r,s>}),$$

where we use all the training data from different relations together to train our model.

3.2.1 Label Information Leaking Constraint

The pre-trained generative model has the ability to store open-domain knowledge during pre-training. Without any constraint, the generated prompts could be trivial and leak the label information.

To avoid label leaking, we develop a novel constraint. We replace the [sub] of $\mathcal{T}_{<r,s>}$ with "None", and get a perturbed prompt $\mathcal{T}^{(\text{None})}_{<r,s>}$. We argue that for a non-trivial $\mathcal{T}_{<r,s>}$, its corresponding $\mathcal{T}^{(\text{None})}_{<r,s>}$ has no ability to trigger the correct [obj] from the downstream MLM, since $\mathcal{T}^{(\text{None})}_{<r,s>}$ is a context-free input. For example, assuming we pass "None was born in [MASK]" into an MLM, the possibility of filling the mask with "Hawaii" will be low without knowing the subject of "Obama". We define the second objective function as:

$$\mathcal{L}_{\text{perturb}} = \frac{1}{|\Pi|} \sum_{<s,r,o>\in\Pi} \log P([\text{MASK}] = o | \mathcal{T}^{(\text{None})}_{<r,s>}),$$

through which the log-likelihood of training set is minimized. Finally, the overall objective function becomes $\mathcal{L} = \mathcal{L}_{\Pi} + \alpha * \mathcal{L}_{\text{perturb}}$, where $\alpha \geq 0$ is a hyper-parameter.

4 Experiments

4.1 Experimental setup

Following the same setting of Shin et al. (2020); Zhong et al. (2021), we use the original test set, and the training LAMA dataset contains 1000 facts for each of the 41 relations from T-REx dataset (ElSahar et al., 2018) and Wikidata. Refer to Appendix for implementation details.

We compare our model with the following baselines: 1) manually created prompts (Petroni et al., 2019). 2) LPAQA (Jiang et al., 2020). 3) Gao et al. (2021) [1]. 4) AutoPrompt (Shin et al., 2020), where "* [T]s" means using * token triggers. 5) OptiPrompt (Zhong et al., 2021), where "* [V]s" means using * vector triggers; "manual" means using manually designed prompts as initialization.

4.2 Results

For all our models, we set m=10, n=5. Our results are in Table 1. The LAMA results are broken down by relation category. Relations from each category can refer to Table 4 in Appendix. Overall, `PromptGen` outperforms the previously reported results in terms of top-1 accuracy on the LAMA benchmark. The improvement is consistent across all categories, except for the "1-1" category, which contains two relations, "capital" and its inverse "capital of". We see that the best result in this category is the manual prompt. The intuitive explanation behind this is that the variety of natural language expressions about "capital of" in open-domain knowledge is low, so it's hard for our model outperforms manually designed prompts.

The detailed results on each relation are in Table 4 in the Appendix.

Method	1-1	N-1	N-M	All
Manual	**68.0**	32.4	24.7	31.1
LPAQA	65.0	35.9	27.9	34.1
Gao et al. (2021)	22.5	12.7	8.5	11.4
AutoPrompt (5 [T]s)	58.0	46.5	34.0	42.2
OptiPrompt (5 [V]s)	49.6	53.1	39.4	47.6
OptiPrompt (10 [V]s)	60.7	53.2	39.2	48.1
OptiPrompt (manual)	59.6	54.1	40.1	48.6
Ours ($\alpha = 0.3$)	54.8	**55.3**	**44.0**	**51.0**

Table 1: Micro-averaged results (top-1 accuracy in %) on the LAMA benchmark using the BERT-base-cased model, averaged over relations.

4.2.1 Hyper-parameter Analysis

In this section, we analyze the effect of hyper-parameter α. We set α equals to 0.0, 0.2, 0.3 and 0.4, separately, and the results of variants are reported in Table 2. The best result comes from $\alpha = 0.3$. Although $\alpha = 0.0$ gives us the second best result, we find that when we replace the [sub] in generated prompts into 'None", the top-1 accuracy is still 48.1, which proves that without label information leaking constraint ($\alpha = 0.0$), the generated prompts are trivial. For $\alpha = 0.2, 0.3, 0.4$, their top-1 accuracy using perturbed prompts all equals to 0, which proves the effectiveness of our label information leaking constraint.

---

[1] We generate one prompt for each relation using T5, given input in the form of "[sub] [extra_id_0] [obj] [extra_id_1]", where [sub] and [obj] are from training set. The filling result of [extra_id_0] and [extra_id_1] will be used as final prompt.

Method	1-1	N-1	N-M	All	"None"
$\alpha = 0.0$	53.9	53.9	43.1	49.7	48.1
$\alpha = 0.2$	53.4	53.5	43.3	49.6	0.0
$\alpha = 0.3$	**54.8**	**55.3**	**44.0**	**51.0**	0.0
$\alpha = 0.4$	39.4	49.3	38.4	44.9	0.0

Table 2: Results of Variants on the LAMA benchmark.

4.2.2 Case Study of Generated Prompts

We show two case studies on relation "instrument" in Table 3 comparing with AutoPrompt, which used a fixed prompt for one relation regardless of input. We report the generated prompts by choosing the highest probability token for each D_i, and the top-1 predictions from BERT. We highlight the [sub] in blue, and wrong predictions in red.

Method	Generated prompt	top-1
AutoPro	Joe Pass playingdrum concertoative electric [MASK].	piano
Ours	Joe Pass and not violin yeah much like majority depending Resources [MASK].	guitar
AutoPro	Marco Benevento playingdrum concertoative electric [MASK].	piano
Ours	Marco Benevento and not violin yeah much like trafficking UNESCO partly [MASK].	piano

Table 3: Case Study on relation "instrument".

We find that AutoPrompt always triggers the MLM to predict the majority label "piano", regardless of the subject. Through dynamic prompts, we bypass this issue.

5 Conclusion

In this work, we propose `PromptGen` for knowledge probing, which can automatically generate prompts conditional on the given query (i.e., subject, relation). Our `PromptGen` leverages a pre-trained generative model, e.g., BART. `PromptGen` is end-to-end trainable, where we fine-tune the parameters of the generative model, while keeping the downstream pre-trained MLM frozen. We evaluate `PromptGen` on the benchmark LAMA dataset. We observe the significant improvement of the performance on the downstream MLM by finding more appropriate dynamic prompts without label information leaking.

Table 4: The accuracy of different prompts on LAMA for each relation using BERT-base-cased.

A.1 Implementation Details

We adopt "BART-large" as our generative module and "BERT-base-cased" as our MLM module, both of which are collected from Huggingface website[2]. We use the Adam optimizer with learning rate $5e-5$, set warm-up ratio to 0.1, and weight decay to 1e-3. We repeat our experiments five times and report the average metrics on the test set.

A.2 Detailed Results

Table 4 shows the per-relation accuracy for each prompting method. We see that our method achieves the best performance for most cases.

Abstract

A key challenge of Conversational Recommendation Systems (CRS) is to integrate the recommendation function and the dialog generation function smoothly. Previous works employ graph neural networks with external knowledge graphs (KG) to model individual recommendation items and integrate KGs with language models through attention mechanisms for response generation. Although previous approaches prove effective, there is still room for improvement. For example, KG-based approaches only rely on entity relations and bag-of-words to recommend items and neglect the information in the conversational context. We propose to improve the usage of dialog context for both recommendation and response generation using an encoding architecture along with the self-attention mechanism of transformers. In this paper, we propose a simple yet effective architecture comprising a pre-trained language model (PLM) and an item metadata encoder to integrate the recommendation and the dialog generation better. The proposed item encoder learns to map item metadata to embeddings reflecting the rich information of the item, which can be matched with dialog context. The PLM then consumes the context-aware item embeddings and dialog context to generate high-quality recommendations and responses. Experimental results on the benchmark dataset ReDial show that our model obtains state-of-the-art results on both recommendation and response generation tasks[1].

1 Introduction

An automated conversational recommendation system (CRS) (Li et al., 2018; Zhou et al., 2020) is intended to interact with users and provide accurate product recommendations (e.g., movies, songs, and consumables). It has been a focal point of research lately due to its potential applications in the e-commerce industry. Traditional recommendation systems collect user preferences from implicit feedback such as click-through-rate (Zhou et al., 2018) or purchase history and apply collaborative filtering (Su and Khoshgoftaar, 2009; Shi et al., 2014) or deep learning models (Covington et al., 2016; He et al., 2017) to construct latent spaces for user preferences. Unlike traditional recommendation systems, CRSs directly extract user preferences from live dialog history to precisely address the users' needs.

Although some progress has been made in this area, there is still room for improvement. First, previous CRSs (Chen et al., 2019; Zhou et al., 2020; Li et al., 2021) track entities mentioned in the dialog context, and then search related items in knowledge graphs to recommend to users. However, these systems require a named-entity recognition (NER) module to extract mentioned entities from the dialog context. Thus we need to collect additional domain-specific data to train the NER module. In practice, such NER modules have deficient performance, leading to a bad accuracy of CRS. Second, existing CRSs built upon graph neural networks (Kipf and Welling, 2017; Schlichtkrull et al., 2018) cannot quickly scale up or respond to rapid changes of the underlining entities. In e-commerce, items for recommendation change frequently due to constant updates of merchants and products. Existing approaches require either re-training the entire system when the structure of knowledge graph changes (Dettmers et al., 2018) or adding complex architectures on top to be adaptive (Wu et al., 2019). A more flexible architecture can help the system react to rapid changes and adapt itself to new items.

Moreover, meta-information about the items can be leveraged. Similar information can be found in both dialog context and item meta-information. For example, in a movie recommendation setting, words like "crime, gangsters, etc." are likely to exist in the dialog context when a user is searching

Findings of the Association for Computational Linguistics: NAACL 2022, pages 38 - 48
July 10-15, 2022

for crime movies. In the synopsis of a crime movie, such keywords are likely to exist as well. Ideally, an alignment between the semantics of dialog context and the item meta-information can be used to improve system's performance.

Driven by the motivations above, we present a **M**etadata **E**nhanced learning approach via **S**emantic **E**xtraction from dialog context i.e. **MESE**. The major components of MESE contain a pre-trained language model (PLM) and an item encoder architecture. The item encoder takes item metadata as input and outputs a vector embedding. By jointly training the encoder and the PLM, the entire system can extract co-occurring information between dialog context and item metadata, and item encoders can systematically construct representations reflecting this alignment. Item embeddings are then consumed with dialog context by the self-attention mechanism of the PLM. This mechanism smoothly integrates dialog context and item information well into the recommendation and response generation tasks.

The key contributions of this paper are summarized as follows: This paper presents MESE, a novel CRS framework that considers both item metadata and dialog context for recommendations. Our model employs a simple yet effective item metadata encoder that learns to represent rich item information during training. Such encoder can adapt to database changes quickly and is independent of task-specific architectures. Extensive experiments on standard dataset REDIAL demonstrate that MESE outperforms previous state-of-the-art methods on both response generation and recommendation with a large margin.

2 Related Work

The current CRS paradigm contains two major modules: a recommendation module that suggests items based on conversational context and a response generation module that generate responses based on dialog history and the recommended items. Integrating these two modules to perform well on both tasks has been a major challenge. Chen et al. (2019) leverage external knowledge and employees graph neural networks as the backbone to model entities and entity relations in the knowledge graph (KG) to enhance performance. Zhou et al. (2020) introduce a word-level KG (Speer et al., 2017) to the system with semantic fusion (Sun et al., 2019a) to enhance the semantic representations of words and items. Since item information and dialog context are processed separately in the above approaches, they loss integrated sentence-level information. We propose to condition recommendation on integrated contextual information of both dialog context and mentioned entity information. More recent works adopt pre-trained language models (PLM) (Vaswani et al., 2017; Radford et al., 2019; Zhang et al., 2020) and template-based methods to facilitate response generation. Liang et al. (2021) generate a response template containing a mixture of contextual words and slot locations to incorporate recommended items better. Wang et al. (2021) expand the vocabulary list of the PLM to include items to unify the process of item recommendation with response generation. We propose to enhance our PLM with an item metadata encoder to extract context-aware representations by jointly training on both recommendation and response generation tasks. We also generate response templates with slot locations to better incorporate recommended items into responses.

Our work is also inspired by studies from other areas. Recent works have shown that cross-modality training across vision and language tasks can lead to outstanding results in building multi-modal representations (Tan and Bansal, 2019; Lu et al., 2019). In (Tan and Bansal, 2019), a large-scale transformer-based model is adapted with cross-modal encoders to connect visual and linguistic semantics and pre-trained on vision-language pairs to learn cross-modality relationships. Prompt tuning (Li and Liang, 2021; Gao et al., 2021) methods show that PLMs are capable of integrating different sources of information into the same embedding space. In terms of using PLM as a recommendation system, Sun et al. (2019b) train a bidirectional self-attention model to predict masked items and achieve remarkable results. Inspired by the above studies, we propose to use an encoder module to map item meta-information to an embedding space. By jointly training on dialog context and encoded item representations, the system can align these two information streams by fusing the semantic spaces.

3 Approach

In this section, we present our framework MESE that integrates item metadata with dialog context. We first introduce how to encode item metadata and how to blend item information into dialog context. We then illustrate how the recommendation module and the response generation module are built. Finally, we describe the training objectives and the testing process.

3.1 Encoding Item Metadata

We propose to use an item encoder to directly map the metadata of each item to an embedding. In the movie recommendation setting, description on title, genre, actors, directors, and plot are collected as metadata and concatenated with a "[SEP]" token for each movie. This concatenated information is the input to the item encoder which produces a vector representation for each item. The item encoder consists of a DistilBERT (Sanh et al., 2019) model that maps the input sequence to a sequence of vector embeddings, a pooling layer that condenses the sequence embeddings to a single vector embedding, and a feed-forward layer to produce the output embedding with a certain dimension. A visualization of this module is shown in Figure 1.

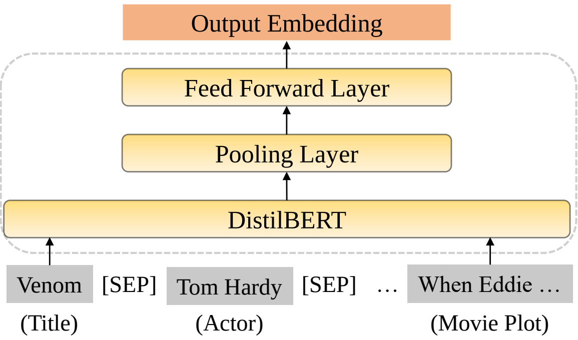

Figure 1: Item Encoder takes in the metadata of an item and outputs an embedding of the item

Next, we discuss how to incorporate items into dialog context with the encoded embeddings and the PLM (Radford et al., 2019). Previous studies have shown that KG-based frameworks cannot always integrate recommended items into generated replies (Wang et al., 2021). To solve this issue, we introduce a special placeholder token "[PH]" to the vocabulary list of the PLM. Every occurrence of item name in the corpus is replaced with this "[PH]" token. This modified dialog sequence is then mapped to a sequence of word token embeddings (WTE) by the vocabulary embedding matrix of the PLM. To include item information into the context, an instance of the item encoder is used to encode item metadata into token embeddings. The item encoder takes in item metadata and outputs an item token embedding (ITE) with the same dimensionality as a WTE of the PLM. The ITE is then concatenated with the WTEs constructed from the dialog context to be consumed by the PLM. An example is shown in 2.

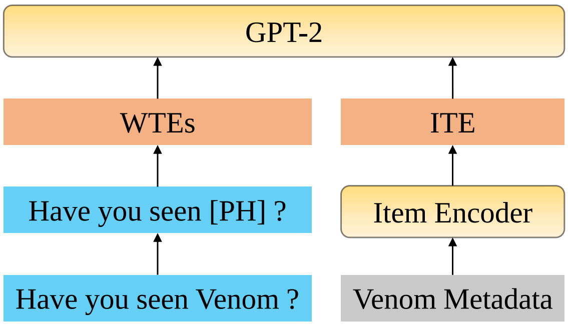

Figure 2: Dialog context is represented as a concatenation of WTEs and ITEs to be consumed by the PLM.

3.2 Recommendation Module

Similar to (Covington et al., 2016), we pose recommendation as a two-phase process: candidate selection and candidate ranking. During candidate selection, the entire item database is traversed and narrowed down to a few hundred candidates based on a calculated similarity score between the dialog context and the item metadata. During candidate ranking, similarity scores between the dialog context and the generated candidates are recomputed with finer granularity by the self-attention mechanism of the PLM.

3.2.1 Candidate Selection

In this section, we describe the training objective of candidate selection. We add a special token "[REC]" to the vocabulary embedding matrix of PLM. This token is used to indicate the start of the recommendation process and to summarize dialog context. At the end of each turn, a token embedding sequence is created following Figure 2 in the format of an interleaving of word token embeddings (WTE) and item token embeddings (ITE) to represent all previous dialog context. When recommendation is labeled in a conversation turn in the training dataset, the WTE of "[REC]" is appended to the previous token embedding sequence to form a new sequence D. Next, the PLM takes in D and produces an output embedding sequence. We denote the last vector of this output embedding sequence as D_R which corresponds to the appended special token "[REC]". D_R summarizes dialog context and can be used to retrieve candidate items.

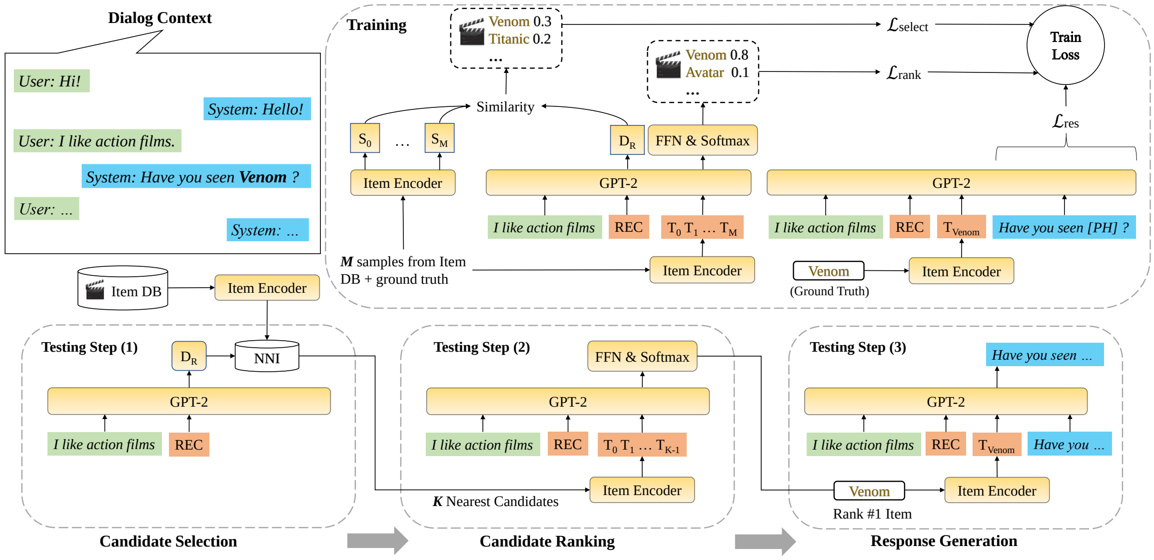

Figure 3: Overview of MESE. During training, M items are sampled from the database to compute the joint loss $\mathcal{L}_{\text{select}}$ and $\mathcal{L}_{\text{rank}}$, which are then combined with the response generation loss $\mathcal{L}_{\text{res}}$ and jointly optimized. During testing, the entire metadata DB is stored as a nearest neighbor index (NNI). First, dialog context is condensed into a vector D_R. An approximate nearest neighbor search is performed on D_R to get candidate items, which is then passed to the ITE Encoder to compute their ranking scores and the the highest-ranked candidate is used as a prompt to generate responses. We only present the case when there's only one ground truth recommendation in the utterance. However, it's easy to extend the above approach to multiple recommendations.

We randomly sample M items and their metadata from the database as negative examples and combine them with the ground truth item labeled in the dataset to get the training samples. Another instance of the item encoder, is used to create candidate token embeddings for each item in the training samples. The item Encoder takes in the metadata of samples items and outputs a set of candidate token embeddings $C = (c_0, c_1, ..., c_M)$, each with the same dimensionality as D_R. The recommendation task at this phase is posed as a multi-class classification problem of predicting the ground truth item over the negative samples (Covington et al., 2016). The probability of each candidate item is defined in (1) and optimized by a cross-entropy loss function, denoted as $\mathcal{L}_{\text{select}}$:

$$P(i) = \frac{e^{c_i \cdot D_R}}{\sum_{n=0}^{M} e^{c_n \cdot D_R}} \qquad (1)$$

Note that the purpose of this learning objective is to let the model learn how to construct the D_R representation instead of learning the probabilities of candidate items. The D_R representation is later used in an approximate nearest neighbor search (Liu et al., 2004) to select candidates from the entire database in testing 3.5.

3.2.2 Candidate Ranking

In this section, we describe the training objective of candidate ranking. The goal of candidate ranking is to further perform more fine-grained scoring on the similarities between generated candidates and dialog context so that the final rankings of items can better reflect users' preferences. We propose to use the PLM and its self-attention to compute ranking scores.

During training, the same context token embedding sequence D and the same training sample with M negative examples are used. The ITE encoder from section 3.1 is used to map the metadata of the sample to an ITE set $T = (t_0, t_1, ..., t_M)$, where the subscript of each t_i corresponds to their index in the database. A concatenation of context sequence D and T are created and consumed by the same PLM used above and the output embeddings are computed. The order of candidate items should not make a difference in the values of the outputs. Therefore, we add the same positional encoding to each ITE in T and remove the attention masks among the ITEs. The output embeddings of PLM that correspond to the ITEs in T are then passed to a feed-forward layer to reduce each vector from a higher dimension to a single number with dimensionality equals 1. This set of numbers is denoted by Q = $(q_0, q_1, ..., q_M)$ where the index of each number corresponds to their index in T. The final ranking score of each candidate item is defined in (2) and optimized by a cross-entropy loss function, denoted as $\mathcal{L}_{\text{rank}}$:

$$R(i) = \frac{e^{q_i}}{\sum_{n=0}^{M} e^{q_n}} \tag{2}$$

3.3 Response Generation Module

In this section, we describe how to train the model to generate responses based on the recommended items' metadata. The same token embedding sequence D is used as context and current system utterance $U = (w_0, w_1, ..., w_n)$ is used as targets where each w_i represents a WTE. We only optimize the PLM to reconstruct system utterances.

If the current utterance contains recommendations, we create ITEs by passing metadata of the recommended items through the item Encoder used in 2 and append the ITEs to context token embedding sequence D to obtain D'. If the current utterance doesn't contain recommendations, D' is the same as D. The PLM is trained to reconstruct the ground truth U based on D'. The probability of generated response is formulated as:

$$P(U|D') = \prod_{i=1}^{n} P(w_i|w_{i-1}, ..., w_0, D') \tag{3}$$

The loss function is set to be:

$$L_{res} = -\frac{1}{N}\sum_{i=1}^{N} log(P(U_i|D')) \tag{4}$$

Where N is the total number of system utterances in one dialog.

3.4 Joint Training

Finally, we use the following combined loss to jointly train both the encoders and the PLM:

$$Loss = a \cdot \mathcal{L}_{\text{select}} + b \cdot \mathcal{L}_{\text{rank}} + c \cdot \mathcal{L}_{\text{res}} \tag{5}$$

Where a, b and c are the weights of language training and recommendation training objectives. During training, all weight parameters of the two item encoders, the PLM and relevant feed-forward layers participate in back-propagation. An overview of training is shown in Figure 3.

3.5 Testing

During testing, a candidate embedding set over the entire item database is built by running metadata through the item encoder used in section 3.2.1 and stored with a nearest neighbor index (NNI) (Muja and Lowe, 2014). During response generation, when a "[REC]" token is generated, candidate selection 3.2.1 is activated. An approximate nearest neighbor search is conducted over the NNI and K closest candidates are selected based on their similarities from the D_R vector[2]. Candidate ranking is then activated and the PLM and the item encoder from Figure 2 are used to generate a score for each candidate. When ranking finishes, the ITE that receives the highest ranking score is appended to the dialog context D and response generation continues until the end-of-sentence token is generated. After generation is completed, we replace the occurrence of the placeholder token "[PH]" with the title of the recommended item to form the final response. Note that when the turn involves no recommendation, our PLM simply generates a clarification question or a chitchat response with no placeholder tokens. An overview of testing is shown in Figure 3.

4 Experiments

In this section, we discuss the datasets used, experimental setup, experimental results on both recommendation and language metrics, and report analysis results with ablation studies.

4.1 Datasets

We evaluated our model on two datasets: ReDial dataset (Li et al., 2018) for comparison with previous models and INSPIRED dataset (Hayati et al., 2020) for ablation studies. Both datasets were collected on Amazon Mechanical Turk (AMT) platform where workers made conversations related to movie seeking and recommending following a set of extensive instructions. The statistics of both datasets are shown in Table 1.

Dataset	dialogs	utterances	avg turns
ReDial	10006	182150	18.2
INSPIRED	1001	35811	10.73

Table 1: Statistics of Datasets

---

[2] Multi-Source Selection in Appendix A

4.2 Experimental Setup

4.2.1 Baselines

The baseline models for evaluation on the ReDial dataset is described below:

ReDial (Li et al., 2018): A dialogue generation model using HRED (Sordoni et al., 2015) as backbone for dialog module

KBRD (Chen et al., 2019): The dialog generation module based on the Transformer architecture (Vaswani et al., 2017). It exploits external knowledge to perform recommendations and language generation.

KGSF (Zhou et al., 2020): Concept-net is used alongside knowledge graph to perform semantic-aware recommendations.

CR-Walker (Ma et al., 2021): performs tree-structured reasoning on a knowledge graph and guides language generation with dialog acts

CRFR (Zhou et al., 2021): conversational context-based reinforcement learning model with multi-hop reasoning on KGs.

NTRD (Liang et al., 2021): an encoder-decoder model is used to generate a response template with slot locations to be filled in with recommended items using a sufficient attention mechanism.

RID (Wang et al., 2021): pre-trained language model and knowledge graph are used to improve CRS performance.

4.2.2 Implementation Details

We employed GPT-2 model (Radford et al., 2019) as the backbone of MESE for dialog generation, which contains 12 layers, 768 hidden units, 12 heads, with 117M parameters. We recruited 2 item encoders (Sanh et al., 2019) to encoder items in candidate generation 3.2.1 and candidate ranking 3.2.2, respectively, each has a distil-bert model with 6 layers, 768 hidden units, 12 heads, with 66M parameters. We used the AdamW optimizer (Loshchilov and Hutter, 2019) with epsilon set to $1e^{-6}$, learning rate set to $3e^{-5}$. The model was trained for 8 epochs on ReDial dataset, and the first epoch was dedicated to warm up with a linear scheduler. We set the sample size M during candidate generation and candidate ranking to be 150. We set a=0.8, b = 1.0 and c = 0.28 as coefficients for 3 loss functions respectively. We chose K = 500 for the number of candidates during testing.

4.2.3 Evaluation Metrics

We performed two evaluations, recommendation evaluation and dialog evaluation, for the model. For recommendation evaluation, we used Recall@X (R@X), which shows whether the top X items recommended by the system include the ground truth item suggested by human recommenders. In particular, we chose R@1, R@10 and R@50 following previous works (Chen et al., 2019; Zhou et al., 2020). We also defined recall accuracy of MESE to be the percentage of ground truth items that appear among the 500 generated candidates in the candidate generation phase 3.2.1 and ranking accuracy to be the percentage of items that appear in the top k (k=1, 10, 50) position of the sorted candidates in the candidate ranking phase 3.2.2. The product of the recall and ranking accuracy is the final recommendation accuracy of MESE. We also adopted end-to-end response evaluation following (Wang et al., 2021). We computed response recall (ReR) as whether the final response contains the target items recommended by human annotators. For dialog evaluation, we adopted perplexity, distinct n-grams (Li et al., 2016), and BLEU score (Papineni et al., 2002) for automatic evaluations. Human evaluation (on a random sampling of 100 dialogs from the test set) is also conducted on dialog evaluation in comparison with **KGSF**. We invite three annotators to score the generated samples in two aspects, Fluency and Informativeness. The annotator is asked to select a better response based on the given context. Ties are allowed if two responses have similar qualities. The score is the percentage of the model's response being selected. The final performance is calculated using the average scores of the three annotators.

5 Experimental Results

5.1 Evaluation Results

We first report recall, ranking, and final accuracy on REDIAL dataset of MESE in table 3. From the results, it can be seen that candidate ranking has remarkable performance gains in scoring the items. It demonstrates that PLMs have great potential in making recommendations. One possible reason behind this is that the PLM and its self-attention mechanism is effective in learning the similarities and discrepancies between item semantics and dialog semantics.

Table 2 compares different models on REDIAL dataset. The superiority of MESE persists across recommendation and language generation. On all recommendation metrics, including R@1, R@10, and R@50, MESE outperforms the state-of-the-art

Model	Recommendation metrics				Language generation metrics					
	R@1	R@10	R@50	ReR	PPL	Dist2	Dist3	Dist4	Bleu2	Bleu4
ReDial	2.4	14.0	32.0	0.7	28.1	0.225	0.236	0.228	0.178	0.074
KBRD	3.1	15.0	33.6	0.8	17.9	0.263	0.368	0.423	0.185	0.074
KGSF	3.9	18.3	37.8	0.9	5.6	0.289	0.434	0.519	0.164	0.074
CR-Walker	4.0	18.7	37.6	-	-	-	-	-	-	-
CRFR	4.0	20.2	39.9	-	-	-	-	-	-	-
RID	-	-	-	3.1	54.1	0.518	0.624	0.598	0.204	0.110
NTRD	-	-	-	1.8	**4.4**	0.578	0.820	1.005	-	-
MESE	**5.6**	**25.6**	**45.5**	**6.4**	12.9	**0.822**	**1.152**	**1.313**	**0.246**	**0.143**

Table 2: Results and comparison with the literature on REDIAL.

top k	Ranking Acc	Recall Acc	Final Acc
@1	7.2	0.778	**5.6**
@10	33.0	0.778	**25.6**
@50	58.5	0.778	**45.5**

Table 3: Recall, Ranking and Final Accuracy of MESE.

models by a large margin. We argue in 5.2 that this significant gain of performance is due to the effectiveness of the item encoder. MESE also performs well on the ReR score, which indicates that the filling placeholder tokens can help integrate recommended items into responses. For language generation, MESE also achieves significantly better performance than all other models on distinct ngrams and bleu scores with the exception that the PPL is worse than those of KGSF and NTRD. This indicates that MESE can generate more diverse responses while sticking to the topic.

Model	Fluency	Informativeness
KGSF	24%	19%
MESE	**38%**	**31%**

Table 4: Human Evaluation of Response Generation

Table 4 presents the results of human evaluation. Our proposed model MESE outperforms KGSF by a large margin on both fluency and informativeness. Responses of MESE have a 50% more chance of being chosen as the better answer than responses of KGSF. By using the encoded item embeddings and joint training, MESE can better integrate its pretrained weights with the injected item information. Therefore, it generates more fluent responses that contain richer information about the items.

5.2 Ablation Studies and Analysis

In this section, we first analyze the reason behind the performance gain of our recommendation module by analyzing the embeddings learned by the item encoder.

How much does metadata help recommendation? We argue that our training objectives on recommendation enable the item encoder to selectively extract useful features pertinent to the recommendation task from item metadata and construct item representations that resonate with instructional semantic properties in the dialog histories. For example, in REDIAL dataset, movie genre information is the most frequently mentioned property in dialog histories and human recommenders often make recommendation decisions based on this property. Although other properties like actors also help with recommendations, they do not appear in the corpus as often as genres or movie plots. We designed the following experiments to test our hypothesis. First, we train MESE with movie genre and plot information removed from the metadata, which we refer to as MESE w/o content, and compare its recommendation performance with MESE in Table 5.

Model	R@1	R@10	R@50
MESE w/o content	3.9	19.5	37.9
MESE	**5.6**	**25.6**	**45.5**

Table 5: Comparison Results of MESE and MESE w/o content.

As we can see from the table, there is a significant performance decrease after we remove genre and plot information, which indicates that MESE depends on the item information to make high-quality recommendations. We also point out that movie titles contain weak genre information but are not able to provide adequate features for the item encoder to extract from.

How does the item encoder help recommendation? We claim that the item encoder can construct embeddings in a systematic way that aligns matching information between its input and dialog context. We designed an experiment to prove the point. Specifically, we select all movie items with only one genre as our candidates, resulting in a subset of ~700 movies. We then select 2 item encoders (section 3.2.2) from MESE, MESE w/o content, and the item encoder before training (MESE raw), respectively, and obtain 3 sets of item embeddings of the selected movie subset. On each set of embeddings, we run a K-means clustering algorithm with K being set to be 3, 4, and 5, respectively. For each cluster obtained, we calculated the proportion of the majority genre among all item candidates. This process is repeated 20 times and the average accuracy is reported in Table 6. Genre information appears most frequently in dialog context and most recommendations are made based on genre attributes. Our item encoder, after joint training, should construct item embeddings that reflect genre information. Hence, the embeddings should be more clustered in terms of genre.

Model	K=3	K=4	K=5
MESE raw	0.492	0.514	0.574
MESE w/o content	0.555	0.589	0.606
MESE	**0.695**	**0.725**	**0.738**

Table 6: Item Encoders Clustering Accuracy

As we can see from the table, without training, MESE raw, being the least sensitive to genre information, achieves the lowest accuracy scores on all clusters. MESE w/o content, although deprived of genre and plot, still has slightly higher accuracy than MESE raw due to its exposure to REDIAL conversations. MESE is most sensitive to genre information. This is an indication that by aligning matching information in both dialog context and item metadata, our item encoder is able to generate meaningful representations, which can facilitate the PLM to produce better rankings through its self-attention mechanism.

What if we remove mentioned entities from dialog context? Mentioned entities are crucial to previous approaches (Chen et al., 2019; Zhou et al., 2020) in terms of recommendations. We train MESE with mentioned entities removed from dialog history and compare its performance with MESE on REDIAL dataset and INSPIRED dataset in table 7.

Dataset	Model	R@1	R@10	R@50
REDIAL	MESE w/o item	3.4	18.1	38.7
	MESE	**5.6**	**25.6**	**45.5**
INSPIRED	MESE w/o item	4.3	11.9	26.7
	MESE	**4.8**	**13.5**	**30.1**

Table 7: Results of MESE and MESE w/o on REDIAL and INSPIRED.

We can see removing the entities led to an average of 26.3% performance drop on REDIAL and an average of 11.2% performance drop on INSPIRED. The recommendation performance on REDIAL is more impacted by the removal of entities because the conversations in REDIAL are rich with entities and weak in semantic information, whereas INSPIRED is more sparse on entities but contains richer dialog information. In REDIAL, there is 1 mentioned movies among every 21.85 word tokens. The sentence level distinct 1-grams and 3-grams are 0.15 and 2.81. In contract, there is 1 mentioned movies among every 63.54 word tokens in INSPIRED. Its sentence level distinct 1-grams and 3-grams are 0.59 and 6.84. This proves that our model can efficiently infer user interests from texts to make high-quality recommendations without explicitly using mentioned entities. This property could be useful in an e-commerce setting where users tend to convey their requirements more with texts than entities. It could also be useful in a cold start scenario where we don't have many entities in the context.

6 Conclusion and Future Work

In this paper, we introduced MESE, a novel CRS framework. By utilizing item encoders to construct embeddings from metadata, MESE can provide high-quality recommendations that align with the dialog history. Our approach yields better performance than existing state-of-the-art models. Ablation studies explain the reason behind this performance gain. As for future work, we will consider applying this approach to a broader domain of CRS datasets. Currently, we only experiment on movie recommendations. However, the encoder of MESE is flexible and can potentially work well with cross-modality tasks. Multi-modal CRSs can be explored in the e-commerce domain with MESE.

A Candidate Selection With Multiple Sources

To maximize the performance of candidate selection, we blend candidates selected from the nearest neighbor search source with a rule based source. The rule based source is constructed by traversing the training data and maintaining a list of co-occurring items for each individual item. For example, if item A and item B both occurred in a conversation in the training set, we add them to each other's list. During testing, if item A is mentioned in the dialog context, the maintained co-occurring item list is combined with the candidates retrieved by nearest neighbor search as the final selection.

B Response Generation and Recommendation Trade-Off

The trade-off between response generation and recommendation during training. We separate language training objective from the jointly trained loss and compare the trained models on language generation metrics on ReDial in table 8. **MESE-LG** denotes the model trained with only the language generation objective $\mathcal{L}_{\text{res}}$.

Model	Dist2	Dist4	Bleu2	Bleu4
MESE-LG	**1.13**	**2.25**	**0.295**	**0.171**
MESE	0.822	1.313	0.246	0.143

Table 8: Results of **MESE** and **MESE-LG** on REDIAL.

As we can see, training only on language generation objective yields better results. In the settings of MESE, both tasks update the weights of the same pre-trained language model simultaneously with different goals: In recommendation, the language model needs to construct meaningful scores for generated candidates; In response generation, the language model aims to generate next token given previous contexts. This experiment showed that this joint training approach induces a trade-off between training on response generation and recommendation: back-propagation on the recommendation objective can lead to catastrophic forgetting of information learned from pre-training, which leads to worse language metrics.

C Response Generation Example

We include example dialog of human seeker and MESE model in table 9.

User: Hello, how are you?
System: Good, how are you?
What type of movies do you like?
User: I'm great. thanks!
I'm looking for crime movies to watch.
System: Have you seen **Goodfellas?**
User: Yes, I love that movie.
Could you recommend another one?
System: If you haven't seen **The Rise of the Krays** you should give it a try.
User: I never saw that I should check it out.
Thank you and have a great afternoon!
System: You too! Have a great day!

Abstract

Recent research showed promising results on combining pretrained language models (LMs) with canonical utterance for few-shot semantic parsing. The canonical utterance is often lengthy and complex due to the compositional structure of formal languages. Learning to generate such canonical utterance requires significant amount of data to reach high performance. Fine-tuning with only few-shot samples, the LMs can easily forget pretrained knowledge, overfit spurious biases, and suffer from compositionally out-of-distribution generalization errors. To tackle these issues, we propose a novel few-shot semantic parsing method – SEQZERO. SEQZERO decomposes the problem into a sequence of sub-problems, which correspond to the sub-clauses of the formal language. Based on the decomposition, the LMs only need to generate short answers using prompts for predicting sub-clauses. Thus, SEQZERO avoids generating a long canonical utterance at once. Moreover, SEQZERO employs not only a few-shot model but also a zero-shot model to alleviate the overfitting. In particular, SEQZERO brings out the merits from both models via ensemble equipped with our proposed constrained rescaling. SEQZERO achieves SOTA performance of BART-based models on GeoQuery and EcommerceQuery, which are two few-shot datasets with compositional data split.[1]

1 Introduction

Semantic parsing is the transformation of input utterance into formal language, such as SQL query (Zelle and Mooney, 1996), and plays a critical role in NLP applications, such as question answering (Yih et al., 2014), dialogue system (Gupta et al., 2018), and information extraction (Yao and Van Durme, 2014). Training neural semantic parsers requires numerous annotated input utterance and formal language pairs. However, the paired data is usually limited, as the annotation requires experts' knowledge and can be expensive. For example, annotating SQL queries requires programming knowledge, while annotating formal meaning representations like Abstract Meaning Representations (AMR) requires linguistics knowledge. Therefore, semantic parsing in the few-shot setting is a demanding technique.

Researchers have adopted large-scale pretrained language models (LMs, Radford et al. (2019); Brown et al. (2020)) to improve few-shot learning performance. The LMs are usually pretrained on large unlabeled open-domain natural language data and achieve impressive performance on few-shot text-to-text generation problems via proper prompt designing (Brown et al., 2020). Considering the difference between natural and formal language, adapting LMs to semantic parsing is non-trivial. Prior works typically first finetune the LMs to generate canonical utterance, which is then transformed into the final formal language through grammars (Shin et al., 2021; Schucher et al., 2021).

However, the canonical utterance is lengthy and complex due to compositional structure of the formal languages. Learning to precisely generate canonical utterances still requires significant amount of data. Meanwhile, fine-tuning with only few-shot samples, the LMs can easily forget pretrained knowledge, overfit spurious biases, and suffer from compositionally out-of-distribution (OOD) generalization errors. Figure 1 presents an compositionally OOD generalization error of direct fine-tuning BART (Lewis et al., 2019) on the GeoQuery, a dataset about querying in a geographic database. The model incorrectly predicts the table name as "*city*", because the training samples always come from the "*city*" table as long as the query follows the "*how many people live in xxx*" pattern. Such errors account for about 75% of all prediction errors of Base model on GeorQuery test set (refer to Section 5.7 for details).

Question:

how many people live in **Utah ?**

Gold SQL:

SELECT **state** . population FROM **state**
WHERE **state** . **state**_name = "Utah"

Finetuned BART Predicted SQL:

SELECT **city** . population FROM **city**
WHERE **city** . **city**_name = "Utah"

Figure 1: Finetuned BART's OOD generalization errors due to overfitting the spurious biases.

To address the aforementioned issues, we propose a novel prompt-based few-shot learning method – SEQZERO. Instead of directly generating the whole formal language, SEQZERO decomposes the problem into a sequence of sub-problems, and the LMs only need to make a sequence of short prompt-based predictions, where zero-shot (unfinetuned) models can also be leveraged to avoid overfitting the spurious biases in specific caluses. Specifically, SEQZERO decomposes the problem into predicting the sub-clauses, which make up the formal languages. When predicting a sub-clause, SEQZERO adopts a slot-filling natural language prompt, where the filled prompt can be transformed into the sub-clause through grammars. For filling each prompt, SEQZERO employs two models: a few-shot model and a zero-shot model. Both models ingest the input utterance and the prompt to fill in the slots in the prompt. The few-shot model uses a fine-tuned LM to fill in the slots of each prompt. The zero-shot model directly infers the value in the slots by decoding a pretrained LM with a constrained vocabulary. We then ensemble the prediction from both models, and convert the results for all sub-clauses into the final output (e.g., SQL query). We notice that, the probability mass of the zero-shot model, on the constrained vocabulary, is much smaller than that of the few-shot model. As a result, the zero-shot model cannot take effect in the vanilla ensemble. Therefore, we propose to rescale the probability of the zero-shot model on the constrained vocabulary before ensemble to bring out the advantages of both models.

We conduct experiments on two datasets: GeoQuery, a benchmark dataset that consists of natural language and formal language pairs from geography domain, and EcommerceQuery, a newly collected dataset from E-commerce domain. Results show that our approach outperforms the baseline algorithm and achieves state-of-the-art performance on the compositional split of the two datasets. To sum up, our contributions are:

- We propose to decompose semantic parsing to filling a sequence of prompts, each corresponding to a sub-clause of original SQL query. Compared with direct fine-tuning, predicting sub-clauses is easier, which enables flexible prompt designing and zero-shot model inference.
- We propose the ensemble of few-shot and zero-shot models with help of constrained probability rescaling, which improves out-of-distribution generalization while maintaining in-distribution performance.
- We create and release a new EcommerceQuery dataset. We empirically verify that our approach achieves SOTA, among BART-based models, on both GeoQuery and EcommerceQuery.

2 Preliminary

Language Modeling aims to estimate the probability distribution for a given sequence of words $x = (w_1, w_2, ..., w_n)$ in an autoregressive way:

$$P_\theta(x) = \prod_{i=1}^{n} P_\theta(w_i|w_1, ..., w_{i-1}),$$

where θ is the parameters of the language model. This approach not only allows estimation of $P_\theta(x)$ but also any conditionals of the form $P_\theta(w_i, w_{i+1}, .., w_n|w_1, ..., w_{i-1})$, which is essentially a seq2seq model. One can leverage a seq2seq model to generate a sequence via a decoding algorithm (e.g., beam-search): $y = \text{Decode}(P_\theta(\cdot|x))$ In recent years, there have been significant progress in training large transformer-based language models (Radford et al., 2019; Brown et al., 2020; Lewis et al., 2019) on large natural language corpus.

Semantic Parsing is to transform an input utterance u into a formal language m. Without loss of generality, we hereafter discuss the case of SQL query as the formal language. One can directly train a language model for semantic parsing:

$$P_\theta(m|u).$$

Directly learning such a language model is challenging as the difference between the formal language and natural language is huge. To bridge the gap, Berant and Liang (2014); Shin et al. (2021) propose **S**emantic **P**arsing via **P**araphrasing (SPP) — a two-stage framework. In the first stage, they paraphrase u to its canonical utterance c using a paraphrasing language model:

$$P_\theta(c|u).$$

In the second stage, the canonical utterance c is transformed into SQL query m by a grammar or a set of rules:

$$m = \mathrm{Grammar}(c).$$

3 Method

In this section, we describe SEQZERO. SEQZERO first decomposes the problem into a sequence of sub-problems as illustrated in Figure 2. For each sub-problem, SEQZERO employs an ensemble of zero-shot and few-shot models to predict a sub-clause of the formal language based on prompts as illustrated in Figure 3.

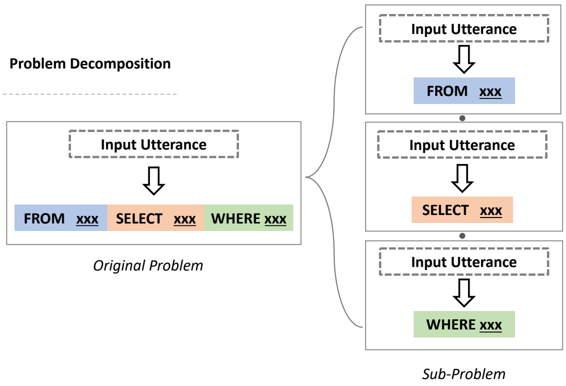

Figure 2: The problem of predicting a SQL can be composed into 3 steps: predicting "FROM" clause, "SELECT" clause, and "WHERE" clause.

3.1 Problem Decomposition and Sequential Prompt Filling

Each SQL query can be regarded as a composition of different types of sub-clauses, such as "SELECT", "FROM", "WHERE":

$$m = \mathrm{Compose}(m_1, ..., m_n),$$

where m_i is the sub-clause of the i-th type, n is the number of all possible types of sub-clauses, and the composition is conducted via a rule-based system. A simple example of the composition function is direct concatenating the sub-clauses, whereas the real implementation requires some dedicated design. For example, m_i can be a null clause, e.g., not every SQL query contains a "WHERE" clause. We discuss the implementation details of the composition in Appendix C.

We turn the problem of direct predicting m into predicting m_i sequentially from m_1 to m_n. We remark that the prediction of m_i depends on $m_1, ..., m_{i-1}$, as illustrated in Figure 3. Similar to the SPP framework, we design a canonical utterance c_i for each sub-clause m_i. The transformation between c_i and m_i is conducted by a grammar:

$$m_i = \mathrm{Grammar}(c_i).$$

Each c_i consists of two parts: a natural language slot-filling prompt p_i and a value in the slot v_i:

$$c_i = \mathrm{FillSlot}(p_i, v_i).$$

The prompt p_i is shared across all sub-clauses of the i-th type, while the value v_i varies for different instances. As a result, the problem is turned into predicting the values $\{v_i\}_{i=1}^n$ given the input utterance u, and prompts $\{p_i\}_{i=1}^n$ sequentially from $i = 1$ to $i = n$. The prediction is conducted via decoding a language model, $P_{\theta_i}(\cdot|u, m_1, \ldots, m_{i-1}, p_i)$, where the canonical utterances of previous sub-clauses $(m_1, \ldots, m_{i-1})$ are also provided as the extra context. We summarize the process in Algorithm 1.

Algorithm 1: Sequential Prompt Filling

```
Input: $u$: input utterance; $\{p_i\}_{i=1}^n$:
       prompts; Grammar: grammar for
       parsing the canonical utterance;
       $\{P_{\theta_i}\}_{i=1}^n$: LMs.
for $i = 1, \cdots, n$ do
    $x = (u, m_1, \ldots, m_{i-1}, p_i)$
    $v_i = \mathrm{Decode}(P_{\theta_i}(\cdot|x))$
    $c_i = \mathrm{FillSlot}(p_i, v_i)$
    $m_i = \mathrm{Grammar}(c_i)$
end
$m = \mathrm{Compose}(m_1, ..., m_n)$
Output: $m$: SQL query
```

3.2 Ensemble of Few-shot and Zero-shot Models

Despite the apparent advantages of sequential prompt filling, directly fine-tuning LMs on few-

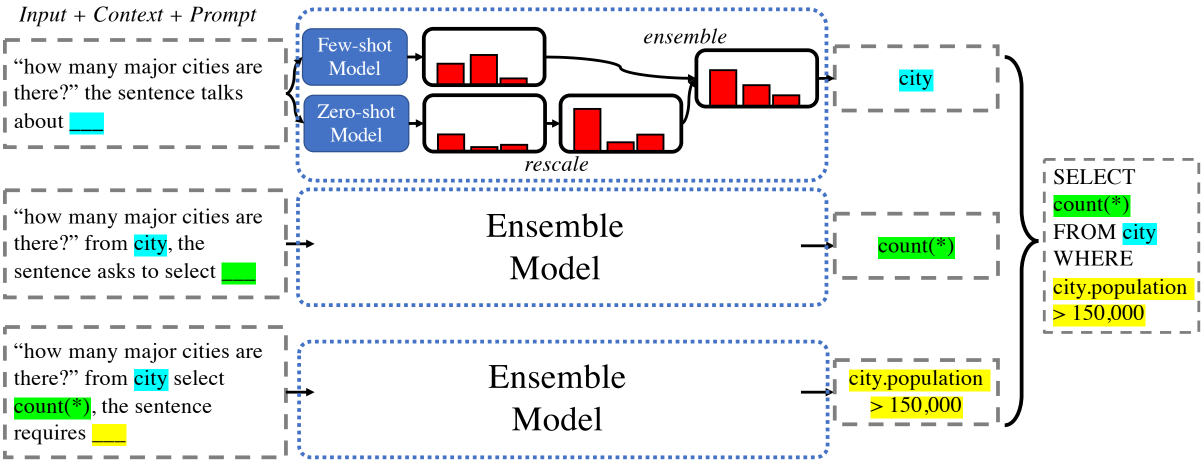

Figure 3: Pipeline of sequential prompt filling and SQL generation on GeoQuery. Note that, the scale of the prediction probability of the zero-shot model is very small before rescaling.

shot samples will fall short due to the overfitting. Because of the better OOD generalizability of zero-shot models, we propose to employ the ensemble of a few-shot model $P_{\theta_{i,f}}$ and a zero-shot model $P_{\theta_{i,z}}$ for each language model P_{θ_i}.

Few-shot Model. Each few-shot model is obtained by finetuning a pretrained language model via minimizing the negative log-likelihood loss:

$$\arg\min_{\theta_{i,f}} -\log P_{\theta_{i,f}}(v_i|u, m_1, \ldots, m_{i-1}, p_i),$$

where $v_i, m_1, \ldots, m_{i-1}$ are the ground truth from the few-shot training data. It is essentially the teacher forcing training strategy. Note that we omit the summation over the training set for simplicity and clarity.

Zero-shot Model. Each zero-shot model directly adopts the pretrained language model P_{θ_0}. Without any guidance, P_{θ_0} may generate any free text even if we provide the input utterance and prompt. In order to mine the knowledge from P_{θ_0}, we only allow the zero-shot model to generate from a list of candidate values. The candidate values are collected from multiple sources including SQL grammar, table schema, input utterance and training data. When predicting the j-th word for v_i, the zero-shot model rescales the probability on a constraint vocabulary, which is specifically designed for the i-th clause:

$$P_{\theta_{i,z}}(w|x) = \frac{\mathbb{1}(w \in V_i(x))P_{\theta_0}(w|x)}{\sum_{w_j \in V_i(x)} P_{\theta_0}(w_j|x)}, \quad (1)$$

where w is a predicting word, $x = (u, m_1, ..., m_{i-1}, p_i, w_1, .., w_{j-1})$ is the context for predicting the i-th value, $\{w_t\}_{t=1}^{j-1}$ is the prefix in the value, $V_i(x)$ is the constraint vocabulary. Given the list of candidate values, we use a trie (prefix tree) to compute all the allowed tokens, and thus $V_i(x) = V_i(\{w_t\}_{t=1}^{j-1})$ depends on the prefix of the values. Note that, to develop a more flexible method, a trie/prompt could start at intermediate steps.

Ensemble. We then obtain P_{θ_i} by a linear ensemble of the few-shot model $P_{\theta_{i,f}}$ and the zero-shot model $P_{\theta_{i,z}}$:

$$P_{\theta_i} = \gamma_i P_{\theta_{i,f}} + (1 - \gamma_i) P_{\theta_{i,z}}, \quad (2)$$

where γ_i is a clause-specific weight for trade-off between two models.

Remark. We employ a normalization step in the zero-shot model Eq. (1). The normalization is not necessary for the zero-shot model itself, but plays a critical role in the ensemble. This is because the scales of the predicted probabilities of few-shot and zero-shot models are different, as illustrated in Figure 3. The P_{θ_0}'s prediction probability is distributed over the whole vocabulary. There is only a very small probability mass assigned to the allowed tokens, $V_i(x)$. On the other hand, the few-shot model's prediction probability is almost entirely distributed over $V_i(x)$. Without rescaling, the zero-shot model will only have little effect when ensembling with the finetuned model.

4 Experiment Setup

Dataset To evaluate the performance of our proposed method, we conduct experiments on the Geo-

Query dataset (Zelle and Mooney, 1996), where there are 880 queries to a database of U.S. geography. To test compositional generalizability, we adopted the compositional split for SQL released by Finegan-Dollak et al. (2018), where templates created by anonymizing entities are used to split the original dataset, to make sure that all examples sharing a template are assigned to the same set. There are 536/159/182 examples for train/dev/test set, thus this setting can be regarded as the few-shot setting. We also experimented with even fewer training examples (50, 150).

Besides, we create and release the EcommerceQuery, a new SQL semantic parsing dataset in E-commerce domain. Specifically, we collect natural language utterances from user input search queries to an e-commerce website. To create corresponding SQL queries, we use some self-defined rules with manual audition. We construct compositional splits, where there are unseen SQL query patterns in the dev/test set. Finally, train/dev/test set contains 1,050/353/355 examples respectively. For details, please refer to Appendix B. Two examples from EcommerceQuery are shown in Table 8.

Baselines and Models We use seq2seq finetuned BART as our main baseline on both datasets. Without explicit notations, we use BART large in all of the following experiments. Otherwise, we denote large or base models. On GeoQuery dataset, we use prior state-of-the-art methods as additional baselines. On EcommerceQuery dataset, we use only LSTM seq2seq and BART as baselines, because Iyer et al. (2017) requires user feedbacks, and Zheng and Lapata (2020) requires domain specific semantic tags, which are not available in EcommerceQuery.

Evaluation Following Andreas (2019), we use exact-match accuracy as the evaluation metric, namely the percentage of examples that are correctly parsed to their SQL queries.

5 Experimental Results

5.1 Main Results

Table 1 shows our main results on GeoQuery and EcommerceQuery datasets. As shown in Table 1, on GeoQuery dataset, the finetuned BART$_{\text{Large}}$ beats all the previous baseline methods. Our approach outperforms all baseline systems by a substantial margin, reaching new SOTA performance. Note that directly combining BART with the semantic parsing via paraphrasing (SSP) framework even decrease the performance of BART, because paraphrased canonical utterances for SQL on GeoQuery is too long and complex to directly generate. Even comparing with Zheng and Lapata (2020), SeqZero achieves a much better performance without the usage of anonymized variables [2]. In addition, on EcommerceQuery dataset, our SeqZero further achieves considerable improvements over the baseline methods, reaching SOTA performance. Comparing with BART, the best baseline model, SeqZero gains improvement in exact-match accuracy by 8.5%. In all words, our model is an extremely strong performer and substantially outperforms baseline methods, which demonstrate the efficiency of our method.

BART$_{\text{Large}}$ + SPP	66.5	37.2
SeqZero$_{\text{Large}}$	**74.7**	**46.2**

Table 1: Results on GeoQuery test set of compositional split, and on EcommerceQuery (EcoQuery) dataset. †: we directly report the metrics in the original papers, while our reproduction achieves similar performance. $^{\diamond}$: Zheng and Lapata (2020) took an unfair advantage of anonymized variables.

5.2 Ablation Study

To demonstrate the utility of sequential prompt filling and zero-shot model, we conduct a set of ablation experiments, as shown in Table 2. In each ablation experiment, we delete one of these two key components of SeqZero, namely "−Seq" and "−Zero".

SeqZero −Zero means that we directly use finetuned few-shot models to fill in sequential prompts without using the zero-shot model.

SeqZero −Seq is equivalent to the ensemble of a finetuned BART and a un-finetuned BART for

---

[2] Zheng and Lapata (2020) could not directly compare with our method, because they use anonymized variables (i.e. oracle entities), while other models including SeqZero require generating entities instead of using oracle entities. Thus, for fair comparison, their method without variable anonymization would have even worse performance, indicating even larger improvements of our method.

Method	GeoQuery	EcoQuery
SeqZero	**74.7**	**46.2**
−Seq	74.2	44.5
−Zero	71.4	37.7

Table 2: Ablation study of SeqZero.

predicting the SQL query directly without sequential prompt filling.

On both datasets, "−Seq" decreases the performance of SeqZero. It indicates that designing clause-specific prompt can better mine the pretrained knowledge from the language model. Meanwhile, zero-shot model ensemble brings our model better out-of-distribution generalization ability. Consequently, when zero-shot model ensemble is ablated, the performance drops a lot ("−Zero" vs "SeqZero").

5.3 Analysis of Sequential Prompt Based Models

Here, we try to understand how the sequential prompt based model performs on different clauses. We report the prediction accuracy of SeqZero and "−Zero" on 5 clauses on the GeoQuery dataset in Table 3. Seq$_{\text{Gold}}$ means we use finetuned BART to generate clauses given previous gold clauses. We can see that finetuned BART has the worst performance on "From" clause because of its poor OOD generalizability. We can clearly see that SeqZero has better performance than "−Zero" because of the zero-shot model's strong performance on the "From" clause.

Method	From	Select	Where	Group	Order
Seq$_{\text{Gold}}$	84.1	87.9	92.3	99.5	99.5
SeqZero	**88.5**	**77.5**	**74.7**	**74.7**	**74.7**
−Zero	84.1	74.2	71.4	71.4	71.4

Table 3: Prediction accuracies on all 5 clauses on GeoQuery dataset.

Method	Exact Match
GeoQuery "From" Clause	
Few shot$_{\text{Base}}$	58.2
Zero shot$_{\text{Base}}$	**67.0**
Few shot$_{\text{Large}}$	84.1
Zero shot$_{\text{Large}}$	78.0
Ensemble$_{\text{Large}}$	**88.5**
EcommerceQuery "Condition" Clause	
Few shot$_{\text{Large}}$	40.0
Ensemble$_{\text{Large}}$	**51.8**

Table 4: Zero-shot and few-shot BART$_{\text{Base}}$ and BART$_{\text{Large}}$ models' performance compares with their ensemble on critical clauses.

Recall that the prediction of the latter clauses depends on the previous ones, the performance of each next clause generally decreases due to error propagation in SeqZero. The same performance of "Where", "Group" and "Order" is because there are very few "Group" and "Order" clauses on test set. SeqZero achieves much better performance than "−Zero" on the "From" clause and thus significantly reduces the error propagation, leading to better performance on all clauses.

5.4 Comparison of Zero-shot, Few-shot models, and Their Ensemble

According to Section 5.3, our model's major improvement comes from the contribution of zero-shot models and ensemble in critical clauses. We further compare the performance of zero-shot, few-shot and ensemble models in Table 4. We can see that on GeoQuery "From" Clause, with BART$_{\text{Base}}$, zero-shot model itself with constraint decoding is already much better than few-shot model, verifying our intuition that few-shot finetuning could lead model to overfit spurious biases, and achieves poor compositional out-of-distribution (OOD) generalizability. With BART$_{\text{Large}}$, zero-shot model's performance is still worse than the few-shot fintuned model, but our ensemble method can effectively leverage the better OOD generalizability of zero-shot model and achieves better performance[3]. Similarly, on EcommerceQuery "Condition" Clause, our ensemble method significantly outperforms the few-shot model.

5.5 Impact of Prompt Designing

Table 5 shows the performance of the few-shot finetuned BART and the zero-shot BART (in constrained decoding setting) with several representative prompts on "From" clause of GeoQuery test

---

[3] We tried both uncertainty based model selection and model ensemble on "From" clause of GeorQuery dataset, and found out that they have similar performance. Thus, we choose model ensemble as our major method, because it leverages all steps' probability to make selection, leading to potentially better performance in other datasets. See Appendix for results of uncertainty based model selection.

Prompt	Few	ZERO
the answer can be obtained from	81.3	65.9
the sentence talks about	**84.1**	**78.0**

Table 5: Impact of prompt designing for few-shot Few and zero-shot ZERO BART on "FROM" clause of GeoQuery test set.

Prompt	attribute+relation	relation
the sentence requires	39.2	49.3
where	21.1	51.5
the condition is :	**51.1**	**57.3**

Table 6: Impact of prompt designing for zero-shot BART on "CONDITION" clause of EcommerceQuery test set. In attribute+relation setting, we let zero-shot model generate both attributes and relations. In relation setting, we let zero-shot model generate relations only.

set. We can see that prompt designing highly affects the the zero-shot model's performance, while it has less impact on few-shot finetuned model. Table 6 shows the performance of the zero-shot BART on "CONDITION" part of EcommerceQuery test set, where different prompts also lead to significantly different performance. These results reveal the necessity of sequential prompt filling. Without this component, one cannot easily come up with a proper prompt for achieving a better model performance. In practice, we design 20 prompt sets and select the best one based on the zero-shot model's performance on the development dataset.

5.6 Impact of Training Data Size

Table 7 shows the performance of baseline BART and our SEQZERO (as well as ablation of ZERO), facing different numbers of training data points in the few-shot setting. With 50, 150 training samples, we make sure that each SQL query template occurs only once to maximize the diversity of training data. For the full dataset, there are 536 samples with 158 different training templates in total.

# of Samples	50	150	536
BART	41.2	73.1	72.5
SEQZERO	**48.9**	**74.2**	**74.7**
−ZERO	31.3	73.1	71.4

Table 7: Model accuracy with different numbers of training samples on GeoQuery dataset.

Our SEQZERO outperforms BART in all settings (50, 150, 536 training samples), which shows the effectiveness of our method in the few-shot setting. From 50 to 150 training samples, the model see more SQL templates, which help compositional generalization, and lead to the increased performance of all models. From 150 to 536 samples, the performance of BART and "−ZERO" decrease slightly. That is because there are multiple samples of the same templates in the 536 training samples, and the models overfit to those training templates. In contrast, SEQZERO avoids such overfitting with the help of zero-shot models and achieves better performance by leveraging more training samples.

Without the aid of zero-shot model, "−ZERO" performs worse than SEQZERO. When there are only 50 samples, the performance degradation is the most significant. When there are 536 samples, the decrease led by ablation of zero-shot model is larger than that of 150 samples. It is because when there are many cases for each template, ensemble of zero-shot model can alleviate overfitting such templates.

Furthermore, "−ZERO" has similar performance with BART when there are over 150 training samples. On the other hand, the performance of "−ZERO" is worse than BART when there are very few training samples (50 samples). We conjecture that this is because BART shares the model parameter between all sub-clauses, while "−ZERO" finetunes models separately on different sub-clauses. The parameter sharing will further lead to knowledge sharing across sub-clauses and improves the performance. How to leverage the benefit from both parameter sharing and SEQZERO could be an interesting future research topic.

5.7 Case Study

Table 8 shows BART and SEQZERO's predictions for some cases. For first example, BART gives a wrong prediction, because few-shot training samples introduce too many spurious biases to the finetuned model. In contrast, SEQZERO gives correct prediction. Actually, after analyzing the errors made by finetuned $\text{BART}_{\text{Base}}$ model on GeoQuery, among all errors on test set, the common error for around 75% examples is the table name error in "FROM" clause, which is due to spurious biases.

For the second example, BART predicts "PRICE <" incorrectly even seeing "*over*", because EcommerceQuery Dataset is designed to include only

"PRICE <" but no "PRICE >" template. Our SEQZERO could give the correct prediction because of better OOD generalizability with the help of zero-shot models.

Even with our SEQZERO, there are still many errors. For instance, in the third example, it still struggles with identifying the size in the natural language query and generating the Size filtering condition in WHERE clause.

6 Related Work

Few/Zero-shot Semantic Parsing Shin et al. (2021); Schucher et al. (2021) conducted few-shot semantic parsing by using pretrained LMs to first generate canonical natural language utterances, and then transform them to final formal language through synchronous context-free grammar (SCFG) (Jia and Liang, 2016). However, dealing with complex structure and lengthy canonical language is still challenging for models in the few-shot setting. Also, canonical languages created through SCFG allows limited space for prompt designing, and canonical language's form is still too strange for language models to understand. Zhong et al. (2020) explored zero-shot semantic parsing via generation-model-based data augmentation. Other ways of bootstrapping a semantic parsing requires rules/grammars to synthesize training examples (Xu et al., 2020; Wang et al., 2015; Yu et al., 2020; Campagna et al., 2019; Weir et al., 2020; Marzoev et al., 2020; Campagna et al., 2020). Yang et al. (2021) used language-independent features for zero-shot cross-lingual semantic parsing.

Semantic Parsing via Paraphrasing Berant and Liang (2014) started the line of work where semantic parsing is finished through an intermediate paraphrasing step. Wang et al. (2015); Marzoev et al. (2020) generated paraphrase candidate values from a grammar of legal canonical utterances, and incrementally filtered the bottom-up or top-down generation by scoring the partial candidates against final formal language. All such work did not exploit the power of pretrained models to generate intermediate paraphrases.

Compositional Generalization in Semantic Parsing Compositional generalization is an essential problem in semantic parsing because formal languages are internally compositional. Generally, one way to improve compositional generalizability is to incorporate inductive biases directly to models through moduler models (Dong and Lapata, 2018), symbolic-neural machines (Chen et al., 2020), latent variables/intermediate representations (Zheng and Lapata, 2020; Herzig and Berant, 2020), meta-learning (Lake, 2019) etc. Another way is to first do data augmentation and then train a model with augmented data (Andreas, 2019; Zhong et al., 2020; Yu et al., 2020; Akyürek et al., 2020). Pretrained models has also been shown useful for compositional semantic parsing (Oren et al., 2020; Furrer et al., 2020). None of prior work used sequential prompts or zero-shot models for compositional generalization. Yang et al. (2022) adopted attention biases to alleviate spurious biases in table semantic parsing.

Prompting for Few/Zero-shot learning Natural language prompts are widely used in few-shot or zero-shot learning. There are several fashions to use prompts in Autoregressive Language Models (Liu et al., 2021a). One is tuning-free prompting, for example, Petroni et al. (2019); Shin et al. (2020) used a fill-in-the-blank paradigm, while Brown et al. (2020); Shin et al. (2021) used "few-shot" prompts that included several examples of inputs followed by target outputs, with the actual task input appended at the end. One is Fixed-LM Prompt Tuning, as used by Li and Liang (2021); Schucher et al. (2021); Qin and Eisner (2021); Liu et al. (2021b), which requires training less parameters compared with tuning the whole model. Another is Fixed-prompt LM Tuning, which is similar to our setting. We choose to use this way because it is demonstrated better than other methods in many few-shot NLP tasks (Gao et al., 2020) when tuning the whole model is not a concern. This is also more efficient at inference time, as it is no longer necessary to select training examples to precede the test input. Note that, Mishra et al. (2021) employed prompt decomposition during tuning-free prompting, which is validated in other NLP tasks.

Zero-shot pretrained models for OOD generalization Wortsman et al. (2021) showed that, in computer vision tasks, although fine-tuning approaches substantially improve accuracy in-distribution, they reduce out-of-distribution robustness, while zero-shot pretrained models have higher OOD generalizability. Thus, model weight ensemble (Wortsman et al., 2021) and model editing (Mitchell et al., 2021) were leveraged to manipulate zero shot pretrained models, which motivetes

Ground Truth	SELECT state . population FROM state WHERE state . state_name = "utah"
Question	*petrol trimmer over 100 dollar*
BART	SELECT * FROM ASINs WHERE Maching Algorithm("petrol trimmer") == True and Price < 100
SEQZERO	SELECT * FROM ASINs WHERE Maching Algorithm("petrol trimmer") == True and Price > 100
Ground Truth	SELECT * FROM ASINs WHERE Maching Algorithm("petrol trimmer") == True and Price > 100
Question	*mi4 64 gb mobile phone*
BART	SELECT * FROM ASINs WHERE Maching Algorithm("mi4 64 gb mobile phone") ORDER BY date
SEQZERO	SELECT * FROM ASINs WHERE Maching Algorithm("mi4 64 gb mobile phone") ORDER BY date
Ground Truth	SELECT * FROM ASINs WHERE Maching Algorithm("mi4 mobile phone") and Size = 64 gb

Table 8: Case study. The first example is from GeoQuery, and the last two examples are from EcoQuery.

us to ensemble zero-shot and few-shot models during the generation process of semantic parsing. We tried weight ensemble proposed by Wortsman et al. (2021), but it does not work in our generation setting. The reason is the same as why direct ensemble in prediction space is not working. That's said, weights in a zero-shot model correspond to the probability over the whole vocabulary while weights in a finetuned model correspond to the probability over constrained vocabulary. Thus, weights in the zero-shot model have little effect on the constrained vocabulary.

7 Conclusion

Although prior work leveraged pretrained LMs and canonical language for few-shot semantic parsing, generating lengthy and complex canonical language is still challenging, leading finetuned models to overfitting spurious biases in few-shot training examples and demonstraining poor compositional generalizability. To tackle this, we propose to filling in sequential prompts with LMs and then compose them to obtain final SQL queries. During the process, our proposed zero-shot pretrained model ensemble or uncertainty-based model selection could significantly boost the performance on critical clauses, leading to overall SOTA performance, among BART based models, on GeoQuery and our released EcommerceQuery semantic parsing dataset. In the future, we plan to extend our methods to other pretrained models (e.g. T5) and other compositional semantic parsing datasets.

Ethical Impact

SEQZERO is a general framework for few-shot semantic parsing on text, such as search queries. SEQZERO neither introduces any social/ethical bias to the model nor amplify any bias in the data. When creating EcommerceQuery dataset, we collected data on an E-commerce search platform without knowing customers' identity. No customer/seller specific-data is disclosed. We build our algorithms using public code bases (PyTorch and FairSeq). We do not foresee any direct social consequences or ethical issues.

A Configuration

A.1 Training Details

During training, we use fairseq (Ott et al., 2019) to implement BART model. We use Adam as optimizer with a learning rate 1e-5. We use dropout and attention dropout with 0.1 as dropout rate. Also, we use label smoothing with a rate 0.1. Batch sizes are 1024 tokens. Besides, we employ a weight-decay rate 0.01. All the parameters are manually tuned based on the dev performance.

We train all models on NVIDIA A100 SXM4 40 GB GPU. We set the max training epoch to be 100 and select the best performed epoch according to dev performance. Training process on each clause or whole sequence could be finished within 3 hours.

A.2 Inference Details

During inference, we use greedy search to decode. We also use ensemble of zero-shot and few-shot models during this process. The ensemble weight γ_i in Eq. (2) is chosen from [0, 1] and tuned by grid search according to performance on dev set.

B EcommerceQuery Dataset

When we create the EcommerceQuery dataset, we first we collect natural language utterances from user input search queries to an e-commerce website. To create corresponding SQL queries, we use regular expressions to create "SIZE" filtering conditions, and use some rules to create "PRICE" filtering conditions, "DELIVERY" attributes and "SUBSCRIBE" attributes in "WHERE" clauses. Finally, we manually audit each pair of data to ensure the quality.

To construct compositional splits, we make sure that there is no "PRICE>", "SIZE=", and "SUBSCRIBE=" SQL templates in training set but the majority of SQL queries on dev and test set contains such templates. Ideally, a model with good compositional generalizability could generalize from "PRICE<" and "SIZE>" to "PRICE>", generalize from "PRICE=" and "SIZE>" to "SIZE=", and generalize from "DELIVERY=" to "SUBSCRIBE=".

C Problem Decomposition on GeoQuery and EcommerceQuery

In this section we introduce the problem decomposition for GeoQuery and EcommerceQuery in details. We answer the following two questions: 1. what are the sub-clauses in the sub-problems? 2. how to compose the final formal language from the sub-clauses.

C.1 GeoQuery

On GeoQuery, there are totally 5 sub-clauses, namely FROM, SELECT, WHERE, GROUP-BY,

Method	Exact Match
FEW SHOT$_{\text{Large}}$	84.1
ZERO SHOT$_{\text{Large}}$	78.0
MOC SELECTION$_{\text{Large}}$	**88.5**
ROC SELECTION$_{\text{Large}}$	**88.5**
ENSEMBLE$_{\text{Large}}$	**88.5**

Table 9: Ensemble of zero-shot and few-shot models compares with uncertainly based selection of zero-shot and few-shot models on GeoQuery "FROM" Clause.

ORDER-BY clauses. we first generate FROM from clause with the prompt "*the sentence talks about*". Then we generate SELECT clause with the prompt "*the sentence talks about*", generate "*Where* clause with the prompt THE SENTENCE REQUIRES", generate GROUP-BY clause with the prompt THE SENTENCE REQUIRES TO GROUP BY, and generate ORDER-BY clause with the prompt "*the sentence requires the result to be ordered by*" Note that prior generated clauses are used as additional prefix to generate current clauses. The filled value for each clause could be "*None*". When the filled value is "*None*", which means there is no such clause in the final SQL query. Finally, we compose all clauses (if the filled value is not "*None*") sequentially to obtain the final SQL query.

C.2 EcommerceQuery

On EcommerceQuery, there are totally 2 subclauses, namely MATCHING, and CONDITION clauses. Because thes two clauses are less dependent, we generate each clause separately and then compose the generated values of each clause. When generating MATCHING clause, we use the prompt "*matching algorithm (*". When generating CONDITION clause, we use the prompt "the condition is :".

D Uncertainty based Model Selection

As an alternative to model ensemble, we can also decide whether to use the predicted sequence of the zero-shot model or the fine-tuned model based on zero-shot model's uncertainty score over the generated sequence. Specifically, during greedy search, we compute an uncertainty metric with the rescaled zero-shot model prediction $p^{\star T}$, where T is the first decoding step after the pre-designed prompt [4]. The uncertainty metric could be Margin of Confidence (MOC) or Ratio of Confidence (ROC) . Formally, assume the largest value in vector $p^{\star T}$ is $p_1^{\star T}$, and the second largest value in vector $p^{\star T}$ is $p_2^{\star T}$, we compute these two uncertainty metrics as:

$$\begin{aligned} \text{MoC} &= 1 - (p_1^{\star T} - p_2^{\star T}) \\ \text{RoC} &= p_2^{\star T} / p_1^{\star T} \end{aligned} \tag{3}$$

The results are shown in Table 9.

---

[4] The reason why we choose Tth step is that we do not want to consider the probability of [EOS] token into uncertainty, because for most table name tokens, there is little probability that the [EOS] token occurs after them in zero-shot models.

MultiVerS: Improving scientific claim verification with weak supervision and full-document context

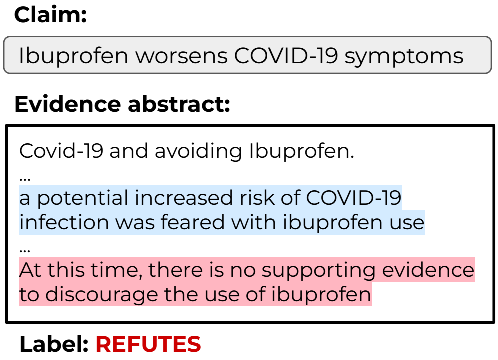
Abstract

The scientific claim verification task requires an NLP system to label scientific documents which Support or Refute an input claim, and to select evidentiary sentences (or *rationales*) justifying each predicted label. In this work, we present MultiVerS, which predicts a fact-checking label and identifies rationales in a multitask fashion based on a shared encoding of the claim and full document context. This approach accomplishes two key modeling goals. First, it ensures that all relevant contextual information is incorporated into each labeling decision. Second, it enables the model to learn from instances annotated with a document-level fact-checking label, but lacking sentence-level rationales. This allows MultiVerS to perform weakly-supervised domain adaptation by training on scientific documents labeled using high-precision heuristics. Our approach outperforms two competitive baselines on three scientific claim verification datasets, with particularly strong performance in zero / few-shot domain adaptation experiments. Our code and data are available at `https://github.com/dwadden/multivers`.

1 Introduction

The proliferation of scientific mis- and disinformation on the web has motivated the release of a number of new datasets (Saakyan et al., 2021; Sarrouti et al., 2021; Wadden et al., 2020; Kotonya and Toni, 2020) and the development of modeling approaches (Pradeep et al., 2021; Li et al., 2021; Zhang et al., 2021) for the task of *scientific claim verification*. The goal of the task is to verify a given scientific claim by labeling scientific research abstracts which Support or Refute the claim, and to select evidentiary sentences (or *rationales*) reporting the findings which justify each label.



Claim:

Ibuprofen worsens COVID-19 symptoms

Evidence abstract:

Covid-19 and avoiding Ibuprofen.
...
a potential increased risk of COVID-19 infection was feared with ibuprofen use
...
At this time, there is no supporting evidence to discourage the use of ibuprofen

Label: REFUTES

Figure 1: A claim from the HealthVer dataset, refuted by a research abstract. The sentence in red is a *rationale* reporting a finding that Refutes the claim. However, this finding cannot be interpreted properly without the context in blue, which specifies that the finding applies to Ibuprofen as a treatment for COVID. MultiVerS incorporates the full context of the evidence-containing abstract when predicting fact-checking labels.

A common approach to this task is to first extract rationales from the larger document context, and then make label predictions conditioned on the selected rationales. This "extract-then-label" approach has two important drawbacks, which we aim to address in this work. First, the rationales may lack information required to make a prediction when taken out-of-context; for instance, they may contain acronyms or unresolved coreferences, or lack qualifiers that specify the scope of a reported finding (Figure 1 provides an example). Second, the "extract-then-label" approach requires training data annotated with both sentence-level rationales and abstract-level labels. While sentence-level rationale annotations are costly and require trained experts, abstract-level labels can be created cheaply using high-precision heuristics, e.g., the titles of research papers sometimes make claims that are supported by their abstracts.

Motivated by these challenges, we introduce MultiVerS (**Multi**task **Ver**ification for **S**cience): Given a claim and evidence-containing scientific abstract, MultiVerS creates a shared encoding of the entire claim / abstract context, using the Longformer encoder (Beltagy et al., 2020) to accommo-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 61 - 76
July 10-15, 2022 ©2022 Association for Computational Linguistics

date long sequences. Then, it predicts an abstract-level fact-checking label and sentence-level rationales in a multitask fashion, enforcing consistency between the outputs of the two tasks during decoding. This modeling approach ensures that label predictions are made based on all available context, and enables training on instances derived via weak supervision for which abstract-level labels are available, but sentence-level rationales are not.

In experiments on three scientific claim verification datasets, we find that MULTIVERS outperforms two state-of-the-art baselines, one of which has more than 10x the parameters of our system. In addition, we show that training MULTIVERS on weakly-labeled in-domain data substantially improves performance in the zero / few-shot domain adaptation settings. The ability to achieve reasonable performance given limited labeled data is especially valuable in specialized domains, due to the high cost of collecting expert annotations.

In summary, our contributions are as follows:

1. We introduce MULTIVERS, a multitask system for full-context scientific claim verification. MULTIVERS improves fully-supervised fact-verification performance by an average of 11% on three datasets over two state-of-the-art baselines, with improvements of 14% and 26% in the few-shot and zero-shot settings.
2. We present weak supervision heuristics to assign fact-checking labels to two large scientific datasets, and show that training on these annotations more than doubles zero-shot domain adaptation performance.
3. Through ablations and analysis, we demonstrate that our multitask modeling approach achieves our goals of incorporating full-document context into label predictions, and facilitating zero / few-shot domain adaptation.

2 Background

2.1 The scientific claim verification task

We use the definition of scientific claim verification from the SCIFACT task (Wadden et al., 2020), and provide a brief overview of the task here. Other works have cast scientific claim verification as a sentence-level natural language inference (NLI) task; in §4.1, we describe how we process these datasets to be compatible with the task as considered in this work.

Task definition Given a claim c and a collection of *candidate abstracts* which may contain evidence relevant to c, the scientific claim verification task requires a system to predict a *label* $y(c, a) \in \{\textsc{Supports}, \textsc{Refutes}, \text{NEI}^{1}\}$, which indicates the relationship between c and a for each candidate a. For all abstracts labeled SUPPORTS or REFUTES, the system must also identify *rationales* $R(c, a) = \{r_1(c, a), \ldots, r_n(c, a)\}$, where each $r_i(c, a)$ is a sentence from a that either entails or contradicts the label $y(c, a)$.[2] The rationales may not be self-contained, and may require additional context from elsewhere in the abstract to resolve coreferential expressions or acronyms, or to determine qualifiers specifying experimental context or study population.[3] Examples of these situations are provided in Figure 1 and Appendix A.3.

Evaluation The SCIFACT task reports four evaluation metrics. We have found that two of these metrics are sufficient to convey the important findings for our experiments: (1) *abstract-level label-only* evaluation computes the model's F1 score in identifying abstracts that SUPPORT or REFUTE each claim. Predicting the correct label $y(c, a)$ is sufficient; models do not need to provide rationales. (2) *Sentence-level selection+label* evaluation computes the point-wise product of the model's F1 score in identifying the rationales $R(c, a)$, with the model's abstract-level label $y(c, a)$; this metric rewards precision in identifying exactly which sentences contain the evidence justifying the label. In this work, we refer to these two metrics as "abstract" and "sentence" evaluation respectively.

Retrieval settings For *open* scientific claim verification, the system must retrieve candidate abstracts from a corpus of documents. In the *abstract-provided* setting, candidate abstracts for each claim are given as input. We describe the retrieval settings for all datasets in §4.1.

Supervision settings We consider three supervision settings. In the *zero-shot domain adaptation* setting, models may not train on any in-domain fact-checking data, though they may train on general-domain fact-checking data and other available scientific datasets. In the *few-shot domain adaptation* setting, models may train on 45 claims from the target dataset. In the *fully-supervised* setting, models

---

[1] NEI stands for "Not Enough Info".

[2] This rationale definition is simplified slightly from the one presented in Wadden et al. (2020).

[3] This convention is consistent with related tasks in rationalized NLP for biomedical literature, such as Lehman et al. (2019) and DeYoung et al. (2020).

may train on all claims from the target dataset.

While most existing work on scientific fact-checking has focused on the fully-supervised setting, some recent work has examined the zero-shot setting. Lee et al. (2021) use language model perplexity as a measure of claim veracity. Wright et al. (2022) generate claims based on citation sentences, and verify each generated claim against the abstracts mentioned in the claim's source citation. Given the high potential impact of fact verification systems for specialized domains, combined with the substantial cost of creating these datasets, we believe that the development of techniques for zero / few-shot domain adaptation represents an important area for continued research.

2.2 Scientific claim verification datasets

Several scientific claim verification datasets have been released in the past few years. COVIDFact (Saakyan et al., 2021) and HealthVer (Sarrouti et al., 2021) verify COVID-19 claims against scientific literature. PUBHEALTH (Kotonya and Toni, 2020) verifies public health claims against news and web sources. SCIFACT (Wadden et al., 2020) verifies claims made in citations in scientific papers. CLIMATE-FEVER (Diggelmann et al., 2020) verifies claims about climate change against Wikipedia. In this work, our focus is verifying claims against scientific literature. We therefore perform experiments on the COVIDFact, HealthVer, and SCIFACT datasets. Preprocessing details and summary statistics for these datasets are included in §4.1.

2.3 Models

Motivated in part by the SCIVER shared task (Wadden and Lo, 2021) and leaderboard, a number of models have been developed for SCIFACT (the focus of the shared task). The two strongest systems on the shared task were VERT5ERINI (Pradeep et al., 2021) and PARAGRAPHJOINT (Li et al., 2021), which we adopt as baselines. More recently, ARSJOINT (Zhang et al., 2021) achieved performance competitive with these two systems.[4]

Given a claim c and candidate abstract a, these models make predictions in two steps. First, they predict rationales $\widehat{R}(c,a) = \{\widehat{r}_1(c,a), \ldots, \widehat{r}_n(c,a)\}$ likely to contain evidence. Then, they make a label prediction $\widehat{y}(c, f_R(\widehat{R}(c,a))$ based on the claim and predicted rationales, where f_R is a function which creates a representation of the predicted rationales.

While existing models share this general approach, they use different functions f_R to construct rationale representations. For VERT5ERINI, rationale selection and label prediction are performed by two separate T5-3B models, and f_R concatenates the text of the selected rationales. As a result, the label predictor may not have access to all context needed to make a correct label prediction. PARAGRAPHJOINT and ARSJOINT attempt to address this issue by encoding the claim and full abstract (truncating to 512 tokens), and using these representations as the basis for both rationale selection and label prediction. The function f_R consists of self-attention layers over the (globally-contextualized) token representations of the predicted rationales. Thus, PARAGRAPHJOINT and ARSJOINT can incorporate abstract-level context into label decisions. However, the mechanism by which this occurs is more complex than for our proposed system and requires rationale supervision for all training instances.

3 The MULTIVERS model

We propose the MULTIVERS model for full-context claim verification. In §3.1, we describe our modeling approach. Rather than predicting rationales $\widehat{R}(c,a)$ followed by the overall fact-checking label $\widehat{y}(c, f_R(\widehat{R}(c,a)))$, we predict $\widehat{y}(c,a)$ directly based on an encoding of the entire claim and abstract, and enforce consistency of $\widehat{R}(c,a)$ with $\widehat{y}(c,a)$ during decoding. A similar idea has been shown to be effective on sentiment analysis and propaganda detection with token-level rationales (Pruthi et al., 2020). In §3.2, we explain how our approach facilitates few-shot domain adaptation using weakly-labeled scientific documents.

3.1 Full-context claim verification

Long-document encoding Given a claim c and candidate abstract a consisting of title t and sentences $s_1, \ldots, s_n$, we concatenate the inputs separated by `</s>` tokens. The `</s>` token following each sentence s_i is notated as `</s>`$_i$:

$$\texttt{<s>}\ c\ \texttt{</s>}\ t\ \texttt{</s>}\ s_1\ \texttt{</s>}_1\ \ldots s_n\ \texttt{</s>}_n$$

The model input sometimes exceeds the 512-token limit common to transformer-based language models like BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019); see Table 1 for details on how frequently this occurs. Therefore, we use the Longformer model (Beltagy et al., 2020) as our encoder.

---

[4] Recent progress can be found on the SciFact leaderboard.

We assign global attention to the `<s>` token, as well as all tokens in c and all `</s>` tokens.

Multitask rationale selection and label prediction Given the full-context Longformer encoding, we predict whether sentence s_i is a rationale via a binary classification head, consisting of two feed-forward layers followed by a two-way softmax, on top of the globally-contextualized token $\texttt{</s>}_i$.

Similarly, we predict the overall fact-checking label $\widehat{y}(c, a)$ by adding a three-way classification head over the encoding of the `<s>` token. Since the `<s>` token is trained with global attention, the model makes predictions based on a representation of the entire claim and abstract.

During training, we compute the cross-entropy losses for the label and rationale predictions, and train to minimize the multitask loss:

$$L = L_{\text{label}} + \lambda_{\text{rationale}} L_{\text{rationale}} \qquad (1)$$

where $\lambda_{\text{rationale}}$ is tuned on the dev set.

At inference time, we first predict $\widehat{y}(c, a)$ to be the label with the highest softmax score. If the predicted label is NEI, we predict no rationales. If the predicted label is either SUPPORTS or REFUTES, then we predict rationales as all sentences with an assigned softmax score of greater than 0.5. If no sentences have a rationale softmax over 0.5, then we predict the highest-scoring sentence as the sole rationale. In §6.2, we show that this ability to condition the rationale predictions on the label prediction (as opposed to conditioning the label on the predicted rationales) leads to substantial improvement in the zero-shot domain adaptation setting.

Candidate abstract retrieval For datasets that require retrieval of candidate abstracts, we rely on the VERT5ERINI (Pradeep et al., 2021) retrieval system, which achieved state-of-the-art performance on the SCIVER shared task (SCIVER used the SCIFACT dataset for evaluation). This model first retrieves abstracts using BM25 (Robertson and Zaragoza, 2009), then refines the predictions using a neural re-ranker based on Nogueira et al. (2020), which is trained on the MS MARCO passage dataset (Campos et al., 2016).

3.2 Training for domain adaptation

Three types of data are available to train scientific claim verification systems. (1) In-domain fact-checking annotations are the "gold standard", but they are expensive to create and require expert annotators. (2) General-domain fact-checking datasets like FEVER (Thorne et al., 2018) are abundantly available, but generalize poorly to scientific claims (see §6.1). (3) Scientific documents – either unlabeled or labeled for different tasks – are abundant, and high precision heuristics (described in §4.2) can be used to generate document-level fact-checking labels $y(c, a)$ for these data.

We train MULTIVERS as follows: we first pretrain on a combination of general-domain fact-checking annotations, combined with weakly-labeled in-domain data.[5] Then, we finetune on the target scientific fact-checking dataset. The multitask architecture of MULTIVERS is well-suited to this strategy, since the model can be trained on data with or without rationale annotations. When no rationales are available, we set $\lambda_{\text{rationale}} = 0$ in the loss function and train as usual. By contrast, training an "extract-then-label" model on weakly-supervised data requires creating rationale annotations $R(c, a)$, which is quite noisy (see §4.2).

4 Datasets

4.1 Scientific claim verification datasets

We experiment with three scientific claim verification datasets. Table 1 provides a summary of important dataset characteristics. Preprocessing steps and additional statistics can be found in Appendix A. HealthVer and COVIDFact were originally released in an NLI format, pairing claims with (out-of-context) evidentiary sentences. We convert to our task format by identifying the abstracts in the CORD-19 corpus (Wang et al., 2020) containing these sentences.

We use the following terminology: an *atomic* claim makes an assertion about a single property of a single entity, while a *complex* claim may make assertions about multiple properties or entities.

SCIFACT Claims in SCIFACT (Wadden et al., 2020) were created by re-writing citation sentences occurring in biomedical literature into atomic claims, which were verified against the abstracts of the cited documents. REFUTED claims were created by manually negating the original claims. Abstracts that were cited but which annotators judged not to contain evidence were labeled NEI. SCIFACT requires retrieval of candidate abstracts.

HealthVer (Sarrouti et al., 2021) consists of COVID-related claims obtained by extracting snippets from articles retrieved to answer questions

---

[5] We use "pretraining" as shorthand for "training on the target task with out-of-domain and/or weakly-supervised labels."

Dataset	Domain	Claim source	Open	Has NEI	Claim complexity	Negation method	Train claims	Eval claims	> 512 tokens
HealthVer	COVID	TREC-COVID	✗	✓	Complex	Natural	1,622	230	14.9%
COVIDFact	COVID	Reddit	✗	✗	Complex	Automatic	903	313	12.4%
SCIFACT	Biomed	Citations	✓	✓	Atomic	Human	1,109	300	27.4%
FEVER	Wiki	Wikipedia	-	✓	Atomic	Human	130,644	-	33.2%
PUBMEDQA	Biomed	Paper titles	-	✓	Complex	Automatic	58,370	-	12.1%
EVIDENCEINFERENCE	Biomed	ICO prompts	-	✓	Atomic	Automatic	7,395	-	42.7%

Table 1: Summary of datasets used in experiments. The top group of datasets are scientific claim verification datasets, and the bottom group are for pretraining. Datasets with a ✓ for "Open" require that candidate abstracts be retrieved from a corpus; those with a ✗ provide candidate abstracts as input. Datasets with a ✓ for "Has NEI" require three-way (SUPPORTS / REFUTES / NEI) label prediction, while those with an ✗ are (SUPPORTS / REFUTES) only. The "> 512 tokens" column indicates the percentage of claim / abstract contexts that exceed 512 tokens.

from TREC-COVID (Voorhees et al., 2020), verified against abstracts from the CORD-19 corpus (Wang et al., 2020). Claims in HealthVer may be complex. REFUTED claims occur naturally in the article snippets. HealthVer provides candidate abstracts for each claim, but some of these candidates do not contain sufficient information to justify a SUPPORTS / REFUTES verdict and are labeled NEI.

COVIDFact (Saakyan et al., 2021) collects claims about COVID-19 scraped from a COVID-19 subreddit, and verifies them against linked scientific papers, as well as documents retrieved via Google search. Claims in COVIDFact may be complex, and candidate abstracts for each claim are provided. All candidates either SUPPORT or REFUTE the claim. Claim negations were created automatically by replacing salient words in the original claims, and as a result the labels $y(c, a)$ are somewhat noisy (see Appendix A).

4.2 Pretraining datasets

We briefly describe our pretraining datasets and the weak supervision heuristics used to construct them. Detailed descriptions of these heuristics can be found in Appendix A.1.

FEVER (Thorne et al., 2018) consists of claims created by re-writing Wikipedia sentences into atomic claims, verified against Wikipedia articles.

EVIDENCEINFERENCE (Lehman et al., 2019; DeYoung et al., 2020) was released to facilitate understanding of clinical trial reports, which examine the effect of an *intervention* on an *outcome*, relative to a *comparator* ("ICO" elements). The dataset contains ICO *prompts* paired with (1) labels indicating whether the outcome *increased* or *decreased* due to the intervention, and (2) rationales justifying each label. We use rule-based heuristics to convert these prompts into claims – for instance "[intervention] increases [outcome] relative to [comparator]".

PUBMEDQA (Jin et al., 2019) was released to facilitate question-answering over biomedical research abstracts. We use the PQA-A subset, which is a large collection of abstracts with "claim-like" titles – for instance, "Vitamin B6 supplementation increases immune responses in critically ill patients." We treat the paper titles as claims and the matching abstracts as the evidence sources.

To train models requiring rationale supervision, we create weakly-supervised rationales by selecting the sentences with highest similarity to the claim as measured by cosine similarity of Sentence-BERT embeddings (Reimers and Gurevych, 2019). These annotations are not used to train MULTIVERS. To estimate the precision of our rationale labeling heuristic, we predict rationales in the same fashion for our supervised datasets and compute the Precision@1 with which this method identifies gold rationales. The scores are relatively low: 49.4, 48.8, and 43.4 for SCIFACT, COVIDFact, and HealthVer respectively.

5 Experimental setup

We describe our model training procedure, the systems against we compare MULTIVERS, and our ablation experiments.

5.1 Model training

Our complete training procedure consists of pretraining on the three datasets from §4.2, followed by finetuning on one of the target datasets from §4.1. We conduct experiments with three different levels of supervision. For *zero-shot* experiments, we perform pretraining only. For *few-shot* experiments, we pretrain followed by finetuning on 45 target examples. For *fully-supervised* experiments, we pretrain and then train on all target data.

Following Li et al. (2021), we found that negative sampling was important to achieve good precision on SCIFACT, which requires document retrieval. We train with 20 negative samples per claim and retrieve 10 abstracts per claim at inference time. Appendix C.3 shows results without negative sampling. For the other datasets, no negative sampling was used. Additional details including batch sizes, learning rates, number of epochs, etc. can be found in Appendix B.

During model development, we experimented with training on all three target datasets combined before predicting on each one, but found that this did not improve performance; see Appendix C.4.

5.2 Baseline systems

We use PARAGRAPHJOINT and VERT5ERINI as baselines. VERT5ERINI is the largest model, with 5.6B parameters. MULTIVERS and PARAGRAPHJOINT are comparably-sized, with 440M and 360M parameters, respectively.

In the fully-supervised setting, we compare against both baselines. For prediction on SCIFACT, we use publicly available model checkpoints as-is. For training on HealthVer and COVIDFact, we use the code provided by the authors, starting from the available checkpoints trained on SCIFACT. Model hyperparameters (learning rate, batch size, epoch number, etc.) for all systems including MULTIVERS were tuned based solely on SCIFACT and not adjusted further. Additional details can be found in Appendix B.4.

Evaluation in the few-shot and zero-shot settings requires pretraining and finetuning as described in §5.1. Due to the expense of pretraining T5-3B, we do not perform these experiments for VERT5ERINI, and compare only against PARAGRAPHJOINT (which shows comparable performance in the fully-supervised setting). We pretrain PARAGRAPHJOINT on the data described in §4.2.

5.3 Ablations

Since PARAGRAPHJOINT and VERT5ERINI differ from MULTIVERS along a number of important dimensions (e.g. model architecture, number of parameters, and base encoder), we conduct ablations to characterize the performance contributions of three key components of MULTIVERS.

Pretraining data We compare the results of three different pretraining strategies. For FEVERSCI, we pretrain on all available data as described in §5.1. For FEVER, we pretrain on FEVER only. For *No-Pretrain*, we perform no pretraining.

Base encoder We compare the performance achieved using LongFormer as the encoder for MULTIVERS, compared to the results when we swap in RoBERTa but keep other settings identical. We use Longformer-large and RoBERTa-large.

Modeling approach We compare three modeling approaches: (1) The *Multitask* approach is the method used by MULTIVERS as described in §3.1. (2) The *Pipeline* approach consists of two separate Longformer modules. The first selects rationales as described in §3.1, but with L_{label} removed from Eq. 1, and the second module predicts a label given the text of the rationales selected by the first module as input. When pretraining on PUBMEDQA, we train on the rationales chosen by Sentence-BERT as described in §4.2. (3) The *Multitask train / Pipeline inference* (MT / PI) approach takes the model trained using the Multitask approach, and performs inference using the Pipeline approach. Specifically, MT / PI is trained to make label predictions based on full abstracts, but must make test-time label predictions based on predicted rationales only. By contrast, the Pipeline model makes label predictions based on gold and predicted rationales at train and test time, respectively.

6 Experimental results

We compare MULTIVERS performance relative to our baseline systems, and present ablation results.

6.1 Main Results

Table 2 compares the performance of MULTIVERS against PARAGRAPHJOINT and VERT5ERINI. A few trends are apparent. First, MULTIVERS outperforms the baselines on all datasets, with relative improvements — averaged over the three datasets and two evaluation methods — of 26%, 14%, and 11% in the zero-shot, few-shot, and fully-supervised settings respectively. We examine possible causes of this improvement in §6.2. Second, while all models score within roughly six points of each other on HealthVer and SCIFACT, variability is much greater on COVIDFact. We suspect that this is due to the automatically-generated nature of COVIDFact negations. Third, we observe that HealthVer appears to be the most challenging dataset of the three. Few-shot abstract-level F1 scores for COVIDFact and SCIFACT are generally

		HealthVer						COVIDFact						SciFact

Table 2: Performance of MultiVerS and baselines. In the fully-supervised setting, we compare to ParagraphJoint and Vert5Erini, which exhibit comparable performance. In the zero and few-shot settings, we compare to ParagraphJoint only due to the high cost of pretraining Vert5Erini. We report performance using abstract-level and sentence-level evaluation as defined in §2.1.

within 10 F1 of their fully-supervised values, while the gap is roughly 20 F1 for HealthVer. This may be due to the high complexity of HealthVer claims.

6.2 Ablations

The results of all ablations are shown in Table 3. We report abstract and sentence-level F1 scores in the main text; full results can be found in Table 9 in Appendix C.

In-domain pretraining substantially improves zero / few-shot performance In Table 3a, we compare the performance of models pretrained on FeverSci, Fever, and No-Pretrain. In the zero-shot setting, removing scientific data during pretraining results in a relative performance decrease of 65%, averaged over the three datasets and two evaluation methods. The decrease is driven primarily by very low recall (see Table 9a).

In the few-shot setting, Fever pretraining scores within 4% of FeverSci, while No-Pretrain results in a 39% decrease relative to FeverSci. This suggests that training on a handful of target examples is sufficient to recalibrate a model trained for a different domain, but not to learn the task from scratch. In the fully-supervised setting, Fever pretraining is only slightly worse than FeverSci, while No-Pretrain lags by roughly 9%. Overall, the results indicate that pretraining always helps, and pretraining on weakly-labeled in-domain data helps especially when target data are scarce.

Longformer improves performance on datasets with long documents Table 3b compares the performance of MultiVerS when Longformer and RoBERTa are used as the base encoder. Using Longformer consistently helps on SciFact, but does not help on the other two datasets. This is unsurprising, since 27% of SciFact instances exceed the RoBERTa token limit, compared to less than 15% for the other two datasets (Table 1).

Multitask modeling improves zero / few-shot performance Results comparing our three different modeling approaches are shown in Table 3c. In the zero-shot setting, we find that Multitask performs best, with both MT / PI and Pipeline exhibiting performance drops greater than 50%. The Multitask approach of predicting rationales conditioned on the predicted label leads to improved recall (see Table 9c). Similarly, in the few-shot setting, both Pipeline and MT / PI perform roughly 10% worse than Multitask. Collectively, the results indicate that Multitask makes the best use of the available data when target annotations are limited.

We also find that MT / PI outperforms Pipeline in the zero-shot setting. This supports our intuition from §3.2 that, while training on weakly-supervised *document-level* labels improves zero-shot performance, training on weakly-supervised *sentence-level* rationales (as for Pipeline) leads to worse performance than not training on these rationales (as for MT / PI).

In the fully-supervised setting, Multitask performs best on SciFact, while Pipeline slightly outperforms Multitask on HealthVer and COVID-Fact. MT / PI performs substantially worse than the other approaches on all datasets. We investigate these findings further in §7.1; our results indicate that Pipeline may, in effect, be trained to make predictions based on insufficient evidence.

	Pretraining	HealthVer	COVIDFact	SciFact
Zero	FeverSci	**30.7 / 7.8**	**47.2 / 23.6**	**46.7 / 27.8**
	Fever	1.3 / 0.7	25.2 / 11.2	23.9 / 11.8
Few	FeverSci	**54.7 / 35.7**	69.7 / 37.4	**63.3 / 45.3**
	Fever	53.4 / 31.9	**74.4 / 42.1**	54.5 / 39.0
	No-Pretrain	39.4 / 27.0	67.8 / 22.6	24.2 / 10.8
Full	FeverSci	**77.6** / 69.1	77.3 / **43.7**	**72.5 / 67.2**
	Fever	77.1 / **70.3**	**77.4** / 43.3	67.9 / 61.7
	No-Pretrain	74.5 / 69.7	69.7 / 36.6	63.3 / 58.4

(a) Effect of pretraining data. In-domain pretraining is very effective in the zero- and few-shot settings. In the zero-shot setting, “No-Pretrain” metrics are not shown since this would correspond to no training at all.

	Encoder	HealthVer	COVIDFact	SciFact
Zero	Longformer	30.7 / 7.8	47.2 / 23.6	**46.7 / 27.8**
	RoBERTa	**34.2 / 9.2**	**48.3 / 26.2**	45.2 / 25.9
Few	Longformer	**54.7** / 35.7	69.7 / 37.4	**63.3 / 45.3**
	RoBERTa	51.2 / **36.9**	**72.1 / 41.0**	50.5 / 34.0
Full	Longformer	77.6 / 69.1	77.3 / **43.7**	**72.5 / 67.2**
	RoBERTa	**78.8 / 72.7**	**78.2** / 43.4	67.6 / 62.3

(b) Effect of base encoder. Longformer improves performance on SciFact, which has the largest fraction of instances exceeding the RoBERTa token limit.

	Approach	HealthVer	COVIDFact	SciFact
Zero	Multitask	**30.7 / 7.8**	**47.2 / 23.6**	**46.7 / 27.8**
	Pipe	3.2 / 0.9	19.0 / 10.5	22.5 / 12.8
	MT / PI	4.5 / 1.8	26.7 / 13.5	28.3 / 17.7
Few	Multitask	**54.7 / 35.7**	**69.7** / 37.4	**63.3 / 45.3**
	Pipe	52.8 / 29.5	68.3 / **38.2**	53.0 / 39.9
	MT / PI	46.7 / 32.3	59.3 / 34.1	56.2 / 41.1
Full	Multitask	77.6 / 69.1	77.3 / 43.7	**72.5 / 67.2**
	Pipe	**78.4 / 69.2**	**77.6 / 47.7**	70.9 / 66.2
	MT / PI	70.6 / 64.3	73.3 / 44.0	60.3 / 57.0

(c) Effect of model architecture. The Multitask approach performs best in the zero- and few-shot settings. We examine the fully-supervised setting in detail in §7.1.

Table 3: Ablations examining the effects of pretraining data, base encoder, and modeling approach. Entries are formatted “{Abstract-level F1} / {Sentence-level F1}”.

	Self-contained			**Context-dependent**			
Approach	P	R	F1	P	R	F1	%**Δ**
Multitask	86.1	82.9	84.5	90.3	60.9	72.7	-14.0%
Pipeline	92.4	89.0	90.7	82.4	60.9	70.0	-22.8%
MT / PI	91.8	54.9	68.7	100.0	13.0	23.1	-66.4%
Count	82			46			

Table 4: Performance of the Multitask, Pipeline, and MT / PI modeling approaches on SciFact instances with rationales that are self-contained (can be interpreted in isolation) or context-dependent (must be interpreted in the context of the abstract). Evaluation is performed in the abstract-provided setting. We report abstract-level metrics; sentence-level results are similar. The %Δ indicates the drop in F1 score on context-dependent instances relative to self-contained instances. Multitask suffers the smallest performance loss, while MT / PI suffers the largest.

7 Analysis

7.1 Fully-supervised Pipeline performance

In §6.2, we found that the Pipeline approach (but not the MT / PI approach) performed on par with the Multitask approach in the fully-supervised setting. To understand this finding, we collected detailed annotations for 128 claim / evidence instances from the SciFact test set. For each instance, an annotator indicated whether the annotated rationales were “self-contained” — i.e. sufficient to justify the fact-checking label when taken in isolation, or “context-dependent” — i.e. only sufficient when taken in the context of the abstract. Figure 1 and Table 8 provide examples; see Choi et al. (2021) for a detailed discussion of different forms of context-dependence.[6]

Table 4 compares the performance of the three modeling approaches on instances with self-contained vs. context-dependent evidence. We find that all approaches have lower performance on context-dependent instances relative to self-contained instances, but the size of the performance drop varies widely. The Multitask approach performs 14.0% worse on context-dependent instances, while the Pipeline approach performs 22.8% worse. Most interestingly, MT / PI performs 66.4% worse, driven predominantly by low recall. The MT / PI model frequently (and correctly) predicts that context-dependent rationales are not sufficient to justify a Supports / Refutes decision. These findings suggest that (1) the Multitask approach is, as expected, best at verifying claims with context-dependent evidence, and (2) the Pipeline approach has, in effect, over-fit to context-dependent rationales and learned to make predictions based on insufficient evidence.

7.2 Performance upper bound

To determine an “upper bound” on the achievable performance of scientific fact-checking models, we

---

[6] Unlike Choi et al. (2021), we do not include the presence of acronyms as “context-dependent,” since an acronym can be matched with its expansion based on surface-level textual features. See Appendix C.2 for further analysis of acronyms.

	Abstract			Sentence		
	P	R	F1	P	R	F1
VERT5ERINI	90.7	74.3	81.7	79.6	62.2	69.8
PARAGRAPHJOINT	87.2	64.4	74.1	76.7	55.1	64.1
MULTIVERS	87.4	75.2	80.9	80.5	70.3	**75.0**
Human	94.8	84.1	**89.1**	67.4	67.4	67.4

Table 5: Performance on SCIFACT in the "abstract-provided" setting. Models exceed human agreement as measured by sentence-level F1, but not abstract-level.

assign 151 claim-evidence pairs from SCIFACT for independent annotation by two different annotators. We estimate human-level performance by treating the first annotator's results as "gold," and the second annotator's results as predictions. For comparison, we make predictions using MULTIVERS and our two baseline models, with candidate abstracts provided as input. The results are shown in Table 5. Existing systems already exceed human agreement for sentence-level evaluation, but not abstract-level, indicating that experts tend to agree on the overall relationship between claim and abstract, but may disagree about exactly which sentences contain the best evidence. This constitutes another reason not to rely solely on selected rationales when predicting a fact-checking label: the choice of rationales is itself somewhat subjective.

In addition, these results suggest that one key subtask of scientific claim verification — namely, predicting whether an evidence-containing abstract SUPPORTS or REFUTES a claim — may be nearly "solved" in the setting where (1) the claims are atomic and (2) roughly 1,000 in-domain labeled claims are available for training.

8 Related work

Background on scientific claim verification is covered in §2; we discuss other relevant work here. Nye et al. (2020) have previously observed that document-level context is often required to properly interpret scientific findings.

DeYoung et al. (2020) use an "extract-then-label" pipeline for the original EVIDENCEINFERENCE task. Multitask label prediction and rationale selection was proposed by Pruthi et al. (2020) and applied to sentiment analysis and propaganda detection. As in this work, the authors condition on the predicted label when predicting rationales. Another alternative to supervised rationale selection is to treat rationales as latent variables (Lei et al., 2016; Paranjape et al., 2020).

Long-document encodings for fact verification have been explored by Stammbach (2021), who use Big Bird (Zaheer et al., 2020) for full-document evidence extraction from FEVER. Domain adaptation for scientific text has been studied in a number of works, including Gururangan et al. (2020); Beltagy et al. (2019); Lee et al. (2020); Gu et al. (2021). In those works, the primary focus is on language model pretraining. Here, we focus on training on the target task using out-of-domain and weakly-labeled data.

9 Conclusion

This work points to a number of promising future directions for scientific claim verification. These include applying the approach presented here to develop scientific claim verification models for new scientific sub-domains or other specialized fields given a handful of labeled examples, and extending the task definition to verify claims against longer contexts (e.g. full scientific papers) or larger corpora. Our task formulation also offers an opportunity to study the effects of rationale decontextualization (Choi et al., 2021), especially in cases where models may be making predictions based on insufficient evidence.

In presenting the MULTIVERS system, we addressed two challenges associated with scientific claim verification: incorporating relevant information beyond rationale boundaries by modeling full-document context, and facilitating zero / few-shot domain adaptation through weak supervision enabled by a multitask modeling approach. Our experiments show that MULTIVERS outperforms existing systems across several scientific claim verification datasets. We hope that the task, data, and modeling resources presented in this paper will encourage further work and progress towards the broader goals of identifying and addressing scientific mis- and disinformation.

10 Ethical considerations and broader impact

One long-term goal of research on scientific claim verification is to build systems that can automatically identify mis- and dis-information, which we believe would be socially beneficial given the current prevalence of mis- and dis-information online.

In the shorter term, this work presents two potential risks. First, automated systems for scientific fact-checking are not mature enough to inform real-world medical decisions. We will include a disclaimer with released software to this effect. Second, bad actors could potentially use this work to develop disinformation generators trained to "fool" automated fact-checkers. While this risk cannot be ruled out, we believe that the benefits of publishing this work and making our models available to the community to facilitate further research outweigh the risks that this work will be misused by malicious actors.

A Data processing and statistics

A.1 Data preprocessing

SCIFACT We use SCIFACT in its original form, as it was released by the paper authors (Wadden et al., 2020).

HealthVer The HealthVer (Sarrouti et al., 2021) data release available at `https://github.com/sarrouti/HealthVer` appears in NLI format, pairing claims with evidence-containing sentences; the documents from which the sentences were extracted are not provided. We match evidence-containing sentences to their abstracts in the CORD-19 corpus (Wang et al., 2020) using a simple substring search, after normalizing for capitalization and whitespace differences. Evidence for which no match was found in the corpus is discarded.

We then segment the abstracts into sentences. Any sentence in the abstract with a string overlap of $> 50\%$ with the evidence provided in the original data is marked as a rationale. A small number of claims in HealthVer had both supporting and refuting evidence in the same abstract; we remove these claims as well to conform to our task definition. Modeling conflicting evidence is a promising direction for future work.

COVIDFact The COVIDFact data available at `https://github.com/asaakyan/covidfact` is released in a similar format to HealthVer. Like HealthVer, we perform string search over CORD-19 to identify the abstracts containing evidence, and use the same procedure for assigning rationale labels to sentences from the abstract. COVIDFact also includes evidence from sources scraped from the web that are not contained in CORD-19, such as news articles. These sources are not provided with the data release; we discard evidence from non-CORD-19 sources[7].

Refuted claims in COVIDFact are generated automatically by replacing words in the original claim. Based on a manual inspection, we found this process to generate a truly refuted claim roughly a third of the time; in most other cases, it generated a claim that was either ungrammatical or for which the provided evidence was irrelevant. A few cases are provided in Table 6.

FEVER We use the FEVER dataset as-is.

EVIDENCEINFERENCE The EVIDENCEINFERENCE dataset consists of "ICO" (intervention / comparator / outcome) prompts, paired with labels indicating whether the intervention leads to an increase, decrease, or no change in the outcome with respect to the comparator. The dataset is available at `https://evidence-inference.ebm-nlp.com/`. We use templates to convert these prompts to claims. See Figure 2 for an example. Rationale annotations are provided for this dataset. Additional examples of templates are below; the full list will be included in the code release. Refuted claims are generated by swapping "increase" and "decrease" templates.

- **Increase**: [intervention] raises [outcome] relative to [comparator]
- **No change**: [intervention] and [comparator] have very similar effects on [outcome]
- **Decrease**: [intervention] results in a decrease in [outcome], relative to [comparator]

PUBMEDQA We use the PQA-A subset released at `https://pubmedqa.github.io/`, which is filtered for "claim-like" titles. We generate negations by identifying titles with the phrases "does not", "do not", "are not", "is not". "Does not" and "do not" are removed and the relevant verbs are modified to have the correct inflection; for instance "smoking does not cause cancer" is converted to "smoking causes cancer". Similarly, "are not" and "is not" are replaced by "are" and "is".

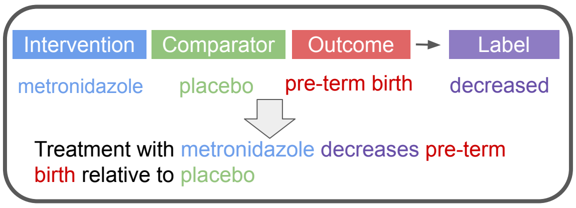

Figure 2: An example showing how an evidence inference prompt (top) can be converted into a claim (bottom) using templates. A refuted claim could be generated by substituting "increases" for "decreases" in the prompt text.

To generate rationales needed to train pipeline models on PUBMEDQA, we employ the following procedure. First, we encode the claim and all abstract sentences using the `all-MiniLM-L6-v2` model from the Sentence-Transformers package `https://www.sbert.net/`. Then, we rank abstract sentences by cosine similarity with the claim and label the top-k sentences as rationales, where k is randomly sampled from $\{1, 2, 3\}$ with a 4:2:1 frequency ratio (this matches the distribution of k in SCIFACT).

A.2 Dataset statistics

Table 7 provides counts showing the number of claim / evidence pairs with each label (SUPPORTS, REFUTES, NEI), in each of our target datasets. Note that a given claim may be (and often is) paired with more than one abstract containing evidence. HealthVer is the largest dataset. COVIDFact is the smallest, in part due to the aggressive evidence filtering described in §A.1.

A.3 Examples of context-dependent rationales

Table 8 provides an example of a context-dependent rationale (as defined in §7.1), as well as an example of a rationale with an undefined acronym. The latter occurs when an acronym appears in a rationale but its full expansion does not; an analysis of undefined acronyms is included in Appendix C.2. The code and data release will contain full annotations indicating which of the 128 human-annotated examples described in §7.1 are context-dependent, and which contain undefined acronyms.

---

[7] Upon request, the paper authors did kindly provide us with scraped evidence documents. Unfortunately, we did not have time to re-run our experiments on these additional sources.

Original claim	**Automatic negation**	**Comment**
Sars-cov-2 reactive t cells . . . are likely expanded by beta-coronaviruses	Sars-cov-2 reactive t cells . . . are not expanded by beta-coronaviruses	Successful negation
Regn-cov2 antibody cocktail prevents and treats sars-cov-2 . . .	On-cov2 antibody cocktail prevents and treats sars-cov-2 infection . . .	Ungrammatical; “On-cov2” isn’t a scientific entity.
. . . immunity is maintained at 6 months following primary infection	. . . immunity is maintained at 6 weeks following primary infection	Not refuted; The original claim entails the negation. Immunity at 6 months implies immunity at 6 weeks.

Table 6: Automatic negations from COVIDFact. Some are successful, in the sense that the attempted negation contradicts the original claim. Others are either ungrammatical or are entailed by the original claim.

Fold	Dataset	SUPPORTS	NEI	REFUTES
Train	SCIFACT	508	485	265
	COVIDFact	299	-	641
	HealthVer	2384	2384	1464
Eval	SCIFACT	113	127	109
	COVIDFact	102	-	215
	HealthVer	374	304	225

Table 7: Evidence distribution by dataset.

A.4 Annotators

In §7, we report an analysis based on annotations performed on the SCIFACT dataset. These annotations were performed by students and / or professional annotators associated with the authors’ research institutions. Annotators were paid between $15 and $20 / hour.

B Modeling details

B.1 Implementation

We implement MULTIVERS using PyTorch Lightning (`https://www.pytorchlightning.ai/`), which relies on PyTorch (`https://pytorch.org/`).

B.2 Model training

Pretraining For pretraining, we train for 3 epochs on FEVER, EVIDENCEINFERENCE, and PUBMEDQA, with the data randomly shuffled. We train on 4 negative samples (i.e. abstracts containing no evidence) per claim, which we find improves precision. We train on 8 NVIDIA RTX 6000 GPUs with a batch size of 1 / gpu (effective batch size of 8), using a learning rate of $1e-5$, using the PyTorch Lightning implementation of the AdamW optimizer with default settings. We initialize from a Longformer-large checkpoint pretrained on the S2ORC corpus (Lo et al., 2020).

Finetuning For finetuning, we train for 20 epochs on the target dataset (SCIFACT, HealthVer, or COVIDFact). For SCIFACT, we train on 20 negative samples / claim. To create “hard” negatives — i.e. abstracts that have high lexical overlap with the claim — we create a search index from 500K abstracts randomly selected from the biomedical subset of the S2ORC corpus. For each claim, we obtain negative abstracts by using the VERT5ERINI retrieval system from §3.1 to retrieve the top-1000 most-similar abstracts from this index, removing abstracts that are annotated as containing evidence, and randomly sampling 20 abstracts to be used as negatives during training.

Since HealthVer and COVIDFact do not have a retrieval step, they do not require negative sampling, and we train on the original datasets as-is.

Retrieval For SCIFACT, we performed dev set experiments retrieving 10, 20, or 50 abstracts / claim, and found that 10 was the best. We use that in our final experiments.

B.3 Model hyperparameters

No organized hyperparameter search was performed. We consulted with the authors of the Longformer paper for suggestions about good model parameters, and generally followed their suggestions.

The loss function in Section 3.1 requires a weight $\lambda_{\text{rationale}}$. This is set to 15 for all final experiments. We informally experimented with values of 1, 5, and 15; no organized hyperparameter search was performed. We selected the learning rate from the values $[9e-5, 5e-5, 1e-5]$.

We performed all experiments with the same random seed, 76, used by invoking the `seed_everything` function in PyTorch Lightning.

All reported results are from a single model run.

B.4 Baselines

VERT5ERINI For prediction on SCIFACT, we use the checkpoint available at

Category	Example	
Context-dependent	**Claim:**	Errors in peripheral IV drug administration are most common during bolus administration
	Context:	*OBJECTIVES: To determine the incidence of errors in the administration of intravenous drugs . . .*
	Evidence:	*. . . Most errors occurred when giving bolus doses*
	Explanation:	The evidentiary sentence reporting the finding does not specify the type of error.
Undefined acronym	**Claim:**	Hematopoietic stem cells segregate their chromosomes randomly.
	Context:	*we tested these hypotheses in hematopoietic stem cells (HSCs). . .*
	Evidence:	*. . . indicated that all HSCs segregate their chromosomes randomly.*
	Explanation:	HSCs is an acronym for Hematopoietic stem cells.

Table 8: Examples from the SCIFACT dataset showcasing rationales that are context-dependent (top example), or include an undefined acronym (bottom example).

https://github.com/castorini/pygaggle/tree/master/experiments/vert5erini. For COVIDFact and HealthVer, we follow the instructions in that repository to convert the data to the required format, and train using the available training code as-is, beginning from the available SCIFACT checkpoint. We used Google Cloud TPU for training and inference.

PARAGRAPHJOINT We use the code available at https://github.com/jacklxc/ParagraphJointModel. For predictions on SCIFACT, we make predictions using the publicly available checkpoint. For the other two target datasets, we use the training code in the repo without modification.

We used PARAGRAPHJOINT as our baseline for zero / few-shot learning experiments, and hence also performed pretraining on PARAGRAPHJOINT. The repository provides code to train on the FEVER dataset, which we used for pretraining with EVIDENCEINFERENCE and PUBMEDQA added to the data.

C Additional results and analysis

C.1 Full ablation results

In Table 3, we presented F1 scores for ablations comparing pretraining data, model architecture, and encoder used. Table 9 presents the full results, including precision and recall.

C.2 Performance on rationales with undefined acronyms

In §7.1, we examined the difference in performance on instances with self-contained vs. context-dependent evidence. Here, we show the results of evaluation on instances containing an undefined acronym vs. cases without one. We find that undefined acronyms do not pose a challenge for Multitask and Pipeline, but do cause a small performance drop on MT / PI.

C.3 Negative sampling

In §5.1 we described how, for SCIFACT, we trained on 20 negative abstracts per claim. The effect of training on these additional negative samples is shown in Figure 11. In the abstract-provided setting, negative sampling is not very beneficial. However, when the model must select evidence from retrieved abstracts, precision drops off dramatically without negative sampling. This is worth noting since it suggests that performance reported when models are provided with "gold" candidate abstracts may not offer an accurate estimate of the accuracy these systems would achieve when deployed in a real-world setting, which could require systems to verify claims over hundreds of thousands of documents.

C.4 Cross-dataset generalization

In §5, we discussed how the available scientific fact-checking datasets differ in a number of important respects. Here, we explore whether models trained on one system are able to generalize to another despite these differences. We train MULTIVERS on each of our three datasets and then evaluate its performance on the other two. We also train a version of MULTIVERS on all three datasets together, and evaluate on each one. Since COVIDFact has no NEI instances, during evaluation we remove all NEI instances from the other two datasets, and evaluate in the abstract-provided setting.

The results are shown in Table 12. The sentence-level evaluation results (Table 12b) indicate that none of the datasets generalize well to each other in their ability to identify rationales. The situation is better for abstract labeling (Table 12a). SCIFACT and HealthVer each generalize reasonably well to

The Δ values indicate the loss in performance from evaluating on a dataset different from the one the model was trained on. The "Combined" row indicates training on all datasets combined.

An Item Response Theory Framework for Persuasion

Anastassia Kornilova **Daniel Argyle** **Vlad Eidelman**
FiscalNote Research
anastassia, daniel, vlad@fiscalnote.com

Abstract

In this paper, we apply Item Response Theory, popular in education and political science research, to the analysis of argument persuasiveness in language. We empirically evaluate the model's performance on three datasets, including a novel dataset in the area of political advocacy. We show the advantages of separating these components under several style and content representations, including evaluating the ability of the speaker embeddings generated by the model to parallel real-world observations about persuadability.

1 Introduction

Persuasion is the art of instilling in someone a given belief or desire to take a given action. The action can be expressing agreement with the speaker in a debate (Durmus and Cardie, 2019), making a donation to a crowdfunding campaign (Yang et al., 2019) or non-profit (Wang et al., 2019), or a Supreme Court ruling (Danescu-Niculescu-Mizil et al., 2012). Social psychology frameworks for understanding persuasion, such as the Elaboration Likelihood Model (ELM), argue that attributes of successful persuasion fall into three groups: (1) message, the text of the argument; (2) audience; and (3) speaker, the source of the argument. (Petty and Cacioppo, 1986; Lukin et al., 2017; Cialdini, 2009).

Although much attention has been given to studying the text, text in isolation fails to capture how the audiences' prior beliefs and predispositions can affect their response to the same argument. Several recent studies have considered all three factors within the context of specific datasets by creating features to represent the audience as a whole or by building separate models for different types of audiences (Lukin et al., 2017; Tan et al., 2016; Durmus and Cardie, 2019; El Baff et al., 2020). In this paper, we present a broad framework that can represent individual audience members in one model across a diverse set of persuasion tasks.

Since implementing the ELM framework requires separate data about the speaker, audience, and argument, it is difficult to validate empirically. Often, we only have access to the observed outcome (e.g. did the person donate money). Both the persuadability of the audience and the persuasiveness of the argument are unobserved. Motivated by this, we explicitly model a persuasive scenario as a function of latent variables describing the persuadability of the audience and the persuasiveness of the text.

Our approach is based on Item Response Theory (IRT), a framework for modeling the interaction between latent traits and observable outcomes. While these types of models are well known in the context of education (Fischer, 1973; Lord, 1980; McCarthy et al., 2021) and politics (Clinton et al., 2004), to our knowledge this is the first application of an IRT model to study persuasion. Using this framework, we model the interaction between the grouped *argument* and *speaker*, and the *audience*, explicitly. The argument and speaker are grouped together because in practice it is hard to separate their effects, especially in the written tasks covered in this study.

We explore two variations on the IRT framework and apply it to three different persuasion tasks. In addition to two previously studied tasks, we introduce a novel setting related to political advocacy group campaigns, where a recipient is asked by an organization to take a specific action.

We evaluate these models with different parameterizations, including style and content features, showing that they are both effective for predicting persuasion, and have the ability to uncover latent characteristics of the audience that were modeled explicitly in previous works.

Our contributions are as follows: 1) we formalize the use of IRT model formulations for persuasion and show the advantages of them over existing approaches, 2) we introduce a new dataset of

Findings of the Association for Computational Linguistics: NAACL 2022, pages 77 - 86
July 10-15, 2022 ©2022 Association for Computational Linguistics

political advocacy emails, 3) we apply the formulations with style and content features on three persuasion tasks, and 4) we show that the separate latent audience component is interpretable and consistent with external information. All code associated with the paper is available at `https://github.com/akornilo/IRT_Persuasion`.

2 Item Response Theory

Item Response Theory (IRT) represents a set of models that explain an observed outcome based on latent traits. These models are frequently used when an outcome is easily observed, but the factors predicting that model are unobservable. For example, in education an outcome could be a student's answer to an exam question, and the latent predictive traits are a students knowledge and the difficulty of the question; in politics an outcome could be a vote on a bill and the unobservable traits are the legislator's and bill's ideology. Crucially, an IRT model provides both a prediction of the outcome, and an interpretable measurement of the latent variables.

In applying IRT to persuasiveness, we can view the audience as having a response to the item, where the item is an argument composed of the speaker and message pair.

2.1 Rasch Testing Model

We build on two specific IRT parameterizations. The first, the **Rasch** model (Rasch, 1960) is commonly used in education research to model the difficulty of standardized test questions (Fischer, 1973; Lord, 1980). In it the probability that an individual i answers test question j is given by:

$$p(y_{ij} = 1 \mid \alpha, \beta) = \sigma(\alpha_i - \beta_j) \tag{1}$$

where α_i represents a respondent (e.g. a student's ability) and β_j represents the item (e.g. the difficulty of a test question). Intuitively, if the ability is greater than the question difficulty, then the student will answer the question correctly. Given a series of exam sessions one can estimate values of α and β for all of the students and questions in the dataset. This can be done using a variety of optimization strategies, such as Expectation Maximization or Bayesian techniques (Bock and Aitkin, 1981; Natesan et al., 2016).

However, one limitation of this approach is that it cannot be used to perform inference on new test questions because all parameters are estimated simultaneously. To solve this problem, Fischer (1973) proposed the linear logistic test model that parameterizes the difficulty, β, as a weighted linear combination of test features. In this formulation, the student (α) remains a latent variable, but the β of an unseen question can be predicted using attributes of the question itself.

Following Fischer (1973), the parameterization used to predict the item parameters is a weighted linear sum of features:

$$\beta_j = \sum_{k=1}^{K} w_k \times \psi_{jk} \tag{2}$$

where ψ_k is an input feature representing the item, and w_k is the associated weight.

In order to apply this model to persuasion, we propose considering argumentation as follows: First, arguments can vary in quality, similar to test questions having different difficulty levels. Second, we can only measure the quality of an argument based on how the audience reacted; similar to how a students ability is measured via their performance. Third, it is possible that a good argument is matched with an audience reticent to persuasion, similar to a good student receiving a particularly hard question. Note that this requires an audience member observe multiple arguments, and that each argument be heard by multiple audience members. Inspired by the linear logistic model, we model the latent argument parameter as a function of attributes of the argument itself, thus allowing us to include attributes of the speaker and text in the model directly.

2.2 Two Parameter IRT

While the simplicity of the Rasch model is powerful, a two parameter generalization of an IRT model (a two parameter logistic - **2PL**) provides additional benefits for our application (Birnbaum, 1968). In the simplest version, a two parameter model (so called because the item is modeled with two parameters) is as follows:

$$p(y_{ij} = 1 \mid \boldsymbol{\alpha}, \boldsymbol{\phi}, \boldsymbol{\beta}) = \sigma\left(\alpha_i \cdot \phi_j - \beta_j\right) \tag{3}$$

where as before, α_i represents the respondent (students ability), and β_j is the item's difficulty,[1] but

---

[1] Analogous to the Rasch model, this tells us the overall difficulty level of the question

now ϕ_j represents the item's discrimination.[2] We similarly generalize this model by estimating the two item parameters, β_j and ϕ_j, as linear functions of features as in Equation 2.

This framework has commonly been be used to explain legislator voting behavior (Clinton et al., 2004), a useful analogy as many of the persuasion contexts we consider have political undertones. In this case, the response y_{ij} is a vote by respondent i (a legislator) on item j (a bill). Clinton et al. (2004) show that the parameter α_i can then be interpreted as the respondent's ideology (e.g negative values are more liberal, positive values are more conservative); ϕ_j is referred to the bills polarity (i.e. discrimination);[3] β_j represents the bill's popularity (i.e. difficulty).[4] Persuasion is a generalization of this framework because popularity can correspond to properties of arguments that are appealing overall, while polarity represents techniques or topics that appeal only to a subset of the audience.

2.3 Audience Analysis

Once a Rasch or a 2PL model is fit, the learned α can be interpreted as a one-dimensional respondent embedding. In the legislator voting context these values can be interpreted as ideologies: legislators with very negative or very positive embeddings reflect very liberal and conservative stances, respectively, while those with small-value embeddings map to moderate legislators. While interpretation of these values will depend on the task, in general, similar embeddings will map to similar audience members and can be grouped together for further analysis.

3 Related Works

Audience Effects The properties of the audience in relation to argument persuasiveness have previously been examined in several predictive studies. Lukin et al. (2017) show that audiences with a more "open" personality respond better to emotional arguments, while El Baff et al. (2020) show that liberals are more affected by the style of a new editorial than conservatives. Wang et al. (2019) also find that people with different personality types respond differently to emotional vs. logical appeals. Tan et al. (2016) show how "malleable" different Reddit users are to new perspectives. Durmus and Cardie (2018, 2019) show that prior beliefs play a strong role in how persuadable someone is. Cano-Basave and He (2016) study persuasiveness of style in political speeches. In contrast to these studies, our method is designed to work when we have limited or no information about the audience of an argument.

Item Response Theory As described in the previous section, IRT models have primarily been applied in politics to measure the ideology of politicians (Clinton et al., 2004; Poole and Rosenthal, 1985). While most IRT implementations here rely only on the responses as data, more recent work augment the models to take advantage of the text through a simultaneously estimated topic model (Gerrish and Blei, 2012; Vafa et al., 2020; Lauderdale and Clark, 2014).

The efficacy of IRT has been applied on large-scale datasets to verify the validity of standardized tests both in the U.S. and internationally (AERA et al., 2014; Rutkowski et al., 2014). Recent advances have focused on polytomous test questions and creating new questions (the 'cold-start' problem: Settles et al., 2020; McCarthy et al., 2021). In this paper, we focus on the simplest form, but this area of research points to many possible extensions.

Argument Quality Argument mining has been studied in various domains (Palau and Moens, 2009). Most relevant here, several studies have attempted to study argument quality through pairwise ranking as the outcome (Habernal and Gurevych, 2016; Gleize et al., 2019; Toledo et al., 2019).

Framing Theory In the study of framing effects, the expectancy value model (Chong and Druckman, 2007) represents an attitude as $\sum_i v_i \times w_i$, where v_i is the favorability of the object of evaluation (e.g. a candidate), on dimension i (e.g. foreign affairs or personality), and w_i is the salience weight ($\sum_i w_i = 1$). Our parameterization of β_j and ϕ_j can be seen in this paradigm as identifying frames in communication, with each feature of the style and content as a dimension, and learning the framing effect of each.

---

[2] Discrimination is how well the question is able to tell which students perform better, a high value indicates clearly separates high scoring students from low scoring, a negative value would indicate that low performing students are more likely to get the question right than high performing.

[3] Large negative or positive values indicate that a bill is strongly ideological, a value close to zero means the vote isn't strongly driven by ideology.

[4] Large values indicate a bill that is "difficult" to vote for and is less likely regardless of ideology.

4 Datasets

In order to apply the IRT framework, an audience member must respond to multiple arguments (and arguments must be observed by multiple audience members). Too few responses implies that an audience member's latent value will be driven entirely by the one or two arguments. While not many existing argument mining datasets meet this criteria, we are able to study three diverse settings. Additionally, our advocacy task is akin to many real-world settings where users on one-platform are asked to complete an arbitrary task (e.g. a retail mailing list getting users to click on a promotion).

4.1 NYTimes Editorials

The NYTimes Editorial corpus[5] consists of 975 editorials from the New York Times news portal (El Baff et al., 2018). Each publication was reviewed by 3 conservatives and 3 liberals from a pool of 12 conservative and 12 liberal reviewers.

Each reviewer rated the editorials as either 'challenging', 'reinforcing' or 'no effect'. These labels must be approached with care as reinforcing could imply 'reinforced view against the article's stance'. El Baff et al. (2020) study this corpus in a ternary setting by aggregating the liberal and conservative votes and building separate models for each side. For our study, we construct a binary task for predicting 'whether this article had an effect'. While this framing elides whether the speaker succeeded according to her intent, it does relay whether the argument was persuasive.

4.2 Debates (DDO) Corpus

DDO is a corpus of 78k debates scraped from `debate.org`.[6] Each debate has two speakers and an audience votes on a winner.[7] In addition, each audience member can fill out their profile with their political and religious ideology, and stance on various political issues (e.g. Abortion or the Border Wall). Originally, it was used to study how prior beliefs and similarities between the audience and the speaker affected debate outcomes (Durmus and Cardie, 2018, 2019).

To preprocess the data, we removed all debates that have fewer than three rounds, end in a forfeit or a tie, have fewer than 100 words per side, or have fewer than 5 points awarded total. In addition, we excluded debates not on the following issues: Politics, Religion, Society, Philosophy, Education and Economics. Since we are interested in modeling individual audience members, we identify audience members who have responded on at least 10 debates, then remove debates where none of those members responded. The final dataset contains approximately 60k datapoints; 6320 debates and 1131 responders.

Each debate has one side with a pro argument and one side with a con argument, resulting in the wining side being "assigned more points". The prediction task consists of whether a responder gave more points to a given debate side. Since our models only consider one argument at a time, we treat each side of the debate as a separate item, concatenating texts from all rounds from that speaker.[8]

4.3 Advocacy Campaign Corpus

Grassroots advocacy is the process wherein organizations (e.g. companies, non-profits, coalitions) encourage individual citizens to influence their government. In the United States, such lobbying often takes the form of advocacy email campaigns, sent by an organization to specific audiences, asking them to take an action, such as contacting their legislators to vote yes or no on a particular bill.

We construct a dataset containing the text and metadata of these emails, from a popular advocacy software platform, paired with whether recipients took the requested action.[9] Organizations will send different messages to the same audience over time, allowing us to identify which emails (items) elicited a response from specific recipients. Thus, it is possible to distinguish messages that did not generate interest overall (popularity) from messages that did not resonate with specific groups of recipients (polarity).

The dataset contains 63,795 individual recipients of 7,067 email campaigns from 328 different organization, resulting in approximately 2 million individual data points. Each recipient has data for

---

[6] `https://www.cs.cornell.edu/~esindurmus/ddo.html`

[7] While the audience can assign points to various aspects of the debate, this study will only consider the cumulative sum of the points.

[8] We are interested in how a single unit of argument affects the audience, and leave extension of this to account for both simultaneously to future work.

[9] Due to privacy concerns, this dataset will not be released, but platform users agreed to terms of services providing for internal analysis.

15 to 100 emails and had an action rate between of 5% - 95%.[10] Each email included in the dataset had at least 6 responses.

The data is not balanced with respect to organizations; while the largest organizations sent over 200 emails, the median is 6. One possibility of this imbalance is overfitting a feature that is only pertinent to one, particularly prevalent organization. To mitigate such effects, we include an indicator variable to specify the organization.[11]

5 Model Features

Argument analysis is often separated into *style* and *content* features (Cano-Basave and He, 2016; Longpre et al., 2019; El Baff et al., 2020), with additional categories included for argument quality and task specific properties. Since we group the speaker and the argument text together, we combine features representing both as inputs to ϕ and β.

Lexicon Style Features Style features represent higher-level properties of words and rhetorical structures. We chose the following sets of such features from lexicons that were commonly used in previous argumentation literature:

LIWC lexicon of 93 metrics ranging from parts-of-speech to thinking styles to emotions (Pennebaker et al., 2015);[12] Valence, Arousal, Dominance (Warriner et al., 2013); Concreteness (Brysbaert et al., 2014). (These features were shown to be useful for argument quality analysis by Tan et al. (2016).) Argument features developed by Somasundaran et al. (2007), including *necessity, emphasizing, desire, contrasting* and *rhetorical question*; NRC Lexicon: Word-level level associations for emotions like anger, disgust and fear (Mohammad and Turney, 2013); Sentiment and Subjectivity: as implemented in the TextBlob Python Library.[13]

Argument Text We use TF-IDF unigrams to represent the text directly (tuned with respect each task). While we initially explored using deep, contextual text representations, they did not show benefit, and the motivation for this paper is to understand the benefits of the IRT framework, rather than optimize performance based on the argument alone.

Debate-Only Speaker Features In the debate platform, users can optionally specify a stance - for, against, undecided or no stance - on 48 issues such as Abortion, Death Penalty or Gay Marriage. These can be viewed as a proxy for the content as users often present arguments that align with their views.

Advocacy-Only Org Indicator An indicator to account for the large variation in action rate between organizations. Additional indicators are used to represent the industry and organization size.

Advocacy-Only Appeals Using data from Wang et al. (2019), we built a multi-class classifier to recognize ‘emotional’, ‘logical’ and ‘credibility’ appeals. The classifier was applied at a sentence level to the emails, and features were created for the average and the sum of the scores across the sentences.

Advocacy-Only Misc Features : The day of the week and time of day have a strong effect on email click rate.[14] We include indicator features for the day of the week and the hour of day. We include an *urgency* indicator feature, based on a custom list of words indicative of high urgency and timeliness (e.g. “soon”, “now”, “hurry”).

IBM Quality Gretz et al. (2019) released a dataset of 30k sentence-level arguments with 0-1 quality ratings. Unlike our tasks where quality is a latent property, these sentences were assessed for quality directly. We re-implemented the BERT-FT model from this paper, using the MACE-P score. Since these scores were trained on short texts, we apply them to individual sentences in the input text, then use the min, max, average, range, 25th, 50th, and 75th percentiles of these scores. As far as we know, this is the first study to transfer the quality model to longer texts. These features will be grouped with Style for the analysis.

---

[10] Those with a lower or higher action rate are unlikely to be illustrative of persuasion characteristics.

[11] Alternatively, we could construct separate models for each organization, but refrain from doing so for three reason. First, about a quarter of recipients are ‘multi-org’ - they receive emails from multiple sources, thus, we would like to model their behavior across all of them. Second, as many of the organizations are not well represented, they benefit from patterns that appear across different organizations. Finally, maintaining a separate model for every recipient and recipient is not as efficient or scalable.

[12] We purchased a copy of the software from `liwc.wpengine.com` to obtain these labels.

Style	0.741
Text	**0.754**
Style + Text	0.750

Table 1: Results for the Editorials Task (Rasch Model).

6 Models and Results

Since the Editorials corpus is the smallest, we use the simpler Rasch parameterization, while the 2PL model is used for the Debates and Advocacy tasks.[15] Each of the models is trained using a regularized binary cross-entropy loss:

$$L(\hat{y}_i, y_i) = -y_i \log \hat{y}_i - (1 - y_i) \log (1 - \hat{y}_i) \\ + c \cdot \|\alpha, \beta, \phi\|$$

where $\hat{y}_i$ is the output from equation 1 or 3, and y_i is the binary label, representing if the persuasion was successful. The second part of the equation represents a regularization parameter. Details on the experimental parameters can be found in Appendix A. For each task, an audience prior baseline is used. It is generated by calculating the rate at which the audience member was persuaded in the training data (e.g. did the article have an effect, how many recipients took the requested action), then drawing labels on the test data accordingly.

6.1 Editorial Results

The results on the Editorial task are shown in Table 1. The performance for all three feature sets is relatively similar, with all outperforming the audience prior.

The embeddings and weights generated by the model can be analyzed separately for further insights. First, in Figure 1 we compare the distribution of audience embeddings (α) for the liberal and conservative reviewers. According to our theory, these can be interpreted as individuals reticence to being persuaded. While a majority of reviewers are close to 0, we see two liberals with larger negative values (meaning they are particularly open to the messages) and several conservatives on the right (suggesting they are more closed off to these messages). This supports El Baff et al. (2020) observation that conservatives are generally resistant to the *New York Times style*; however, the fact that the majority of reviewers from both sides have similar embeddings, suggests that the pattern is not very strong.

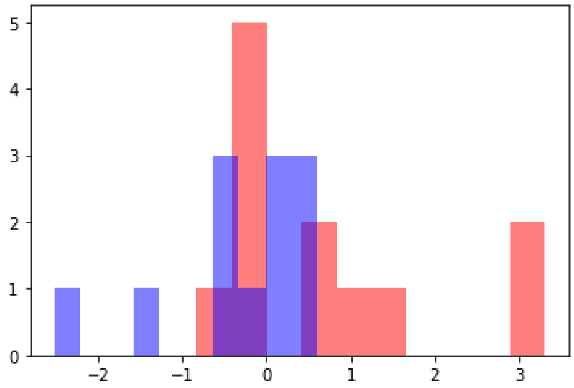

Figure 1: Reviewer Embeddings for the Editorial Rasch Model on the x-axis. Blue represents liberal reviewers, red represents conservative reviewers.

This data also contained information from each reviewers Big 5 Personality test. We measured the Pearson correlation between the reviewers embeddings and found a strong correlation with extroversion (r=-0.568, $p<0.05$) and openness (r=-0.344, $p<0.1$). These findings closely match El Baff et al. (2018)'s analysis between Big 5 Personality Ratings and the affectedness labels. The audience embedding is a latent parameter, thus, it does not explicitly represent personality or political preferences. This analysis has two implications: first, the IRT framework is successful in situations where additional data about the audience is not available; second, analyzing the embeddings lets us learn qualities of the audience post-hoc.

For style, the highly weighted features included negative sentiment markers (*nrc_negative, liwc_negative_emotions*); this aligns with El Baff et al. (2020)'s observation that ineffective editorials tend to have a neutral tone (although their study only focuses on liberal reviewers). The quality features do not show consistent behavior: the *quality_mean* feature has a large negative weight (e.g sign of a bad editorial), but the 75th and 25th percentile features have positive weights; suggesting that the quality measure does not transfer well to editorials.

6.2 Debate Results

The Debates data is approximately 10 times larger than Editorials and contains a more diverse audience. The results are shown in Table 2. Without the

---

[15] In addition, there is natural polarity in the Debate task that lends itself to the 2PL model, as ϕ in equation 2 is designed to model such an effect.

Model	Accuracy
Random	0.500
Style	0.561
Text	0.581
Speaker	0.611
Speaker + Style	0.626
-β (popularity) layer	0.604

Table 2: Results for Debates Task (2PL Model).

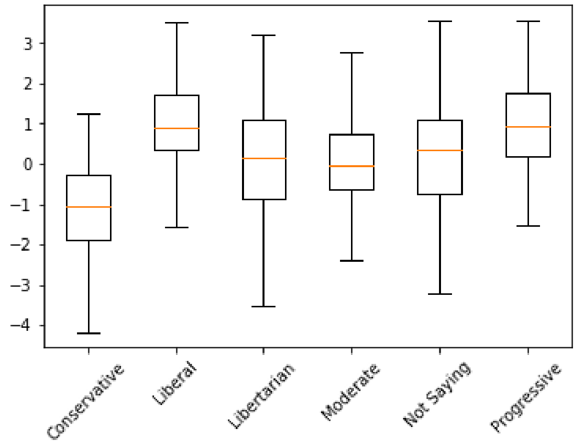

Figure 2: Distribution of one-dimensional audience embeddings on the y-axis.

popularity parameter, β the performance decreases, which confirms the theory that both polarity and popularity are necessary to adequately represent the argument and the speaker. The Speaker stance model outperforms just Text; a probable explanation is that the stances are a proxy for the actual opinions expressed in the text that a simple unigram representation can not capture.

To understand the latent audience embeddings we compare them to the self-reported political affiliations from their profiles. Figure 2 shows a clear separation between liberals and conservatives (the two largest groups). This finding supports the work of Durmus and Cardie (2019) which showed that similarity on 'Big Issue Stance' between the speaker and the audience member is a good indicator for predicting outcome. As with Editorials, the advantage of our approach is that we were able to infer audience member preferences without using their profiles.

To understand what ϕ and β tells us about persuasive theory, we will focus on the Speaker+Style model:

High Polarity: Abortion, Gay Marriage, Progressive Tax;

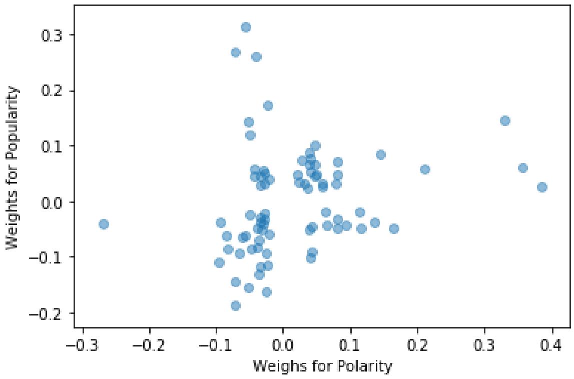

Figure 3: Contrast of weights from popularity vs polarity features.

Low Polarity: Border Fence, Gun Rights, Homeschooling;

High Popularity: quality_max, quality_range, liwc_differ;

Low Popularity: liwc_Exclam, liwc_authentic, liwc_drives

For popularity the significant factors are related to style and quality. The high 'quality_max' feature suggests that the quality model transfers better to this context than Editorials. The low popularity value for 'liwc_authentic' is interesting, as El Baff et al. (2020) also found that authenticity generally led to No Effect editorials.

For polarity, the highest weighted are the stances. 'Polarity High' corresponds to having a Pro stance on those issues, which in this case represent a Liberal view point. This corresponds with the Liberal recipient embeddings in Figure 2 having generally positive embeddings (alignment in weights results in positive final weight). The opposite is true for the Conservative issues and embeddings. This alignment reinforces the finding that prior beliefs play a strong role in outcomes (Durmus and Cardie, 2018).

Figure 3 plots the weights learned for each feature for the polarity and popularity parameters.[16]

Notably, the orthogonal pattern extends beyond the top features, features that strongly predict whether the audience responds to an argument do not usually strongly predict whether the argument is popular overall.

---

[16] This figure excludes features that had very small weights along both dimensions.

	Overall		Audience Average		Org Average	
	Acc.	Macro-F1	Acc.	Macro-F1	Acc.	Macro-F1
Org Prior	0.608	0.514	0.606	0.263	0.630	0.513
Audience Prior	0.710	0.415	0.716	0.318	0.714	0.472

- β (popularity)	0.750	0.653	0.749	0.643	0.756	0.654
Sep Feat V1	0.725	0.619	0.726	0.571	0.700	0.520
Sep Feat V2	0.748	0.678	0.750	0.604	0.698	0.654

Table 3: Results For Advocacy Task (2PL Model).

6.3 Advocacy Results

Table 3 shows the results for the Advocacy task.[17] The overall accuracy and macro-F1 scores represent results across all data, while the Org and Audience average accuracy represent data for individual organizations and respondents. Due to the variation in action rate and sample size, the macro-F1 results are particularly important.

While the Org Only model performs well,[18] the improved performance with the additional of Style suggests that the style of an email still affects the user. The style features may have an advantage for recipients associated with a diverse set of organizations. Without β, the performance is significantly worse, again confirming the need for both parameters.

To better understand the effect of style and org features, two additional models are trained that separate between polarity and popularity. In **Sep Feat V1**, ϕ receives style features, β receives org indicators. In this setting, $(\alpha \cdot \phi)$ represents how individuals are affected by style, while β models the organizations base rate. In **Sep Feat V2** the features are reversed. V1 has the worst performance of all five 2PL models, suggesting that modeling the interaction between the recipient and organization $(\alpha \cdot \phi)$ is important. Org-Only and V2 have mixed performance on accuracy, but V2 performs better on macro-F1, suggesting that style influences the recipients' decisions to act.

Finally, we analyze the features with lowest and highest magnitudes from β in the Org+Style model. The highest weighted features include *concreteness, average-logical-appeal, word count* and *quality 75th percentile*. The lowest weighted features (unlikely to produce action) include *valence, quality mean, arousal* and *liwc-we*. Similar to the Editorials, the quality features are contradictory, suggesting the connection between sentence level and document level quality needs to be investigated further. The logical appeal feature shows they are particularly effective (the corresponding scores for emotional and credibility appeals had smaller, negative weights).

7 Conclusion and Future Work

In this paper, we validate the social psychology frameworks for persuasion using the IRT framework to explicitly model the audience and the speaker. Our approach lets us analyze how different audience members respond to the same argument, and we show that our representation implicitly learns latent audience features modeled explicitly by other models.

We empirically showed several additional insights about persuasion. In the Debates and Advocacy tasks, the Popularity parameter improved performance showing that certain stylistic elements are universally appealing. In the Debates task, the audiences' embeddings aligned with their political affiliation, showing that prior beliefs play a strong role in their argument perception. While the background information about the audiences was available for these tasks, we did not need to model it explicitly; as a result this setup allows us to make predictions for audiences who do not report their affiliation.

A potential negative side of the models is they may learn latent characteristics of the speaker or

---

[17] Due to computational constraints, we omitted the raw text model from this task.

[18] One likely explanation for this performance is that audience is not independent of the speaker - by virtue of receiving emails from this organization, recipients may also have similar preferences.

audience they may not be aware of or consider private. However, all datasets studied in this paper were either public and anonymous or private with audiences who consented to analysis.

This study focused on simple representations to show the viability of our method and provide for explainability. To build on this foundation in future work, we will: expand argument text representations with contextual word embeddings and stance detection models; include higher dimensional embedding for audience and item parameters (the IRT models easily generalize to this set-up). These improvements will allow us to better capture the elements of persuasion, especially in a complex case like Advocacy.

A Model Training Details

The models described in section 6 were trained as follows. In equation (6), c is set to $1e^{-4}$ for all experiments. $L2$ loss is used for the Editorials and Advocacy corpus and text model for Debates, $L1$ is used for the remaining models in the Debates corpus. Editorial models are trained for 200 epochs; Debates for 25; Advocacy for 5. A learning rate of 0.01 is used for Editorials and Debates; 0.005 is used for Advocacy.

All results are reported over 5-fold cross-validation, with the splits performed at an argument level. All models are fit using the AdamW optimizer. The α embedding initializations are drawn from a uniform distribution of -0.5 to 0.5.

Self-Supervised Contrastive Learning with Adversarial Perturbations for Defending Word Substitution-based Attacks

Abstract

In this paper, we present an approach to improve the robustness of BERT language models against word substitution-based adversarial attacks by leveraging adversarial perturbations for self-supervised contrastive learning. We create a word-level adversarial attack generating hard positives *on-the-fly* as adversarial examples during contrastive learning. In contrast to previous works, our method improves model robustness without using any labeled data. Experimental results show that our method improves robustness of BERT against four different word substitution-based adversarial attacks, and combining our method with adversarial training gives higher robustness than adversarial training alone. As our method improves the robustness of BERT purely with unlabeled data, it opens up the possibility of using large text datasets to train robust language models against word substitution-based adversarial attacks.

1 Introduction

Pretrained language models such as BERT (Devlin et al., 2019, inter alia) have had a tremendous impact on many NLP tasks. However, several researchers have demonstrated that these models are vulnerable to adversarial attacks, which fool the model by adding small perturbations to the model input (Jia and Liang, 2017).

A prevailing method to improve model robustness against adversarial attacks is adversarial training (Madry et al., 2018). In NLP, adversarial training in the input space has been challenging, as existing natural language adversarial attacks are too slow to generate adversarial examples *on the fly* during training (Alzantot et al., 2018; Ebrahimi et al., 2018; Ren et al., 2019). While some recent works (Wang et al., 2021c) have started exploring efficient input space adversarial training (e.g., for text classification), scaling adversarial training to pretrained language models like BERT has been challenging.

In this work, we in particular focus on improving the robustness of BERT against word substitution-based adversarial attacks. We propose an approach to adversarially finetune BERT-like models without using any labeled data. In order to achieve this, we rely on self-supervised contrastive learning (Chen et al., 2020). Self-supervised contrastive learning has recently gained attention in the community and contrastive learning has been used to learn better representations for text classification (Giorgi et al., 2021; Kim et al., 2021; Gao et al., 2021). However, how to use these methods to improve model robustness remains an open question.

We combine self-supervised contrastive learning with adversarial perturbations by using adversarial attacks to generate hard positive examples for contrastive learning. To efficiently create adversarial examples, we leverage an adversarial attack, that is capable of generating multiple adversarial examples in parallel. The attack adversarially creates hard positive examples for contrastive learning by iteratively replacing words to follow the direction of the contrastive loss (see fig. 2).

Experiments show that our method can improve the robustness of pretrained language models *without looking at the labels* (in other words, before finetuning). Additionally, by combining our method with adversarial training, we are able to obtain better robustness than conducting adversarial training alone (see section 4.4). Our study of the vector representations of clean examples and their corresponding adversarial examples indeed explains that our method improves model robustness by pulling clean examples and adversarial examples closer.

Our contributions[1] in this paper are two-fold. On the one hand, we improve the robustness of

Findings of the Association for Computational Linguistics: NAACL 2022, pages 87 - 101
July 10-15, 2022 ©2022 Association for Computational Linguistics

the pretrained language model BERT against word substitution-based adversarial attacks by using self-supervised contrastive learning with adversarial perturbations (see section 3.2). On the other hand, to facilitate adversarial self-supervised contrastive learning, we create for BERT a word-level adversarial attack to create hard positive examples. The attack makes contrastive learning and adversarial training with *on-the-fly* generated adversarial examples possible. Additionally, we also show that our method is capable of using out-of-domain data to improve model robustness (see table 2 and section 4.4). This opens an opportunity for using large-scale unlabeled data to train robust language models against word substitution-based adversarial attacks.

2 Related Work

2.1 Adversarial Training for NLP

Adversarial training improves model robustness by augmenting clean examples with adversarial examples during training. Previous works on adversarial training for natural language mainly focus on perturbations in the vector space, while actual adversarial attacks create adversarial examples by changing natural language symbols. For example, Zhu et al. (2020) and Liu et al. (2020) improve model generalization ability by adversarial training on the word embedding space, without mentioning model robustness. However, they either ignore model robustness, or only test model robustness against the adversarial dataset ANLI, without paying attention to actual adversarial attacks. Other works conduct adversarial training in the word space (Alzantot et al., 2018; Ren et al., 2019). Still, they can only do adversarial training on a limited number of pre-generated adversarial examples due to the low efficiency of the attacks. A recent work (Wang et al., 2021c) conducts adversarial training efficiently in the word space, but their method is limited to non-contextualized models.

Apart from adversarial training, other supervised learning methods (Dong et al., 2021; Zhou et al., 2021; Wang et al., 2021a; Li and Qiu, 2020) have also been proposed to improve robustness. However, these methods are supervised and are not comparable to our work.

Our work also differs from previous works in natural language adversarial training. On the one hand, as opposed to previous works, which are supervised, we propose a self-supervised learning scheme to improve the robustness of pretrained language models. On the other hand, while previous works mostly focus on adversarial training in embedding space, we conduct efficient adversarial training with pretrained language models at the word level.

2.2 Contrastive Learning for NLP

Contrastive learning was first proposed in the image domain to improve model performance in a self-supervised fashion (He et al., 2020; Chen et al., 2020). These methods bring representations of similar examples closer and push representations of dissimilar examples further apart. Additionally, researchers also find that by adding adversarial perturbations during contrastive learning, image classification models become more robust against adversarial attacks (Kim et al., 2020).

In NLP, previous works on contrastive learning mainly focus on improving model generalization. Gunel et al. (2021) boost performance of RoBERTa by adding supervised signals during fine-tuning on downstream tasks. Lee et al. (2021) tackle the “exposure bias" problem in text generation by adding adversarial signals during contrastive learning. Other similar works include Pan et al. (2021), Giorgi et al. (2021), and Gao et al. (2021). Although these works have demonstrated the usefulness of contrastive learning in NLP applications, few have addressed the robustness of NLP models, particularly pretrained language models, against word substitution-based natural language adversarial attacks.

Recently, Wang et al. (2021b) claimed that their method improves model robustness against adversarial sets. However, such sets are pre-generated and are less challenging than adversarial examples generated on the fly by actual adversarial attacks (Jin et al., 2020; Ren et al., 2019). In this paper, we focus on improving the robustness of pretrained language models against word substitution-based adversarial attacks. We present the details of our method in section 3.

3 Methodology

In this section, we describe our method for self-supervised contrastive learning with adversarial perturbations. Specifically, section 3.1 gives the background and motivation of our problem, and section 3.2 describes the adversarial contrastive learning framework. Finally, in section 3.3, we

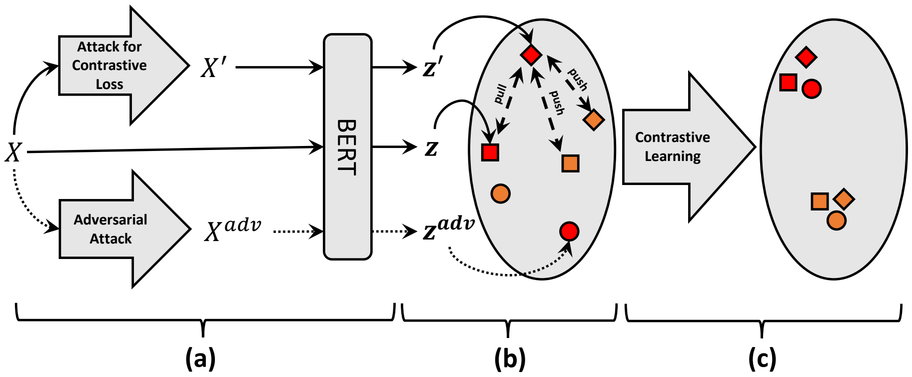

Figure 1: An illustration of our method. **(a)** For the original example X, we obtain the hard positive example X' by Geometry Attack for contrastive loss (see section 3.3). **(b)** Before contrastive learning, in the vector space, the clean example $\boldsymbol{z}$, the hard positive example $\boldsymbol{z}'$, and the adversarial example $\boldsymbol{z}^{adv}$ are far from each other. Contrastive learning pulls the clean example $\boldsymbol{z}$, and the hard positive example $\boldsymbol{z}'$ together. **(c)** After contrastive learning, the clean example $\boldsymbol{z}$, the hard positive example $\boldsymbol{z}'$, and the adversarial example $\boldsymbol{z}^{adv}$ are close. We omit MLP in this figure for simplicity. We use a different color to show another example from the dataset. See section 3 for details. Note that the adversarial example X^{adv} and its corresponding vector $\boldsymbol{z}^{adv}$ are not used in contrastive learning. We nevertheless show X^{adv} and $\boldsymbol{z}^{adv}$ for illustration purposes.

describe the adversarial attack used in contrastive learning.

3.1 Background and Motivation

In this work, we focus on text classification tasks[2]. Let us assume that we have an example text $X_i = \{w_1, w_2, \ldots, w_L\}$ with L words and let y_i be the corresponding class label for X_i. Our text classification model consists of a BERT encoder $f(\cdot)$ and an MLP classification head $c(\cdot)$.

We obtain the vector representation $\boldsymbol{h}_i \in \mathbb{R}^d$ of the example X_i by feeding X_i into the BERT encoder $f(\cdot)$. Then the MLP classification head $c(\cdot)$ takes $\boldsymbol{h}_i$ as input to give us the prediction. Formally, we have:

$$\begin{aligned} \boldsymbol{h}_i &= f(X_i) \\ \hat{y}_i &= c(\boldsymbol{h}_i) \end{aligned}$$

where $\hat{y}_i$ is the predicted label. We have $\hat{y}_i = y_i$ if the model prediction is correct.

A word substitution-based adversarial attack $a(\cdot)$ takes an original example X_i as input and generates an adversarial example X_i^{adv} by substituting the k-th original word w_k in X_i with another word w_k^{adv}. To make the orignal example X_i and the adversarial example X_i^{adv} close in semantics, existing works often use synonyms as substitutions (Ren et al., 2019; Morris et al., 2020).

By conducting the word substitution, the attack $a(\cdot)$ aims to fool the model with X_i^{adv}. Formally, we have:

$$\begin{aligned} X_i^{adv} &= a(X_i) \\ \boldsymbol{h}_i^{adv} &= f(X_i^{adv}) \\ \hat{y}_i^{adv} &= c(\boldsymbol{h}_i^{adv}) \end{aligned}$$

where $X_i^{adv} = \{w_1, w_2, \ldots, w_k^{adv}, \ldots, w_L\}, 1 \leq k \leq L$. Assuming the attack successfully fools the model, we would have $\hat{y}_i \neq \hat{y}_i^{adv}$. The key assumption in our approach is that although X_i and X_i^{adv} are very similar to each other at the word level, it is possible that the encoder f embeds them in such a way that the distance between their representations $\boldsymbol{h}_i$ and $\boldsymbol{h}_i^{adv}$ are large and the classification head $c(\cdot)$ predicts X_i and X_i^{adv} to be of different classes.

Thus, the goal of our method is to obtain a robust model, on which we have $y_i = \hat{y}_i$ and $\hat{y}_i = y_i^{adv}$. In other words, the robust model defends an adversarial example X_i^{adv} of the original example X_i successfully, if the robust model gives the same correct prediction on the original example X_i and the adversarial example X_i^{adv}. We use *attack success rate* as the evaluation metric for model robustness. The attack success rate is defined as the rate of an attack successfully fooling the model on all test examples.

To obtain a robust model, we optimize the encoder such that $\boldsymbol{h}_i$ and $\boldsymbol{h}_i^{adv}$ become similar to each other. We achieve this goal by conducting

---

[2] Although our formulation can also be extended to several other problems.

self-supervised contrastive learning on the encoder with adversarial perturbations, during which we use an attack to create *hard positive examples*, maximizing the contrastive loss. The rest this section gives the details of our method.

3.2 Self-Supervised Contrastive Learning with Adversarial Perturbations

Following previous works on self-supervised contrastive learning (He et al., 2020; Chen et al., 2020), we formulate our learning objectives as follows. Consider we have a batch of n examples and X_i is the i-th input, we first obtain $X_i' = t(X_i)$ as an augmentation of X_i by transformation $t(\cdot)$. We call X_i and X_i' a pair of positive examples. All other examples in the same batch are considered negative examples of X_i and X_i'.

To take advantage from using more negative examples, we use `MoCo` (He et al., 2020) as our framework, in which we employ an encoder f_q for the positive examples, and another momentum encoder f_k for the negative examples. We then have:

$$\boldsymbol{h}_i = f_q(X_i)$$
$$\boldsymbol{h}_i' = f_k(X_i')$$

where $\boldsymbol{h}_i, \boldsymbol{h}_i' \in \mathbb{R}^d$ are representations of X_i and X_i', respectively. During training, f_q and f_k are initialized the same. We update f_k momentarily:

$$\theta_k \leftarrow m \cdot \theta_k + (1-m) \cdot \theta_q$$

where θ_k and θ_q denote the parameters of f_k and f_q, respectively. We then have:

$$\boldsymbol{z}_i = g_q(\boldsymbol{h}_i)$$
$$\boldsymbol{z}_i' = g_q(\boldsymbol{h}_i')$$

where $\boldsymbol{z}_i, \boldsymbol{z}_i' \in \mathbb{R}^c$, $g_q(\cdot)$ and $g_k(\cdot)$ are MLPs with one hidden layer of sigmoid activation, respectively. Following Chen et al. (2020), we conduct contrastive learning on $\boldsymbol{z}$ instead of $\boldsymbol{h}$ to prevent the contrastive learning objective from removing information useful for downstream tasks. After contrastive learning, we use $\boldsymbol{h}$ as the sentence representation for downstream tasks.

Additionally, we also maintain a dynamic first-in-first-out queue for the negative examples. During training, before computing contrastive loss at the end of each batch, all encoded examples of the current batch are enqueued into the queue, and the oldest examples are dequeued simultaneously.

In our experiments, we use the attack described in section 3.3 or back-translation (Zhu et al., 2015) for augmentation $t(\cdot)$. Assume that we have an encoded example $\boldsymbol{z}_i$ and the encoded examples in the queue are $\{\boldsymbol{z}_0, \boldsymbol{z}_1, \cdots, \boldsymbol{z}_{Q-1}\}$, where Q is the size of the queue. Among the encoded examples in the queue, one of them is $\boldsymbol{z}_i'$, which forms a pair of positive examples with $\boldsymbol{z}_i$. We use contrastive loss to maximize the similarity between positive examples, while minimizing the similarity of negative examples. We then have:

$$\ell_i = -\log \frac{\exp(\mathrm{sim}(\boldsymbol{z}_i, \boldsymbol{z}_i')/\tau)}{\sum_{k=0}^{Q} \exp(\mathrm{sim}(\boldsymbol{z}_i, \boldsymbol{z}_k)/\tau)} \tag{1}$$

where τ is the temperature parameter, $\mathrm{sim}(\cdot,\cdot)$ is the similarity function, and Q is the size of the dynamic queue. In this paper, we compute similarity by dot product as in `MoCo`.

By optimizing eq. (1), the goal is to maximize the similarity of representations between similar (positive) pairs of examples while minimizing the similarity of representations between dissimilar (negative) examples. We use the geometry-inspired attack described in section 3.3 as the transformation $t(\cdot)$ to create pairs of examples that are similar on the word level but at the same time are distant from each other in the representation space.

We illustrate our method in fig. 1. In fig. 1 (b) and (c), by conducting contrastive learning and using the Geometry Attack generated adversarial examples as hard positives, the vector representations obtained from the model become *invariant* to the adversarial attacks.

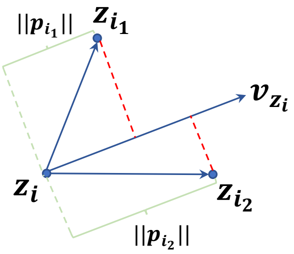

Figure 2: An illustration of one iteration in Geometry Attack for contrastive loss. See section 3.3 for details.

3.3 Creating Hard Positive Examples by Geometry Attack

As mentioned in section 3.2, we use an attack as the transformation $t(\cdot)$ during contrastive learning.

We describe how this attack creates adversarial examples for contrastive loss during self-supervised contrastive learning (see fig. 1 (b)) in this subsection.

Inspired by Meng and Wattenhofer (2020), who leverage geometry of representations to generate natural language adversarial examples for text classification tasks, we also use the geometry of pre-trained representations to create adversarial examples for contrastive loss. The created adversarial examples are used as positive examples of the original examples in our contrastive learning framework, and at the same time are created to maximize the contrastive loss. Hence, we refer to adversarial examples created by the attack as *hard positive examples*.

The intuition of our attack is that we repeatedly replace words in the original texts such that in each iteration, the replaced word increases the contrastive loss as much as possible. To be specific, consider an example X_i, we then have:

1. **Determine Direction for Sentence Vector** Compute the gradients of ℓ_i with respect to $\boldsymbol{z}_i$. In this step, we find the direction we should move from $\boldsymbol{z}_i$ to increase the contrastive loss ℓ_i. We have the gradient vector $\boldsymbol{v}_{z_i} = \nabla_{\boldsymbol{z}_i}\ell_i$.
2. **Choose Original Word to be Replaced** Compute the gradients of ℓ_i with respect to input word embeddings of X_i. For words tokenized into multiple tokens, we take the average of the gradients of the tokens. In this step, we find the word w_t which has the most influence in computing ℓ_i. Specifically, assuming we have L words, then we choose $t = \arg\max_t\{||\boldsymbol{g}_1||, ||\boldsymbol{g}_2||, \ldots, ||\boldsymbol{g}_L||\}$, where $\boldsymbol{g}_k$ is the gradients of l_i with respect to the embeddings of word w_k, $1 \leq k \leq L$.
3. **Generate Candidate Set** Suppose we choose the word w_t in step 2. In this step, we use a pre-trained BERT to choose the most probable candidates w_t to replace it in the original text. We have the candidates set = $\{w_{t_1}, w_{t_2}, \cdots, w_{t_T}\}$. Following Jin et al. (2020), we filter out semantically different words from the candidate set by discarding candidate words of which the cosine similarity of their embeddings between the embeddings of w_t is below a threshold ϵ. We set the threshold $\epsilon = 0.5$ and use counter-fitted word embeddings (Mrkšić et al., 2016) to compute the cosine similarity.
4. **Choose Replacement Word** Replace w_t with words in the candidates set, resulting in text vectors $\{\boldsymbol{z}_{i_1}, \boldsymbol{z}_{i_2}, \cdots, \boldsymbol{z}_{i_T}\}$. We compute delta vector $\boldsymbol{r}_{i_j} \leftarrow \boldsymbol{z}_{i_j} - \boldsymbol{z}_i$. The projection of $\boldsymbol{r}_{i_j}$ onto $\boldsymbol{v}_{z_i}$ is: $\boldsymbol{p}_{i_j} \leftarrow \frac{\boldsymbol{r}_{i_j} \cdot \boldsymbol{v}_{z_i}}{||\boldsymbol{v}_{z_i}||}$. We select word w_{t_m}, where $m \leftarrow \mathrm{argmax}_j\, ||\boldsymbol{p}_{i_j}||$. In other words, w_{t_m} results in the largest projection $\boldsymbol{p}_{i_m}$ onto $\boldsymbol{v}_{z_i}$.
5. **Repetition** Replace w_t with w_{t_m} in X_i, then we have $\boldsymbol{z}_i \leftarrow \boldsymbol{z}_{i_m}$. Repeat step 1-4 for N iterations, where N is a hyperparameter of our method. We expect ℓ_i to increase in each iteration.

Figure 2 illustrates an iteration of our attack, in which we have two options to choose from the candidate set. This attack can be easily implemented in a batched fashion, making it possible for us to generate adversarial examples *on the fly* during training. Furthermore, our efficient implementation makes it possible to conduct contrastive learning with adversarial perturbations as well as adversarial training with adversarial examples generated on the fly. We give a speed comparison of our attack and other attacks in appendix D. We also give pseudocode of the attack in algorithm 1 of appendix A.

4 Experiments

4.1 Datasets and Evaluation Metrics

We test how our method improves model robustness on four text classification datasets: AG's News, Yelp, IMDB, and DBpedia (See appendix B for details).

We report the *attack success rate* and the *replacement rate* of the attacks as the evaluation metrics. Following Alzantot et al. (2018); Ebrahimi et al. (2018), to prevent the model accuracy on clean examples from confounding the results, we define the success rate of an attack on all *correctly classified* examples in the test set. Lower success rates indicate higher robustness. The replacement rate refers to the percent of original words replaced in the clean example. Higher replacement rates indicate that the attack needs to replace more words to fool the model, and thus mean that the model is more robust.

4.2 Attacks for Evaluating Robustness

We use four word substitution-based adversarial attacks to evaluate the model robustness.

Geometry Attack We use the same attack described in section 3.3 to generate adversarial examples for sentence classification tasks by replacing contrastive loss with *cross-entropy classification loss*. We set the maximum number of replaced words to 20.

TextFooler, **PWWS**, and **BAE-R** We use the default implementations from TextAttack (Morris et al., 2020).

All these attacks will give up and terminate once the *maximum number of replaced words* (sometimes also called *perturbation budget*) is reached.

4.3 Experimental Design

We have the following hypotheses for our method:

H1: Self-supervised contrastive learning improves model robustness against adversarial attacks. Moreover, using adversarial perturbations during contrastive learning further improves robustness.

To validate this hypothesis, we set three different pretraining schemes:

`BTCL`: Pretraining with back-translation as the transformation $t(\cdot)$ for self-supervised contrastive learning.

`ADCL`: Pretraining with Geometry Attack for contrastive loss (see section 3.3) as transformation $t(\cdot)$ for self-supervised contrastive learning.

`NP`: Apart from the above two settings, we also add a *No Pretraining* baseline to understand the general effectiveness of contrastive learning.

H2: Combining self-supervised contrastive learning with adversarial training gives higher robustness than conducting adversarial training alone.

We use different finetune strategies to understand how adding adversarial training to our method affects model robustness. We have two settings:

`FTC`: We finetune the pretrained model on the clean examples of the corresponding downstream dataset.

`ADV`: We conduct adversarial training by leveraging supervisedly generated adversarial examples. Note that our adversarial training is different from previous works (Ren et al., 2019; Alzantot et al., 2018), which merely finetune the model on a fixed number of pre-generated adversarial examples. Instead, our adversarial training scheme is similar to Madry et al. (2018), where the model is finetuned on clean examples and adversarial examples generated *on the fly* during each batch of training.

We use Geometry Attack for adversarial training as the remaining three attacks are not efficient enough to generate adversarial examples *on the fly* (see appendix D for details).

H3: Our contrastive learning method is capable of using out-of-domain data to improve the model robustness.

While in H1 and H2, we use the same dataset for pretraining and finetuning, we want to test how our method can leverage out-of-domain data. Hence, we have two additional experimental settings:

`In-Domain`: We use the same dataset during contrastive learning and finetuning.

`Out-of-Domain`: We use different datasets for contrastive learning and finetuning.

H4: By optimizing eq. (1), our method pulls the representations of the clean samples and their corresponding hard positive examples closer in the vector space while pushing other different examples further. In this way, the representations of clean examples and their adversarial examples are also closer in the vector space.

We validate this hypothesis by conducting a vector space study. See section 4.4 for details.

Note that to avoid confusing adversarial examples generated during contrastive learning and adversarial examples generated during finetuning, we refer to the former as *hard positive examples* (see section 3.3).

4.4 Results

Table 1 shows the experimental results for validating H1 and H2. For each dataset, when evaluating the model robustness, we use the same perturbation budget across different settings. Note that although the replacement rates vary across different settings of the same dataset, *the perturbation budget for the same attack is the same* in these settings. By using the same perturbation budget, we ensure that the success rates of the attacks provide us with a fair evaluation of the robustness of the model (Wang et al., 2021c; Ren et al., 2019).

H1: To validate H1, we focus on rows with the `FTC` setting during finetuning. We can observe that models without any contrastive pretraining (`NP`) are the most vulnerable to adversarial attacks. For example, the success rate of the Geometry Attack for AG's News dataset is 86.2% for the `NP` model. In contrast, for `BTCL` and `ADCL`, the success rate of the Geometry Attack is at least 5.6% lower than this setting. This shows that *self-supervised contrastive learning does improve model robustness.*

Additionally, we can also see from table 1 that `ADCL` improves the model robustness more than `BTCL`. For example, in the IMDB dataset, the model pretrained with `ADCL` is 9.1% more robust than the model pretrained with `BTCL` (93.3% → 84.2%), showing that *using adversarial perturbations during contrastive learning further improves model robustness against adversarial at-*

Dataset	Pretrain	Finetune	Acc. (%)	Success Rate (%) ↓				Replaced (%) ↑

Table 1: Experimental results for H1 and H2. In-Domain setting is used. We **bold** the best results, while the second best is in *italic*.

tacks. Hence, we do not combine BTCL with ADV in later experiments for simplicity.

To further understand how contrastive learning improves the model robustness, we study the transferability of the adversarial examples between models without any contrastive pretraining (NP) and the models pretrained with ADCL. To be specific, the models are first pretrained using either NP or ADCL, and then finetuned on clean examples (FTC). Then, we use a NP model to generate adversarial examples on the test set of each dataset, and then test the corresponding model pretrained with ADCL on these adversarial examples. And vice versa.

Table 3 shows the results. We can see that adversarial examples generated by models pretrained with ADCL have much higher success rates on models without any contrastive pretraining (NP). For example, for the AG's News dataset, the success rates increase by 32.1%, 35.3%, 33.8%, and 22.1% for Geometry Attack, TextFooler, BAE-R, and PWWS, respectively. This demonstrates that by self-supervised contrastive learning with adversarial perturbations, the models become more robust against attacks.

H2: To validate H2, we compare two settings of NP + ADV and ADCL + ADV. We note that when compared with conducting adversarial training alone (NP + ADV), *combining our self-supervised contrastive learning method with adversarial training (ADCL + ADV) constantly results in higher robustness*. In other words, the adversarial attacks have lower success rates and higher replacement rate in ADCL + ADV models than in NP + ADV models. For instance, for the IMDB dataset, the ADCL + ADV model is 2.7% more robust than the NP + ADV model, when both models are tested against the Geometry Attack (Success rates of Geometry attack: ADCL + ADV: 48.7%, NP + ADV: 51.4%; Replacement rates: ADCL + ADV: 8.1%, NP + ADV: 7.4%).

Note that when test NP + ADV models and ADCL + ADV models against the other three adversarial attacks, ADCL + ADV models do not show an advantage over NP + ADV models in terms of replacement rates, despite that ADCL + ADV models still constantly make lower success rates against the adversarial attacks. We argue that this is because we use the Geometry Attack for adversarial training during finetuning, and the adversarial examples from the Geometry Attack might not fully match the distribution from the other attacks. Nevertheless, we can still conclude that ADCL + ADV models are more robust than NP + ADV models.

Our experiments also show that during con-

Table 3: Transferability of adversarial examples. The models are pretrained under either `NP` or `ADCL`, and then finetuned on clean examples. `NP` → `ADCL`: Generate adversarial examples with the model pretrained with `NP`, then test the model pretrained with `ADCL` on these adversarial examples. Same applies to `ADCL` → `NP`.

trastive learning, the queue size (see section 3.2) has an impact on the final performance. We give the detailed analysis in appendix C.

H3: For the `Out-of-Domain` setting, we use the DBpedia dataset as the out-of-domain dataset for the AG's News and IMDB datasets, mainly because (1) Computational limits: While using larger datasets such as BookCorpus or Wikipedia might be more useful, conducting self-supervised contrastive learning on these datasets exceeds the limits of our computational infrastructure; (2) The DBpedia dataset is several times larger than AG's News and IMDB. This should give us a glimpse of what it looks like when we scale self-supervised contrastive learning with adversarial perturbations to even larger out-of-domain datasets; (3) The DBpedia dataset (topic classification on Wikipedia) has a different task and domain compared to the AG's News dataset (news classification from a newspaper) and IMDB dataset (sentiment classification on movie reviews). This discrepancy allows us to understand how *out-of-domain* datasets could help.

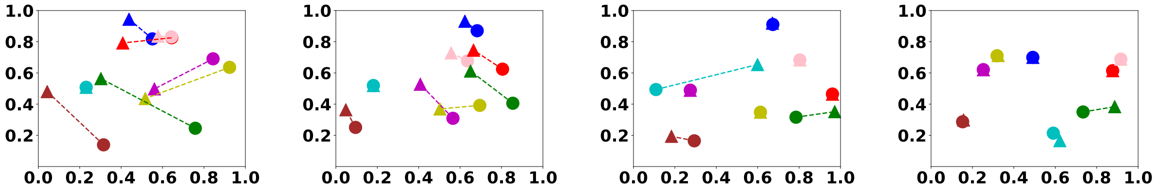
Table 2 shows our results. We can see that models pretrained with `ADCL` under the `Out-of-Domain` setting are more robust than models without any pretraining at all (`NP`). This shows that *our method can improve model robustness using out-of-domain data.* For instance, for the IMDB dataset, the success rate of TextFooler decreases from 98.7% for FT models to 92.3% for `Out-of-Domain` `ADCL` models. This shows that our method can improve the model robustness even if the dataset used for contrastive learning is from a completely different domain. Note that in table 2, after pretraining, we finetune the model on clean examples (`FTC`).

We also notice that models pretrained with `ADCL` under the `Out-of-Domain` setting are not as robust as models pretrained with `ADCL` under the `In-Domain` setting. This indicates we might need to use much larger unlabeled raw datasets to obtain more improvements.

H4: To validate this hypothesis, we study the vector representations of $M = 1000$ clean examples of the AG's News dataset and their corresponding adversarial examples. We obtain the adversarial examples by attacking a `NP` + `FTC` model.

Let $\boldsymbol{v}_1, \boldsymbol{v}_2 ... \boldsymbol{v}_M$ and $\boldsymbol{v}'_1, \boldsymbol{v}'_2 ... \boldsymbol{v}'_M$ be the vector representations of the clean examples and corresponding adversarial samples, respectively. For each setting, we evaluate three metrics:

- Average distance d_{pos} between each of the posi-



(a) `NP + FTC` (b) `ADCL + FTC` (c) `NP + ADV` (d) `ADCL + ADV`

Figure 3: t-SNE plot of the vector representations of clean examples and adversarial examples from the AG's News dataset. Markers of the same color indicate a pair of clean example (○) and adversarial example (△). Check section 4.4 for the evaluation settings. The ranges of x-axis and y-axis are normalized to [0, 1]. We connect each clean example by a dotted line to its corresponding adversarial example.

Dataset	**Distance ($d_{pos}/d_{neg}/\delta$)**			
	`NP + FTC`	`ADCL + FTC`	`NP + ADV`	`ADCL + ADV`
AG	2.4/3.9/1.5	1.8/4.0/2.2	0.7/4.1/3.4	0.7/4.4/3.7
Yelp	3.5/3.7/0.2	2.9/4.0/1.1	0.7/3.2/2.5	0.5/3.4/2.9
IMDB	3.0/3.7/0.7	2.3/3.8/1.5	0.6/3.4/2.8	0.6/3.8/3.2
DBpedia	2.8/4.8/2.0	2.3/5.1/2.8	0.4/4.9/4.5	0.4/5.2/4.8

Table 4: Vector space study. For each setting, we evaluate three metrics: (a) Average distance between positive pairs; (b) Average distance between negative pairs; (c) Difference between (a) and (b).

tive pairs v_i and v_i', where $1 \leq i \leq M$. Then we have:

$$d_{pos} = \frac{1}{M} \sum_{i=1}^{M} d(\boldsymbol{v}_i, \boldsymbol{v}_i')$$

where $d(\cdot, \cdot)$ denotes the distance between two vectors.

- Average distance d_{neg} between negative pairs:

$$d_{neg} = \sum_{i=1}^{M} \sum_{j=1}^{M} \frac{\mathbb{1}_{i \neq j}(d(\boldsymbol{v}_i, \boldsymbol{v}_j) + d(\boldsymbol{v}_i, \boldsymbol{v}_j'))}{2(M-1)}$$

- Difference $\delta = d_{neg} - d_{pos}$ between (a) and (b).

Furthermore, we evaluate the above metrics under the following settings:

- `NP + FTC`: Finetune on clean examples.
- `ADCL + FTC`: First do `ADCL` pretraining, and then finetune on clean examples.
- `NP + ADV`: Finetune with adversarial training.
- `ADCL + ADV`: First do `ADCL` pretraining. Then finetune with adversarial training.

Table 4 shows the results. We can see that our method (1) increases the distance between negative pairs in all settings; (2) decreases the distance between positive pairs in `NP + FTC` and `ADCL + FTC` models, while the distances between positive pairs barely change in `NP + ADV` and `ADCL + ADV` models; (3) increases δ in all settings. The above observations validate H4 in section 4.3, and further explain that our method achieves higher robustness by pushing vector representations of clean examples and adversarial examples closer.

In fig. 3, we further give qualitative analysis on the distances between clean examples and adversarial examples of the AG's News dataset by showing the t-SNE plot. We can see from the plot that the distances between the clean examples and the corresponding adversarial examples are closer when we apply `ADCL` pretraining, and that combining `ADCL` with `ADV` gives the smallest distance between supervised adversarial examples. Additional plots of other datasets are available in appendix H.

5 Conclusion and Future Work

In this paper, we improve the robustness of pre-trained language models against word substitution-based adversarial attacks by using self-supervised contrastive learning with adversarial perturbations. Our method is different from previous works as we can improve model robustness without accessing annotated labels. Furthermore, we also conduct word-level adversarial training on BERT with *on-the-fly* generated adversarial examples. Our adversarial training is different from previous works in that (1) it is on the word level; (2) we generate adversarial examples on the fly, instead of generating a fixed adversarial set beforehand. Experiments show that our method improves model robustness. We find that combining our method with adversarial training results in better robustness than conducting adversarial training alone. In the future, we plan to scale our method to even larger out-of-domain datasets.

Ethical Considerations

To the best of our knowledge, the data used in our work does not contain sensitive information. Although our models are evaluated on academic datasets in this paper, they could also be used in sensitive contexts, e.g. healthcare or legal scenarios. It is essential that necessary anonymization and robustness evaluation is undertaken before using our models in these settings.

A Geometry Attack for Contrastive Loss

Algorithm 1 is the pseudocode of our Geometry Attack for contrastive loss. Refer to Section 3.3 for more details.

B Datasets

Dataset	Labels	Avg Len	Train	Test
AG's News	4	44	120K	7.6K
IMDB	2	292	25K	25K
DBPedia	14	67	560K	70K
Yelp	2	177	560K	38K

Table 5: Statistics of the datasets.

The statistics of each dataset are shown in Table 5. In our work, the maximum sequence length is set to 128 for AG's News and DBpedia, 256 for Yelp, and 512 for IMDB. To save time during evaluating the model robustness against attacks, we randomly select a part of the test examples in each dataset for evaluation. Specifically, we select 1,000 samples from IMDB, 2,000 samples from Yelp, and 5,000 samples from DBpedia. We use all 7,600 samples from the AG's News test set for evaluation.

AG's News[3] Topic classification dataset with four types of news articles: World, Sports, Business and Science/Technology.

IMDB (Maas et al., 2011) Binary sentiment classification dataset on positive and negative movie reviews.

Yelp Yelp review dataset for binary sentiment classification. Following Zhang et al. (2015), reviews with star 1 and 2 are considered negative, and reviews with star 3 and 4 are considered positive.

DBpedia (Zhang et al., 2015) Topic classification dataset with 14 non-overlapping classes. Both content and title fields are used in our work.

C Effect of Queue Size

We conduct additional experiments to study the effect of queue size. We use a queue size of 8192, 16384, 32768, and 65536 under the setting of ADCL+FT for the AG's News dataset. As is shown in Table 6, a larger queue size generally helps improve the model robustness. However, we also notice that when the queue size is too large (65536), the model robustness starts to decrease. We argue that this is because a too large queue size results in less frequent queue updates, which makes the vectors in the queue stale.

Queue Size	Original Acc. (%)	Success (%)	Replaced (%)
Vanilla	94.2	86.2	18.6
8192	94.4	77.8	18.9
16384	94.3	76.9	18.7
32768	94.3	**76.5**	19.1
65536	94.4	76.7	19.3

Table 6: Effect of queue size. We use the Geometry Attack to evaluate the robustness of each model. The FT model is finetuned without contrastive learning.

D Speed of Different Attacks

We show in Table 7 the average number of seconds each attack needs for one example. We obtain the average time by attacking 1000 examples and then taking the average. We can observe that the Geometry attack is at least four times faster than TextFooler, and 4 to 10 times faster than PWWS and BAE-R.

Attack	AG's News	IMDB	DBpedia	Yelp
Geometry	0.44	2.02	0.69	1.16
TextFooler	2.48	8.69	2.89	4.86
PWWS	6.29	21.86	2.52	10.27
BAE-R	5.37	24.10	7.74	16.03

Table 7: Average number of seconds each attack needs for an example.

E Adversarial Training with Pre-generated Examples

We compare two different methods for adversarial training:

- **Pre-generated** We pre-generate for each example in the training set an adversarial example. We then augment the original training set with the adversarial examples. Finally, the model is finetuned on the augmented dataset.
- **On-the-fly** This setting is the same as ADV in Table 1, where we generate adverarial examples on the fly for each mini-batch during training.

Table 8 shows the results on the AG's News dataset. We can see that on all four attacks, adversarial training with on-the-fly generated adversarial

Initialize $\boldsymbol{z}_i \leftarrow g(f(X_i))$
for iter = 1 to $N$ do
    calculate $\ell_i$ using Equation 1
    $\boldsymbol{v}_{z_i} \leftarrow \nabla_{\boldsymbol{z}_i} \ell_i$
    $\boldsymbol{E} \leftarrow \texttt{BertEmbeddings}(X_i') = \{\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots, \boldsymbol{e}_L\}$
    $\boldsymbol{G} \leftarrow \nabla_{\boldsymbol{E}} \ell_i = \{\boldsymbol{g}_1, \boldsymbol{g}_2, \ldots, \boldsymbol{g}_L\}$
    $t \leftarrow \arg\max_t ||\boldsymbol{g}_t||$
    $C \leftarrow \texttt{BertForMaskedLM}(\{w_1, \cdots, w_{t-1}, \texttt{[MASK]}, w_{t+1}, \cdots, w_L\})$
    $C \leftarrow \texttt{Filter}(C)$ // construct candidates set $C = \{w_{t_1}, w_{t_2}, \cdots, w_{t_T}\}$; filter using counter-fitted embeddings
    for each $w_{t_j} \in C, 1 \le j \le T$ do
        $X_{i_j} \leftarrow \{w_1, \cdots, w_{t-1}, w_{t_j}, w_{t+1}, \cdots, w_L\}$
        $\boldsymbol{z}_{i_j} \leftarrow g(f(X_{i_j}))$
        $\boldsymbol{r}_{i_j} \leftarrow \boldsymbol{z}_{i_j} - \boldsymbol{z}_i$
        $\boldsymbol{p}_{i_j} \leftarrow \frac{\boldsymbol{r}_{i_j} \cdot \boldsymbol{v}_{z_i}}{||\boldsymbol{v}_{z_i}||}$
    end for
    $m \leftarrow \arg\max_j ||\boldsymbol{p}_{i_j}||$
    $X_i \leftarrow X_{i_m}$
    $\boldsymbol{z}_i \leftarrow \boldsymbol{z}_{i_m}$
end for
$X_i' \leftarrow X_i$
return $X_i$
```

Dataset	Success Rate / Replaced (%)			
	Geometry	TextFooler	PWWS	BAE-R
Pre-generated	55.3/17.1	59.4/22.6	42.0/17.4	16.5/7.3
On-the-fly	20.7/20.5	25.1/29.3	26.1/22.3	10.7/7.7

Table 8: Comparison between adversarial training with pre-generated adversarial examples and on-the-fly generated adversarial examples.

examples gives higher robustness than adversarial training with pre-generated adversarial examples.

F Implementation Details

In our paper, we use PyTorch Lightning[4] and HuggingFace Transformers[5] in our implementation. We use BERT as the encoder $f(\cdot)$, and the representation of the `[CLS]` symbol in the last layer is used for $\boldsymbol{h}$. $g(\cdot)$ is a two-layer MLP, of which the output size c is 128. $g(\cdot)$ uses `Tanh` as activation function in the output layer. We use FP16 in training step to reduce GPU memory usage, and use FusedAdam from DeepSpeed[6] as the optimizer. We enable DeepSpeed ZeRO Stage 2 to further speed up training. We conduct all our experiments on 8 RTX TITAN GPUs.

Contrastive learning For Geometry Attack for contrastive loss, to reach a balance between attack success rate and efficiency, the maximum number of iterations K is set to 10 for AG's News, DBpedia, and Yelp, and 15 for IMDB dataset. We do not perturb words that were already perturbed in previous iterations. For an example $X_i = \{w_1, w_2, \ldots, w_L\}$, at most $min\{K, 0.2 \cdot L\}$ words can be perturbed. For each word $w_t, 1 \le t \le L$, the upper limit of the candidate set size T is set to 25. Due to the various maximum lengths in downstream datasets and GPU memory limits, we use different batch sizes for different datasets. During contrastive learning, the batch size is set to 1024 for AG's News and DBpedia, 448 for Yelp, and 192 for IMDB.

Fine-tuning During finetuning, we train the model for two epochs for AG's News and DBpedia, 3 for

---

[4] `https://www.pytorchlightning.ai/`

[5] `https://huggingface.co/transformers/`

[6] `https://www.deepspeed.ai/`

Yelp, and 4 for IMDB. The learning rate is set to $2e-5$ and is adjusted using linear scheduling.

Adversarial training For adversarial training, the number of training epochs is set to 3 with an additional first epoch of finetuning on clean examples. The adversarial examples are generated *on the fly* in each batch during training. For the Geometry Attack in adversarial training, at most $\mathtt{min}\{K, 0.4 \cdot \mathtt{len}(X_i)\}$ words can be perturbed in an example. The upper limit of the candidate set size is set to 50.

Back Translation We use pretrained translation models `opus-mt-en-roa` and `opus-mt-roa-en` from Helsinki-NLP to generate one translation for each example.

G Hard Positive Examples from Geometry Attack for Contrastive Loss

In Table 9, we show hard positive examples generated by our Geometry Attack for contrastive loss from the AG's News dataset.

`Original`	Zurich employees plead guilty in probe new york (reuters) - two senior insurance underwriters at zurich american insurance co pleaded guilty on tuesday to misdemeanors related to bid-rigging in the insurance market.
`Adversarial`	Zurich employees plead guilty in probe new york (reuters) - two senior insurance agents at zurich american insurance co testified guilty on tuesday to violations related to bid-rigging in the insurance market.
`Original`	Black watch troops move into position the first units of a black watch battlegroup are due to arrive today in their new positions south of baghdad as tony blair indicated that more british troops may replace them in the american - controlled zone before the end of the year.
`Adversarial`	Black watch troops move into place the first units of a black watch operation are due to arrive today in their new positions south of baghdad as tony blair indicated that more british troops may replace them in the american - controlled zone before the end of the year.

Quiz Design Task:
Helping Teachers Create Quizzes with Automated Question Generation

{plaban, wu.jason, l.murakhovska, wenhao.liu, cxiong}@salesforce.com

Abstract

Question generation (QGen) models are often evaluated with standardized NLG metrics that are based on n-gram overlap. In this paper, we measure whether these metric improvements translate to gains in a practical setting, focusing on the use case of helping teachers automate the generation of reading comprehension quizzes. In our study, teachers building a quiz receive question suggestions, which they can either accept or refuse with a reason. Even though we find that recent progress in QGen leads to a significant increase in question acceptance rates, there is still large room for improvement, with the best model having only 68.4% of its questions accepted by the ten teachers who participated in our study. We then leverage the annotations we collected to analyze standard NLG metrics and find that model performance has reached projected upper-bounds, suggesting new automatic metrics are needed to guide QGen research forward.

1 Introduction

Question generation is a text generation task with practical applications in several settings such as asking clarification questions in dialogue systems (Braslavski et al., 2017), recommending questions during a reading session (Laban et al., 2020), or other educational scenarios such as creating quizzes to emphasize core concepts and engage learners through interaction (Kurdi et al., 2020; Steuer et al., 2021).

The most common automatic evaluation of QGen borrows from other NLG tasks, using metrics such as BLEU (Papineni et al., 2002) to compare system-generated questions with held-out human-written references in terms of n-gram overlap (Amidei et al., 2018). Although they are straightforward to compute, these metrics have been shown to correlate weakly with human opinion in NLG (Gatt and Krahmer, 2018), do not provide a ceiling performance, or insights into the types of errors prevalent in generated questions.

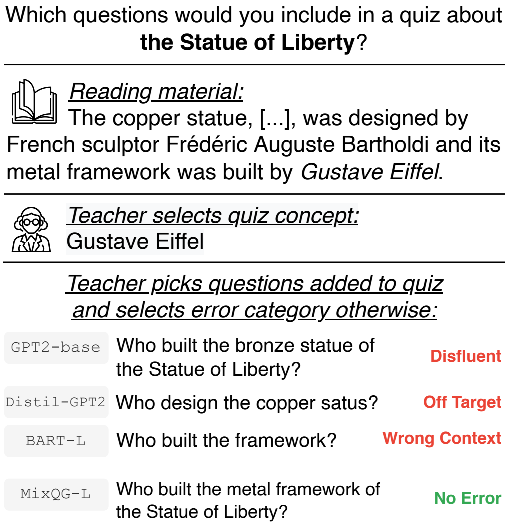

Figure 1: **Illustration of the Quiz Design Task.** For a topic, a teacher selects a quiz concept, picks which candidate questions from various models to include in the quiz, and gives a reason to reject others.

Some prior work has proposed automatic metrics that are specific to QGen, however the metrics are either rule-based (Nema and Khapra, 2018), matching for the presence of certain elements in generated question with limited flexibility, or shown not be beneficial when used to optimize a QGen model through Reinforcement Learning, according to human raters (Hosking and Riedel, 2019).

In this paper, we propose to evaluate QGen with the help of teachers through the **Quiz Design Task**, illustrated in Figure 1. Human teachers are tasked with creating reading comprehension quizzes for hypothetical students, and QGen models interactively suggest quiz questions which can be accepted or rejected by the teachers. Model performance is tied to the acceptance rate of each model, in other words, the best QGen model is the one with the largest proportion of accepted questions.

There are several definitions for QGen, from clarification question generation (Rao and Daumé III,

Findings of the Association for Computational Linguistics: NAACL 2022, pages 102 - 111
July 10-15, 2022 ©2022 Association for Computational Linguistics

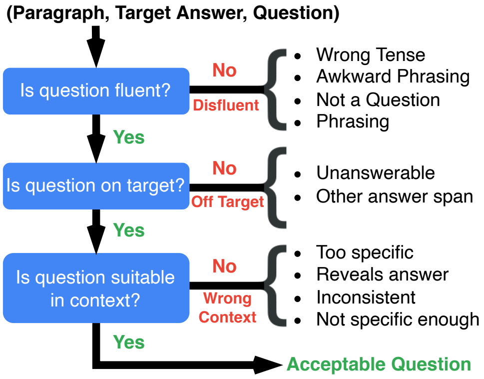

Figure 2: **Hierarchical categorization of errors for question generation.** Three error categories (Disfluent, Off Target, Wrong Context) each with several subtypes.

2018), to knowledge-graph QGen (Indurthi et al., 2017), multiple-choice distractor generation (Araki et al., 2016) and answer-aware QGen (Sun et al., 2018), in which given a context paragraph and a target answer, the model must generate a question answered by the target. We select the answer-aware QGen setting for our evaluation, as it allows for teachers to guide the QGen model by selecting desired concepts to include in the quiz by selecting target answers.

Our contribution is threefold: 1) we propose the Quiz Design Task, a conceptually simple task that allows us to evaluate QGen models in the setting of helping teachers design quizzes. 2) We collect 3,164 human-annotated samples from running the Quiz Design Task with 10 teachers. We find that acceptance rates of generated questions vary widely from as low as 30% for small pre-trained Transformer models, up to 68% for the best performing model we evaluated. 3) We carefully analyze annotator agreement levels and compare between our results and n-gram-based metrics, revealing that there is some correlation between the widely used metrics and model performance in the Quiz Design Task. We also report an estimate of a ceiling for these automatic scores, which are already neared by the state-of-the-art QGen models we evaluate. We release all annotations as well as the interface used during the study publicly.[1]

2 Quiz Design Task

We propose to evaluate QGen models by measuring how helpful they are for quiz creation. Teachers often have experience with carefully crafting quiz questions, and possess knowledge as to what makes a quality question for a quiz (Pearson and Gallagher, 1983; Kendeou et al., 2016). Meanwhile, they are for the most part unfamiliar with recent progress in language modeling, and do not necessarily know of the limitations of deep learning-based text generation. Therefore they can act as impartial judge in this particular setting in verifying whether question generation models have reached a level at which they can be used to facilitate reading comprehension quiz creation.

2.1 Task Definition

Teachers with experience in designing quizzes are invited to use a quiz design interface (Figure A1), and follow the steps illustrated in Figure 1. They begin by selecting a *quiz topic*, such as the history of the Statue of Liberty in Figure 1. The system loads *reading material* relevant to the topic, which can be sourced from a textbook or Wikipedia.

The objective for the teacher is to leverage the reading material and automated QGen models to design an entire quiz composed of 8-12 questions. The teachers proceed by selecting a *quiz concept*, such as an entity, phrase, or keyword they wish to probe students on. Each evaluated QGen model then generates a candidate question given the entire reading material and the selected quiz concept.

After receiving candidate questions from the QGen models, teachers review and pick which to include in the quiz. Importantly, candidate questions are anonymized and presented in a shuffled order. It is possible that several QGen models generate identical candidates, so we deduplicate the candidates before presenting them to annotators.

Existing question answering human evaluation design either automatically select quiz concepts or answers and questions are evaluated by distinct crowd-workers (Du et al., 2017; Trischler et al., 2017). In the case of Quiz Design Task, we believe that it is important to enable teachers to select quiz concepts themselves, as it allows them to have specific learning objectives, permitting them to assess generated questions with this context in mind.

2.2 Question Error Categorization

To understand model performance beyond overall acceptance rates and assess model limitations, annotators were made to select a reason for each rejected question. However, unlike other NLG tasks, QGen does not have an established error categorization. Therefore, we carried out a formative

---

[1] `https://github.com/salesforce/QGen`

study to construct a reusable error categorization for QGen. We collected questions by sampling the QGen models used in the study, and gradually constructed the categorization by labeling and refining the annotations on 976 generated questions. The final categorization is illustrated in Figure 2.

The QGen error categorization we propose is hierarchical, with errors falling in three nested categories. First, similar to the MQM categorization (Lommel et al., 2014) used for translation, the question can be rejected because it is *disfluent* for example with errors in grammar or repetition. Second, if the question is fluent, it can be rejected for being *off target*: the answer to the generated question is not the target answer originally selected. Third, if the question is fluent and on target, it can be rejected for being wrong in context (*wrong context*), for example by being too specific to be natural or not specific enough to be self-contained. Examples of question errors in each category in Table A1.

3 Quiz Setup and Results

3.1 Participant Recruitment

We recruit teachers or ex-teachers from an online group forum. In total, 20 participants filled out an interest form, 14 were selected, and 10 completed the study (with the other 4 either forgetting to complete the task, or completing it partially). The participants had been teachers for at least a year and 3.6 years on average, and had taught diverse subjects such as sciences, history, literature, and IT topics, at various levels from primary school to college-level. The study was meant to last a maximum of two hours, and participants were gifted a $50 gift card upon completion.

The study session began with a tutorial on the interface (see Appendix B) and detailed examples of the error categories. Participants could then clarify any detail before commencing annotation.

3.2 Quiz Topic Selection

Participants were tasked with creating between 5-7 quizzes, each with a minimum of 8 concepts, and could pick from a set list of 7 quiz topics, which we pre-selected from the list of featured Wikipedia articles[2]. We purposefully selected articles within different domains to benchmark the QGen models in diverse topical settings: two in physics (Sustainable Energy, Californium Atom), two in biology (DNA, Enzymes), two in history (Statue of Liberty, Palazzo Pitti), and one in geology (the K-T extinction). Participants were given the first 500 words of the Wikipedia page of each topic as reading material to select Quiz concepts from.

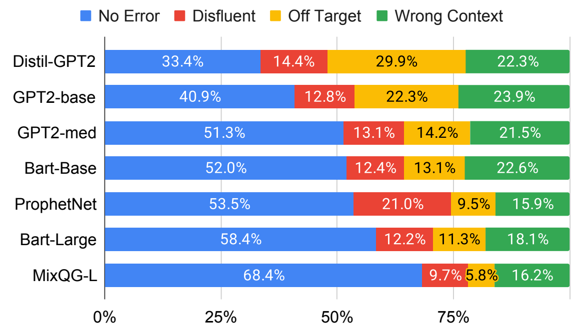

Figure 3: **Error distribution**. Seven QGen models are evaluated by 10 teachers on the Quiz Design Task. The high proportion of disfluency errors of ProphetNet is explained in Section 4.1.

3.3 QGen Models Evaluated

We include seven QGen models of varying size and architecture in our study. First, we finetune three GPT2 baselines (Radford et al., 2019) on the SQuAD dataset (Rajpurkar et al., 2016): `GPT2-distil` (Sanh et al., 2019), `GPT2-base` and `GPT2-medium`. We further add two BART-based (Lewis et al., 2020) models trained on SQuAD as well: `BART-base` and `BART-large`. Finally, we include two recent QGen top-performers, `ProphetNet` (Qi et al., 2020) and `MixQG-L` (Murakhovs'ka et al., 2022). We limit ourselves to seven models, and exclude larger models (such as GPT2-XL and MixQG-3b) to maintain an interface latency of under 200ms and limit burden to users (Miller, 1968). Details on model training and usage in Appendix A.

3.4 Annotated Results

In total, the study participants annotated 3,164 questions, with 52% of them accepted into a quiz. The distribution of errors per model is summarized in Figure 3. As expected, model size has an effect on performance, with the largest model MixQG-L achieving the highest performance with an acceptance rate of 68.4%, which is more than double the 33.4% achieved by Distil-GPT2.

Almost all models have the largest portion of errors coming from the Wrong Context category. In fact, model improvement mostly comes from

---

[2] https://en.wikipedia.org/wiki/Wikipedia:Featured_articles

the other two categories of errors, with a decrease of 40-80% in numbers of errors made in the `Disfluent` and `Off Target` categories. In contrast, the MixQG model still generates a `Wrong Context` question 16.2% of the time, a modest decrease from Distil-GPT2's 22.3%.

As expected, the `Wrong Context` category is the most challenging: models have learned to generate fluent questions that are answered by a desired target concept, and still struggle with phrasing the question in a fashion adequate to the context.

4 Analysis

With the annotations collected, we calculate inter-annotator agreement and use the data to benchmark commonly-used NLG metrics.

4.1 Inter-Annotator Agreement

Even though we allow teachers to select their own quiz concepts, in 95 cases, two or more annotators selected the same concept and annotated an identical set of seven candidate questions. This leads us to have a total of 665 questions on which we can compute inter-annotator agreement. On this subset, we measure a Pearson correlation coefficient (Benesty et al., 2009) of 0.47 which can be interpreted as moderate inter-annotator agreement (Schober et al., 2018).

When breaking down the analysis by model origin, the two lowest-performing models (Distil-GPT2 and GPT2-base) obtain the highest agreement rates (above 0.6), showing a stronger agreement on low-quality questions. Notably, ProphetNet obtained the lowest agreement level (0.26). Further investigation reveals that it is the only model generating questions in lowercase. Because our guidelines did not specify how to deal with improper capitalization, some annotators labeled lower-cased questions as a fluency error. This further explains why ProphetNet generated the largest number of disfluent questions. Future work should carefully indicate how to deal with casing and other normalization (such as punctuation) errors.

4.2 Analysis of Existing Metrics

Because several questions for each given context are annotated, we have a unique opportunity to study the commonly-used NLG metrics, and assess which correlate with our annotators' judgements. We evaluate four of the most commonly used metrics in QGen evaluation: BLEU (Papineni et al., 2002), ROUGE (Lin, 2004) (we include ROUGE-1 and ROUGE-L variants), METEOR (Banerjee and Lavie, 2005), and BERTScore (Zhang et al., 2019). Results are detailed in Table 1.

Model Name	%Acc.	BLEU	R-1	R-L	MET	BERT
Distil-GPT2	33.4	21.2	47.4	45.4	36.8	50.2
GPT2-base	40.9	26.3	53.1	51.1	43.0	56.1
GPT2-med	51.3	31.2	57.6	55.4	46.1	59.5
BART-Base	52.0	31.2	57.2	54.8	46.0	59.9
ProphetNet	53.5	33.3	62.1	59.3	51.7	57.4
Bart-Large	58.4	32.4	59.2	56.9	48.8	61.1
MixQG-L	68.4	33.5	59.6	57.2	50.6	60.0
Upper Bound	100.0	33.9	60.4	58.0	50.2	61.4
Instance Corr.	-	.201	**.233**	.231	.221	**.244**
System Corr.	-	**.724**	.665	.672	.689	.711

Table 1: **NLG evaluation metrics.** For each metric, an upper-bound, and correlations at the instance-level and system-level are computed.

First, we can use accepted questions as references, and compute metric performance by each system on the dataset we've collected. For each metric, we can compute an instance-level correlation (i.e., how well does a metric correlate with annotations for each individual question), as well as system-level correlation (i.e. how similar is the ranking of models according to annotators and according to the metric). As echoed in previous work (Novikova et al., 2017; Chaganty et al., 2018), instance-level correlations are low, but the aggregated metric scores provide high correlation at the system level, with BLEU achieving the highest system-level correlation.

Second, in cases where several questions were marked as acceptable, we can consider each as a valid reference. In such a case, we generate all pairs of references, treating one as a candidate, the other as a reference and computing scores with the standard metrics. The score obtained can be interpreted as an upper-bound for each metric, as they are scores obtained by questions that are judged to all be acceptable.

For all metrics, we find that MixQG has already either surpassed this upper-bound or is within 0.4-1.4 points of doing so. This analysis reveals that even though standard metrics have been useful at measuring progress in NLG, upper-bound performance may be reached soon, and better metrics are needed to guide future progress in QGen and NLG research.

5 Limitations

We now discuss the limitations of the work we've presented.

First, even though we attempted to create a realistic scenario in which to evaluate QGen models, some components of the protocol are simplified for practical purposes. For example, the created quiz were not assigned to students, and we rely solely on the teacher's opinion of the questions as a signal of question quality. Pushing the study further by assigning the quizzes to students and tying question quality to student performance on the quiz would add complexity, but render the protocol more realistic and provide practical learning signals from students.

Second, although we treat teacher annotations as the ground truth, there is some level of disagreement amongst the teachers we recruited, and we measured a moderate level of agreement in Section 4.1. This emphasizes the necessity of thorough and precise guidelines requirements for evaluation protocols, as our lack of rules around the treatment of capitalization of questions led to low agreement on questions generated by an uncased model.

Third, although we gathered a large number of annotations overall, with 3,164 questions annotated in total, this remains small due to the fact that there are many variables on which to break down performance on (e.g., source document, model of origin, annotator). We plan to release the annotation interface as well as the content and models we used to allow future work to expand and reproduce the results.

6 Conclusion

We introduce the Quiz Design task, a human evaluation protocol used to evaluate Question Generation models in an applied scenario. In the QD task, teachers creating a quiz for their students are recommended generated questions, which they can accept in their quiz or reject with a reason from a newly proposed error categorization. We run a QD task with 10 teachers, annotating 3,164 questions originating from seven models, and find that acceptance rates vary widely with the latest QGen models obtaining the highest acceptance rate of 68.4%. Finally, analysis of automatic metrics on our task's data reveals that even though metrics correlate well with system-level ranks, models have reached potential metric upper-bounds, and improved metrics are required to guide NLG forward.

7 Ethical Considerations

Our experiments were all run for the English language, and even though we expect the study design to be adaptable to other languages, we have not verified this assumption experimentally and limit our claims to the English language. Expanding the claims to other languages would require trained question generation models in the studied language.

The teacher annotators that participated in our study were compensated at a rate above minimum wage, and we have insured that no personally identifiable information is available in the annotations we've released.

Appendix

A Training Details

We trained five of the QGen models used in the Quiz Design study. They were all trained for ten epochs on the training portion of the SQuAD dataset (Rajpurkar et al., 2016), using the ADAM optimizer (Kingma and Ba, 2015), with hyper-parameter tuning based on model loss on the validation set. The model checkpoint that achieves the lowest validation loss is selected as the final model. Selected hyper-parameters were:

Distil-GPT2: batch-size 32, learning rate $2 * 10^{-5}$.

GPT2-base: batch-size 32, learning rate $2 * 10^{-5}$.

GPT2-medium: batch-size 16, learning rate $2 * 10^{-5}$.

BART-base: batch-size 32, learning rate $1 * 10^{-4}$.

BART-large: batch-size 32, learning rate $2 * 10^{-5}$.

Finally, the last two QGen we used are publicly available on the HuggingFace model hub (Wolf et al., 2020), and we use them as is:

ProphetNet: `microsoft/prophetnet-large-uncased-squad-qg`

MixQG: `Salesforce/mixqg-large`

With all models, we used beam search to generate candidate questions, using a beam-size of 2, and a sequence length maximum of 30.

B Guidelines to Annotators

We provide the exact guidelines that were given to study participants before they started the annotation procedure:

1. Your objective is to design a quiz about a particular topic for a class of students. The procedure is the following:
2. Select a quiz topic from the list (for example "Sustainable Energy")
3. The system will load a text about the topic.
4. Select a concept that you want to quiz your students on (for example a phrase, a figure, or a keyword) and confirm your selection.
5. **Important:** It is recommended to select **shorter concepts**, and not full sentences to obtain more precise question. Selecting concepts of up to about 8 words is ideal.
6. The system will load a list of questions that attempt to quiz students about the selected concept.
7. Go over each question, and remove ones you would not include in your quiz. We will next go over types of questions that should be removed.
8. **Important:** you can keep one, multiple or none of the questions (if none of the questions are satisfactory). For each question you remove, you have to choose the reason that the question is unsatisfactory (more on this later).
9. Once you've finalized the question for a concept, select another concept and repeat the question selection process. Try to select **8-12** concepts per topic to generate long enough quizzes.
10. Once you've finished a full quiz set, you can move on to another quiz topic. We have found that in one hour, you should be able to complete the quizzes for 5 topics.

Following these guidelines, the annotators were provided definitions for each error category, as well as examples similar to the ones shown in Table A1.

C Error Categorization Question Examples

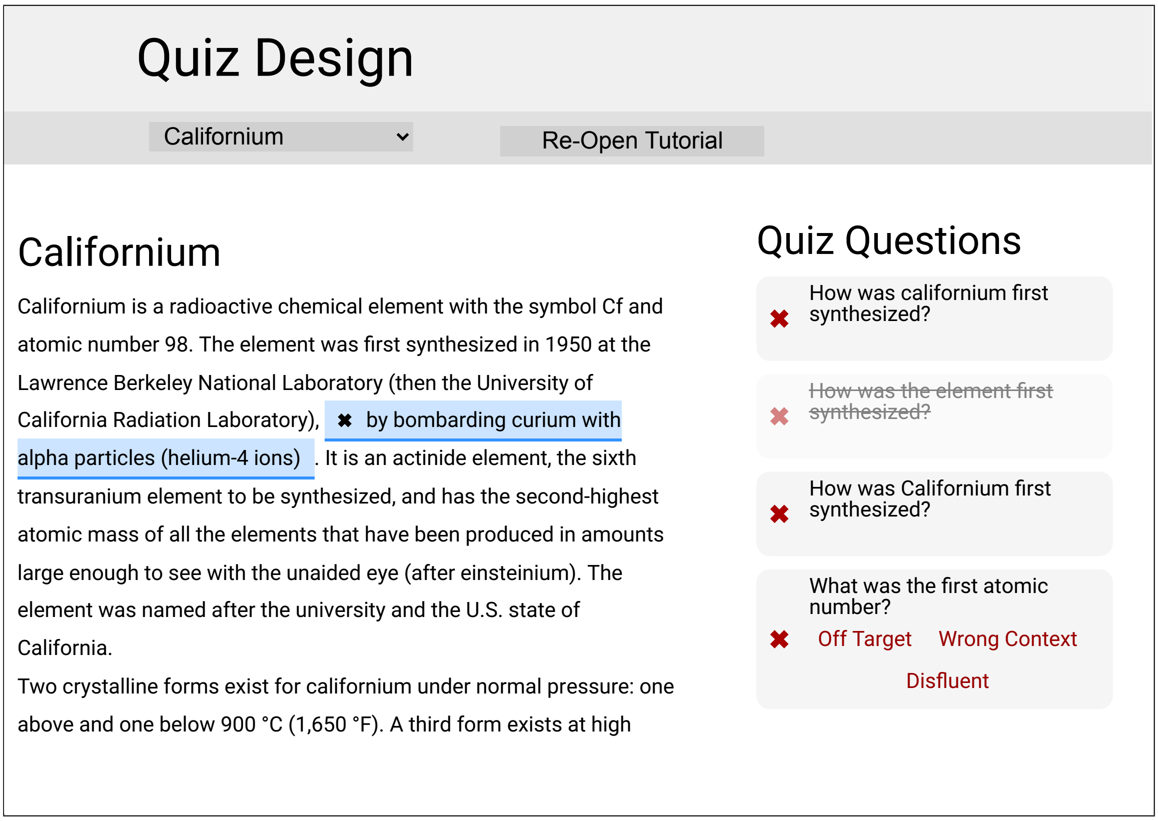
The examples listed in Table A1 were collected during a formative study to establish an error categorization for the task of Question Generation.

D Interface Screenshot

Figure A1 displays a screenshot of the interface used for the Quiz Design Task.

Category	**Finer Category**	**Example Question**	**Rationale**
Disfluent	Wrong Tense	What were historically used to disenfranchise racial minorities?	Should be "What was historically..."
	Awkward Phrasing	When did the woolly mammoth die?	Should be "go instinct" rather than "die"
	Not a Question	In January 2020, scientists reported that climate-modeling of the extinction event favors the asteroid impact and not volcanism?	Sentence in declarative format
	Repetition	Who led the team that led the K-Pg boundary clay?	"led" is repeated twice
Off Target	Unanswerable	Why are DNA studies so important?	Not answered in the DNA Wikipedia page.
	Other Answer Span	Who designed the Statue of Liberty?	True answer is Bartholdi, even though target answer was Eiffel (the metalwork builder)
Wrong Ctxt	Too Specific	Where was the 181 km (114 mi) crater discovered?	Not standard to have unit translations in questions
	Reveals Answer	What was the name of the Federal Reserve System? (leading to the creation of the Federal Reserve System)	Question's target answer is Federal Reserve System
	Inconsistent	What are the only two animals that survived the Cretaceous-Paleogene extinction?	The Wikipedia article mentions species and not animals
	Not Specific Enough	What are some ectothermic species?	Too many ectothermic species are mentioned in the article.

Table A1: **Example generated questions collected during formative study.** These examples form the basis for the error categorization we propose for the QGen task.



Californium

Californium is a radioactive chemical element with the symbol Cf and atomic number 98. The element was first synthesized in 1950 at the Lawrence Berkeley National Laboratory (then the University of California Radiation Laboratory), ✖ by bombarding curium with alpha particles (helium-4 ions) . It is an actinide element, the sixth transuranium element to be synthesized, and has the second-highest atomic mass of all the elements that have been produced in amounts large enough to see with the unaided eye (after einsteinium). The element was named after the university and the U.S. state of California.

Two crystalline forms exist for californium under normal pressure: one above and one below 900 °C (1,650 °F). A third form exists at high

Quiz Questions

✖ How was californium first synthesized?

✖ ~~How was the element first synthesized?~~

✖ How was Californium first synthesized?

What was the first atomic number?

✖ Off Target Wrong Context Disfluent

Figure A1: **Screenshot of annotation interface used for the Quiz Design Task.** The teacher has selected the concept highlighted in blue in the reading material in the left column. In the right column, the system gives proposes candidate questions, which can be added to the quiz, or refused with a reason.

In-BoXBART: Get Instructions into Biomedical Multi-Task Learning

Mihir Parmar[1] **Swaroop Mishra**[1] **Mirali Purohit** **Man Luo**[1]
M. Hassan Murad[2] **Chitta Baral**[1]

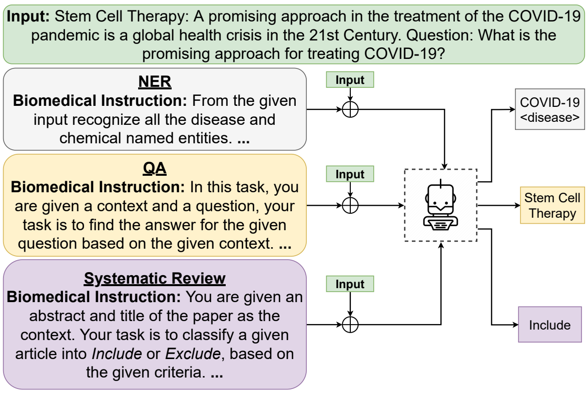
[2]murad.mohammad@mayo.edu

Abstract

Single-task models have proven pivotal in solving specific tasks; however, they have limitations in real-world applications where multi-tasking is necessary and domain shifts are exhibited. Recently, instructional prompts have shown significant improvement towards multi-task generalization; however, the effect of instructional prompts and Multi-Task Learning (MTL) has not been systematically studied in the biomedical domain. Motivated by this, this paper explores the impact of instructional prompts for biomedical MTL. We introduce the BoX, a collection of 32 instruction tasks for **Bio**medical NLP across (**X**) various categories. Using this meta-dataset, we propose a unified model termed as In-BoXBART, that can jointly learn all tasks of the BoX without any task-specific modules. To the best of our knowledge, this is the first attempt to propose a unified model in the biomedical domain and use instructions to achieve generalization across several biomedical tasks. Experimental results indicate that the proposed model: 1) outperforms single-task baseline by ∼3% and multi-task (without instruction) baseline by ∼18% on an average, and 2) shows ∼23% improvement compared to single-task baseline in few-shot learning (i.e., 32 instances per task) on an average. Our analysis indicates that there is significant room for improvement across tasks in the BoX, implying the scope for future research direction.[1]

1 Introduction

For long, task-specific models have played a central role in achieving state-of-the-art performance in both general and biomedical NLP (Wang et al., 2021a; Banerjee et al., 2021). During 2017-2019, pre-train and fine-tune paradigm (Liu et al., 2021) became the prevalent approach in NLP. Due to success of Language Models (LMs) in the biomedical domain such as BioBERT (Lee et al., 2020), ClinicalXLNET (Huang et al., 2020), and others (Alrowili and Shanker, 2021; Kraljevic et al., 2021; Phan et al., 2021), this paradigm is widely used for creating many task-specific models (Wang et al., 2021a; Banerjee et al., 2021). However, task-specific models have limitations to real-world applications because this approach is computationally expensive (i.e., require large computational resources) and time-consuming (Strubell et al., 2019; Schwartz et al., 2020). Hence, there is a need for generalization where a single model can perform various tasks leading to a computationally efficient approach. Past attempts have been made in general-domain NLP to achieve generalization across tasks such as MQAN (McCann et al., 2018), UNICORN (Lourie et al., 2021), and UnifiedQA (Khashabi et al., 2020). However, approaches to achieve generalization across various biomedical NLP tasks have not been systematically studied. Hence, this paper studies the multi-tasking approach that can generalize over different biomedical NLP tasks. Figure 1 shows the overview of our proposed multi-tasking approach for various biomedical NLP tasks.



Input: Stem Cell Therapy: A promising approach in the treatment of the COVID-19 pandemic is a global health crisis in the 21st Century. Question: What is the promising approach for treating COVID-19?

NER
Biomedical Instruction: From the given input recognize all the disease and chemical named entities. ...

QA
Biomedical Instruction: In this task, you are given a context and a question, your task is to find the answer for the given question based on the given context. ...

Systematic Review
Biomedical Instruction: You are given an abstract and title of the paper as the context. Your task is to classify a given article into *Include* or *Exclude*, based on the given criteria. ...

Figure 1: Schematic representation of multi-tasking in biomedical domain using instructional prompts. In this approach, a model is allowed to utilize tasks to get familiar with instructions and use them to map a given input to its corresponding output.

[1] `https://github.com/Mihir3009/In-BoXBART`

Findings of the Association for Computational Linguistics: NAACL 2022, pages 112 - 128
July 10-15, 2022

Recently, prompt-based models have been widely used because of their ability to achieve generalization instead of task-specific models (Liu et al., 2021). Mishra et al. (2021b); Wei et al. (2021) and Sanh et al. (2021) show the effectiveness of instructional prompts in generalizing on seen as well as unseen general-domain NLP tasks. In this paper, we adapt this instructional prompt-based approach for the first time to achieve generalization across various biomedical NLP tasks. To this extent, this paper introduces a collection of 32 instruction tasks for **Bio**medical NLP across (**X**) various categories (BoX) and proposes a unified model that can generalize over 32 different biomedical NLP tasks. The proposed unified model (i.e., In-BoXBART) is trained on the instruction-based meta-dataset (i.e., BoX) and evaluated on each task individually from the BoX.

To evaluate the proposed approach, we compare our model (i.e., In-BoXBART) with two baselines: (1) single-task models (i.e., models trained on one task and evaluated on the same task), and (2) multi-task model (i.e., a single model trained on a combination of all tasks) without instructions. Experimental results show that In-BoXBART outperforms single-task baseline by ∼3%, and multi-task baseline by ∼18%. We also analyze few-shot learning scenario using In-BoXBART since obtaining annotated data in the biomedical domain is costly and time-consuming (Luo et al., 2022b). In the few-shot setting (i.e., 32 instances per task), In-BoXBART outperforms the single-task baseline by 23.33%. This indicates that Multi-Task Learning (MTL) and instruction-tuning have an advantage in the low resources settings. Although the performance of the In-BoxBART is promising, our analysis reveals that there is still room for improvement on some tasks, implying the scope for future research direction. Concisely, our contributions can be summarized in three folds:

1. This paper introduces the first benchmark meta-dataset in biomedical domain, i.e., BoX: a collection of 32 instruction tasks for Biomedical NLP across (X) various categories. Each task is processed in a unified format and equipped with instructions that can be used to train sequence-to-sequence models.
2. Using this meta-dataset, we propose an instruction-tuned Bidirectional and Auto-Regressive Transformer (BART) model, termed as In-BoXBART. The comparison of In-BoxBART and two baselines shows that In-BoXBART outperforms single-task baseline by $\sim 3\%$ and multi-task (without instruction) baseline by $\sim 18\%$.
3. In the few-shot setting, we show that In-BoxBART significantly outperforms the single-task baseline by $\sim 23\%$. This indicates the potential application of instruction-tuning in the biomedical domain where annotated data is difficult to obtain.

2 Related Work

Multi-task Learning Owing to the problems associated with single-task learning in terms of their space and time requirements, several multi-task learning approaches have been proposed over the years. DecaNLP (McCann et al., 2018) built a multi-tasking model by converting format of each tasks to question answering format. Several other works have followed similar approach, for example, by converting tasks to reading comprehension (Mishra et al., 2022) and textual entailment format (Wang et al., 2021b). The multitasking model T5 (Raffel et al., 2020) was built with the help of a unified framework that converts all text-based language problems into a text-to-text format. SCIFIVE (Phan et al., 2021) involved building a text-to-text model for the biomedical literature. Aghajanyan et al. (2021) introduced pre-finetuning, an additional large-scale learning stage between language model pre-training and fine-tuning to improve multitask learning performance. Models empowered by multi-task learning have achieved SOTA in many different tasks, e.g., Question Answering (QA) (Khashabi et al., 2020), commonsense reasoning (Lourie et al., 2021) and structured knowledge grounding tasks (Xie et al., 2022).

Instruction Learning The turking test (Efrat and Levy, 2020) was proposed to measure the efficacy of models to follow instructions. Studies have been made to investigate the effect of natural language instructions on model performance (Hase and Bansal, 2021; Ye and Ren, 2021b; Zhong et al., 2021; Weller et al., 2020). Moreover, Mishra et al. (2021b) proposed Natural Instructions which break down each task to multiple sub-tasks that help models in following instructions and subsequently generalize to unseen tasks (i.e., cross-task generalization). FLAN (Wei et al., 2021) and T0 (Sanh et al., 2021) models were built by leveraging instruction/prompt-tuning on diverse range

of tasks and achieving zero-shot generalization on target unseen tasks. Task reframing (Mishra et al., 2021a) proposed several guidelines to reframe task instructions to improve model response to follow instructions. Analysis introduced to understand in-context learning better on a large set of training tasks (Min et al., 2021, 2022). InstructGPT model (Ouyang et al., 2022) is proposed, which is fine-tuned with human feedback to follow natural instructions. Furthermore, many works focused on investigating whether LMs understands meaning of natural language and prompts (Webson and Pavlick, 2021; Zhao et al., 2021). Weller et al. (2020) and Ye and Ren (2021a) use task descriptions to achieve generalization to new tasks. Puri et al. (2022) introduced instruction augmentation to improve model performance and sample complexity. Wang et al. (2022) has developed instruction-based multi-task framework for few-shot Named Entity Recognition (NER) task. Prasad et al. (2022) introduced Gradient-free Instructional Prompt Search (GrIPS) for improving task instructions for large LMs. Recently, many approaches have been proposed to improve model performance using instructions (Wu et al., 2021, 2022; Lin et al., 2021; Kuznia et al., 2022).

3 BoX

We use 29 existing, widely adopted biomedical NLP datasets collected from various challenges, platforms and organizations to create BoX. We define the BoX as a benchmark dataset for biomedical MTL across 9 different categories. In the BoX, we reframed all the datasets as text generation tasks (see examples in Appendix B) and created 32 instruction tasks. BoX consists of high-quality human-authored Biomedical Instructions (BIs) for all 32 tasks. Figure 2 shows the 9 different categories and corresponding generated tasks. Each category is defined as colored box and each box contains instruction tasks re-purposed from original datasets.

3.1 Tasks

Table 1 shows the number of training samples we have used for each category. Further details of each instruction task statistics is shown in Appendix A. Each category and corresponding tasks from the BoX are defined as below:

Named Entity Recognition (NER) NER has been considered a necessary first step in processing literature for biomedical text mining where the model helps in identifying named entities such as protein, gene, chemical, disease, treatment. We use fifteen publicly available biomedical NER datasets (Crichton et al., 2017) to create instruction tasks.

De-Identification (DI) In this task, the model takes medical discharge records of a patient as input and identify Private Health Information (PHI) such as organizations, persons, locations, dates. We use n2c2 2006 de-identification challenge dataset (Uzuner et al., 2007) to perform this task.

Part-Of-Speech (POS) Tagging The goal of this task is to identify various POS tags from the biomedical text. We use GENIA corpus (Tateisi et al., 2005) built from MEDLINE abstracts for the POS tagging task.

Question-Answering (QA) QA models receive a question and a corresponding context as input and output the relevant answer from the given context. To execute this task, we used the BioASQ-8b dataset (Nentidis et al., 2020) for different question types, i.e., yes/no, factoid, and list type questions. We created three different tasks from this dataset. Also, we use PubMedQA dataset (Jin et al., 2019) for this task.

Relation Extraction (RE) We used two datasets for this task: (1) CHEMPROT corpus from biocreative VI precision medicine track (Islamaj Doğan et al., 2019), and (2) Drug-Drug Interaction (DDI) corpus from SemEval 2013 DDI Extraction challenge (Herrero-Zazo et al., 2013). Here, we only consider binary RE tasks without any label describing the type of the relation.

Systematic Review (SR) We have included data from the following five Systematic Reviews (SRs) that were conducted using the traditional (manual) process and published in relevant venues by Mayo Clinic physicians: (1) Hormone Replacement Therapy (HRT), (2) Cooking, (3) Accelerometer, (4) Acromegaly, and (5) COVID for this task (Parmar, 2021). More details about these datasets creation and statistics are given in Appendix C.

Sentiment Analysis (SA) Analyzing the sentiment of people towards medical drugs is an essential task in the biomedical domain. To that effect, we use medical drug sentiment analysis dataset[2] to identify one of three sentiments: (1) positive, (2) negative, and (3) neutral.

Document Classification (DC) We have used the Hallmarks of Cancer (HoC) dataset (Baker et al., 2016) for this task.

Risk Factor Identification (RFI) The goal of this task is to identify risk factors for Coronary Artery Disease (CAD) in diabetic patients over time. For this, we used n2c2 2014 shared task track 2 dataset (Kumar et al., 2015) with two different purposes: (1) identify if the risk factor is presented in the medical discharge summary and (2) time of risk factor present in the discharge records.

3.2 Biomedical Instructions

Motivated by Mishra et al. (2021b), we have used a similar approach to create Biomedical Instructions (BIs). BI consists of natural language instructions that describe a task and contain instances of that task. Here, we introduce a unified schema to present BI and described how we can construct BI for each task given in the BoX. Figure 3 illustrates the schematic representation of the schema, and Figure 4 shows an example of BI that describes a "Named Entity Recognition (NER)" task accompanied with a few positive examples.

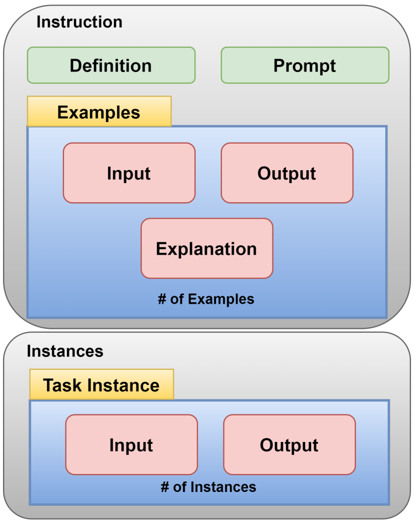

Figure 3: Unified schema used to create a Biomedical Instruction (BI).

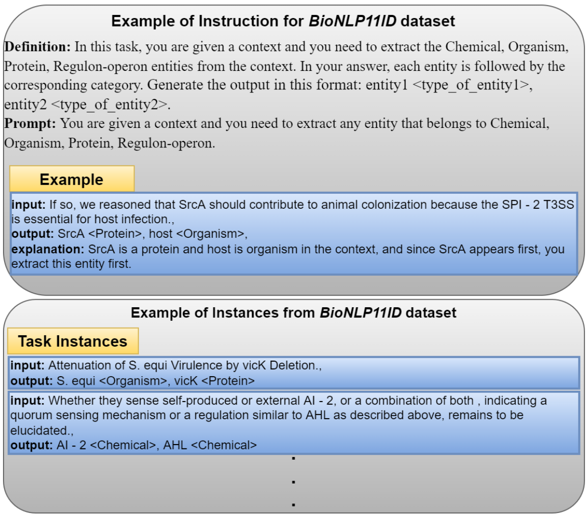

Example of Instruction for *BioNLP11ID* dataset

Definition: In this task, you are given a context and you need to extract the Chemical, Organism, Protein, Regulon-operon entities from the context. In your answer, each entity is followed by the corresponding category. Generate the output in this format: entity1 <type_of_entity1>, entity2 <type_of_entity2>.
Prompt: You are given a context and you need to extract any entity that belongs to Chemical, Organism, Protein, Regulon-operon.

Example

input: If so, we reasoned that SrcA should contribute to animal colonization because the SPI - 2 T3SS is essential for host infection.,
output: SrcA <Protein>, host <Organism>,
explanation: SrcA is a protein and host is organism in the context, and since SrcA appears first, you extract this entity first.

Example of Instances from *BioNLP11ID* dataset

Task Instances

input: Attenuation of S. equi Virulence by vicK Deletion.,
output: S. equi <Organism>, vicK <Protein>

input: Whether they sense self-produced or external AI - 2, or a combination of both , indicating a quorum sensing mechanism or a regulation similar to AHL as described above, remains to be elucidated.,
output: AI - 2 <Chemical>, AHL <Chemical>

.
.
.

Figure 4: Example of Biomedical Instruction (BI) and task instances from ***BioNLP11ID*** (NER) dataset.

3.2.1 Unified Schema

All BIs are mapped to the unified schema. As shown in Figure 3, unified schema consists of a definition, prompt, and positive examples. This schema helps in organizing each BI. Each of the elements of the schema is explained below:

---

[2] `https://www.kaggle.com/arbazkhan971/analyticvidhyadatasetsentiment`

Definition contains the core explanation about the task and detailed instruction to the model that what needs to be done in the given task.

Prompt is the short explanation of the task that needs to be done.

Examples contain the input/output pairs of the task instance along with the explanation of how the output is generated. Generally, we provide 2-3 examples for each task.

Instances contain the input/output pairs of training samples from the task datasets.

3.2.2 Construction of BI

We have created a BI for each dataset given in the BoX. To create BI, we manually fill in the fields of unified instruction schema (Figure 3). For each dataset, the BI is created by one author and were verified by other authors.

Quality of BIs In the instruction verification process, we edit BIs if needed in terms of grammar, typos, ambiguity, etc. to improve the quality. According to (Beltagy et al., 2020), concise instructions are more beneficial compared to repetition, hence, we also redact repetition from BIs. As a result, our BIs consists of high-quality, short, and meaningful task definition, and prompts.

Positive examples and its explanation For each dataset, we have provided 2-3 positive examples and corresponding explanations to give an idea of how to perform the given task. As we know, the selection of examples has an impact on model performance (Lu et al., 2021). To that extent, we have been careful in selecting examples for text generation and classification tasks. For text generation, we have provided 2-3 examples with a detailed explanation about how the output is generated. For text classification tasks, we have included examples corresponding to each class with an explanation of why the particular class is assigned to a given input instance. All positive examples are drawn from training instances and have been removed from training in order to avoid repetition. All the explanations of examples pass through the verification process to maintain high quality.

Collection of input/output instances Since each biomedical NLP dataset included in the BoX has its own annotated input/output instances, we converted them into text-to-text format (Lourie et al., 2021). Example of instances converted for each task is given in Appendix B. After this, we appended all instances tuple (i.e., <input, output>) with instruction schema (as shown in Figure 3).

4 Problem Setup and Models

4.1 Problem setup

Let us assume, we have input/output instances pair (X_t, Y_t) for given task t. Along with that, each task is described in terms of its instruction BI_t.

Single-task models Traditional supervised models learn a mapping function (f_M) between input (x) and output (y), where $(x, y) \in ({X_t}^{\text{train}}, {Y_t}^{\text{train}})$ and are evaluated on the same task $({X_t}^{\text{test}}, {Y_t}^{\text{test}})$. We refer this setup as single-task learning.

Multi-task models In this setup, we combined training data and corresponding biomedical instruction of all tasks together. The goal of multi-task learning models is to learn mapping function (f_M) between input (x), output (y) and biomedical instruction BI_t, i.e., $f_M(BI_t, x) = y$, where $(x, y) \in (X_t, Y_t)$. This model is evaluated on task-specific instances $(x, y) \in ({X_t}^{\text{test}}, {Y_t}^{\text{test}})$ In contrast to single-task models, a single model is used here to solve various tasks, hence, achieving generalization. We refer this setup as MTL.

4.2 Models

We propose an instruction-based model to achieve multi-tasking and compare it with two baselines: (1) single-task models, and (2) multi-task models without instructions. We have fine-tuned the BART (base) model (Lewis et al., 2020) to build baselines as well as the proposed model.

4.2.1 Baselines

Single-Task models As formulated in the single-task problem setup, we have trained the BART model on each task from the BoX and evaluated it on the same task.

Multi-task without instruction To build this baseline, we have combined training data of each task from the BoX together without appending BIs and trained a single model on the combined data. We refer this model as Vanilla-BoXBART. This model is evaluated on each task of the BoX.

4.2.2 Proposed Model

As formulated in the multi-task problem setup, we have combined training data and the corresponding BI of each task. To combine instruction with input instances, we map a BI and an input (x) into the textual format and obtain $enc(BI_t, x)$. After that, BART model is used to predict an output (y) using a mapping function $f_M : enc(BI_t, x) \rightarrow y$. To perform encoding, a standard NLP paradigm of mapping is used, i.e., mapping an input to text. Here, we map each element of BI (i.e., definition and positive examples as shown in the schema) to a textual format and append it before the input instances. After appending BI of each task to instances, we combined all training data of each task. Now, we fine-tuned the BART model with this combined instruction meta-dataset. We refer this instruction-tuned model as In-BoXBART.

5 Experiments and Analysis

5.1 Experimental Setup

We have used BART (base) model to build all baselines and proposed model. All the experiments are performed using *Quadro RTX 8000* GPU. All models are trained for 3 epochs. In particular, we have used *huggingface implementation* (Wolf et al., 2020) of the BART and its pre-defined functions for the training and evaluation with default parameters.

Instance Selection As we know, BART (base) can accept the input of a maximum 1024 token length. Since there are few instances in some datasets that exceed this limit (after including instructions), we have discarded those instances while creating instruction tasks. We have also removed the same instances while training two baselines to do a fair comparison. We have discarded long samples (>1024 token length) from validation and testing data as well.

Example Selection As discussed in Lu et al. (2021), the selection and order of the examples included in instructions matters for mainly classification tasks and affects the performance of the model. We empirically conclude that the proposed model benefits from ignoring examples from biomedical instructions for classification tasks during training and evaluation. Hence, we have discarded all examples from the BIs associated with the classification instruction tasks.

Instance Sampling Some classification datasets used to create the BoX are imbalanced. To balance these datasets, we have applied the sampling techniques (Poolsawad et al., 2014) before using datasets to create BoX. In particular, we have analyzed three sampling techniques: (1) under-sampling, (2) average-sampling, and (3) over-sampling. In under-sampling, we have reduced instances for all the classes to the class with the lowest number of instances. In contrast, we have over-sampled instances via replication of random instances to the class with the highest number of instances to achieve over-sampling. In average sampling, we calculated mean of number of instances across all the classes and over-sampled or under-sampled instances accordingly for each class.

Few-shot setting Similar to the (Schick and Schütze, 2021), we have started with 32 randomly selected instances for each instruction task from the BoX to exhibit few-shot learning. After that, we have increased randomly selected instance instances per task to 100/$1k$/$4k$. If any task have already less number of instances than the threshold (i.e., 100/$1k$/$4k$), we keep all the instances from that task. While selecting the instances, we made sure that we select balanced data for the classification tasks. Moreover, the BoX contains an average $6k$ instances per task.

Evaluation Metric We use Rouge-L (Lin, 2004) as our evaluation metric since we treat all the tasks as text generation problems. We also use F_1-Score for evaluations.

5.2 Results and Findings

Effect of Sampling As mentioned above, we conduct three experiments to analyze the effect of sampling on In-BoXBART. We train our model using training data obtained from (1) under-sampling, (2) average-sampling, and (3) over-sampling. We achieve on an average (across all instruction tasks) 69.62, 70.23 and 73.49 Rouge-L for under-, average- and over-sampling, respectively. Here, we observe from the experimental results that over-sampling gives better performance compared to under- and average-sampling since there is a loss of training data samples for under- and average-sampling. Hence, we report results of over-sampling as the main result in Table 2.

Performance comparison Table 2 presents the results for single-task model, Vanilla-BoXBART and In-BoXBART. We can see from Table 2 that the single-task model, Vanilla-BoXBART, and In-BoXBART achieve on an average (across all tasks) Rouge-L of 70.51, 55.55, and 73.49, respectively. They achieve 70.15%, 55.21%, and 73.01%

Category	Task	Rouge-L			F_1-Score

Table 2: Results comparison between single-task baseline, Vanilla-BoXBART and In-BoXBART in terms of Rouge-L and F_1-Score. All the results for F_1-Score are presented in %. V-BB: Vanilla-BoXBART, I-BB: In-BoXBART, RFHD: Risk Factor for Heart Disease.

F_1-Score, respectively, exhibiting the same performance behaviour as Rouge-L. Hence, we use Rouge-L for further comparisons. From the result, we can observe that Vanilla-BoXBART reduces the complexity compared to the single-task model (i.e., 110 million parameters *vs.* 32x110 million parameters), however, on an average the performance drops by 14.96% in terms of Rouge-L, and compared to single-task models. This indicates that multi-task learning in the biomedical domain is more difficult than general domain NLP since many previous works have shown that the multi-task

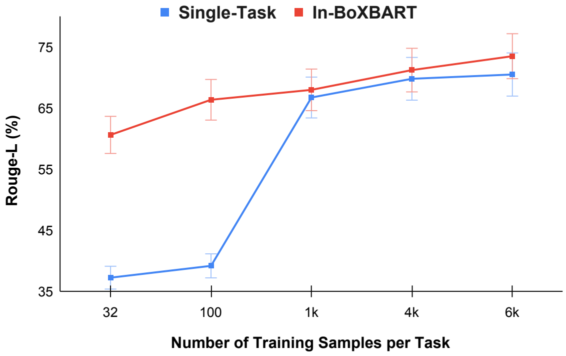

Figure 5: Comparison of on an average Rouge-L across all instruction tasks between single-task and In-BoXBART based on the average number of training instances per task.

model outperforms the single-task model (Lourie et al., 2021; McCann et al., 2018). On the other hand, In-BoXBART, which has the same complexity as Vanilla-BoXBART, significantly outperforms Vanilla-BoXBART by on average 17.94%, and also outperforms the single-task model by a 2.98% margin, precisely. This indicates the benefit of using instructions to achieve the MTL in the biomedical domain.

Effect of instruction in few-shot learning We have compared the average Rouge-L of In-BoXBART with a single-task baseline for few-shot setting. Figure 5 shows the relative performance of In-BoXBART compared to single-task baseline. We have shown results for all few-shot learning experiments in Appendix D. From the results, we see that In-BoXBART achieves on an average 60.64% Rouge-L and the single-task model achieves 37.31% for 32 instances per task. In-BoxBART significantly outperforms the single-task baseline by 23.33%. From Figure 5, we can see that In-BoXBART consistently perform better compared to the baseline. As we know, obtaining a large annotated dataset in the biomedical domain is difficult, time-consuming and costly. From few-shot learning, we can see that instructions are beneficial in achieving high performance compared to task-specific models.

5.3 Analysis

For which tasks, instruction is helpful? From Table 2, we can see that In-BoXBART outperforms baselines for 5 categories, i.e., NER, de-identification, RE, SR and risk factor identification. From this, we can see that instructions are more helpful in these five categories. However, In-BoXBART achieves performance lower or par with the single-task baseline for the tasks from QA, POS tagging, sentiment analysis and document classification which indicates room for improvement in this direction.

Which are harder tasks to solve using instructions? Although instructions help in achieving better performance for some tasks compared to the single-task model, the overall performance is still lower. For example, instruction improves performance for de-identification, but overall performance on this task is only 50.82% which can be improved. A similar pattern we can see for BioNLP12CG and CRAFT from NER; BioASQ-8b (factoid, list) and PubmedQA from QA; and Medical Drug from the sentiment analysis category. In general, we can observe that tasks that include either multi-class scenario or answer generation from the context are most likely to be harder to solve using instructions. For example, CRAFT and BioNLP13CG have 6 entity types which are higher than any other tasks from NER, and we can see that the performance for these two tasks is lower compared to other tasks of NER.

For which tasks, instruction is the most beneficial in few shot setting? From the results shown in Appendix D, tasks from the NER, de-identification, QA, sentiment analysis and risk factor identification shows on average larger improvement compared to baselines for the few-shot settings (i.e., 32 and 100 instances per task). This indicates that instructions are beneficial for the tasks from the above categories.

6 Discussion

Can we design better instructions? Since instruction teach the model how to solve a given task, domain specific information rich instructions can improve model performance. One potential way is to use the knowledge of domain experts. However, designing a good biomedical instruction can be one research direction.

How to handle long-context input? Training instances of many biomedical datasets consist Electronic Health Records (EHRs) or discharge summaries of patients. Because of this, these instances are long and exceed the maximum input length of LMs such as BERT, BART. In this scenario, encoding extra information in terms of prompts or instructions becomes difficult. One potential solution is to use Longformer (Beltagy et al., 2020), and another solution is to use T5 kind of models which use relative position embeddings so that the inference length can be longer (Luo et al., 2022a).

How to handle multi-class classification tasks? Multiple classes cause an issue while creating biomedical instructions because we can not present one example per class. If we do that, the encoding of BI and input will exceed the maximum length of LMs. A naive solution is to select examples of a few labels or remove the examples. However, this will cause a label bias issue or performance degradation. Potential future research direction can be designing a methodology to handle multi-class classification tasks.

How far we are from the SOTA? We have presented preliminary comparison of our results w.r.t. state-of-the-art (SOTA) single-task systems for 21 instruction tasks from the BoX as shown in Appendix E. Form the results, we can see that the performance of the proposed model remains far from the SOTA for some tasks, indicating significant room for further research in this domain.

7 Summary and Conclusions

This research shows the impact of instructions in MTL for the first time in the biomedical domain. To this extent, we introduced the BoX, a first benchmark dataset consisting of 32 instruction tasks across various biomedical NLP domains. Using this meta-dataset, we proposed a unified model, i.e., In-BoXBART which outperforms single-task baseline and Vanilla-BoxBART by $\sim 3\%$ and $\sim 18\%$, respectively. Our proposed approach also shows an effective performance for a few-shot setting which is more beneficial in the biomedical domain where obtaining large annotated datasets is difficult. We hope that the BoX benchmark, In-BoXBART, and experimental results encourage future research into more unified models for biomedical NLP.

A Statistics of Instruction Tasks

This section provides all the statistics of training, validation and inference data used for experiments in Table 3. All the number of instances provided in Table 3 are calculated after discarding the instances with more than 1024 token length as described in the section 5.1. We have divided the dataset into standard 70/10/20 splits for train/validation/test if there is no separate validation and testing set provided in the dataset.

B Instruction Tasks and Examples

To build all the models (baselines, proposed model and few-shot learning), we adapt the unified format for all the tasks of BoX. We converted all the tasks into the text-to-text format, including the classification tasks. Table 4 shows an example of input and output from each category. Moreover, we have also re-purposed some biomedical datasets to create more than one task as described in the section 3.1.

C Systematic Review Datasets

This section describes the brief data creation process for Systematic Reviews (SRs) that are used in this study. The relentless growth in clinical research and published articles have created a need for automation to expedite the process of SRs and to enable Living Systematic Reviews (LSRs). A crucial step in both SRs and LSRs is the title and abstract-based screening of the articles. A new dataset was developed from six SRs in the clinical domain by Mayo clinic physicians. In this study, we used data from the following five SRs that were conducted using the traditional (manual) process and published in relevant venues: (1) Hormone Replacement Therapy (HRT), (2) Cooking, (3) Accelerometer, (4) Acromegaly, and (5) COVID. The initial bibliographic search was designed and conducted by an experienced librarian with guidance from the principal investigators for the respective studies. The search was conducted in different bibliographic databases like PubMed, PubMed Central (PMC), Embase, EBM Reviews, and Ovid MEDLINE(R). Each article in the bibliographic search results was categorized by two physicians with domain expertise as “Include” or “Exclude”, by reading the title and abstract of the article. When there was a disagreement between two annotators, a positive class (i.e., “Include”) was preferred.

D Few-Shot Learning results

This section presents the results of few-shot learning for all instruction tasks in Table 5.

E State-of-the-art results

In Table 6, we present State-Of-The-Art (SOTA) results for 21 tasks. To compare the SOTA results with the proposed model, we calculate the corresponding metric used in particular research from our model predictions. For each task, we gather the best performance, and specifically, they are BioASQ-8b (Nentidis et al., 2020), Chemprot (Peng et al., 2019), DDI (Peng et al., 2019). In Chemprot and DDI, we compare results with the base LMs instead of large for a fair comparison. SOTA results for all 15 NER datasets are obtained from (Banerjee et al., 2021). Best performance for the HoC dataset is obtained from (Peng et al., 2019). Here, we have considered the result of the best system submitted to (Stubbs et al., 2015) as SOTA result.

How to Translate Your Samples and Choose Your Shots? Analyzing Translate-train & Few-shot Cross-lingual Transfer

Iman Jundi and **Gabriella Lapesa**
Institute for Natural Language Processing
University of Stuttgart
`first.last@ims.uni-stuttgart.de`

Abstract

Translate-train or few-shot cross-lingual transfer can be used to improve the zero-shot performance of multilingual pretrained language models. Few-shot utilizes high-quality low-quantity samples (often manually translated from the English corpus). Translate-train employs a machine translation of the English corpus, resulting in samples with lower quality that could be scaled to high quantity. Given the lower cost and higher availability of machine translation compared to manual professional translation, it is important to systematically compare few-shot and translate-train, understand when each has an advantage, and investigate how to choose the shots to translate in order to increase the few-shot gain. This work aims to fill this gap: we compare and quantify the performance gain of few-shot vs. translate-train using three different base models and a varying number of samples for three tasks/datasets (XNLI, PAWS-X, XQuAD) spanning 17 languages. We show that scaling up the training data using machine translation gives a larger gain compared to using the small-scale (higher-quality) few-shot data. When few-shot is beneficial, we show that there are random sets of samples that perform better across languages and that the performance on English and on the machine-translation of the samples can both be used to choose the shots to manually translate for an increased few-shot gain.[1]

1 Introduction

With the emergence of large-scale multilingual Pretrained Language Models like mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020), a significant amount of research went into exploring the cross-lingual transfer capabilities of these models, allowing for an easier adaptation to a task in many various languages. This is achieved through a number of approaches.

Zero-shot cross-lingual transfer has become a research focus, e.g. XTREME / XTREME-R benchmark (Hu et al., 2020; Ruder et al., 2021). In this approach, transfer to new languages is done by fine-tuning a multilingual PLM on the task at issue, using only an English corpus (source language) and reporting the performance on multiple target languages.

Few-shot cross-lingual transfer was recently shown to give an advantage over zero-shot cross-lingual transfer (Lauscher et al., 2020). In this approach, it is shown that fine-tuning the model using a small amount of target-language task data (few-shot) improves the performance, especially for low-resource languages.

Translate-train is another common approach to improve the performance. Here the full training dataset is machine translated to the target language and used for fine-tuning. There exists relatively good Machine Translation (MT) systems for the languages that are usually studied in the few-shot approach[2] that could be used in translate-train.

In the following, we use few-shot to refer to fine-tuning using fewer samples of high-quality professional manual translation. Translate-train is used to refer to fine-tuning using lower-quality machine translation that has the potential to be scaled to a larger number of samples. Although some research has dealt with few-shot cross-lingual transfer and analyzing it (Lauscher et al., 2020; Zhao et al., 2021), no systematic study was done to compare it to translate-train. Given that both zero-shot and few-shot cross-lingual transfer assume the availability of a large-scale English corpus of the task for source training, we hypothesize that the *translate-train approach might have an advantage over few-shot given the scale of data that would be available even if not at the best quality.*

https://cloud.google.com/translate/docs/languages

Findings of the Association for Computational Linguistics: NAACL 2022, pages 129 - 150
July 10-15, 2022

On the other hand, when there is a need for few-shot cross-lingual transfer for some task and therefore a need for professional translation of some training samples, this entails significantly more effort and cost compared to MT. It is then important to *find out which samples to manually translate given the high variance in performance depending on the choice of samples as shown in* (Zhao et al., 2021).

We investigate both those research directions using 3 base models (mBERT$_{base}$, XLM-R$_{base}$, XLM-R$_{large}$) on 3 high-level semantic tasks and datasets: XNLI (Natural Language Inference), X-PAWS (Paraphrase Detection) and XQUAD (Question Answering), spanning 17 diverse languages. We investigate the following research questions:

Q1. How does the performance of few-shot cross-lingual transfer compare to that of translate-train?
We show that there is a performance advantage for few-shot transfer over translate-train given the same number of samples, but that with the increase of samples used for translate-train, this gap shrinks, and using the full large-scale corpus in translate-train results in a clear advantage over few-shot. We show that at a scale of 10x-100x of machine-translation to manual-translation, quantity trumps quality and it is recommended in this case to use translate-train if MT is available for the language. Few-shot transfer still has an advantage when less source data is available and it is therefore not possible to benefit from the scale gain of using MT.

Q2. Are there sets of samples that have better few-shot performance if translated and how can those sets be identified?
We show that when few-shot transfer is beneficial for the task, there are random sets of samples that perform better across most target languages and across different model initializations. We investigate using the performance on the English version of the samples and the machine-translated version to choose the best candidates to manually translate and use for few-shot transfer. We show that there is a correlation between the performance of the same set of shots across languages and that the few-shot samples that perform better on the source language, English, perform also better across languages. A similar observation is made also using MT of the samples. We further show empirically that choosing the sets of samples for few-shot transfer using those heuristics or a model, using such features of the samples, results in more bang for your shots.

2 Related Work

Cross-lingual transfer: The cross-lingual transfer capabilities of multilingual pretrained language models have led to major recent advances and a growing number of such models have been introduced, e.g., mBERT (Devlin et al., 2019), XLM-R (Conneau et al., 2020), mT5 (Xue et al., 2021) etc. The cross-lingual transfer is usually exploited in a zero-shot setup, and benchmarks are built based on this assumption e.g. XTREME/XTREME-R (Hu et al., 2020; Ruder et al., 2021).

Few-shot: There has been recently some focus on few-shot cross-lingual transfer and its analysis. Lauscher et al. (2020) shows the effectiveness of few-shot compared to zero-shot cross-lingual transfer especially in lower-resource and distant languages, where zero-shot is least effective and few-shot gives a large gain. Zhao et al. (2021) analyzes few-shot cross-lingual transfer emphasizing that the choice of shots has a significant effect on the performance. The experiments are conducted at a small scale of around 10 samples. Compared to this, we conduct larger-scale few-shot experiments with a size up to hundreds of samples and focus on choosing the best-performing samples.

Translate-train: is commonly used to boost the performance for a target language using a machine translation of the source corpus (Conneau et al., 2018; Lample and Conneau, 2019; Conneau et al., 2020; Hu et al., 2020). Xue et al. (2021) shows that, similar to zero-shot, translate-train performance increases with the scale of the model. No systematic study tested the effect of the scale of the translated data in comparison with few-shot to understand the interplay of data quality vs. quantity in this context.

Choosing samples: Two related areas are sample selection (Rousseeuw, 1984) which is used for robust training on noisy data (Song et al., 2019) and active learning (Cohn et al., 1994; Krogh and Vedelsby, 1994) used to choose the best potential samples to annotate (Siddhant and Lipton, 2018). Both assume access to the actual sample input (with or without label). On the other hand, this work investigates choosing samples while only having access to the source-language sample input/output.

3 Datasets

We focus on high-level tasks and conduct our experiments on 2 classification tasks and a question answering task (Table 1) from the XTREME benchmark. The details and properties of the languages

Dataset	|Train|	|mDev|	|mTest|	|Langs|	metric
XNLI	392,702	2,490	5,010	15	Acc
PAWS-X	49,401	2,000	2,000	7	Acc
XQuAD	87,599	261	1,190-261= 930	11	F1

Table 1: Datasets statistics. Train is the English training dataset. |mDev| and |mTest| are used to indicate the size of the multilingual split of the dataset.

can be found in Appendix Table 6. When attempting to choose the shots, we rely on measuring the performance of the same set of samples across different languages, so we are limited to datasets with parallel corpus, i.e. the target language corpus is created by translating the English corpus as opposed to collecting and annotating the target language corpus from scratch: **XNLI** (Conneau et al., 2018) is a professional translation of the dev and test set of the MultiNLI dataset (Williams et al., 2018) into 14 languages. The dataset consists of pairs of sentences, a premise and a hypothesis, where the task is to predict whether the premise entails, contradicts, or is neutral to the hypothesis. **PAWS-X** (Yang et al., 2019) dataset is a professional translation of the dev and test set of the PAWS dataset (Zhang et al., 2019) into 6 languages. The dataset consists of pairs of sentences and the task is to predict whether those two sentences are paraphrases of each other. **XQuAD** (Artetxe et al., 2020b) is a professional translation of the dev set from SQuAD v1.1 (Rajpurkar et al., 2016) into 10 other languages. The dataset consists of a paragraph and a set of questions. The task is to select the span of the paragraph that answers the question. 10 paragraphs from the multilingual split are reserved, similar to Lauscher et al. (2020), as dev (total of 261 question/answer samples) and the rest as test set.

4 Experiments

Three main models are used: mBERT (base), XLM-R$_B$ (base) and XLM-R$_L$ (large). We report results on XLM-R$_B$ if not specified otherwise, because it strikes a balance between good performance and efficient training. For each task, we fine-tune the model on the source language (English) corpus for 5 epochs with early stopping using the loss on the English dev set. We then continue fine-tuning the model on the target language either in a few-shot or translate-train setup as explained in the following sections. Training details are in Appendix A.

4.1 Few-shot experiments

We use samples from the multilingual dev set as training samples. Few-shot fine-tuning is done as follows: for each language, we separately continue fine-tuning the source model for one epoch on $n \in \{10, 50, 100, 500, 1k\}$ samples from the target language corpus for the two classification tasks and for $n \in \{10, 50, 100, 250\}$ for the Question Answering task, given the smaller amount of data available for training in this case. We report the results on the test set for each target language. For each n number of samples, the performance is averaged across 5 different sets of random samples using 5 different fine-tuned models with different random initializations, 25 runs in total. This is to ensure more robust results when measuring the gain over zero-shot given the high variance across different sets of samples (Zhao et al., 2021) as well as the variance in zero-shot performance across all random initializations (Keung et al., 2020). For comparing the performance across shots, we make sure to use the same set of parallel samples across languages, using the sample ids, to compare how a set of samples performs when translated to different languages. This is possible due to our selection of tasks and datasets that have a parallel corpus for the various target languages.

4.2 Translate-train experiments

We train using MT of the source train set to each target language[3] and adapt a similar setup as few-shot: for each language, continue fine-tuning separately on $n \in \{10, 50, 100, 500, 1k, 10k, |dataset|\}$ samples from the machine-translated train set and report the results on the test set of the target language.

5 Results

5.1 How to translate your samples? Few-shot vs. translate-train

To demonstrate the full potential for each approach, Table 2 shows a **performance summary** for zero-shot, few-shot and translate-train when the maximum possible number of samples is used. The gap to English performance is the average of the gap between the target language performance and the performance on the English test set. Both few-shot and translate-train help bridge the gap, but using translate-train on a large scale has an advantage

Table 2: **Performance summary**. The average performance on all languages along with the gap to the English performance and the gain over zero-shot performance. Using translate-train on a large scale has a clear advantage.

in further narrowing the gap as compared to the small scale of few-shot transfer. This results in translate-train having the best performance for all models across all datasets. The highest *gain* is seen for the model with the highest *en gap* (mBERT) for both few-shot and translate-train. For XLM-R on XQuAD, the gain is low and negligible. Given that there is a significant gain for mBERT and the same experimental setup is used for all models, the lack of gain is probably not dataset-specific and possible happens with some models.

To see the effect of the available dataset size in each scenario, Figure 1 shows the average performance across languages for **few-shot vs. translate-train** across varying number of samples. We can see an advantage of having manual over machine translation resulting in a clear performance gap between both on XNLI for the same number of samples. This gap increases with the increase of the number of samples as seen at 1k. The availability of manual translation for few-shot is limited though and starting from 10k-100k, the scale of translate-train has an advantage for all tasks (similar results for the other models are in Appendix Figure 7, 8). The performance on PAWS-X and XQuAD does not improve much with few-shot as shown in Figure 1b and 1c, and the clear boost comes from using the large scale machine-translated dataset. We discuss the observed large variance on XQuAD across languages near the end of the following section.

Detailed results & language analysis: Figure 2 shows the translate-train performance gain (over zero-shot) across a varying sample size for each **language family** (More details about the languages

Figure 2: **Translate-train gain on language families.** European languages especially Germanic have the least gain, whereas various other families like Koreanic and Niger-Kongo have the most gain (detailed results in Appendix C)

in Appendix Table 6). We can see, across all tasks and models, that European languages have a small gain compared to non-European languages which show the largest gain e.g. Swahili (Niger-kongo) in XNLI, Korean and Japanese in PAWS-X, and Turkish and Chinese for XQuAD. Those languages also tend to have a larger zero-shot performance gap to English and are more distant to it (the source language). Those results are comparable to the few-shot results of Lauscher et al. (2020). We can see that the languages with the most gain differ between mBERT and XLM-R mainly because XLM-R extends the pre-training corpus using Common-Crawl to have more data that less-spoken languages benefit especially from e.g. Turkish zero-shot performance on XQuAD is low with mBERT as compared to XLM-R models which result in more gain for Turkish with mBERT on XQuAD (detailed results on XQuAD in Appendix Figure 15, 14, 16).

Appendix C contains the **detailed performance gains** for few-shot and translate-train over zero-shot for each language across varying sizes of sam-

Figure 3: **Detailed Results on XNLI** using **XLM-R**$_B$. Gains in performance over zero-shot for few-shot and translate-train. Low-resource languages like Swahili have the most gains in both cases

ples. Figure 3 shows the detailed results for XNLI as an example, where we see that once the full machine-translated training set is used, a clear advantage for translate-train is seen across almost all languages and in all tasks. We can see that the gain for Urdu (ur) is the highest on XNLI up until 100k when it starts decreasing. We think this might be due to a lower-quality MT. The same effect is seen for Thai (th) on XQuAD with a significant performance degrade when the full training dataset is used (details in the Appendix in Figure 15). This is also the reason for the **degrade and high variance in performance** seen at this point in Figure 19b.

We investigate whether **longer training** would have changed the results and would have been beneficial, especially for few-shot where longer training on the high-quality manual translation might be beneficial. We split the available set of samples into train/dev and train for 10 epochs with early stopping on dev. Although some languages benefit from this setup, it still yields comparable results and translate-train still has a clear advantage. (results in Appendix Figure 17 and 18).

5.2 How to choose your shots? Which samples to translate for few-shot?

Few-shot can still have an advantage over translate-train when the English dataset is not large enough to benefit from the scale effect of translate-train. It can also be necessary when adapting to a target language that does not have an existing machine translation system or does not have a good one. Creating few-shot samples, in this case, can be done by collecting and labeling new samples or by translating samples from the available English dataset. The latter is a common method and 4 out of the 7 non-retrieval datasets in XTREME use manual professional translation to create samples in the target languages (all of which high-level semantic tasks). It is beneficial then to support in selecting the samples with higher performance-potential to translate and do few-shot training on.

To emphasize the significance of choosing the samples, we plot in Figure 4 the XNLI **performance variance on different shots** (using the same model initialization) across 20 sets of random few-shot samples varying in size from 10 to 1k samples. The performance varies, sometimes significantly, depending on the set of samples used. Zhao et al. (2021) shows similar variance obser-

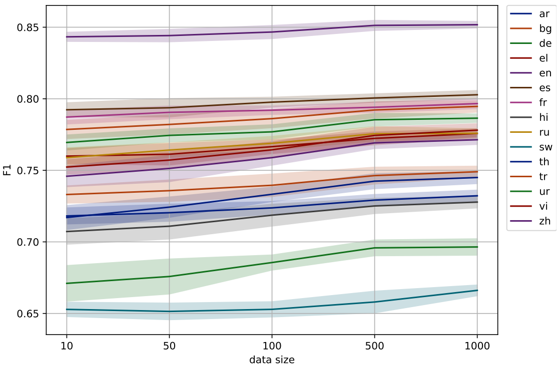

Figure 4: **XNLI accuracy variance on different shots**. High variance decreases with an increased data size

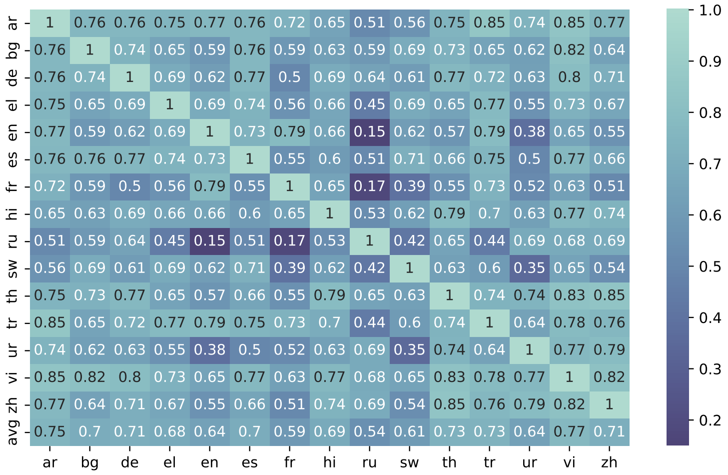

Figure 5: **XNLI Pearson correlation** between the performance on **English** and the performance on other languages.

Table 3: **XNLI Pearson correlation** between the performance of **machine translation** and manual translation

vations on a smaller number of samples (around 10). We consider a larger size range that is more representative of the data size if a manual translation is conducted. The performance variance across shots decreases with the increased number of shots. This means that choosing the shots to translate is more important when a smaller size of samples is used. (similar results on PAWS-X and XQuAD are in Appendix Figure 19 although for XQuAD the variance increases with the size). In the following, we focus mainly on XNLI as the task that had the most few-shot gain. We investigate whether there are sets of samples that have a potential for better performance across languages and what could be an indication of that. For a set of shots, we consider two indicators: the performance of this set in another language, and the performance on the MT of the samples in the set.

5.2.1 Correlation between performance across languages

If the performance of a set of samples for one language can be an indication of its performance on another language, a high correlation between the performance for both languages is expected. To estimate this, we calculate the performance using the manual translations across languages of the same set of training samples. We then calculate the Pearson correlation of the performance across 5 random sets of samples (with varying sample-set sizes) using 5 models with different random initialization. As seen in Figure 5, there is a **high positive correlation** between the performance on XNLI for the various languages (using XLM-R$_B$). This is also the case, but to a lesser degree for PAWS-X as seen in the Appendix Table 8. XQuAD, on the other hand, has low and sometimes even negative correlation (Appendix Table 11), which might be due to the QA task being harder and requiring more data and the fact that we have less data in this case for both training and test. It is also worth noting that the correlation is lower for both tasks, PAWS-X and XQuAD, which had low few-shot gain.

A breakdown of the English correlation based on data size is show in the Appendix Table 7 and 9. As an example of this, Figure 6 shows **XNLI few-shot gain** over zero-shot performance for 5 random sets of samples $\{A, B, C, D, E\}$ each containing 10 samples. The performance is shown for 3 different XLM-R$_B$ initializations. The sets $\{A, C, E\}$ perform better than $\{B, D\}$ across target languages and on average as well as across different initializations. The performance on English can be used as an indicator of the best shots to choose as seen when comparing the English performance (top) to

Figure 6: **XNLI few-shot gain** over zero-shot across 5 sets of samples (size=10) for 3 different model initializations. Sets C, A, and E yield better performance for the 3 different initializations. The English performance can be used as an indicator when choosing samples to translate

the average (bottom, excluding the English performance). This is here the case even when further fine-tuning a model on English samples results in a decreased English performance as seen for the 2nd model initialization. The least negative sets of samples still correspond to the best performing shots. The results generalize for varying sizes of few-shot sets e.g. 1000 samples in Appendix Figure 20.

5.2.2 Correlation between manual and machine translation performance

Another possible indicator of the best performing set of samples could be the performance of the samples in the set when they are machine translated to the target language. Artetxe et al. (2020a) has shown that subtle patterns in the (machine or manual) translated samples can have a notable impact on the model performance, so it is important to empirically study the relation between both. Similar to the above, we calculate the correlation between the performance for both manual and machine translation of the same set of samples for each target language. As seen for XNLI in Table 3, there is an even higher correlation than with the English performance. A somewhat lower correlation is seen for PAWS-X in Appendix Table 10. Lower correlation might be a result of lower-quality MT or a result of the different patterns introduced by MT as mentioned before.

5.2.3 Gain from choosing shots

We show in Table 4 the **few-shot performance gain** resulting from choosing the shots with the highest English performance and the highest MT performance. Random samples are used for few-shot cross-lingual transfer in related work, so we compare to the average few-shot gain across the different shots in *no choosing (avg)*, and also to the minimum in *no choosing (min)*, because an important aspect of choosing shots is avoiding the worst-performing ones (Comparing to the average hides the fact that we might accidentally use a very bad set of shots). We can see a clear gain in most cases across all models when using *en performance* or *mt performance*. When there is no gain compared to *no choosing (avg)*, the performance is still comparable and the benefit of not choosing the worst performing shots is still there as compared to *no choosing (min)*. The few-shot gain with chosen-shots is most significant at smaller number of samples where the gain is almost double that from *no choosing (avg)*.

Combining both En and MT performance when choosing the shots is expected to result in more gain, so we investigate feeding the performance values as features to a **linear model** that takes as input the performance of a set of samples and predicts the performance gain when this set is manually translated and used for few-shot. Predicting the performance gain is also helpful to avoid translating any set of samples if all are expected to result in a negative or low gain. We use the performance metrics as a dataset: collecting the performance of En/MT of random sets of samples along with the performance of the actual manual translation. This is done using 5 different random sets of samples for 5 different XLM-R$_B$ initialization with varying

Table 4: **Chosen-shots performance gain**. Gain over zero-shot performance when choosing the best set of shots using a heuristic (en or mt performance) or a linear model that predicts the performance.

sample sizes across all languages (excluding English) resulting in 1750, 750, 1100 data points for XNLI, PAWS-X and XQuAD. For each language, we train the model using the data from all other languages and evaluate on the selected language. Cross-validation is done on the data after excluding the selected language to choose the best hyperparameters. The following **features** are considered as input: En and/or MT performance gain for the set of samples corresponding to each data point. In all cases, we consider: the zero-shot performance (since the gain is usually larger when the zero-shot performance is lower), and the number of samples used for that data point. We also investigate whether adding **language features**[4] can improve the prediction in a way similar to the analysis by Lauscher et al. (2020). lang2vec [5] from Littell et al. (2017) is used to obtain the feature vectors for each language. The cosine similarity between the English vectors and the vectors for each language are added as 5 new scalar features (values are in Appendix Table 6). Those features can help the model better use the English performance depending on the similarity between the language and English. The prediction error of the linear models is reported in Appendix Table 13. We can see in Table 4 that using the models improves the chosen-shots performance gain for XNLI with the best result, as before, using a combination of all features. This is not the case for PAWS-X and could be partially due to having a smaller performance data and fewer languages to train on (7 as compared to 15 for XNLI).

The **detailed results** for the different languages are in the Appendix Figure 21. Choosing the shots improves the few-shot performance on XNLI for all languages across almost all sample sizes. For PAWS-X, there is mixed gain/loss but the improvement when using English performance at maximum size is concentrated in the European languages.

6 Conclusion and Future Work

This work conducted a systematic comparison between translate-train and few-shot cross-lingual transfer. It quantified the performance gain for each and showed that starting from 1k samples, MT data could be used to improve over zero-shot performance, and that at 10k-100k, there is an advantage for translate-train over few-shot.

For the tasks that benefit from few-shot, we show that there are random sets of samples that perform better across languages and that the English performance of the samples in those sets can help us identify them. The performance of the MT of the samples can also be used as another indicator. When not incurring gain, both help at least avoid the worst performing samples.

Further analysis in the future could help identify why some datasets do not benefit from few-shot transfer with certain models, and analysing the samples might lead to uncovering interesting properties in the best/worst performing sets of samples.

In *Proceedings of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (Volume 1: Long Papers)*, pages 5751–5767, Online. Association for Computational Linguistics.

A Training Details

Software: We use the Huggingface Transformers [6] for fine-tuning the pretrained language models. We use scikit-learn [7] to train the performance prediction models. Our code is made publicly available [8].
Hardware: NVIDIA GeForce GTX 1080 Ti with 11G memory is used for most experiments. The linear model is trained locally on a CPU.
Model: mBERT (base, cased) has 12-layer, 768-hidden, 12-heads, 110M parameters. Trained on cased text in the top 104 languages with the largest Wikipedias. XLM-R_B (base) has ∼270M parameters with 12-layers, 768-hidden-state, 3072 feed-forward hidden-state, 8-heads, and trained on on 2.5 TB of newly created clean CommonCrawl data in 100 languages. XLM-R_L (large) ∼355M parameters with 24-layers, 1027-hidden-state, 4096 feed-forward hidden-state, 16-heads,[9].
Hyperparameters: For the two classification tasks, we use a maximum sequence length of 128. We limit hyperparmeter tuning to a search for the learning rate in $\{7e-6, 1e-5, 3e-5\}$ and use a batch size of 32. For Question Answering, we use a maximum sequence length of 384 with a paragraph slide of 128. We train using a learning rate of $3e-5$ and a batch size of 12 for 2 epochs. The used learning rate for XLM-R_B along with the dev performance for a model with seed=42 is reported in Table 5. We use four other models fine-tuned on the English train split with $seed \in \{2, 4, 8, 16\}$

XNLI	PAWS-X	XQuAD
1e-5	7e-6	3e-5
84.82	92.45	89.10
Accuracy	Accuracy	F1

Table 5: learning rate and English dev performance

Training & Evaluation Runs: Starting from each of the 5 source fine-tuned models, we fine-tune on the target language for 5 different sets of samples. This is repeated for each size resulting in 25 runs per size. The runtime for the target language fine-tuning varies based on the number of samples used and the number of languages in each dataset. For smaller sample sizes, most runtime is spent for the evaluation on the large test set.

Figure 14: **Detailed Results on XQuAD** using **mBERT**. Gains in performance over zero-shot for few-shot and translate-train. Non-European languages show the most gain especially Chinese. Thai shows a significant degrade when using the full machine-translated dataset. This might be due to lower-quality machine translation for Thai.

Figure 17: Detailed Results on **XNLI using a part of the available data as dev**. The few-shot performance only changes slightly with minor increases and decreases for across the languages. The highest increase on average is at 10 samples with an increase of 0.05%. Translate-train performance decreases for almost all languages and on average.

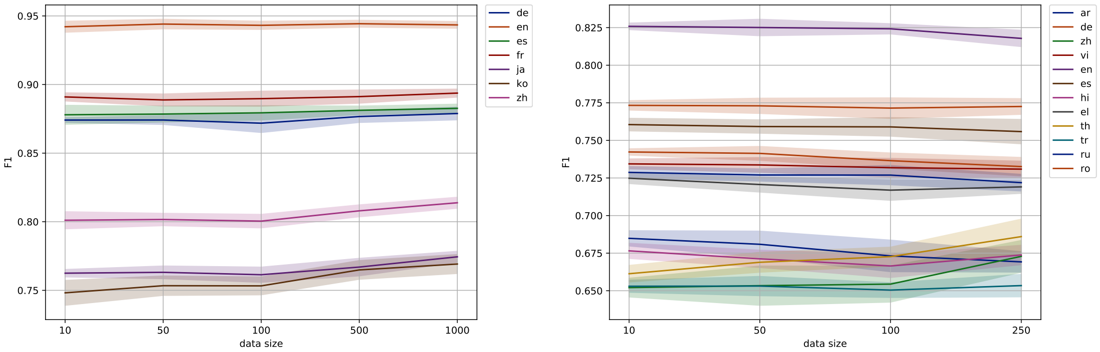
Figure 18: Detailed Results on **PAWS-X using a part of the available data as dev**. The few-shot performance shows mixed gains decreasing by ∼0.60% for 10 samples, increasing by ∼0.40% at 100 then decreasing againg by ∼0.10%. Translate-train performance decreases util the full dataset is used where it increases by ∼1%.



(a) **PAWS-X Performance variance on different shots**. Variance decreases with an increased data size

(b) **XQuAD Performance variance on different shots**. Variance increases with an increased data size

Table 12: **XQuAD Pearson correlation** between the performance on **English** and the performance on other languages using the same set of samples.

	XNLI		PAWS-X	
	MSE	RMSE	MSE	RMSE
avg (baseline)	1.05±0.56	0.99±0.26	1.26±0.76	1.08±0.34
model using features:				
en performance	0.68±0.41	0.80±0.23	1.08±0.92	0.97±0.42
mt performance	0.34±0.28	0.56±0.20	0.92±0.56	0.93±0.28
en + mt performance	0.33±0.26	0.55±0.18	0.91±0.56	0.92±0.28
+ lang features	**0.32±0.25**	**0.54±0.18**	**0.58±0.27**	**0.75±0.17**
only lang features	0.93±0.47	0.93±0.24	1.01±0.45	0.98±0.25

Table 13: **Performance prediction error**. Predicting the few-shot performance gain using models with the English and MT performance as features. For each language, the average performance gain for all other languages is used as a baseline. *+lang features* further adds features from lang2vec. Having a combination of English and MT performance with language features achieves the best results.

(h) PAWS-X chosen-shots gain
using (en + mt + lang features) model

Figure 21: **Chosen-shots gain in performance**. The gain of choosing shots over the average of no-choosing (average over 5 random sets). The actual few-shot gain (compared to zero-shot) is shown in parenthesis as follows: *chosen-shots-gain (few-shot-gain)*. When *chosen-shots-gain* is positive (green), choosing the shots results in more gain. When negative (red), it hurts and results in less gain.

Abstract

Open-domain question answering systems need to answer question of our interests with structured and unstructured information. However, existing approaches only select one source to generate answer or only conduct reasoning on structured information. In this paper, we propose a Document-Entity Heterogeneous Graph Network, referred to as DEHG, to effectively integrate different sources of information, and conduct reasoning on heterogeneous information. DEHG employs a graph constructor to integrate structured and unstructured information, a context encoder to represent nodes and question, a heterogeneous information reasoning layer to conduct multi-hop reasoning on both information sources, and an answer decoder to generate answers for the question. Experimental results on HybirdQA dataset show that DEHG outperforms the state-of-the-art methods.

1 Introduction

Open-domain question answering (ODQA) is a task to answer any form of question in general domains with provided evidence (Chen and Yih, 2020; Sun et al., 2019, 2018b). The evidence that is used can be categorized into unstructured text like Wikipedia passages (Yang et al., 2018; Min et al., 2020; Izacard and Grave, 2021) and structured data like WikiData/WikiTables (Pasupat and Liang, 2015; Chen et al., 2020b; Wang et al., 2020; Feng et al., 2022). In practice, an ideal ODQA model should be able to analyze evidence from both unstructured text and structured data sources, as both types of evidence have their own advantages: 1) the unstructured text covers more general domains; 2) the structured data has better explainability to solve complex multi-hop reasoning.

One line of research accesses unstructured text and structured data independently (Sun et al., 2019; Xiong et al., 2019; Pan et al., 2021; Eisenschlos et al., 2021). The input question is sent to unstructured text system (TextQA) and structured knowledge base system (KBQA), and one of them is selected to output the final answer. These methods cannot combine the two sources of information properly. Recently, a new line of research aggregates heterogeneous information to find the answer (Chen et al., 2020b), which can construct connection between passages and table data. However, the method only conducts multi-hop reasoning on table data. It is difficult to handle questions that need to be answered when multi-hop reasoning on both sources is required.

In this work, we propose a novel Document-Entity Heterogeneous Graph Network (referred to as DEHG) for open-domain question answering which can conduct multi-hop reasoning on aggregated heterogeneous information. DEHG comprises a graph constructor to integrate heterogeneous information sources, a context encoder to generate representations for nodes and question, a heterogeneous information reasoning layer to explore multi-hoop connectivity of both information sources, and an answer decoder to generate answers for the question.

Our contributions can be summarized as follows: (1) we examine how to homogenize structured and unstructured knowledge in open-domain question answering for multi-hop reasoning. To the best of our knowledge, our work is the first to conduct multi-hop reasoning on integrated heterogeneous information in open-domain question answering. (2) We propose a Document-Entity Heterogeneous Graph Network to analyze complex relation of heterogeneous information in open-domain question answering. (3) We present experimental results that show DEHG outperforms previous state-of-the-art on HybirdQA dataset. We also perform an ablation study of our model to provide further insights.

July 10-15, 2022

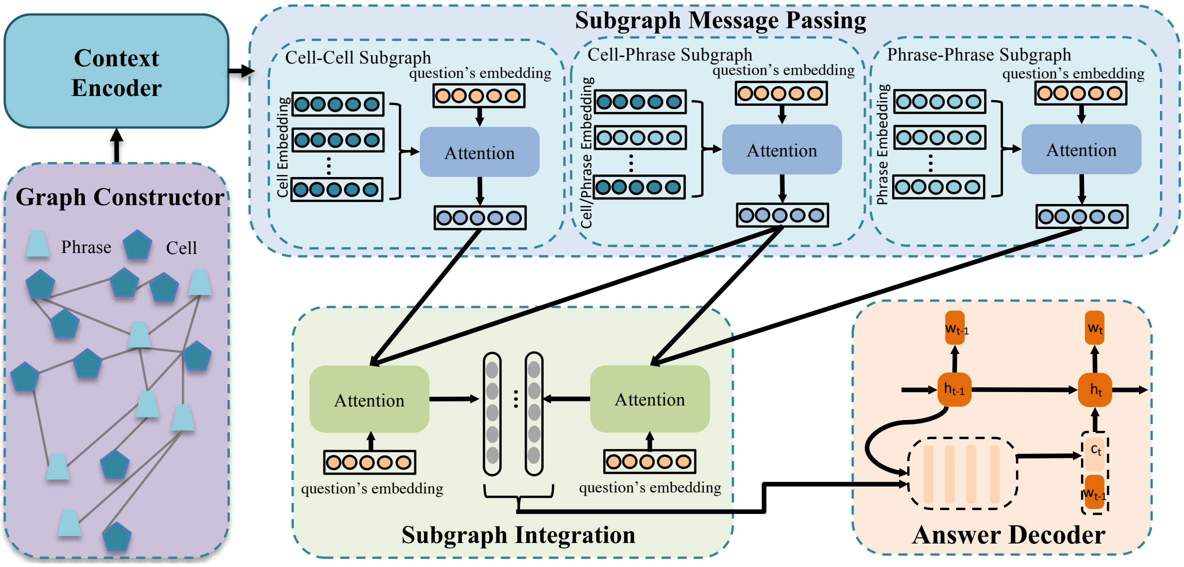

Figure 1: Overview of DEHG.

2 Our Approach

2.1 Graph Constructor

In order to cope with heterogeneous information, we propose a Document-Entity Heterogeneous Graph Constructor to enable rich heterogeneous information interaction. We divide the graph building process into two phases and describe them separately below:

Linking: This phase is aimed to link questions to their related information in tables and passages from two sources: 1) *Table Cell Matching*: in order to link related table cells to the question, we follow these three criteria: the table cell's value is explicitly mentioned by the question; the table cell's value is greater/less than the mentioned value in question; the table cell's value is maximum/minimum over the whole column if the question involves superlative words. 2) *Passage Matching*: it aims to link cells implicitly mentioned by the question through its hyperlinked passage. The linking model is a TF-IDF retriever with 3-gram lexicon which calculates the distances with all the passages in the pool and highlight the ones with distance lower than a threshold.

Building: this phase is aimed to build a heterogeneous graph to connect all linked cells and their corresponding hyperlinked passages. The structure of a heterogeneous graph is shown in Figure 1. For a heterogeneous graph $G = (V, E)$, V and E denote the set of nodes and the set of edges in the graph. The nodes V consist of the set of cells V_C, and the set of phrases of hyperlinked passages V_P. The edges E have three types, Cell-Cell edges E_{cc} that reflect the relations between cells, Cell-Phrase edges E_{cp} that describe the hyperlinked relation between cell and phrase, and Phrase-Phrase edges E_{pp} that express the semantic relation between phrases in the passage.

We utilize Open Information Annotation (OIA) (Sun et al., 2020), which is a predicate-function-argument annotation system for texts, to split passage into phrases and obtain the relation between phrases. Cells are connected to root phrase of its corresponding hyperlinked passage. All selected cells are connected to transfer information between cells on the heterogeneous graph.

2.2 Context Encoder

We use a BERT encoder to generate representations for every table cell, phrase of passage, and question as the initial node embedding in DEHG.

Each linked cell is encoded by 4-element tuple (Content, Location, Source, Score). Content represents the string representation in the table; Location refers to the absolute row and column index in the table; Source denotes where the entry comes from (e.g. equal/greater/less/min/max/passage); Score denotes the score of linked score normalized to [0, 1]. The first input token is [CLS], followed by the tokens of 4-element tuple, separated by [SEP]. The state of the first [CLS] is used as the cell's embedding s_c.

Each phrase in the passage is encoded by 2-

element tuple (TYPE, CONTENT). TYPE refers to the type of phrase extract by OIA (e.g. constant/predicate/function); CONTENT represents the sub-string in the passage; The input sequence starts with [CLS], followed by the tokens of 2-element tuple with [SEP] as a separator. The representation of [CLS] is used as the phrase's embedding s_p.

To generate the question's semantic embedding s_q, a BERT encoder is given the token sequence $X = ([\text{CLS}], x_1, ..., x_N, [\text{SEP}])$, where the sub-word tokens of the question are denoted as $x_1, ..., x_N$. [CLS] and [SEP] are start-of-text and separator pseudo-tokens respectively. The state of the first [CLS] is used as the question's embedding.

2.3 Heterogeneous Information Reasoning

Message passing: we define how information propagates over the graph in order to do reasoning over DEHG. According to the types of edges, the heterogeneous graph can be divided into three subgraphs: Cell-Cell subgraph, Cell-Phrase subgraph, and Phrase-Phrase subgraph. In each subgraph, we follow the message passing design in GCN (Kipf and Welling, 2017) to discriminate the importance of neighbors. To fuse the information of all subgraphs, we use the question-based attention to learn the corresponding weight of different subgraphs. With the learned weights as coefficients, we can fuse these subgraph embeddings to produce the finial node embedding.

Information Propagation: To explore the higher-order connectivity information of cells and passages, we stack T layers of subgraph representation and subgraph integration. Each layer k takes the node embedding from the previous layers as input, and outputs the updated node embedding after the current diffusion process finishes. The updated node embeddings are sent to the $k+1$ layer for the next diffusion process.

2.4 Answer Decoder

The state decoder sequentially generates the answer for the given question, which is represented as a sequence of pointers to cells of the tables and tokens of the passages. The pointers point to the nodes in the heterogeneous graph.

The state decoder is an LSTM using pointer (Vinyals et al., 2015) and attention (Bahdanau et al., 2015). It takes nodes semantic representations as input. At each decoding step t, the decoder receives the embedding of the previous item w_{t1}, the utterance context vector c_t, and the previous hidden state h_{t1}, and produces the current hidden state h_t,

$$h_t = \text{LSTM}(w_{t-1}, h_{t-1}, c_t). \tag{1}$$

We adopt the attention function in (Bahdanau et al., 2015)to calculate the context vectors as follows,

$$c_t = \text{atten}(h_{t-1}, N, N). \tag{2}$$

The decoder then generates a pointer from the set of pointers in the cells in the table and the phrases in the passages on the basis of the hidden state h_t. Specifically, it generates a pointer of item w according to the following distribution,

$$y_w = v^T \tanh(W_1 h_t + W_2 n_w), \tag{3}$$

$$P(w) = softmax(y_w), \tag{4}$$

where w is the pointer of node w, n_w is the representation of node w, v, W_1, and W_2 are trainable parameters, and softmax is calculated over all possible pointers.

3 Experiment

3.1 Dataset

We evaluate our multi-hop reasoning model DEHG on the HybridQA (Chen et al., 2020b) dataset, which contains factual questions that requires multi-hop reasoning using table and text. Tables and text are crawled from Wikipedia. Each row in the table describes several attributes of an instance. A table has its hyperlinked Wikipedia passages that describe the detail of attributes.

3.2 Baselines

In the following experiments, we compare our approach against previously published state-of-the-art approaches on the HybridQA dataset.

HyBrider (Chen et al., 2020b): A hybrid model that combines heterogeneous information to find the answer. *Unsupervised-QG* (Pan et al., 2021): An unsupervised framework that can generate questions by first selecting/generating relevant information from each data source. *DocHopper* (Sun et al., 2021): A multihop retrieval method that retrieves a paragraph or sentence. *Pointer* (Eisenschlos et al., 2021): A Transformer architecture that uses heads to attend to either rows or columns in a table.

3.3 Evaluation Measures

We use the following automatic evaluation metrics in our experiments. *Exact Match (EM)*: Measures what part of the predicted knowledge span matches the ground truth factoid exactly. *Token-Level F1*: We treat the predicted spans and ground truth factoids as bags of tokens, and compute F1.

3.4 Implementation Details

We use the pre-trained BERT model ([BERT-Base, Uncased]), which has 12 hidden layers of 768 units and 12 self-attention heads to encode cell, phrase, and question. The hidden size of LSTM decoder is also 768. The dropout probability is 0.1. We also use beam search for decoding, with a beam size of 5. The batch size is set to 4. Adam (Kingma and Ba, 2015) is used for optimization with an initial learning rate of 1e-4. We implement the algorithm using the PaddlePaddle Deep Learning Platform (Ma et al., 2019).

3.5 Experimental Results

In Table 1, we show the results of the our proposed DEHG graph based model on both development and test set and compare it with previously published results. It shows that our proposed DEHG works significantly better than the baselines in terms of EM and F1 on HybridQA. The results indicate that DEHG is really a general and effective model for multi-hop question answering over tabular and textual data. Specifically, DEHG can leverage the cell and phrase for question answering. It can also effectively handle multi-hop reasoning on the heterogeneous graph.

Model	**Dev**		**Test**	
	EM	F1	EM	F1
Unsupervised-QG	25.7	30.5	-	-
HyBrider	44.0	50.7	43.8	50.6
DocHopper	47.7	55.0	46.3	53.3
POINTR	63.4	71.0	62.8	70.2
DEHG	**65.2**	**76.3**	**63.9**	**75.5**

Table 1: Performance of our model and related work on the HybridQA dataset; Numbers in **bold** denote best results in that metric.

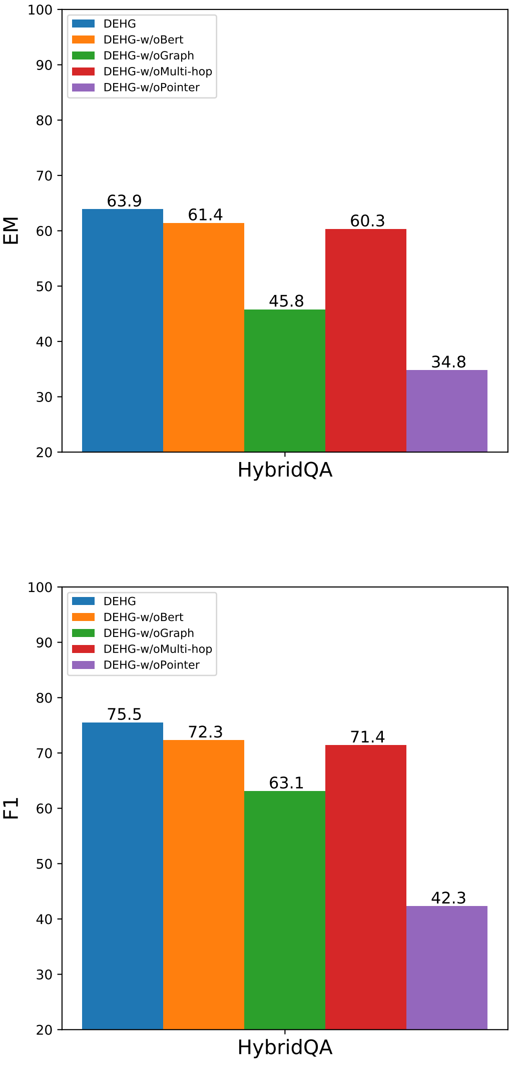

Figure 2: Ablation study results of DEHG.

3.6 Ablation Study

We conduct ablation study on test set. We validate the effects of three factors: BERT-based encoder, heterogeneous information reasoning, and pointer generation decoder. The results indicate that all the components of DEHG are indispensable.

Effect of BERT: To investigate the effectiveness of using BERT in the context encoder, we replace BERT with Bi-directional LSTM and run the model on HybridQA. As shown in Figure 2, the performance of the BiLSTM-based model DEHG-w/oBert in terms of EM and F1 decreases compared with DEHG. It indicates that the BERT-based context encoder can create and utilize more accurate representations for tabular and textual data and question understanding.

Effect of Heterogeneous Information Reasoning: To investigate the effectiveness of using the heterogeneous graph, we compare DEHG with DEHG-w/oGraph which eliminates the heterogeneous information graph, and DEHG-w/oMulti-hop which removes the multi-hop information propagation. From Figure 2, one can observe that without the heterogeneous information graph the performances deteriorate considerably. In addition, the performances of DEHG-w/oGraph are inferior to DEHG-w/oMulti-hop. Thus, utilization of heterogeneous graph to representation multi-hop relation between passages and tables is desirable.

Effect of Pointer Decoder: To investigate the effectiveness of the pointer generation mechanism, we directly generate words from the vocabulary instead of generating pointers in the decoding process. Figure 2 also shows the results of DEHG-w/oPointer. From the results we can see that pointer generation is crucial for coping answer from cells and passages. It is due to HybridQA contains a large number of questions which answers are extracted from the tabular and textual data.

4 Related Work

Most work on QA uses structured and structured data independently (Talmor and Berant, 2018; Sun et al., 2018a; Kwiatkowski et al., 2019; Sun et al., 2019; Xiong et al., 2019; Chen et al., 2020a; Zhang et al., 2020; Liu et al., 2020; Pan et al., 2021; Eisenschlos et al., 2021; Yu et al., 2021). They use unstructured text system (TextQA) and structured knowledge base system (KBQA) to utilize different information. These methods cannot integrate different sources of information. A new method is proposed to aggregate heterogeneous information to find answer (Chen et al., 2020b; Feng et al., 2021). However, it only conducts multi-hop reasoning on table data. It is difficult to handle questions when multi-hop reasoning on both sources is required.

5 Conclusion

We have proposed a new approach to multi-hop question answering over tabular and textual data. The approach, referred to as DEHG, takes question answering as a problem of reasoning answers on the basis of a heterogeneous information graph. DEHG employs BERT in encoding of questions and passages respectively and generates pointers in decoding of answer generation. Experimental results show that DEHG significantly outperforms the state-of-the-art methods.

Abstract

Increasing concerns and regulations about data privacy and sparsity necessitate the study of privacy-preserving, decentralized learning methods for natural language processing (NLP) tasks. Federated learning (FL) provides promising approaches for a large number of clients (e.g., personal devices or organizations) to collaboratively learn a shared global model to benefit all clients while allowing users to keep their data locally. Despite interest in studying FL methods for NLP tasks, a systematic comparison and analysis is lacking in the literature. Herein, we present the FedNLP[1], a benchmarking framework for evaluating federated learning methods on four common formulations of NLP tasks: text classification, sequence tagging, question answering, and seq2seq generation. We propose a universal interface between Transformer-based language models (e.g., BERT, BART) and FL methods under various non-IID partitioning strategies. Our extensive experiments with FedNLP provide empirical comparisons between FL methods and help us better understand the inherent challenges of this direction. The comprehensive analysis points to intriguing and exciting future research aimed at developing FL methods for NLP tasks.

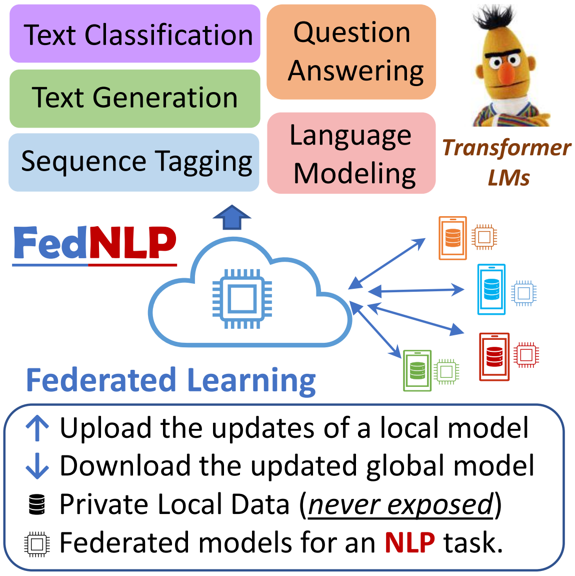

Figure 1: The FedNLP benchmarking framework.

1 Introduction

Fine-tuning large pre-trained language models (LMs) such as BERT (Devlin et al., 2019) often leads to state-of-the-art performance in many realistic NLP applications (e.g., text classification, named entity recognition, question answering, summarization, etc.), when large-scale, *centralized* training datasets are available. However, due to the increasing concerns and regulations about data privacy (*e.g.,* GPDR (Regulation, 2016)) emerging data from realistic users have been much more *fragmented* and *distributed*, forming *decentralized private datasets* of multiple "data silos" (a *data silo* can be viewed as an individual dataset) — across different clients (e.g., organizations or personal devices).

To respect the privacy of the users and abide by these regulations, we must assume that users' data in a *silo* are not allowed to transfer to a centralized server or other clients. For example, a client cannot share its private user data (e.g., documents, conversations, questions asked on the website/app) with other clients. This is a common concern for *organizations* such as hospitals, financial institutions, or legal firms, as well as *personal computing devices* such as smartphones, virtual assistants (e.g., Amazon Alexa, Google Assistant, etc.), or a personal computer. However, from a machine learning perspective, models trained on

a centralized dataset that combine the data from all organizations or devices usually result in better performance in the NLP domain. Therefore, it is of vital importance to study NLP problems in such a realistic yet more challenging scenario — i.e., training data are distributed across different clients and cannot be shared for privacy concerns.

The nascent field of *federated learning* (et al, 2019; Li et al., 2020a) (FL) aims to enable many individual clients to train their models jointly while keeping their local data *decentralized* and completely *private* from other users or a centralized server. A common training schema of FL methods is that each client sends its model parameters to the server, which updates and sends back the global model to all clients in each round. Since the raw data of one client has never been exposed to others, FL is promising as an effective way to address the above challenges, particularly in the NLP domain, where many user-generated text data contain sensitive and/or personal information.

Despite the growing progress in the FL domain, research into and application for NLP has been rather limited. There are indeed several recent works on using FL methods for processing medical information extraction tasks (Sui et al., 2020). However, such prior work usually has its experimental setup and specific task, making it difficult to fairly compare these FL methods and analyze their performance in other NLP tasks. We argue that future research in this promising direction (FL for NLP) would highly benefit from a universal benchmarking platform for systematically comparing different FL methods for NLP. To the best of our knowledge, such a benchmarking platform is still absent from the literature.

Therefore, our goal in this paper is to provide comprehensive comparisons between popular FL methods (e.g., FedAvg (McMahan et al., 2017a), FedOPT (Reddi et al., 2021), FedProx (Li et al., 2020b)) for four mainstream formulations of NLP tasks: text classification, sequence tagging, question answering, and seq2seq generation. Although there are few available realistic FL datasets for NLP due to privacy concerns, we manage to use existing NLP datasets to create various non-IID data partitions over clients. These non-IID partitions simulate various kinds of distribution shifts (e.g., label, features, quantities, etc.) over the clients, which often happen in real-world NLP applications. As for the base NLP models, we use the Transformer architecture (Vaswani et al., 2017) as the backbone and support a wide range of pre-trained LMs such as DistilBERT (Sanh et al., 2019), BERT (Devlin et al., 2019), BART (Lewis et al., 2020), etc. To conduct extensive experiments, we need to support the experiments with multiple options on dimensions such as (1) *task formulations*, (2) *NLP models*, (3) *FL algorithms*, and (4) *non-IID partitions*. Therefore, we propose FedNLP, a modular framework with universal interfaces among the above four components, which is thus more extensible for supporting future research in FL for NLP.

We aim to unblock the research of FL for NLP with the following two-fold contributions:

- **Evaluation and analysis.** We systematically compare popular federated learning algorithms for mainstream NLP task formulations under multiple non-IID data partitions, which thus provides the first comprehensive understanding. Our analysis reveals that there is a considerably large gap between centralized and decentralized training in various settings. We also analyze the efficiency of different FL methods and model sizes. With our analysis, we highlight several directions to advance FL for NLP.
- **Resource.** The implementation of our experiments also forms a general open-source framework named FedNLP, which is capable of evaluating, analyzing, and developing FL methods for NLP. We also provide decentralized NLP datasets of various task formulations created by various non-IID partitioning strategies for future research.

The remainder of this paper is structured as follows. We introduce the background knowledge of federated learning and several typical FL algorithms in §2. Then, we present the proposed non-IID partitioning strategies to create synthetic datasets for different task formulations in §3. Our results, analysis, and findings are in §4. Finally, we discuss related work (§5) and conclusions (§6).

2 Federated Learning for NLP

In this section, we first introduce the background knowledge of federated learning (FL) in the context of NLP tasks. Then, we illustrate a unified FL framework that we used to study typical FL algorithms. Based on this, we build our research framework, a general pipeline for benchmarking and developing FL methods for NLP.

2.1 Federated Learning Concepts

Federated learning (FL) is a machine learning paradigm where multiple entities (clients) collaborate in solving a machine learning problem under the coordination of a central server or service provider. Each client's raw data is stored locally and not exchanged or transferred; instead, focused updates intended for immediate aggregation are used to achieve the learning objectives (Kairouz et al., 2019). Therefore, federated learning has been seen as a promising direction to decrease the risk of attack and leakage, reduce the difficulty and cost of data movement, and meet the privacy-related data storage regulations.

In the basic conception of federated learning, we would like to minimize the objective function,

$$\begin{aligned} F(\boldsymbol{x}) &= \mathbb{E}_{i\sim\mathcal{P}}[F_i(\boldsymbol{x})], \\ \text{where} \quad F_i(\boldsymbol{x}) &= \mathbb{E}_{\xi\sim\mathcal{D}_i}[f_i(\boldsymbol{x},\xi)]. \end{aligned} \tag{1}$$

$\boldsymbol{x} \in \mathbb{R}^d$ represents the parameter for the global model, $F_i : \mathbb{R}^d \rightarrow \mathbb{R}$ denotes the local objective function at client i, and $\mathcal{P}$ denotes a distribution on the collection of clients $\mathcal{I}$. The local loss functions $f_i(\boldsymbol{x},\xi)$ are often the same across all clients, but the local data distribution $\mathcal{D}_i$ will often vary, capturing data heterogeneity.

Federated averaging (FedAvg) (McMahan et al., 2017a) is a common algorithm to solve (1) by dividing the training process into rounds. At the beginning of the t-th round ($t \geq 0$), the server broadcasts the current global model $\boldsymbol{x}^{(t)}$ to a *cohort* of participants: a random subset of clients from $\mathcal{S}^{(t)}$ which includes M clients in total. Then, each sampled client in the round's cohort performs τ_i local SGD updates on its own local dataset and sends the local model changes $\Delta_i^{(t)} = \boldsymbol{x}_i^{(t,\tau_i)} - \boldsymbol{x}^{(t)}$ to the server. Finally, the server uses the aggregated $\Delta_i^{(t)}$ to update the global model: $\boldsymbol{x}^{(t+1)} = \boldsymbol{x}^{(t)} + \frac{\sum_{i\in\mathcal{S}^{(t)}} p_i \Delta_i^{(t)}}{\sum_{i\in\mathcal{S}^{(t)}} p_i}$. where p_i is the relative weight of client i. The above procedure will repeat until the algorithm converges. In the *cross-silo* setting where all clients participate in training on every round (each cohort is the entire population), we have $\mathcal{S}^{(t)} = \{1, 2, \ldots, M\}$. Consequently, we can learn a global model to benefit all clients while preserving their data privacy.

2.2 Our Unified Framework for FL

Algorithm 1: FedOpt (Reddi et al., 2021)): A Generic FedAvg Algorithm

```
Input: Initial model $x^{(0)}$, ClientOpt,
       ServerOpt
for $t \in \{0, 1, \ldots, T-1\}$ do
    Sample a subset $\mathcal{S}^{(t)}$ of clients
    for client $i \in \mathcal{S}^{(t)}$ in parallel do
        Initialize local model $x_i^{(t,0)} = x^{(t)}$
        for $k = 0, \ldots, \tau_i - 1$ do
            Compute local stochastic gradient
              $g_i(x_i^{(t,k)})$
            Perform local update $x_i^{(t,k+1)} =$
              ClientOpt$(x_i^{(t,k)}, g_i(x_i^{(t,k)}), \eta, t)$
        Compute local model changes
          $\Delta_i^{(t)} = x_i^{(t,\tau_i)} - x_i^{(t,0)}$
    Aggregate local changes
      $\Delta^{(t)} = \sum_{i\in\mathcal{S}^{(t)}} p_i \Delta_i^{(t)} / \sum_{i\in\mathcal{S}^{(t)}} p_i$
    Update global model
      $x^{(t+1)} =$ ServerOpt$(x^{(t)}, -\Delta^{(t)}, \eta_s, t)$
```

In this work, we propose to use FedOPT (Reddi et al., 2021), a generalized version of FedAvg, to build the `FedNLP` platform. As the pseudo-code presented in Algorithm 1, the algorithm is parameterized by two gradient-based optimizers: ClientOpt and ServerOpt with client learning rate η and server learning rate η_s, respectively. While ClientOpt is used to update the local models, ServerOpt treats the negative of aggregated local changes $-\Delta^{(t)}$ as a pseudo-gradient and applies it to the global model. This optimization framework generalizes to many aggregation-based FL algorithms and simplifies the system design.

To make our research general, we explore different combinations of SeverOpt and ClientOpt. The original FedAvg algorithm implicitly sets SeverOpt and ClientOpt to be SGD, with a fixed server learning rate η_s of 1.0. FedProx (Li et al., 2020b), tackling statistical heterogeneity by restricting the local model updates to be closer to the initial (global) model, can be easily incorporated into this framework by adding L2 regularization for better stability in training. Moreover, given that AdamW (Loshchilov and Hutter, 2019) is widely used in NLP, we set it for `ClientOpt` and let the `ServerOpt` be SGD with momentum to reduce the burden of tuning.

2.3 The Proposed FedNLP Framework

To support our research in this paper and other future work in the area of federated learning for NLP, we build a general research framework named FedNLP, based on the above universal optimization framework. We here briefly highlight its unique features and leave the details in the following content and a detailed design is shown in App. F. First, FedNLP is the very first framework that connects multiple FL algorithms with Transformer-based models, to our best knowledge. Also, we implement a flexible suite of interfaces to support different types of NLP tasks and models, as well as different non-IID partitioning strategies (Sec. 3.2). To study security and privacy guarantees, we incorporate state-of-the-art secure aggregation algorithms such as LightSecAgg (see F.5).

3 Benchmarking Setup with FedNLP

In this section, we introduce the creation of our benchmark datasets from a set of chosen NLP tasks with different non-IID partition methods. We evaluate various FL methods on these datasets.

3.1 Task Formulations, Datasets, and Models

There are numerous NLP applications, but most of them can be categorized based on four mainstream formulations: text classification (TC), sequence tagging (ST), question answering (QA), and seq2seq generation (SS). The formal definition of each formulation is detailed in Appendix §B. To cover all formulations while keeping our experiments in a reasonable scope, we select one representative task for each formulation:

- **Text Classification**: `20Newsgroup` (Lang, 1995) is a news classification dataset with annotations for 20 labels. We showcase our FedNLP with this dataset as it has a larger output space (20 labels) than sentiment-analysis datasets, which is an important factor for the label-distribution shift scenarios. .
- **Sequence Tagging**: `OntoNotes` (Pradhan et al., 2013) (5.0) is a corpus where sentences have annotations for the entity spans and types. We use it for the named entity recognition task, which is fundamental to information extraction and other applications.

Task	Txt.Cls.	Seq.Tag.	QA	Seq2Seq
Dataset	20News	Onto.	MRQA	Giga.
# Training	11.3k	50k	53.9k	10k
# Test	7.5k	5k	3k	2k
# Labels	20	37*	N/A	N/A
Metrics	Acc.	F-1	F-1	ROUGE

Table 1: Statistics of the selected datasets for our experiments. *37 is the size of the tag vocabulary.

- **QA**: `MRQA` (Fisch et al., 2019) is a benchmark consisting of 6 popular datasets[2]: `SQuAD` (Rajpurkar et al., 2016) (8529/431), `NewsQA` (Trischler et al., 2017) (11877/613), `TriviaQA` (Joshi et al., 2017) (4120/176) , `SearchQA` (Dunn et al., 2017) (9972/499) , `HotpotQA` (Yang et al., 2018b) , and `NQ` (Kwiatkowski et al., 2019) (9617/795).
- **Seq2Seq Generation**: `Gigaword` (DBL, 2012) is a news corpus with headlines that are often used for testing seq2seq models as a summarization task. Other tasks such as dialogue response generation and machine translation can also be adapted to this format.

We show the basic statistics of the above datasets in Table 1. Note that our FedNLP as a research platform supports a much wider range of specific tasks of each formulation, while we only introduce the ones used in our experiments here with typical settings. Moreover, our contribution is more of a general FL+NLP benchmarking platform instead of particular datasets and partitions.

Base NLP Models. Fine-tuning pre-trained LMs has been the *de facto* method for NLP research, so we focus on testing Transformer-based architectures in FedNLP. Specifically, we choose to use BART (Lewis et al., 2020), a text-to-text Transformer model similar to the T5 model (Raffel et al., 2020), for seq2seq tasks.

3.2 Non-IID Partitioning Strategies

The existing datasets have been used for centralized training in NLP. As our focus here is to test decentralized learning methods, we need to distribute the existing datasets to a set of clients. It is the non-IIDness of the client distribution that

---

[2] We only use part of the data to demonstrate and verify our hypothesis; we show the train/test split in brackets.

makes federated learning a challenging problem. Thus, we extend the common practice widely used in prior works to the NLP domain for generating synthetic FL benchmarks (Li et al., 2021a). We first introduce how we control the *label distribution shift* for TC and ST, then the *quantity distribution shift*, and finally how we model the distribution shift in terms of input features for non-classification NLP tasks (e.g., summarization).

Non-IID Label Distributions. Here we present how we synthesize the data partitions such that clients share the same (or very similar) number of examples, but have different *label distributions* from each other. We assume that on every client training, examples are drawn independently with labels following a categorical distribution over L classes parameterized by a vector $\boldsymbol{q}$ ($q_i \geq 0, i \in [1, L]$ and $\|\boldsymbol{q}\|_1 = 1$). To synthesize a population of non-identical clients, we draw $\boldsymbol{q} \sim \mathrm{Dir}_L(\alpha \boldsymbol{p})$ from a *Dirichlet* distribution, where $\boldsymbol{p}$ characterizes a prior class distribution over L classes, and $\alpha > 0$ is a concentration parameter controlling the identicalness among clients. For each client C_j, we draw a $\boldsymbol{q}_j$ as its label distribution and then sample examples without replacement from the global dataset according to $\boldsymbol{q}_j$. With $\alpha \to \infty$, all clients have identical distributions to the prior (i.e., uniform distribution); with $\alpha \to 0$, on the other extreme, each client holds examples from only one class chosen at random. In Fig. 2, we show heatmaps for visualizing the distribution differences between each client. Figure 3 shows an example of the concrete label distributions for all clients with different α. We can see that when α is smaller, the overall label distribution shift becomes larger.

Controlling non-IID Quantity. It is also common that different clients have very different data quantities while sharing similar label distribution. We thus also provide a quantity-level Dirichlet allocation $\boldsymbol{z} \sim \mathrm{Dir}_N(\beta)$ where N is the number of clients. Then, we can allocate examples in a global dataset to all clients according to the distribution $\boldsymbol{z}$ — i.e., $|\mathcal{D}_i| = z_i|\mathcal{D}_G|$. If we would like to model both quantity and label distribution shift, it is also easy to combine both factors. Note that one could assume it is a uniform distribution $\boldsymbol{z} \sim U(N)$, (or $\beta \to \infty$) if we expect all clients to share a similar number of examples. A concrete example is shown in Figure 8 (Appendix).

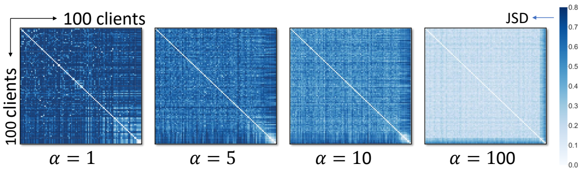

Figure 2: The *J-S divergence* matrix between 100 clients on the *20News* dataset when $\alpha \in \{1, 5, 10, 100\}$. Each sub-figure is a 100x100 symmetric matrix. The intensity of a cell (i, j)'s color here represents the distance between the label distribution of Client i and j. It is expected that when α is smaller, the partition over clients is more non-IID in terms of their label distributions.

Controlling non-IID Features. Although straightforward and effective, the above label-based Dirichlet allocation method has a major limitation — it is only suitable for text classification tasks where the outputs can be modeled as category-based random variables. To create synthetic partitions for other non-classification NLP tasks and model distribution shifts, we thus propose a partition method based on feature clustering. Specifically, we use Sentence-BERT (Reimers and Gurevych, 2019) to encode each example to a dense vector by their text then we apply K-Means clustering to get the cluster label of each example; finally, we use these cluster labels (as if they were classification tasks) to follow the steps in modeling *label distribution shift*. There are two obvious benefits of this clustering-based Dirichlet partition method: 1) It enables us to easily synthesize the FL datasets for non-classification tasks (i.e., ST, QA, SS) as they do not have discrete labels as output space; 2) The BERT-based clustering results naturally imply different sub-topics of a dataset, and thus feature shift can be seen as a shift of latent labels — we can reuse the same method for the label-based Dirichlet partition method.

Natural Factors For datasets like MRQA, we consider a cross-silo setting where each client is associated with a particular sub-dataset (out of the six datasets of the same format), forming a natural distribution shift based on the inherent factors such as data source and annotating style.

Task	Dataset	Partition	Clients	FedAvg	FedProx	FedOPT	# Rounds
Text Classification	20news	α =1 (label shift)	100	0.5142	0.5143	0.5349	22
Sequence Tagging	OntoNotes	α =0.1 (label shift)	30	0.7382	0.6731	0.7918	17
Question Answering	MRQA	natural factor	6	0.2707	0.2706	0.3280	13
Seq2Seq Generation	Gigaword	α =0.1 (feature shift)	100	0.3192	0.3169	0.3037	13

Table 2: The comparisons between different FL methods under the same setting on different NLP tasks. The number of workers per round are 10, expect for the MRQA task, which uses 6.

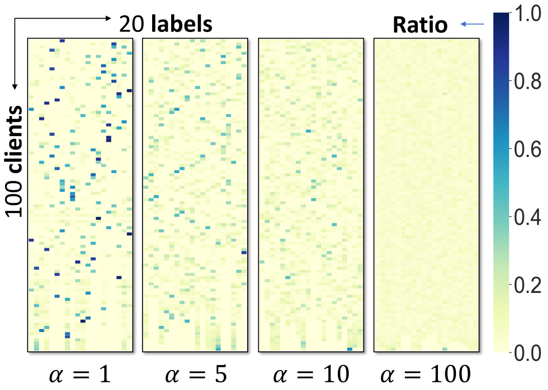

Figure 3: Visualizing the **non-IID label distributions** on *20News* with α being $\{1, 5, 10, 100\}$. Each subfigure is a 100x20 matrix, where 100 is the number of clients, and 20 is the number of labels. The intensity of a cell here represents the ratio of a particular label in the local data of a client. When α is smaller (1, 5, 10), each client has a relatively unique label distribution, thus the differences between clients are larger; when $\alpha = 100$, every client has a nearly uniform label distribution.

4 Experimental Results and Analysis

In this section, we aim to analyze typical federated learning methods (introduced in our benchmark datasets with multiple dimensions with the base NLP models listed previously. We put more implementation details and additional results in Appendix. We organize our extensive experimental results and findings from the analysis as a collection of research questions with answers.

Experimental Setup and Hyper-parameters. We use DistilBERT and BART-base for most of our experiments, as the former is a distilled version of the BERT model and has a 7x speed improvement over BERT-base on mobile devices — a common scenario for FL applications; the BART-base model is the most suitable option considering the trade-off between performance and computation cost. We leave our implementation details and the selected hyper-parameters in the submitted supplementary materials.

Our experiments cover both cross-device and cross-silo settings. As shown in Table 2, in the cross-device setting, we use uniform sampling to select 10 clients for each round when the client number in a dataset is very large (e.g., 100). For the cross-silo setting, each round will select the same number of clients (we use 6 for the QA task). The local epoch number is set to 1 for all experiments. To make our results reproducible, we use *wandb.ai* to store all experiment logs and hyper-parameters as well as running scripts.

Q1: How do popular FL methods perform differently under the same setting?

We compare the three typical FL methods under the same setting (i.e., data partition, communication rounds, etc.) for each task formulation. As shown in Table 2, we report the results of FedAvg, FedProx, and FedOPT. We can see that overall FedOPT performs better than the other two methods, with the only exception being in the seq2seq generation task. FedAvg and FedProx perform similarly with marginal differences, but FedAvg outperforms FedProx in sequence tagging. These two exceptions are surprising findings, as many prior works in the FL community show that FedOPT is generally better than FedProx and FedAvg on vision tasks and datasets.

We conjecture that such inconsistent performance across tasks suggests the difference in terms of the loss functions has a great impact on FL performance. Seq2seq and sequence tagging tasks usually have more complex loss landscapes than text classification, as they are both typical structured prediction tasks, while the text classification has a much smaller output space. From Fig. 4, we see that the FedOPT outperforms the other two methods at the beginning while gradually becoming worse over time.

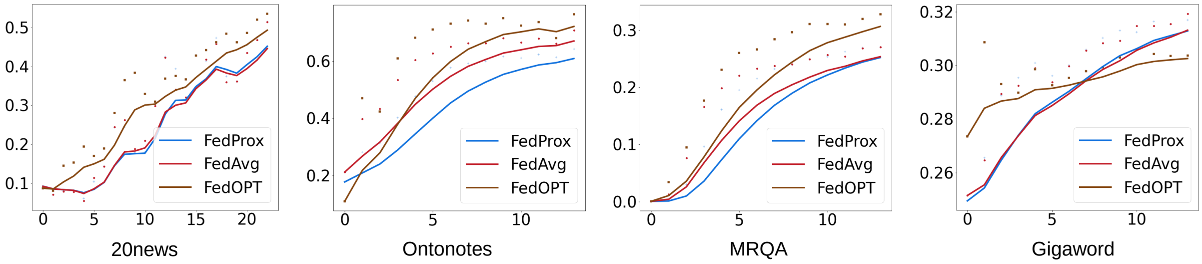

Figure 4: The learning curves of the three FL Methods on four different task formulations. The metrics used for these tasks are accuracy, span-F1, token-F1, and ROUGE respectively; The x-axis is the number of rounds.

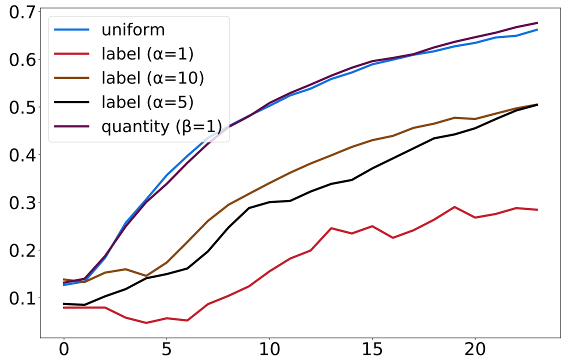

Figure 5: Testing FedOPT with `DistilBERT` for `20News` under different data partition strategies.

This tells us that the use of AdamW as the client optimizer may not always be a good choice, especially for a complex task such as the Seq2Seq ones, as its adaptive method for scheduling learning rates might cause implicit conflicts. These observations suggest that federated optimization algorithms need to be tailored for various NLP tasks, and exploring FL-friendly model architecture or loss function can also be promising directions to address these challenges.

Q2: How do different non-IID partitions of the same data influence FL performance?

The FedNLP platform supports users to investigate the performance of an FL algorithm with a wide range of data partitioning strategies, as discussed in §3.2. Here we look at the training curves of the FedOPT on different partitions, as shown in Figure 5. We reveal several findings:

- When α is smaller (i.e., the partition is more non-IID in terms of their label distribution), the performance tends to degrade, based on the three curves ($\alpha = \{1, 5, 10\}$).
- The variance is also larger when the label distribution shift is larger. Both uniform and quantity-skew partitions have a smoother curve, while the variance is smaller for a larger α (e.g., 10).
- Quantity skew does not introduce a great challenge for federated learning when the label distribution is closer to the uniform one.

Frozen Layers	# Tunable Paras.	Cent.	FedOpt.
`None`	67.0M	86.86	55.11
E	43.1M	86.19	54.86
$E + L_0$	36.0M	86.54	52.91
$E + L_{0\rightarrow 1}$	29.0M	86.52	53.92
$E + L_{0\rightarrow 2}$	21.9M	85.71	52.01
$E + L_{0\rightarrow 3}$	14.8M	85.47	30.68
$E + L_{0\rightarrow 4}$	7.7M	82.76	16.63
$E + L_{0\rightarrow 5}$	0.6M	63.83	12.97

Table 3: Performance (Acc.%) on 20news (TC) when different parts of `DistilBERT` are frozen for centralized training and FedOpt (at 28-th round). E stands for the embedding layer and L_i means the i-th layer. The significant lower accuracy are underlined.

These findings suggest that it is important to design algorithms to mitigate data heterogeneity. One promising direction is *personalized* FL, which enables each client to learn its personalized model via adapting its local data distribution and system resources (Dinh et al., 2020; Fallah et al., 2020; Li et al., 2021b).

Q3: How does freezing of Transformers influence the FL performance?

Communication cost is a major concern in the federated learning process. It is thus natural to consider freezing some Transformer layers of the client models to reduce the size of the trainable parameters that will be transmitted between servers and clients. To study the influence of freezing layers on the FL performance, we conduct a series of experiments that freeze the layers from the embed-

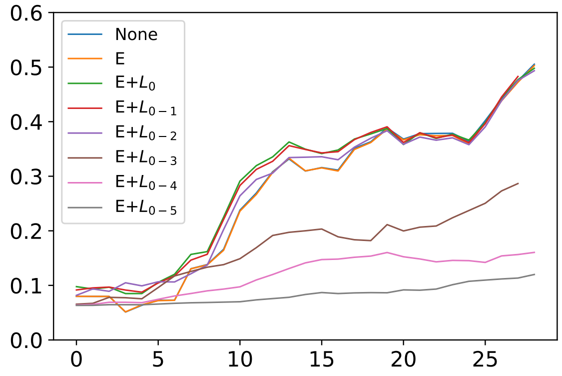

Figure 6: Testing `FedOPT` with `DistilBERT` for `20News` under different frozen layers.

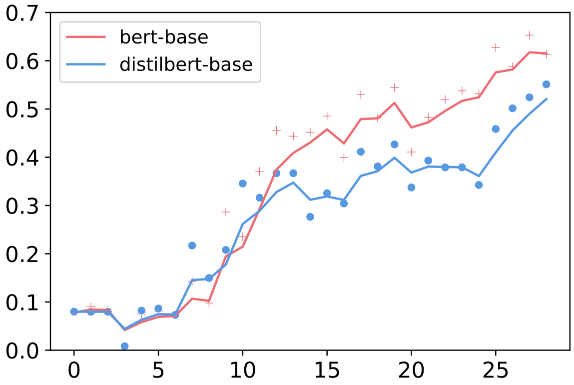

Figure 7: `FedOPT` for `20News` with different LMs.

ding layer (E) to the top layer (L_5) of DistilBERT with both centralized training and FedOPT on the text classification task.

We report our results in Table 3 and Figure 6. We find that in centralized training, the largest performance gain happens when we unfreeze the last layer, while in FedOPT we have to unfreeze the last three layers to enjoy a comparable performance with the full model. This suggests that reducing communication costs via freezing some layers of Transformer LMs is feasible, though one should be aware that the experience in centralized training may not generalize to the FL experiments.

Q4: Are compact model DistilBERT adequate for FL+NLP?

We know that BERT has a better performance than DistilBERT for its larger model size. However, is it cost-effective to use BERT rather than DistilBERT? To study this, we compare the performance of both models with FedOPT on text classification, sharing the same setting as the above experiments. As shown in Figure 7, although BERT-base achieves better performance, the performance of DistilBERT is not significantly worse. Considering the communication cost (BERT-base is almost 2x larger), we argue that using DistilBERT is a more cost-effective choice for both experimental analysis and realistic applications.

5 Related Work

FL benchmarks and platforms. In the last few years a proliferation of frameworks and benchmark datasets have been developed to enable researchers to better explore and study algorithms and modeling for federated learning, both from academia: LEAF(Caldas et al., 2018), FedML (He et al., 2020c), Flower (Beutel et al., 2020), and from the industry: PySyft (Ryffel et al., 2018), TensorFlow-Federated (TFF) (Ingerman and Ostrowski, 2019), FATE (Yang et al., 2019), Clara (NVIDIA, 2019), PaddleFL (Ma et al., 2019), Open FL (Intel®, 2021). However, most platforms only focus on designing a unified framework for federated learning methods and do not provide a dedicated environment for studying NLP problems with FL methods. LEAF (Caldas et al., 2018) contains a few text datasets, however, it is limited to classification and next-word prediction datasets and does not consider the pre-trained language models. We want to provide a dedicated platform for studying FL methods in realistic NLP applications with state-of-the-art language models.

Federated learning in NLP applications. There are a few prior works that have begun to apply FL methods in privacy-oriented NLP applications. For example, federated learning has been applied to many keyboard-related applications including (Hard et al., 2018; Stremmel and Singh, 2020; Leroy et al., 2019; Ramaswamy et al., 2019; Yang et al., 2018a), sentence-level text intent classification using Text-CNN (Zhu et al., 2020), and pretraining and fine-tuning of BERT using medical data from multiple silos without fetching all data to the same place (Liu and Miller, 2020). FL methods also have been proposed to train high-quality language models that can outperform the models trained without federated learning (Ji et al., 2019; Chen et al., 2019). Besides these applications, some work has been done in medical relation extractions (Ge et al., 2020) and medical name entity recognition (Sui et al., 2020). These methods use federated learning to preserve the privacy of sensitive medical data and learn data on different platforms, excluding the need for exchanging data between different platforms.

Our work aims to provide a unified platform for studying various NLP applications in a shared environment so that researchers can better design new FL methods either for a specific NLP task or as a general-purpose model. The aforementioned prior works would thus be a particular instance of the settings supported by the FedNLP platform.

6 Conclusion and Future Directions

Our key contribution is providing a thorough and insightful empirical analysis of existing federated learning algorithms in the context of NLP models. Notably, We compare typical FL methods for four NLP task formulations under multiple non-IID data partitions. Our findings reveal both promise and the challenges of FL for NLP. In addition, we also provide a suite of resources to support future research in FL for NLP (e.g., a unifying framework for connecting Transformer models with popular FL methods and different non-IID partition strategies). Thus, we believe our well-maintained open-source codebase to support future work in this area.

Promising future directions in FL for NLP include: 1) minimizing the performance gap, 2) improving the system efficiency and scalability, 3) trustworthy and privacy-preserving NLP, 4) personalized FL methods for NLP, etc. (Please see Appendix E for more details.)

Ethical Considerations and Limitations(*)

Ethical considerations. The key motivation of FedNLP (and FL) is to protect the data privacy of general users by keeping their data on their own devices while benefiting from a shared model from a broader community. Among the risks that need to be considered in any deployment of NLP are that responses may be wrong, or biased, in ways that would lead to improperly justified decisions. Although in our view the current technology is still relatively immature, and unlikely to be fielded in applications that would cause harm of this sort, it is desirable that FedNLP methods provide audit trails, and recourse so that their predictions can be explained to and critiqued by affected parties.

Limitations. One limitation of our work is that we have not analyzed the privacy leakage of FL methods. We argue that novel privacy-centric measures are orthogonal to the development of FL methods, which is beyond the scope of our work. How to fairly analyze the privacy leakage is now still an open problem for both FL and NLP, and it is only possible to study this when we have an existing platform like FedNLP.

Appendix

A FL+NLP

Many realistic NLP services heavily rely on users' local data (e.g., text messages, documents and their tags, questions and selected answers, etc.), which can be located at either personal devices or larger data-silos for organizations. These local data are usually regarded as highly private and thus not directly accessible by anyone, according to many data privacy regulations; this makes it difficult to train a high-performance model to benefit users. Federated learning aims to solve machine learning under such a privacy-preserving use case, thus offering a novel and promising direction to the community: FL+NLP.

Apart from the goal of learning a shared global model for all clients, FL also provides a new perspective for many other interesting research questions in NLP. One related direction is to develop personalized models for NLP applications, which requires both protection of data privacy and transferred ability on users' own input feature distribution caused by language styles, interested topics and so on. The recent concerns on adversarial attacks and safety issues of NLP models are also highly related to FL+NLP. We thus believe FL+NLP is of vital importance for applying NLP technologies in realistic use cases and could benefit many relevant research areas.

A.1 Challenges of Applying FL in NLP

Given the promising benefits of studying FL+NLP, however, this research direction is currently blocked by the lack of a standardized platform providing fundamental building blocks: benchmark datasets, NLP models, FL methods, evaluation protocols, etc. Most of the current FL platforms either focus on unifying various FL methods and use computer vision models and datasets for their experiments, but lack the ability to connect the study of pre-trained language models, the most popular NLP , and realistic NLP applications of various task formulations.

The first challenge in developing a comprehensive and universal platform for FL+NLP is to deal with various task formulations for realistic NLP applications, which have different input and output formats (Section B). As the non-IID data partition over clients is the major feature of FL problems, it is also a challenge to simulate the realistic non-IID partition for existing NLP datasets (Section 3.2). Finally, a platform also must integrate various FL methods with the Transformer-based NLP models for a variety of task types, and thus a flexible and extensible learning framework is needed. In particular, the conventional trainer component of Transformers now needs to be modified for efficient and safe communications towards federated learning (Section F).

B Basic Formulations of NLP Tasks

There are various types of NLP applications, but many of them share a similar task formulation (i.e., input-and-put formats). We show four common task formulations that can cover most of the mainstream NLP applications: text classification, sequence tagging, question answering, sequence-to-sequence generation.

Text Classification (TC) The input is a sequence of words, $x = [w_1, w_2, \dots]$, and the output is a label y in a fixed set of labels $\mathcal{L}$. Many NLP applications can be formulated as text classification tasks. For example, we can use TC models for classifying the topic of a news article to be *political*, *sports*, *entertainment*, etc., or analyzing movie reviews to be *positive*, *negative* or *neutral*.

Sequence Tagging (ST) The input is a sequence of words, $x = [w_1, w_2, \dots, w_N]$, and the output is a same-length sequence of tags $y = [t_1, t_2, \dots, t_N]$, where t_i is in a fixed set of labels $\mathcal{L}$. The main difference between TC and ST is that ST learns to classify the label of each token in a sentence, which is particularly useful in analyzing syntactic structures (e.g., part-of-speech analysis, phrase chunking, and word segmentation) and extracting spans (e.g., named entity recognition).

Question Answering (QA) Given a passage $P = [w_1, w_2, \dots, w_N]$ and a question q as input, the task is to locate a span in the passage as the answer to the question. Thus, the output is a pair of token index (s, e) where $s, e \in \{1, 2, \dots, N\}$ for denoting the begin and end of the span in the passage. This particular formulation is also known as *reading comprehension*.

Natural Language Generation (NLG) Both in-

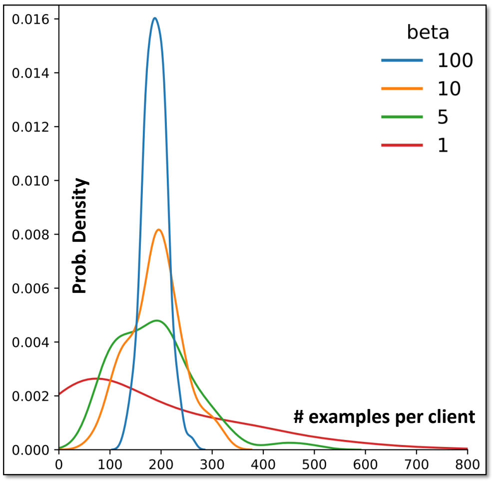

Figure 8: The probability density of quantity of training examples in each of the 100 clients on the *20News* dataset with different β. When β is larger, then all clients share more similar numbers of examples; when β is smaller, then the range of the quantity is much wider — i.e., the larger differences between clients in terms of their sizes of datasets.

put and output are sequence of words, $x = [w^i_1, w^i_2, \dots, w^i_N]$, $y = [w^o_1, w^o_2, \dots, w^o_M]$. It is shared by many realistic applications such as summarization, response generation in dialogue systems, machine translation, etc.

Language Modeling (LM) The left-to-right language modeling task considers a sequence of words as the input $x = [w_1, w_2, \dots, w_n]$ and a token $y = w_{n+1}$ as the output. The output token is expected to be the most plausible next word of the incomplete sentence denoted as x. Although the direct application of LM is limited, a high-performance pre-trained language model can benefit a wide range of NLP applications (as above) via fine-tuning. It also serves as an excellent test bed as it requires no human annotations at all.

Others. There are some other applications that not are covered by the above four basic formulations, and our extensible platform (detailed in Section F) enables users to easily implement their specific tasks. For each task formulation, we show which datasets are used in FedNLP and how we partition them in Section 3.

C Implementation Details

Non-IID. Label Distribution Note that this might cause a few clients not to have enough examples to sample for particular labels if they are already used up. Prior works choose to stop assigning early and remove such clients, but it consequently loses the other unused examples and also causes the inconsistency of client numbers. Thus, to avoid these issues, we propose a *dynamic reassigning* method which complement the vacancy of a label by filling in the examples of other labels based on their current ratio of remaining unassigned examples.

C.1 The FedNLP Training Pipeline: Security and Efficiency

Under the definition of federated learning in Algorithm 1, we design a training system to support the research of NLP in the FL paradigm. We highlight its core capabilities and design as follows.

Supporting diverse FL algorithms. `FedNLP` aims to enable flexible customization for future algorithmic innovations. We have supported a number of classical federated learning algorithms, including FedAvg (McMahan et al., 2017a), FedOPT (Reddi et al., 2021), and FedProx (Li et al., 2020b). These algorithms follow the same framework introduced in Algorithm 1. The algorithmic APIs are modularized: all data loaders follow the same format of input and output arguments, which are compatible with different models and algorithms and are easy to support new datasets; the method of defining the model and related trainer is kept the same as in centralized training to reduce the difficulty of developing the distributed training framework. For new FL algorithm development, worker-oriented programming reduces the difficulty of message passing and definition. More details are introduced in Appendix F.3.

Enabling secure benchmarking with lightweight secure aggregation. In particular, `FedNLP` enhances the security aspect of federated training, which is not supported by existing non-NLP-oriented benchmarking libraries (e.g., TFF, LEAF). This is motivated by the fact that model weights from clients may still have the risk of privacy leakage (Zhu et al., 2019). To break this barrier, we integrate secure aggregation (SA) algorithms to the `FedNLP` system. NLP researchers do not need to master security-related knowledge and also benefit from a secure distributed training environment. To be more specific, `FedNLP` supports state-of-the-art SA algorithms `LightSecAgg`, `SecAgg` (Bonawitz et al., 2017), and `SecAgg+` (Bell et al., 2020). At a high-level understanding, SA protects the client model by generating a single random mask and allows their cancellation when aggregated at the server. Consequently, the server can only see the aggregated model and not the raw model from each client. In this work, our main effort is to design and optimize these SA algorithms in the context of the `FedNLP` system. We provide an algorithmic performance comparison in Appendix F.5.

Realistic evaluation with efficient distributed system design. `FedNLP` aims to support distributed training in multiple edge servers (e.g, AWS EC2) or edge devices (e.g., IoTs and smartphones). To achieve this, the system is designed with three layers: the application layer, the algorithm layer, and the infrastructure layer. At the application layer, FedNLP provides three modules: data management, model definition, and a single-process trainer for all task formats; at the algorithm layer, FedNLP supports various FL algorithms; at the infrastructure layer, FedNLP aims at integrating single-process trainers with a distributed learning system for FL. Specifically, we make each layer and module perform its own duties and have a high degree of modularization. We refer readers to Appendix F for a detailed description of the system architecture and design philosophy.

D More Related Works

Federated Learning Methods. Federated Learning (FL) is a widely disciplinary research area that mainly focuses on three aspects: statistical challenge, trustworthiness, and system optimization. Numerous methods have been proposed to solve statistical challenges, including FedAvg (McMahan et al., 2017b), FedProx (Li et al., 2020b), FedOPT (Reddi et al., 2021), FedNAS (He et al., 2020a,d), and FedMA (Wang et al., 2020b) that alleviate the non-IID issue with distributed optimization, and new formulations, MOCHA (Smith et al., 2017), pFedMe (Dinh et al., 2020), perFedAvg (Fallah et al., 2020), and Ditto (Li et al., 2021b), that consider personalization and fairness in federated training.

For trustworthiness, security and privacy are the two main research directions that are mainly concerned with resisting data or model attacks, reconstruction, and leakage during training (So et al., 2021b,a, 2020; Prakash et al., 2020; Prakash and Avestimehr, 2020; Elkordy and Avestimehr, 2020; Prakash et al., 2020; Wang et al., 2020a; Lyu et al., 2020). Given that modern deep neural networks are over-parameterized and dominate nearly all learning tasks, researchers also proposed algorithms or systems to improve the efficiency and scalability of edge training (He et al., 2020b,c, 2019, 2021). We refer readers to the canonical survey (Kairouz et al., 2019) for details.

Although tremendous progress has been made in the past few years, these algorithms or systems have not been fully evaluated on realistic NLP tasks introduced in this paper.

E Future Directions

Minimizing the performance gap. In the FL setting, we demonstrate that federated fine-tuning still has a large accuracy gap in the non-IID dataset compared to centralized fine-tuning. Developing algorithms for Transformer models with NLP tasks is of the highest priority.

Improving the system efficiency and scalability. Transformer models are usually large, while resource-constrained edge devices may not be able to run large models. Designing efficient FL methods for NLP tasks is thus a practical problem worth solving. How to adopt a reasonable user selection mechanism to avoid stragglers and speed up the convergence of training algorithms is also a pressing problem to be solved.

Trustworthy and privacy-preserving NLP. We argue that it is an important future research direction to analyze and assure the privacy-preserving ability of these methods, although our focus in this paper is the implementation and performance analysis of the FL methods for NLP tasks. It is now an open problem for both FL and NLP areas, while it is an orthogonal goal for improving the trustworthy of decentralized learning, and it is only possible to study privacy preservation when we have an existing FL+NLP platform. This is also part of our motivation in proposing FedNLP, and we believe our framework provides a set of flexible interfaces for future development to analyze and improve the privacy-preserving ability of FL methods for NLP tasks and beyond.

Personalized FedNLP. From the perspective of the data itself, user-generated text is inherently personalized. Designing personalized algorithms to improve model accuracy or fairness is a very promising direction. In addition, it is also an interesting problem to adapt the heterogeneous model architecture for each client in the FL network. We show that it is feasible to only fine-tune a small amount of the parameters of LMs, so it is promising to adapt recent prefix-tuning methods (Li and Liang, 2021) for personalizing the parameters of NLP models within the FedNLP framework.

F The System Design of FedNLP

The FedNLP platform consists of three layers: the application layer, the algorithm layer, and the infrastructure layer. At the application layer, FedNLP provides three modules: data management, model definition, and single-process trainer for all task formats; At the algorithm layer, FedNLP supports various FL algorithms; At the infrastructure layer, FedNLP aims at integrating single-process trainers with a distributed learning system for FL. Specifically, we make each layer and module perform its own duties and have a high degree of modularization.

F.1 Overall Workflow

The module calling logic flow of the whole framework is shown on the left of Figure 9. When we start the federated training, we first complete the launcher script, device allocation, data loading, and model creation, and finally call the API of the federated learning algorithm. This process is expressed in Python-style code (see Alg. 2).

F.2 The Application Layer

Data Management. In data management, What `DataManager` does is control the whole workflow from loading data to returning trainable features. To be specific, `DataManager` is set up for reading h5py data files and driving a `preprocessor` to convert raw data to features. There are four types of `DataManager` according to the task definition. Users can customize their `DataManager` by inheriting one of the `DataManager` class, specifying data operation functions, and embedding a particular preprocessor. Note that the raw data's `H5Py` file and the non-IID partition file are preprocessed offline, while `DataManager` only loads them in runtime.

Algorithm 2: The FedNLP Workflow

```
# using text classification (TC) as an example

# initialize distributed computing environment
process_id, ... = FedNLP_init()

# GPU device management
device = map_process_to_gpu(process_id, ...)

# data management
data_manager = TCDataManager (process_id, ...)
# load the data dictionary by process_id
data_dict = dm.load_federated_data(process_id)

# create model by specifying the task
client_model, ... = create_model(model_args,
     formulation="classification")

# define a customized NLP Trainer
client_trainer = TCTrainer(device,
                     client_model, ...)

# launch the federated training (e.g., FedAvg)
FedAvg_distributed(..., device,
                   client_model,
                   data_dict, ...,
                   client_trainer)
```

Model Definition. We support two types of models: Transformer and LSTM. For Transformer models, to dock with the existing NLP ecology, our framework is compatible with the *HuggingFace Transformers* library (Wolf et al., 2020), so that various types of Transformers can be directly reused without the need for re-implementation. Specifically, our code is compatible with the three main classes of `Tokenizer`, `Model`, and `Config` in *HuggingFace*. Users can also customize them based on `HuggingFace`'s code. Although LSTM has gradually deviated from the mainstream, we still support LSTM to reflect the framework's integrity, which may meet some particular use cases in a federated setting.

NLP Trainer (single process perspective). As for the task-specific NLP `Trainer`, the most prominent feature is that it does not require users to have any background in distributed computing. Users of FedNLP only need to complete single-process code writing. A user should inherit the `Trainer` class in the application layer

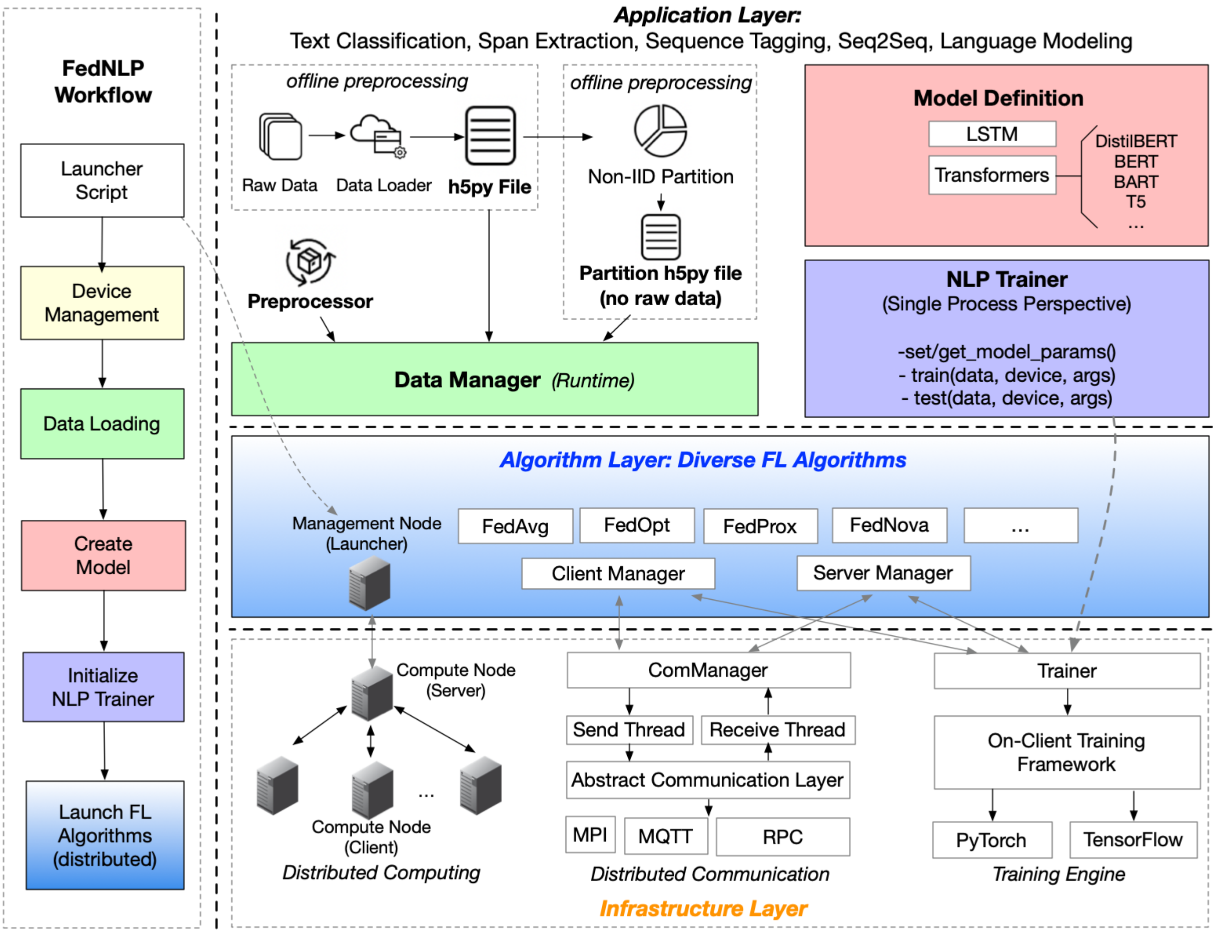

Figure 9: The overall workflow and system design of the proposed FedNLP platform.

to implement the four methods as shown in the figure: 1. the `get_model_params()` interface allows the algorithm layer to obtain model parameters and transmit them to the server; 2. the `set_model_params()` interface obtains the updated model from the server's aggregation and then updates the model parameters of the local model; 3. the programming of the `train()` and `test()` function only needs to consider the data of a single user, meaning that the trainer is completely consistent with the centralized training.

F.3 The Algorithm Layer

In the design of the algorithm layer, we follow the principle of one-line API. The parameters of the API include model, data, and single-process trainer (as shown in Algorithm 2). The algorithms we support include:

Centralized Training. We concatenate all client datasets and use the global data $\mathcal{D}_G$ to train a global model — i.e., the conventional protocol for learning an NLP model on a dataset.

FedAvg (McMahan et al., 2017a) is the *de facto* method for federated learning, assuming both client and server use the *SGD* optimizer for updating model weights.

FedProx (Li et al., 2020b) can tackle statistical heterogeneity by restricting the local model updates to be closer to the initial (global) model with L2 regularization for better stability in training.

FedOPT (Reddi et al., 2021) is a generalized version of `FedAvg`. There are two gradient-based optimizers in the algorithm: `ClientOpt` and `ServerOpt` (please refer to the pseudo code in the original paper (Reddi et al., 2021)). While `ClientOpt` is used to update the local models, `SerevrOpt` treats the negative of aggregated local changes $-\Delta^{(t)}$ as a pseudo-gradient and applies it on the global model. In our FedNLP framework, by default, we set the `ClientOpt` to be AdamW (Loshchilov and Hutter, 2019) and the

`SerevrOpt` to be SGD with momentum (0.9) and fix server learning rate as 1.0.

Each algorithm includes two core objects, `ServerManager` and `ClientManager`, which integrate the communication module `ComManager` from the infrastructure layer and the `Trainer` of the training engine to complete the distributed algorithm protocol and edge training. Note that users can customize the Trainer by passing a customized `Trainer` through the algorithm API.

F.4 The Infrastructure Layer

The infrastructure layer includes three modules:

1) Users can write distributed scripts to manage GPU resource allocation. In particular, FedNLP provides the GPU assignment API (`map_process_to_gpu()` in Algorithm 2) to assign specific GPUs to different FL Clients.

2) The algorithm layer can use a unified and abstract `ComManager` to complete a complex algorithmic communication protocol. Currently, we support MPI (Message Passing Interface), RPC (Remote procedure call), and MQTT (Message Queuing Telemetry Transport) communication backend. MPI meets the distributed training needs in a single cluster; RPC meets the communication needs of cross-data centers (e.g., cross-silo federated learning); MQTT can meet the communication needs of smartphones or IoT devices.

3) The third part is the training engine, which reuses the existing deep learning training engines by presenting as the `Trainer` class. Our current version of this module is built on `PyTorch`, but it can easily support frameworks such as `TensorFlow`. In the future, we may consider supporting the lightweight edge training engine optimized by the compiler technology at this level.

F.5 Enhancing Security with Secure Aggregation (SA)

`FedNLP` supports state-of-the-art SA algorithms `LightSecAgg`, `SecAgg` (Bonawitz et al., 2017), and `SecAgg+` (Bell et al., 2020). Here, we provide a short performance comparison of these three algorithms. In general, `LightSecAgg` provides the same model privacy guarantees as SecAgg (Bonawitz et al., 2017) and SecAgg+ (Bell et al., 2020)) while substantially reducing the aggregation (hence run-time) complexity (Figure **??**). The main idea of `LightSecAgg` are that each user protects its local model using a locally generated random mask. This mask is then encoded and shared with other users, in such a way that the aggregate mask of any sufficiently large set of surviving users can be directly reconstructed at the server. Our main effort in `FedNLP` is integrating these algorithms, optimizing its system performance, and designing user-friendly APIs to make them compatible with NLP models and FL algorithms.

`SemAttack`: Natural Textual Attacks via Different Semantic Spaces

***Boxin Wang[1], *Chejian Xu[1], Xiangyu Liu[2], Yu Cheng[3], Bo Li[1]**

Abstract

Recent studies show that pre-trained language models (LMs) are vulnerable to textual adversarial attacks. However, existing attack methods either suffer from low attack success rates or fail to search efficiently in the exponentially large perturbation space. We propose an efficient and effective framework `SemAttack` to generate natural adversarial text by constructing different semantic perturbation functions. In particular, `SemAttack` optimizes the generated perturbations constrained on generic semantic spaces, including typo space, knowledge space (*e.g.*, WordNet), contextualized semantic space (*e.g.*, the embedding space of BERT clusterings), or the combination of these spaces. Thus, the generated adversarial texts are more semantically close to the original inputs. Extensive experiments reveal that state-of-the-art (SOTA) large-scale LMs (*e.g.,* DeBERTa-v2) and defense strategies (*e.g.,* FreeLB) are still vulnerable to `SemAttack`. We further demonstrate that `SemAttack` is general and able to generate natural adversarial texts for different languages (*e.g.,* English and Chinese) with high attack success rates. Human evaluations also confirm that our generated adversarial texts are natural and barely affect human performance. Our code is publicly available at `https://github.com/AI-secure/SemAttack`.

Original Input: They need to hire experienced sales rep who are mature enough to handle questions and sales.
Adversarial Input: They need to hire skilled sales rep who are mature enough to handle questions and sales.
Sentiment Prediction: Most Negative → Most Positive

Original Input: 拿什么能吸引你：我们的海外学子?
(**Translation:** What can attract you: our overseas students?)
Adversarial Input: 拿甚么能吸引你：我们的海外学子?
(**Translation:** What can attract you: our overseas students?)
Topic Prediction: Education News → Entertainment News

Table 1: Adversarial texts generated against English and Chinese BERT classifiers by `SemAttack` on Yelp and THUCTC datasets. Replacing a word/character with an adversarial one misleads the correct prediction to a wrong class without fooling human.

1 Introduction

Deep neural networks have achieved remarkable success in many machine learning tasks. Particularly, BERT (Devlin et al., 2019) has inspired a suite of large-scale pre-trained language models (Yang et al., 2019; Zhang et al., 2019; Lan et al., 2019), which achieved new SOTA for many NLP tasks. In addition to BERT's dominant performance on English datasets, Tenney et al. (2019) points out that BERT is similarly effective on other languages such as Chinese, whose granularity of words is more complex, given the model's ability to disambiguate information from high-level representations (Ding et al., 2019).

Although effective for many NLP tasks, the robustness of these neural models is often challenged by carefully crafted adversarial examples. Specifically, attackers can add subtle human-imperceptible perturbation to the original input and induce dramatic changes in model output. Current adversarial text generation (Jia and Liang, 2017; Li et al., 2018; Alzantot et al., 2018) is mainly heuristic and only achieves low attack success rates for BERT-based models. Other work (Cheng et al., 2020; Ebrahimi et al., 2018) allows an input word to be substituted by any other word in the vocabulary, which fails to consider the semantic perturbation constraints and is prone to invalid adversarial examples. Recent work (Jin et al., 2020; Zang et al., 2020) relies on external knowledge to constrain the perturbation yet poorly handles large search space that grows exponentially with the input length, as it requires hundreds of queries to generate one adversarial example in practice.

Furthermore, most existing textual adversarial attacks are not generalizable to other languages, due to unique language-dependent characteristics

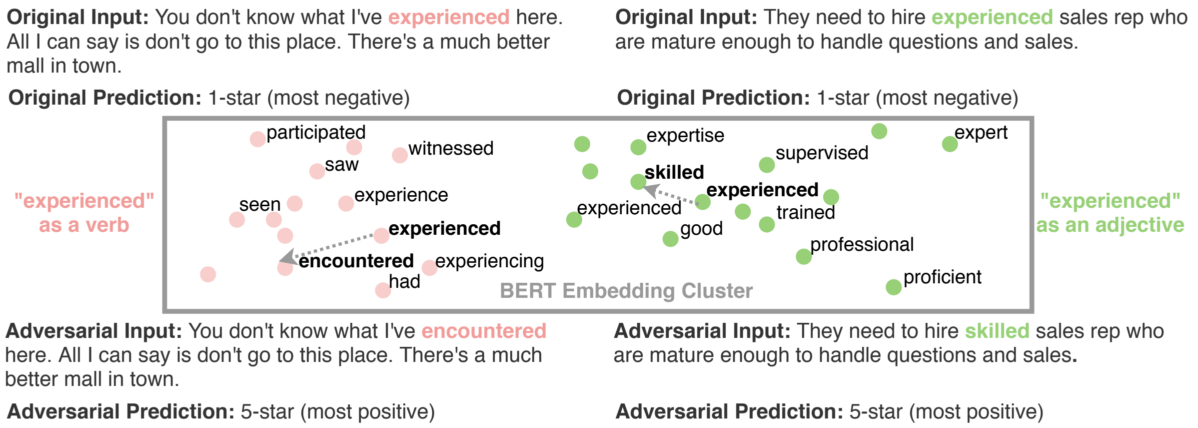

Figure 1: Adversarial texts against BERT sentiment classifier generated by `SemAttack` that formulates two different contextualized semantic perturbation spaces based on BERT embedding clusters (the embedding space is projected by PCA onto 2D space). The word "experienced" reveals different meanings (past tense of the verb "experience" or adjective form) in different contexts (clusters). Our contextualized semantic perturbation chooses "saw" or "encountered" as the perturbation for verb "experienced", while "skilled" or "trained" for the adjective form.

and the lack of universal linguistic resources. Moreover, character-level adversarial attacks designed in English context (Ebrahimi et al., 2017) are often ineffective for Chinese-character-level attacks, as the size of candidate characters increases by two orders of magnitude, resulting in surging computational costs especially for BERT-based models.

We tackle these limitations in textual adversarial attacks by proposing an effective and efficient framework `SemAttack`, which can be used to further evaluate the robustness of NLP models. We generalize existing word-level attacks and propose generic semantic perturbation functions, which optimize and constrain the perturbations within different semantic spaces, so that the generated adversarial texts retain their semantic meaning. We mainly consider three types of semantic spaces: (1) *Typo Space*, using typo words or characters that can fool the models but not human judges; (2) *Knowledge Space*, utilizing external linguistic knowledge base (*e.g.*, WordNet (Miller, 1995)) as valid perturbation candidates; and (3) *Contextualized Semantic Space*, exploiting the embedding space of BERT to generate a contextualized perturbation set semantically close to the original word (Figure 1). The contextualized semantic space does not require additional knowledge, and therefore can scale to other languages, especially low-resource languages where a large knowledge base is unavailable.

After the candidate semantic space is determined, `SemAttack` searches for the optimal perturbation combination. Instead of requiring thousands of queries to generate one adversarial example, optimal perturbations can be efficiently found in the embedding space by solving an optimization problem. We also control the magnitude of perturbation to be small as shown in Table 1. Extensive experiments on four datasets demonstrate that SOTA LMs and defense methods are still vulnerable to our adversarial attack, which are natural and barely affects human judgment. For example, the accuracy of BERT sentiment classifier drops from 70.6% to 2.4% by simply replacing fewer than 5% words with our method. Although these adversarial examples are generated in the whitebox setting, they can effectively transfer to two different blackbox attack settings while retaining higher than 90% attack success rate for BERT and other large-scale LMs such as DeBERTa-XXLarge.

Our contributions are summarized as follows: 1) We propose a unified and effective adversarial attack framework `SemAttack` by constructing semantic perturbation functions, which constraint perturbations within different semantic spaces and their combinations. 2) `SemAttack` generates contextualized perturbations that require no external knowledge and thus can easily adapt to different languages. 3) We conducted extensive experiments on different datasets and languages to show that adversarial texts generated by `SemAttack` are more semantically close to the benign inputs, and achieve much higher attack success rates than existing attack algorithms in different settings. 4) Comprehensive studies demonstrate that SOTA LMs and defenses are still vulnerable to `SemAttack`, and human evaluation verifies the naturalness and validity of our adversarial examples.

2 `SemAttack`

2.1 Problem Formulation

Given an input $\boldsymbol{x} = [x_0, x_1, ..., x_n]$, where x_i is the i-th input token, the classifier f maps the input to final logits $\boldsymbol{z} = f(\boldsymbol{x}) \in \mathbb{R}^C$, where C is the number of classes, and outputs a label $y = \arg\max f(\boldsymbol{x})$.

During attack, we evaluate the effectiveness of attack algorithms by calculating the targeted attack success rate (TSR):

$$\text{TSR} = \frac{1}{|D_{\text{adv}}|} \sum_{\boldsymbol{x}' \in D_{\text{adv}}} \mathbb{1}[\arg\max f(\boldsymbol{x}') \equiv y^*] \tag{1}$$

and untargeted attack success rate (USR):

$$\text{USR} = \frac{1}{|D_{\text{adv}}|} \sum_{\boldsymbol{x}' \in D_{\text{adv}}} \mathbb{1}[\arg\max f(\boldsymbol{x}') \neq y] \tag{2}$$

where the attack algorithm generates one adversarial sentence for each sample to form an adversarial dataset D_{adv} , y^* is the targeted false class, y is the ground truth label, and $\mathbb{1}(\cdot)$ is the indicator function.

2.2 Semantic Perturbation Functions

To control adversarial examples to be semantically close to the original input, we design a general form of semantic perturbation function $\mathcal{F}$, which takes one token x as input, and returns its candidate perturbation space $\mathcal{S} = \{x_0^*, x_1^*, ..., x_n^*\}$. We next discuss the types of perturbation function $\mathcal{F}$.

Typo-based Perturbation Function $\mathcal{F}_T$ constrain the search space $\mathcal{S}$ in the *typo space*, which uses typo words or characters to replace original tokens so that human can still understand the original meaning while models are fooled. In English, we follow the generation process introduced in TextBugger (Li et al., 2018) to generate typos.

In order to illustrate how our proposed method can be easily adapted to multilingual settings, we also generate typo-based semantic space for Chinese. Specifically, for each Chinese token x, we prepare a set of common Chinese characters $\mathcal{S}$ that look similar ("形近字") or have the same pronunciation ("音近字") as the original token x. We use the open-source similar Chinese character list that contains more than 9,000 common Chinese characters. To search for the Chinese characters with the same pronunciation (*i.e.,* pinyin), we first query the pronunciation of input x and then choose the characters returned based on the same pronunciation. If x is a heteronym that has multiple pronunciations, we only use one pronunciation to do the query. We also limit the size of Chinese characters of the same pronunciation to be less than 6 so that the search space is not too large. For the Chinese example shown in Table 1, we use "甚" to replace "什" as they share the same pronunciation and are a common typo that will not affect human understanding.

Knowledge-based Perturbation Function $\mathcal{F}_K$ considers the *knowledge space* to constrain the perturbation search space $\mathcal{S}$. Specifically, $\mathcal{F}_K$ utilizes existing knowledge base to build a candidate perturbation set. In our work, we use WordNet as an example to illustrate how our framework can integrate rule-based knowledge to enhance the quality of adversarial examples. WordNet is a large lexical dataset of more than 200 languages that groups words into sets of cognitive synonyms. With the manually labeled semantic relations among words, synonyms queried from WordNet (*i.e.*, synsets) share the same semantic meaning as the query word x. Therefore we choose these synonyms returned from WordNet to be the search space $\mathcal{S}$. We note that WordNet also contains hypernyms and hyponyms information, but including them into the search space may incur some unnatural replacement (*e.g.*, replacing "fifth" with "rank"). Therefore, we only consider synsets as the candidate search space $\mathcal{S}$. In addition, even for the same token (*e.g.*, "use") in WordNet, it may have different part-of-speech (POS) tags (*e.g.*, "use" as verb or as noun), and thus has different synonyms (*e.g.,* "exploitation" for noun "use" and "practice" as verb "use"), which may result in nonsensical replacement. In order not to include synonyms that have unusual part of speech, we counted the frequency of POS in the synset and only selected the words with the most frequent POS. Using the synonym set $\mathcal{S}$ after filtering, we are able to generate adversarial input texts that mislead models' prediction while barely affect on human understanding.

Contextualized Semantic Perturbation Function $\mathcal{F}_C$ is a novel perturbation function that explores the BERT embedding space and searches for contextualized perturbation to tackle the issue of most language tokens being polysemous. Previous work (Li et al., 2018; Jin et al., 2020) takes it as a standard practice to use the proximity in embedding space to query the semantic similarity. However, their embedding space is built on a non-contextualized word embedding from GLoVE (Pennington et al., 2014) or Word2Vec (Mikolov et al., 2013), thus failing to consider the polysemy when generating the perturbation. We propose to explore the BERT embedding space, which is verified by (Hewitt and Manning, 2019; Coenen et al., 2019; Papadimitriou et al., 2021) that BERT embeddings can preserve syntactic and semantic information for word sense disambiguation better than GLoVE or Word2Vec. So the contextualized space from $\mathcal{F}_C$ is valid semantic perturbations. Similar to our parallel work (Li et al., 2020) of using BERT to generate adversarial perturbations, $\mathcal{F}_C$ also does not require external linguistic resources such as POS checker. Thus $\mathcal{F}_C$ can be adapted to other languages, as long as pre-trained BERT of such language models is available.

Specifically, we first choose a set of commonly used tokens $\mathcal{X}$. For each word $x \in \mathcal{X}$, we select at most 100 example sentences from Wikipedia that contain the word x so that these sentences represent different meanings of x in different contexts. We then feed these sentences into a pretrained BERT model to obtain the contextualized embeddings for each word x. Finally, the contextualized embeddings for all words in $\mathcal{X}$ formulate a large BERT embedding space. Figure 1 visualizes a BERT embedding space projected into 2D space by PCA.

To query the search space $\mathcal{S}$ for token x, we first calculate the BERT embedding of token x given its context sentence. Even for the same token, given different contexts and meanings, BERT will generate distinct representations in the high dimensional embedding space. For the example in Figure 1, the token "experienced" given different contexts have different latent representations and neighbors. Then we use k nearest neighbors (KNN) algorithm to choose the neighbors of the contextualized embedding of x as its perturbation search space $\mathcal{S}$. To ensure high quality of search space $\mathcal{S}$, we further filter $\mathcal{S}$ and only return the words that appear more frequently than a threshold ϵ among k nearest neighbors. In this way, we remove the noisy tokens that are rarely used and retain the high-quality neighbor tokens whose contextualized semantics are mostly close to the original token x.

Discussion. The final search space $\mathcal{S}$ can be the union of the search spaces mentioned above. This makes existing defense algorithm (Jones et al., 2020) difficult to apply, as they can only defend against typo-based perturbation but fails to detect other types of perturbation.

$\mathcal{F}$ is a generalization of most existing word-level textual adversarial attacks. Though $\mathcal{F}_T$ and $\mathcal{F}_K$ have been discussed in the previous literature (see §Related Work), we note that the goal of our paper is not to improve or propose better typo or knowledge perturbation, but to consider multiple semantic spaces at the same time to help generate natural high-quality adversarial examples.

2.3 Attack Algorithm `SemAttack`

The full pipeline is shown in Appendix Algorithm 1. Essentially, `SemAttack` searches for the optimal perturbations from different semantic spaces determined by semantic perturbation functions, which is efficiently solved as an optimization problem so that we only perturb as few tokens as possible while achieving the targeted attack.

Unlike generating adversarial examples in the continuous data domain, it is difficult to directly utilize the gradient to guide token substitution due to the discrete nature of text. Thus, we search perturbation in the embedding space and map the perturbed embedding back to tokens. Specifically, the one-hot representation of each discrete token $\boldsymbol{x_i} \in \mathbb{R}^{|V|}$ (V is the vocabulary set) is mapped into an embedding space of dimension d_c via the embedding matrix $\boldsymbol{M_e} \in \mathbb{R}^{d_c \times |V|}$

$$[\boldsymbol{e_1}; \boldsymbol{e_2}; ...; \boldsymbol{e_n}] = \boldsymbol{M_e}\Big[\boldsymbol{x_0}; \boldsymbol{x_1}; ...; \boldsymbol{x_n}\Big]. \qquad (3)$$

We optimize perturbation $\boldsymbol{e}^*$ added to the original embedding $\boldsymbol{e}$ for m iterations. In each iteration, we freeze all the parameters of the classifier f and optimize variable $\boldsymbol{e}^*$ only. Following Carlini and Wagner (2016), we minimize the loss function as:

$$\mathcal{L}(e^*) = ||e^*||_p + c \cdot g(\boldsymbol{x'}), \qquad (4)$$

where the first term controls the magnitude of perturbation, while $g(\cdot)$ is the attack objective function depending on the attack scenario. c weighs the attack goal against attack cost.

In *targeted attack* scenarios, we define $g(\cdot)$ as:

$$g(\boldsymbol{x'}) = \max[\max\{f(\boldsymbol{x'})_i : i \neq t\} - f(\boldsymbol{x'})_t, -\kappa],$$

where t is the targeted false class and $f(\boldsymbol{x'})_i$ is the i-th class logit. A larger κ encourages the classifier to output targeted false class with higher confidence.

In *untargeted attack* scenarios, $g(\cdot)$ becomes

$$g(\boldsymbol{x'}) = \max[f(\boldsymbol{x'})_t - \max\{f(\boldsymbol{x'})_i : i \neq t\}, -\kappa],$$

where t is the ground truth class.

After each iteration of gradient descent, we have an optimized perturbation $\boldsymbol{e}^*$ in the embedding space that tends to fool the classifier f with small perturbations. We choose the perturbed token $\boldsymbol{x_i'} \in \mathcal{S} = \mathcal{F}(x_i)$ that is from the semantic search space $\mathcal{S}$ returned by $\mathcal{F}(x_i)$ and semantically closest to the perturbed embedding $\boldsymbol{e}'_i$.

$$\begin{aligned} \boldsymbol{e}'_i &= \boldsymbol{e}_i + \boldsymbol{e}^*_i, \\ \boldsymbol{x}'_i &= \arg\min_{\boldsymbol{x}'_i \in \mathcal{S}} (||\boldsymbol{e}'_i - \boldsymbol{M}_e \boldsymbol{x}'_i||_p). \end{aligned} \quad (5)$$

Finally, we obtain an optimal perturbation $\boldsymbol{e}^*$ after repeating the optimization step and token substitution step for m iterations. Under such settings and constraints, most tokens remain the same and very few are perturbed to their semantically close neighbors. Thus, the adversarial examples still look valid to humans but can fool the models.

3 Experimental Results

In this section, we conduct comprehensive experiments to evaluate our attack method in various settings. We **first** apply our attack method to two standard NLP models, BERT and SOTA Self-Attention LSTM. We evaluate on *two different types of NLP tasks*, sentiment analysis and natural language inference (NLI). **Secondly**, we investigate the effectiveness of `SemAttack` against SOTA large-scale language models and defense methods. **Thirdly**, we take Chinese as an example to measure `SemAttack`'s generalization ability across different languages. We evaluate BERT models finetuned on two Chinese datasets. **Finally**, we conduct extensive human evaluations on both English and Chinese datasets.

We find that: 1) `SemAttack` can achieve better attack success rates than existing textual adversarial attack methods with better language quality and adversarial transferability. 2) SOTA LMs and defense methods are still vulnerable to our `SemAttack`. 3) `SemAttack` is a general textual adversarial attack framework and can be easily adapted to other languages in addition to English with high attack success rates. 4) Adversarial examples generated by `SemAttack` are natural and barely affect human performance.

3.1 Whitebox and Blackbox Attack

Datasets For sentiment classification task, we choose the standard 5-class sentiment classification dataset, Yelp dataset. Note that unlike previous work (Li et al., 2020; Jin et al., 2020) that uses binary sentiment classification dataset, we focus on the standard 5-class Yelp dataset to further evaluate the **targeted attack capability** of `SemAttack`. For NLI task, we choose SNLI dataset. The detailed dataset descriptions are in Appendix §C.

Models We evaluate the robustness of *BERT* and *Self-Attention LSTM* (Lin et al., 2017). We present their test accuracy on the benign test sets in Table 2. More hyperparameter settings and training details are discussed in Appendix §B.

Attack Baselines We consider SOTA whitebox and blackbox attack baselines.

- **HotFlip** (Ebrahimi et al., 2017) is a whitebox attack method for generating adversarial examples on both character-level and word-level. In terms of preserving semantic meaning, we only use word-level attacks in our experiments, which uses gradient-based optimization method to flip words.
- **TextFooler** (Jin et al., 2020) is a blackbox attack method for generating adversarial text, which uses similarities between pre-calculated word embeddings to find synonyms for each word.
- **BERT-Attack** (Li et al., 2020) is a strong blackbox attack method using pre-trained masked language models such as BERT to replace words in input sentences, where pre-trained masked language models provide candidate words that have high semantic similarity between original texts.

These methods all perform untargeted attacks. We adapt them to both untargeted and targeted attack settings in our experiments.

Attack Goal In the sentiment analysis task, we consider the **targeted attack**, and choose the most opposite sentiment class as the targeted class, so sentences with original label lower than 2 (*negative*) are attacked to class 4 (*most positive*), and others are attacked to class 0 (*most negative*). In the NLI task, *Contradiction* and *neutral* will be attacked to *entailment* while *entailment* will be attacked to *contradiction*.

Adversarial Attack Evaluation We perform `SemAttack` on BERT and LSTM-based classifiers in both the whitebox and blackbox settings. The whitebox setting approximates the worst-case scenario, where attackers have the access to the model parameters and gradients; while the blackbox setting assumes that attackers can only access the model's output confidence.

For the **whitebox attack** shown in Table 2, `SemAttack` can outperform all the SOTA baselines and achieve the highest success rates in both untargeted and targeted settings for BERT and LSTM-based models with smaller or comparable perturbation rates. For example, untargeted `SemAttack` achieves 97.6% attack success rate

Model	Attack Method	% USR/TSR	% Perturbation

Table 3: Zero-query blackbox attack success rate for different attacks under targeted/untargeted attacks (TSR/USR) and corresponding word perturbation percentage against large-scale LMs and defense methods on SNLI datasets.

for BERT models by perturbing 4% words on the Yelp dataset, when searching from the combination of the semantic spaces of $\mathcal{F}_T$, $\mathcal{F}_K$ and $\mathcal{F}_C$.

To adapt `SemAttack` to the blackbox attack setting, we distill the blackbox (teacher) model to train a whitebox (student) model, and *transfer* the adversarial examples from the whitebox student model to attack the blackbox model. More details can be found in Appendix §D.

For the **blackbox attack** shown in Appendix Table 8, the transferability-based `SemAttack` achieves higher attack success rates than SOTA blackbox attacks for self-attention LSTM. We also observe that BERT-ATTACK achieves a higher attack success rate on BERT than `SemAttack`. We think it is mainly because that BERT-ATTACK adopts an aggressively large candidate perturbation size (top-k=48), which may lead to large semantic changes (indicated by the worse human performance as shown in Table 5). For instance, we observe that some words are even changed to their antonym in BERT-ATTACK. On the contrary, the average size of search spaces for `SemAttack` (+all) is only 11.87, aiming to guarantee the naturalness and validity of the generated adversarial examples. We present more details of our semantic space in Appendix §D.3.

In addition, we observe that Self-Attention LSTM models are more robust than BERT in most settings. For example, we achieve the highest USR of 88.1% in whitebox attack on the Yelp dataset, which is 9.5% lower than BERT in the same setting. This suggests that self-attention mechanism can improve the robustness of vanilla WordLSTM by a large margin, as WordLSTM is known less robust than BERT (Jin et al., 2020).

3.2 Attack SOTA LMs and Defense Methods

In this section, we evaluate `SemAttack` and baseline attacks against various SOTA large-scale language models and defense methods.

Dataset and Attack Baselines Following §3.1, we evaluate `SemAttack` on SNLI dataset. We choose the same blackbox attack methods, TextFooler and BERT-Attack, as our baselines.

Models We consider the following models and defense methods following the Adversarial GLUE Benchmark (Wang et al., 2021). The selected large-scale models and defense methods not only represent SOTA performance on NLU tasks, but also achieve the highest robustness in the leaderboard.

- **DeBERTa (He et al., 2020)** improves BERT-based models by introducing disentangled attention mechanism and enhanced mask decoder, which is one of the best models in the GLUE leaderboard (Wang et al., 2018). In our experiment, we use DeBERTa (Large) and DeBERTa (XXLarge-v2).
- **FreeLB (Zhu et al., 2019)** is an adversarial training algorithm that defends adversarial attacks by adding perturbations to word embeddings and

minimizing the corresponding adversarial loss.

Attack Goal To demonstrate the model robustness in an approximately real-world scenario, we consider a **zero-query setting**, a more rigorous and common scenario that assumes the target models are not accessible during the attack phase. Since we can not access the target model, we perform a transferability-based backbox attack. Specifically, we attack the selected language models and defense methods using adversarial SNLI texts generated by `SemAttack` against BERT classifier in §3.1.

Adversarial Attack Evaluation We finetune the above models on the SNLI dataset and attack them using adversarial texts generated against BERT. The results are shown in Table 3.

For the **zero-query setting**, `SemAttack` always achieves the highest success rates. Specifically, among all the attack methods, `SemAttack` (+$\mathcal{F}_T$) always has the highest USR regardless of the model it is tested on. For example, on the largest model, DeBERTa (XXLarge-v2), we achieve 90.5% USR, which is 7.1% higher than BERT-ATTACK.

Furthermore, we find that *increasing the number of model parameters and expanding the model architecture have little effect on defense against adversarial attacks*. DeBERTa (XXLarge-v2), for example, is substantially larger than DeBERTa (Large), yet the attack success rates are similar. In some cases DeBERTa (XXLarge-v2) is even less robust than DeBERTa (Large). We also observe that introducing some defense strategies slightly improves the model's robustness. When we use the defense strategy of FreeLB, we can see that the robustness increases, but it is still not satisfactory to defend existing adversarial attacks.

3.3 Adapt `SemAttack` to Chinese

Datasets We evaluate our performance on the following two datasets in Chinese: 14-category news classification dataset THUNews (Sun et al., 2016) and 11-class Wechat Finance dataset. More details about these datasets are introduced in Appendix C.

Models We use BERT pre-trained on Chinese corpora and finetune on the two datasets separately. After finetuning, our BERT achieved 0.818 accuracy on THUNews dataset and 0.891 on Wechat Finance Dataset, as shown in Table 4

Attack Baselines Since both TextFooler and BERT-Attack adopt an aggressively large perturbation candidate space and thus require additional language resources (e.g., POS checker; stop words filtering) to ensure the proposed candidate words are valid, they cannot be adapted to Chinese due to the lack of corresponding language resources. Therefore, we adapt **HotFlip** for Chinese classification task, since it does not rely on any other linguistic resources. We also adapt it to transferability-based blackbox attack settings as well as the targeted attack setting for fair comparison.

Dataset	Setting	Attack Method	% USR/TSR	% Perturbation
THUNews (Acc: 0.818)	White-box Attack	HotFlip	81.4/40.4	21.7/27.9
		`SemAttack` (+$\mathcal{F}_T$)	96.6/81.7	20.1/34.7
		`SemAttack` (+$\mathcal{F}_K$)	15.6/3.6	16.1/17.4
		`SemAttack` (+$\mathcal{F}_C$)	95.0/78.3	17.4/29.4
		`SemAttack` (+all)	**99.0/92.1**	15.1/26.3
	Black-box Attack	HotFlip	44.3/10.0	15.4/10.8
		`SemAttack` (+$\mathcal{F}_T$)	52.3/34.0	19.7/35.3
		`SemAttack` (+$\mathcal{F}_K$)	8.4/1.3	12.7/13.1
		`SemAttack` (+$\mathcal{F}_C$)	55.9/37.0	17.6/28.6
		`SemAttack` (+all)	**58.6/48.2**	16.4/25.8
Wechat (Acc: 0.891)	White-box Attack	HotFlip	95.2/0.0	11.4/-
		`SemAttack` (+$\mathcal{F}_T$)	86.0/88.3	7.2/12.4
		`SemAttack` (+$\mathcal{F}_K$)	32.8/24.5	5.2/7.6
		`SemAttack` (+$\mathcal{F}_C$)	96.8/96.4	5.8/9.4
		`SemAttack` (+all)	**98.7/98.0**	4.6/8.7
	Black-box Attack	HotFlip	21.7/0.0	8.9/-
		`SemAttack` (+$\mathcal{F}_T$)	49.4/35.8	7.3/17.4
		`SemAttack` (+$\mathcal{F}_K$)	19.5/11.7	4.0/7.7
		`SemAttack` (+$\mathcal{F}_C$)	51.8/**42.4**	5.3/12.2
		`SemAttack` (+all)	**54.5**/36.7	4.0/11.7

Table 4: Whitebox and blackbox attack success rate for different attacks under targeted/untargeted attacks (TSR/USR) and corresponding word perturbation percentage against Chinese BERT on THUNews and Wechat Finance datasets.

Attack Goal In this paper, we choose the targeted attack class as "technology news" for THUNews dataset and "Bank" for Wechat dataset (when the ground truth label is the targeted class, we switch the target to another random class). This strategy achieves the highest targeted attack success rate as shown in Appendix F.7.

Adversarial Attack Evaluation In the **whitebox attack** scenario in Table 4, `SemAttack` is able to make the model mistakenly classify nearly all sentences with only a small number of characters being manipulated in both targeted and untargeted settings. The untargeted attack achieves 99% success rate by substituting merely two tokens on average on the THUNews dataset. On Wechat Finance dataset, it achieves 98.7% attack success rate by perturbing 4.6% tokens on average in the input sequences. In the targeted attack scenario, we always make BERT output as our expected false class on both datasets, resulting in a huge performance drop on BERT models. We achieve 92.1% and 98.0% on THUNews dataset and Wechat Finance dataset, respectively.

Dataset	Attack Method	% Perturbation	PPL	BertScore	Human Ratings
Yelp (English)	HotFlip	14.9	57.1	0.79	3.337 ± 1.650
	TextFooler	13.5	43.7	0.78	3.361 ± 1.326
	BERT-ATTACK	**4.2**	**31.4**	**0.92**	3.513 ± 1.280
	`SemAttack` (+all)	4.3	34.4	0.91	**3.524** ± **1.584**
THUNews (Chinese)	HotFlip	21.7	488.3	0.60	3.770 ± 1.061
	`SemAttack` (+all)	**15.1**	**317.4**	**0.76**	**3.846** ± **0.906**

Table 5: Language quality evaluation for the generated adversarial texts in both Chinese and English.

Dataset		Human	BERT
Yelp (English)	clean	0.9562 ± 0.0006	0.706
	adversarial	0.9390 ± 0.0010	0.000
THUNews (Chinese)	clean	0.9400 ± 0.0014	0.818
	adversarial	0.9369 ± 0.0015	0.000

Table 6: Human performance compared to BERT classifiers on the original and adversarial datasets.

We also present the **blackbox attack** results in Table 4. We can see that `SemAttack` (+all) achieves the highest success rates in most cases, which suggests that our semantic perturbation spaces have high adversarial transferability. Note that we do not present the targeted attack on Wechat Finance dataset for HotFlip since all attack attempts failed.

Ablation Studies We conduct a series of ablation studies such as exploration of BERT embedding space, attack strategies, ℓ_p norm selection for Eq.(4), hyper-parameter selection, and attack efficiency comparison, etc. in Appendix F.

3.4 Adversarial Text Quality Evaluation

To confirm that our generated adversarial texts are valid and natural to humans, we conduct both *automatic evaluation* and *human evaluation* on both English and Chinese NLP tasks, considering language quality and utility preservation. More evaluation details can be found in Appendix G.

Language Quality Evaluation We sample 100 original sentences from the test set for both Chinese and English such that all of them can be successfully attacked by `SemAttack` and our baselines. For automatic evaluation, we consider the average perturbation rate, perplexity (PPL) (based on GPT-2), and BertScore as metrics to indicate the language quality. For human evaluation, we present every generated adversarial sentence to 5 human annotators, ask them to rate the language quality from 1 to 5, and calculate the average ratings. We present the evaluation results in Table 5.

We can see that `SemAttack` has the best human ratings across different baselines for both Chinese and English. In terms of automatic evaluation metrics, we observe that `SemAttack` is quite close to the SOTA BERT-ATTACK. We think the reason why `SemAttack` is slightly weaker than BERT-ATTACK in terms of PPL and BertScore is that `SemAttack` also considers typos and knowledge-based perturbations. Such perturbations usually look good to humans, but may greatly impact the scores calculated by pretrained language models such as GPT-2 and BERT.

Utility Preservation Evaluation To evaluate human performance on our generated adversarial data, we randomly sample 50 clean sentences and 50 adversarial sentences generated by the targeted `SemAttack` (+all) for both the English Yelp and the Chinese THUNews dataset. For each sentence, we present the annotators with two labels: a ground truth label and a targeted wrong label (e.g., the most opposite sentiment), and request annotators to choose the correct one. Both clean text and adversarial text are randomly shuffled.

The detailed evaluation results with standard deviation are shown in Table 6. We find that our adversarial text barely impacts human perception, as the human performance on adversarial Yelp data is 93.9%, only 2% lower than the clean data. Human performance on the adversarial Chinese THUNews is 93.7%, which is very close to the performance of 94.0% on the clean dataset.

4 Related Work

Our proposed semantic perturbation functions generalize the existing textual adversarial attacks.

For typo-based perturbation function $\mathcal{F}_T$, existing work (Li et al., 2018; Ebrahimi et al., 2017) applies character-level perturbation to carefully crafted typo words (*e.g.*, from “foolish” to “fo0lish”), thus making the model ignore or misunderstand the original statistical cues.

Knowledge-based perturbation function $\mathcal{F}_K$ uses knowledge base to constrain the search space. For example, Zang et al. (2020) uses sememe-based knowledge base from HowNet (Dong et al., 2010) to construct a search space for word substitution.

Different from our contextualized semantic perturbation function $\mathcal{F}_C$, other work (Jin et al., 2020; Li et al., 2018) uses a non-contextualized word embedding from GLoVe (Pennington et al., 2014) or Word2Vec (Mikolov et al., 2013) to build synonym candidates, by querying the cosine similarity or euclidean distance between the original and candidate word and selecting the closet ones as the replacements. However, some antonyms also have high cosine similarity in the Word2Vec space. Thus, additional hand-crafted filtering rules are needed to ensure that the meaning is not changed.

Other work (Garg and Ramakrishnan, 2020; Li et al., 2020, 2021) also leverages pre-trained models to generate contextualized perturbations by masked language modeling, which is a parallel work to `SemAttack`, where we explore the BERT embedding clusters to generate high-quality adversarial examples.

In terms of optimization, unlike the *heuristic-based* previous work that uses greedy (Jin et al., 2020) or genetic algorithms (Zang et al., 2020) which search for the optimal perturbations, or *gradient-based* methods (Wang et al., 2020; Guo et al., 2021) which search for perturbation on a tree-autoencoder with only syntactic constraints or a distribution of adversarial examples, we use an *optimization-based* method to efficiently and effectively search for the optimal adversarial perturbation in the semantic preserving spaces to ensure the validity and naturalness of perturbed sentences.

5 Conclusion

In this paper, we propose a novel semantic adversarial attack framework `SemAttack` to probe the robustness of LMs. Comprehensive experiments show that `SemAttack` is able to generate natural adversarial texts in different languages and achieve higher attack success rates than existing textual attacks. We also demonstrate that existing SOTA LMs and defense methods are still vulnerable to `SemAttack`. We expect our study to shed light on future research on evaluating and enhancing the robustness of LMs for different languages.

A Broader Impact

In this paper, we propose an effective and novel adversarial attack framework `SemAttack` to probe the robustness of state-of-the-art NLP models. Our experiments show that even pre-trained large-scale language models for different languages are not robust under `SemAttack`. We will open-source our code to shed light on future research to evaluate and enhance the robustness of NLP models. Considering attackers may leverage our code to perform adversarial attacks to NLP models, we suggest using adversarial training as an effective approach to improving adversarial robustness, and our proposed framework has provided an efficient way to generate these adversarial training data.

B Model Settings

Whitebox Classifier For English dataset, we use BERT and self-attention LSTM as the classifiers. BERT is a transformer (Vaswani et al., 2017) based model, which is unsupervised pretrained on large corpora. We use the 12-layer BERT-base model with 768 hidden units, 12 self-attention heads, and 110M parameters. For self-attention LSTM, we set the self-attention LSTM to 10 attention hops internally, and use a 300-dim BiLSTM and a 512-units fully-connected layer before the output layer.

We fine-tune BERT on Yelp dataset with a batch size of 64, learning rate of $2e-5$ and early stopping. We train the Self-attention LSTM-based model on 500K review training set for 29 epochs with stochastic gradient descent optimizer under the initial learning rate of 0.1. We run our experiments on i7-7820X CPU with 128GB memory on one RTX 2080Ti GPU.

For both Chinese datasets, we use BERT (Devlin et al., 2019) as the classifier. Chinese BERT is a transformer (Vaswani et al., 2017) based model, which is unsupervisedly pretrained on large Chinese corpora and is effective for downstream Chinese NLP tasks. We use the 12-layer BERT-base model with 768 hidden units, 12 self-attention heads and 110M parameters. We fine-tune BERT on each dataset independently with a batch size of 64, learning rate of 2e-5 and early stopping.

Blackbox Classifier The blackbox LSTM and BERT classifiers are trained/finetuned from scratch. The parameters of blackbox models are different from the whitebox ones.

C Dataset Details

- **Yelp Dataset** consists of 2.7M yelp reviews and each one has its corresponding star level to be predicted by our model. The target stars level is an integer number in the inclusive range of $[0, 4]$, which can be treated as 5 classes. We follow the process in Lin et al. (2017) to randomly select 500K review-star pairs as the training set, $2,000$ as the development set, and $2,000$ as the test set.
- **SNLI Dataset** (Bowman et al., 2015) consists of 570k human-written English sentence pairs and each pair contains one premise and one hypothesis. These pairs are manually labeled as entailment, contradiction, or neutral, which can be predicted by our model. We use 550k pairs as training set, 10k as the development set, and 10k as the test set. We follow the baseline setting (Li et al., 2020) and only allow perturbations on hypotheses (Table 2) or premises (Appendix Table 9 & 10).
- **THUNews (Sun et al., 2016)** is a public Chinese 14-category news classification dataset. It consists of more than 740k news articles from Sina News between 2005 and 2011. These articles are classified into 14 categories, such as education, technology, society and politics. To speed up the evaluation process, we use the news titles for classification. We evenly sample articles from all classes, and use $585,390$ articles as the training set, $250,682$ as the development set, and another $1,000$ as the testing set for the adversarial evaluation.
- **Wechat Finance Dataset** is a private dataset from the Wechat team, who collect $13,051$ subscription accounts in the finance domain. They use crowd-sourcing to classify the account into 11 sub-classes, such as insurance, banks and funds. Each account description has 94.18 Chinese characters on average. We split the dataset into training set ($10,000$ descriptions), validation set ($1,163$ descriptions) and test set ($1,888$ descriptions).

Dataset	avg length	LSTM Acc	BERT Acc
Yelp	135	0.705	0.706
SNLI	13(P)/7(H)	0.716	0.829

Table 7: Statistics of Yelp Dataset and SNLI Dataset together with benign accuracy of two models. In SNLI Dataset, we calculate the average length of premises (P) and hypotheses (H) separately.

Algorithm 1 `SemAttack`: Generating multilingual natural adversarial examples

```
Input: Input tokens $\boldsymbol{x} = [\boldsymbol{x_0}, \boldsymbol{x_1}, ..., \boldsymbol{x_n}]$, classifier $f : \boldsymbol{x} \rightarrow \boldsymbol{z}$ maps input to logits, attack objective function $g(\cdot)$, embedding matrix $\boldsymbol{M_e}$, constants $c$ and $\kappa$, max iteration steps $m$, semantic perturbation function $\mathcal{F}$
Output: Adversarial text $x'$
Initialize perturbation $\boldsymbol{e_0^*} \leftarrow 0$
$\boldsymbol{e} \leftarrow \boldsymbol{M_e x}$
$\boldsymbol{e'} \leftarrow \boldsymbol{e} + \boldsymbol{e_0^*}$
$\boldsymbol{x'} \leftarrow \boldsymbol{x}$
for $k = 0, 1, ..., m-1$ do
    // Phase I: Optimize over the $\boldsymbol{e_k^*}$
    $\mathcal{L}(\boldsymbol{e_k^*}) \leftarrow ||\boldsymbol{e_k^*}||_p + c \cdot g(\boldsymbol{x'})$
    $\boldsymbol{e_{k+1}^*} \leftarrow \boldsymbol{e_k^*} - \alpha \nabla \mathcal{L}(\boldsymbol{e_k^*})$
    // Phase II: Token Substitution
    $\boldsymbol{e'} \leftarrow \boldsymbol{e} + \boldsymbol{e_{k+1}^*}$
    for $i = 1, 2, ..., n$ do
        $\mathcal{S} = \mathcal{F}(x_i)$ // Get the perturbation search space
        $\boldsymbol{x_i'} \leftarrow \arg\min_{\boldsymbol{x_i'} \in \mathcal{S}}(||\boldsymbol{e_i'} - \boldsymbol{M_e x_i'}||_p)$
    end for
end for
return $\boldsymbol{x'}$
```

D Experimental Setting

D.1 Attack Setup

`SemAttack` is a whitebox attack method which requires access to the model parameters and gradients. However, it can be easily adapted to blackbox settings. In our experiment, we consider the following two blackbox settings: a soft-label blackbox setting and a more rigorous zero-query blackbox setting. In soft-label blackbox setting, attackers can only query the classifier for output probabilities on a given input. We adapt our method to this setting by distillation. The output confidence of the blackbox (teacher) model is used to train a student model. Then we run whitebox attacks on the student model and attack the teacher model with adversarial instances provided by the student model. In zero-query blackbox setting, the target models (usually state-of-the-art large-scale language models enhanced with cutting-edge defense methods) are unavailable during the attacking phase, which is a common scenario in real-world applications and better demonstrates the algorithm's ability to generalize across models. We adapt `SemAttack` and baseline methods to this setting by performing a transferability-based backbox attack, in which we use adversarial texts created by BERT to attack the target models.

D.2 Embedding Space Construction

To construct the contextualized semantic perturbation function $\mathcal{F}_C$, we select $22,271$ English words commonly used as $\mathcal{X}$, which is also the vocabulary used by English BERT. For each word, We select at most 100 sentences that contain this specific word from wikidump. These contextualized embeddings form an embedding space of $2,181,622$ vectors in total. We choose $k = 700$ and $\epsilon = 8$, which means we only choose words that appear more than 8 times in the 700 nearest neighbors as the perturbation set $\mathcal{S}$. We apply similar strategies when constructing Chinese BERT embedding space, by choosing $5,178$ Chinese tokens appearing in the training data and up to 100 sentences from Chinese Wikipedia, which form an embedding space of $508,619$ vectors in total. When performing KNN, we choose $k = 700$ and $\epsilon = 5$. The query time of $\mathcal{F}_C$ is around 2.6s for English and 0.9s for Chinese. We provide more detailed settings in Appendix E.

D.3 Semantic Perturbation Functions

English We evaluate the following semantic perturbation functions for English corpus: typo-based perturbation function $\mathcal{F}_T$, knowledge-based perturbation function $\mathcal{F}_K$, and contextualized semantic perturbation function $\mathcal{F}_C$ based on BERT embedding clusters, together with the combination of $\mathcal{F}_T$, $\mathcal{F}_K$ and $\mathcal{F}_C$. The average sizes of search spaces obtained by $\mathcal{F}_T$, $\mathcal{F}_K$ and $\mathcal{F}_C$ are 5.03, 2.38 and 4.46, respectively.

Chinese We implement semantic perturbation functions for Chinese corpora as follows: (1) typo-based perturbation function $\mathcal{F}_T$, where typos are defined as Chinese characters with similar strokes or pronunciations, (2) knowledge-based perturbation function $\mathcal{F}_K$, where synonyms are obtained from Chinese WordNet, (3) contextualized semantic perturbation function $\mathcal{F}_C$ by Chinese BERT embedding clusters, and (4) the combination of these three functions.

Because in Chinese there are many characters with the same pronunciation, we limit the number of characters obtained by similar pronunciations to 5. The average sizes of perturbation search space collected by $\mathcal{F}_T$, $\mathcal{F}_K$ and $\mathcal{F}_C$ are 8.53, 0.27 and 17.06. $\mathcal{F}_K$ gives fewer candidate perturbations because Chinese WordNet has limited hand-crafted knowledge, while $\mathcal{F}_C$ gives more choices because it searches in BERT embedding space without human supervision.

D.4 Attack Hyper-parameter Settings

For English dataset, we set the max optimization steps m to 100 and use ℓ_2 norm in the loss function (equation 4) that is iteratively optimized via Adam (Kingma and Ba, 2014). Constants c and κ are set to $1e2$ and 1 in Yelp dataset, $1e4$ and 0 in SNLI dataset, which result in higher attack success rate and lower perturbation rate based on a series of ablation studies provided in Appendix Figure 5. We set our random seed to 1111 for reproducibility.

For Chinese dataset, we follow the experiment setting in English attacks for optimizing adversarial examples and training BERT models. Constants c and κ are set to 100 and 1 respectively to get the best performance. We set our random seed to 1111 for reproducibility. We experiment with different attack strategies in Appendix Table 11 to 13.

E `SemAttack` Implementation Details

E.1 Typo-based Perturbation Function Implementation

We use the similar Chinese character list[1] that contains more than 9,000 common Chinese characters. We use the existing Python library[2] to query the pronunciations for Chinese characters and another library[3] to search for the words that share the same pronunciations. Because in Chinese there are many characters with the same pronunciation, we limit the number of characters obtained by similar pronunciations to 5.

E.2 Knowledge-based Perturbation Function Implementation

In this paper, we use WordNet as an example to illustrate how our framework can integrate the rule-based knowledge to enhance the quality of our adversarial examples. For an input token x, we first query the synonym set s in the WordNet. For each meaning of the input word, the output synonym set s contains several synonyms that have this specific meaning. The output synonyms are given with their corresponding part-of-speech tags. In order not to include synonyms that have unusual part of speech, which may result in strange grammatical errors after replacement, we counted the frequency of each part of speech in set s and only selected the words with the highest frequency of part of speech. Using the synonym set after filtering, we are able to generate adversarial input texts that mislead models' prediction while having little effect on human understanding.

F Ablation Studies

F.1 Perturbation space size selection

In Figure 2, 3, we present the attack success rates and perplexity scores of generated adversarial examples under different sizes of perturbation search space. We observe that in both languages, larger K lead to higher attack success rates. In English, PPL score decreases when K continues to increase, while in Chinese PPL score remains at a similar level.

F.2 Attack Efficiency

`SemAttack` is more efficient than existing baselines since it can substantially decrease the query time when performing attacks. SemAttack searches for the optimal perturbation e^* for a whole sentence in one query, instead of querying every word. Quantitatively, `SemAttack` is designed to query the model for less than 100 iterations, while BERT-ATTACK and TextFooler require hundreds of queries to generate one adversarial example on average.

(a) Visualization. (b) Confusion matrix.

Figure 4: Ablation studies. (a) shows the visualization of English words in BERT embedding clusters. (b) shows the TSR confusion matrix on THUNews dataset.

F.3 BERT Embedding Space

In Figure 4a, we visualize three clusters: "car", "bird" and "keyboard". Here "keyboard" is used as an instrument, not a peripheral device of PCs. As we can see, 'bird' has neighbors such as "pigeons", "parrot" and "flyer", which are not present in knowledge space. Word "keyboard" has neighbors such as "drummer", "violin" and "guitarist", which are contextualized based on the query context.

F.4 Additional Results on Attacking SNLI

We follow the setting of (Li et al., 2020) and perturb only hypotheses or premises for SNLI tasks. Attack results for perturbing hypotheses are shown in main paper Table 2. Attack results for perturbing premises only are shown in Table 9 and 10.

F.5 Ablation Studies on Attack Capability

In this section, we will evaluate the possible factors that will affect the attack success rate. Here, we set the candidate search space $\mathcal{S}$ to be the whole vocabulary V to eliminate variables introduced by the perturbation function.

Model	Method	% USR/TSR	% Perturbed

Table 10: The blackbox attack success rate (in terms of "USR/TSR") and corresponding word perturbation percentage against LSTM and BERT on the SNLI dataset by only perturbing premises.

F.6 Norm selection

In the main experiment, we use l_2 norm for our attack loss function (equation 7). However, because l_1 norm is known for good at feature selection and generating sparse features, we conduct the following experiments by setting l_p to l_1 and make an comparison with l_2 norm. The experimental results are shown in Table 11 and 12. We find the overall attack success rates decrease when switching to l_1 norm. However, given the same set of constants c and κ, we find the l_1 attack does change less words.

Dataset	Original		`SemAttack` (l_2 untargeted)			`SemAttack` (l_1 untargeted)			Baseline
	Acc	c/k	5/5	10/5	10/10	10/10	10/100	20/20	(untargeted)
THUCTC	0.818	target	-	-	-	-	-	-	-
		untarget	**1.000**	**1.000**	**1.000**	0.983	0.983	**0.995**	0.040
		#/chars	**1.583**	1.690	1.718	**1.577**	1.614	1.884	2.000

Table 11: Untargeted attack success rates on Chinese BERT-based classifier for THUCTC dataset. “target” and “untarget” calculate the targeted attack success rate (equation 1) and the untargeted attack success rate (equation 2). “#/chars” counts the number characters are modified in average.

Dataset	Original		`SemAttack` (l_1 targeted)			`SemAttack` (l_2 targeted)			Baseline
	Acc	c/k	10/10	10/20	30/30	5/5	10/5	10/10	(untargeted)
THUCTC	0.818	target	0.797	0.797	**0.898**	0.941	**0.945**	**0.945**	-
		untarget	0.828	0.828	**0.920**	0.953	**0.958**	**0.958**	0.040
		#/chars	2.000	**1.956**	3.280	**2.924**	3.186	3.045	2.000

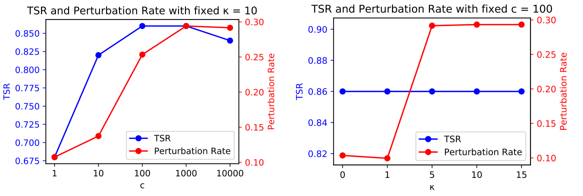
Table 12: Targeted attack success rates on Chinese BERT-based classifier for THUCTC dataset. “target” and “untarget” calculate the targeted attack success rate (equation 1) and the untargeted attack success rate (equation 2). “#/chars” counts the number charcters are modified in average.

F.7 Attack Strategy

As we have achieved 100% attack success rate in the untargeted attack scenario, we now focus on the targeted attack scenario and see which factor contributes to the targeted attack success rate. It is straightforward to think different targeted attack strategies will impact the targeted attack success rate, because maybe some classes look "farther" than semantic closer classes. So we tried two strategies on THUCTC dataset: 1) as used in the main paper, we set the targeted false class as “technology news”. 2) we enumerate all the classes and set the targeted false class to be numerically the next class index. The targeted attack success rate is shown in Table 13. We do find choosing different attack strategies will impact the attack success rate.

F.8 Hyper Parameter Selection

We have two constants in our attack algorithm, c and κ, which control the attack success rates and the perturbation rates in our experiments. In order to find out the impact of these hyper parameters, we test with several combinations of different c and κ. We test on Yelp Dataset and we use BERT as our model. We show our results in Figure 5. As shown in Figure 5a, we first fix $\kappa = 10$ and test how TSR and perturbation rate will change according to different c. We find that under the same κ, c mainly controls the attack success rate at the cost of perturbation rate. In some certain range, a larger c encourages the algorithm to achieve our attack goal with the expense of more substitutions. And after exceeding a certain value, TSR will start to decrease while perturbation rate remains high. We then fix $c = 100$ and test different κ. We show our results in Figure 5b. We find that κ doesn’t help to increase TSR and a smaller κ helps to limit the words changed without affecting TSR.



(a) Fixed κ and different c. (b) Fixed c and different κ.

Figure 5: Hyper parameter selection. In Figure 5a, we first fix $\kappa = 10$ and test different c to see how TSR and perturbation rate will change. we test $c = 1, 10, 10^2, 10^3, 10^4$ and find best $c = 100$ to obtain the highest TSR with less perturbations. A smaller or larger c will result in a low TSR or a high perturbation rate. In Figure 5b, after fixing $c = 100$, we test $\kappa = 0, 1, 5, 10, 15$. We find that κ has little influence on TSR while it can change perturbation rate dramatically. A smaller κ is able to effectively limit the number of words to be changed. In our experiment, we choose $\kappa = 0, 1$.

For hyper-parameter selection for Chinese datasets, we witness the same phenomenon in English attacks that increasing constant c can improve the attack success rate at the cost of more perturbed characters, while lowering constant κ limits the perturbation rate without affecting the attack success rate.

Dataset	Original		`SemAttack` (targeted $c/\kappa = 10/10$)		Baseline
	Acc		strategy 1	strategy 2	(untargeted)
THUCTC	0.818	target	**0.945**	0.903	-
		untarget	**0.958**	0.913	0.040
		#/chars	3.045	4.543	2.000

Table 13: Attack success rates on Chinese BERT-based classifier for two datasets. "target" and "untarget" calculate the targeted attack success rate (equation 1) and the untargeted attack success rate (equation 2). "#/chars" counts the number characters are modified in average.

Transfer	Method	% TSR	% USR
Self-Attention LSTM → BERT	TextFooler	42.4	43.9
	BERT-ATTACK	8.1	33.5
	`SemAttack` (+$\mathcal{F}_T$)	44.4	32.5
	`SemAttack` (+$\mathcal{F}_K$)	57.7	62.0
	`SemAttack` (+$\mathcal{F}_C$)	**74.3**	**81.2**
	`SemAttack` (+all)	70.0	79.8
BERT → Self-Attention LSTM	TextFooler	30.8	31.9
	BERT-ATTACK	17.6	28.5
	`SemAttack` (+$\mathcal{F}_T$)	26.8	34.6
	`SemAttack` (+$\mathcal{F}_K$)	35.3	35.6
	`SemAttack` (+$\mathcal{F}_C$)	**35.5**	**36.0**
	`SemAttack` (+all)	30.9	31.0

Table 14: Targeted and untargeted attack success rate of transferability attack on Yelp Dataset, evaluating adversarial examples generated against Self-attention LSTMs on BERT, and vice versa.

F.9 Vulnerability Between Classes

In THUNews dataset, the article titles are classified into 14 categories. In order to find out the vulnerability of each class, we test the attack success rate of each source class and target class. The heatmap of results is provided in Figure 4b. We find that "technology news" and "entertainment news" as target classes have higher average success rates than other classes, while "lottery ticket" is the lowest. We also find that "constellation news" has the highest average success rate as source class, while "sports news" has the lowest, which means "constellation news" is vulnerable and easy to attack while "sports news" is much more robust.

F.10 Transferability Analysis

We evaluate the transferability of adversarial examples between different models by attacking a blackbox BERT classifier by using adversarial text generated from a whitebox LSTM, and vice versa.

The transferability-based attack results on Yelp Dataset are shown in Table 14. We find that the robustness of the two models is highly different from each other. When we feed adversarial texts generated from the LSTM model into the blackbox BERT model, attack success rate is higher than 70%. However, when we test the performance of the blackbox LSTM model on adversarial texts generated from the whitebox BERT, attack success rate is around 30%, which is much lower than previous experiment. These results show that Self-Attention LSTMs are more robust than BERT models, and the adversarial examples generated from a robust model has higher attack transferability than non-robust one. Therefore, we can attack blackbox BERT models using a strong Self-Attention LSTM trained by ourselves to generate adversarial texts with high success rates. We also observe that the USR of transferability-based attack is generally higher than that of targeted attack. Particularly, we achieve the highest success rate of 81.2% when attacking blackbox BERT with text generated by LSTM attacks under untargeted setting.

Furthermore, we find that the adversarial examples generated by the contextualized semantic perturbation functiuon $\mathcal{F}_C$ have the highest attack transferability, which suggests that our contextualized semantic perturbation is more generalizable than rule-based perturbation functions.

G Human Evaluation Details

Language Quality Evaluation Details We use Amazon Turk for English adversarial example quality annotations, and Alibaba Cloud for Chinese example quality annotations. Each sentence is annotated by 5 annotators. This evaluation only evaluates language quality and grammatical correctness, and thus does not require additional background or domain knowledge.

We present the annotation instructions on Amazon Turk below.

Please **rate the language quality** (from 1 to 5, in terms of coherence, fluency, and grammar correctness) of the presented sentence. 5 means the best language quality, and 1 means the lowest language quality.

- 5: The sentence looks totally correct. There are no grammatical errors. I can fully understand the sentence.

- 4: The sentence looks somewhat correct. There are one or two grammatical errors or typos. But I can mostly understand the sentence.
- 3: The sentence looks OK to me. There are some grammatical errors or typos. I can partly understand the sentence.
- 2: The sentence looks bad to me. There are grammatical errors or typos everywhere. I can understand it a little.
- 1: The sentence totally does not make any sense. I cannot understand it.

Utility Preservation Evaluation Details We use the targeted `SemAttack` to generate the adversarial dataset with with $c/\kappa = 100/1$. In total, we collected annotations from 21 graduate students from US universities for English datasets and 26 annotators from native Chinese speakers for Chinese datasets. Both classification tasks do not require domain knowledge. The detailed human performance results are shown in Table 6.

H Perturbation Search Space Examples

H.1 English Perturbation Search Space $\mathcal{S}$ Examples

Table 15: English Perturbation Search Space $\mathcal{S}$ Examples Generated by `SemAttack` for BERT-based Classifier using $\mathcal{F}_T$, $\mathcal{F}_K$ and $\mathcal{F}_C$. In the first example, we list some words and corresponding candidate sets generated by these functions. We can see that words generated by $\mathcal{F}_C$ reflect the meaning of the current context. For example, when we say that a hotel is *good*, we may say it's *spacious*. When word *come* is followed by *back*, we may mean *return*. In the following two examples, we show that the same word may have different perturbation sets in different contexts. In the second example, by using *order*, the person means that he ordered food. Considering the context, $\mathcal{F}_C$ provides *eat*, *taste* in its candidate set. In the last example, *order* means the person orders a drink. As a consequence, we have *drink* as a verb with a similar meaning in its candidate set.

Input English Text: This was my fifth time traveling to vegas! I have stayed at hotels such as the Bellagio, Aria, Cosmopolitan, the venetian, and fortunately enough got a chance to **stay** at vdara. Considering the reviews I didn't expect vdara to be that-**good** of a hotel! Vdara was extremely **clean**, very modern, new, great customer service, **close** to the strip-connected to the bellagio. easy access to casinos and heart of the strip. Definitely **coming** back to vegas and booking a room at vdara.

$\mathcal{F}_T(stay)$ = stay
$\mathcal{F}_K(stay)$ = quell, last out, bide, persist, stay
$\mathcal{F}_C(stay)$ = staying, stay, vacationing, stays, relax, internship, enroll, stayed, visit, settle

$\mathcal{F}_T(good)$ = good, god
$\mathcal{F}_K(good)$ = estimable, adept, full, effective, dear, beneficial, dependable, good
$\mathcal{F}_C(good)$ = spacious, marvelous, marvel, wonderful, good

$\mathcal{F}_T(clean)$ = clean
$\mathcal{F}_K(clean)$ = blank, clean, uninfected
$\mathcal{F}_C(clean)$ = spacious, luxurious, lively, vibrant, cleanest, cozy, cleaned, renovated, clean

$\mathcal{F}_T(close)$ = close
$\mathcal{F}_K(close)$ = close, conclude, close up
$\mathcal{F}_C(close)$ = connected, near, close, nearer, closeness

$\mathcal{F}_T(coming)$ = coming
$\mathcal{F}_K(coming)$ = come, derive, issue forth, arrive, hail, total, occur, do, fall
$\mathcal{F}_C(coming)$ = returning, traveling, transferring, staying, relocating, visiting, talking, coming

---

Input English Text: Stopped by this place for lunch . **Ordered** the veggie slice and patty they put lettuce cheese and mayo in it and both the slice and patty were amazing. Definitely will be back for more.

$\mathcal{F}_T(Ordered)$ = ordered
$\mathcal{F}_K(Ordered)$ = rate, ordain, arrange, order, regulate
$\mathcal{F}_C(Ordered)$ = ate, tasted, ordered

Input English Text: Love this speakeasy bar. Last time I was at this location it was still the Panda bar. The place itself is super cozy and intimate. We went there to grab a drink before our Ali Wong show. Hubby **ordered** a Hendricks gin tonic (12$-happy hour price?) and I got a cocktail with Pimms (9$ before 9pm). The drinks were HUMONGOUS! So much so I couldnt finish mine and hubby was tipsy lol.

$\mathcal{F}_T(Ordered)$ = ordered
$\mathcal{F}_K(Ordered)$ = rate, ordain, arrange, order, regulate
$\mathcal{F}_C(Ordered)$ = ate, drank, ordered

H.2 Chinese Perturbation Search Space $\mathcal{S}$ Examples

Table 16: Chinese Perturbation Search Space $\mathcal{S}$ Examples Generated by `SemAttack` for BERT-based Classifier using $\mathcal{F}_T$, $\mathcal{F}_K$ and $\mathcal{F}_C$. Chinese characters are intrinsically polysemous, which requires candidate characters to be contextualized. We list four examples here. In the first two examples, we show two different meanings of character “美” in two different sentences. One referring to *the US* which has some other countries’ names in its perturbation set, another meaning *poignant* which is used as an adjective. In the last two examples, we show “长”, a well-known Chinese character that has multiple pronunciations and multiple meanings. We show that our two perturbation functions return different candidate sets. In the third example, “长” means a job title, while in the last example it means *growth*.

Input Chinese Text: 访谈：美国签证官解读学生签证获签要领 **Translation:** Interview: **U.S.** visa officer interprets the essentials of student visa $\mathcal{F}_T$(美) = 芥, 美, 界, 养, 镁, 每, 楣(mustard, nice, world, support, magnesium, each, lintel) $\mathcal{F}_K$(美) = 美(US) $\mathcal{F}_C$(美) = 美, 英, 香, 欧, 日, 澳, 俄, 荷, 德, 港, 华, 葡, 韩(US, Britain, Hong Kong, Europe, Japan, Australia, Russian, Netherlands, Germany, Hong Kong, China, Portugal, Korean)
Input Chinese Text: 陈嘉上《画皮》大换皮凄美爱情赢得眼泪(图) **Translation:** Chen Jia’s "Painted Skin" changes skin, **poignant** love wins tears (photo) $\mathcal{F}_T$(美) = 芥, 美, 界, 养, 镁, 每, 楣(mustard, nice, world, support, magnesium, each, lintel) $\mathcal{F}_K$(美) = 美(poignant) $\mathcal{F}_C$(美) = 寞, 挚, 妙, 美, 腻, 酷, 烂, 凑, 坷, 凄, 惨, 悲, 慨(lonely, sincere, wonderful, nice, greasy, cool, rotten, make up, bumpy, sad, awful, sad, sad)
Input Chinese Text: 北京房协副秘书长陈志谈地产业诚信问题 **Translation:** Chen Zhi, Deputy Secretary-**General** of the Beijing Housing Association, talks about the integrity of the real estate industry $\mathcal{F}_T$(长) = 氏, 氐, 掌, 涨, 长(clan name, foundation, palm, rise, long) $\mathcal{F}_K$(长) = 长(general) $\mathcal{F}_C$(长) = 长, 授, 卿, 员, 师, 委, 厅, 秘, 副, 顾, 官, 董(general, professor, minister, member, teacher, committee, office, secretary, deputy, consultant, official, director)
Input Chinese Text: IMF大幅下调明年全球经济增长预期 **Translation:** IMF sharply lowered its forecast for global economic **growth** next year $\mathcal{F}_T$(长) = 氏, 氐, 掌, 涨, 长(clan name, foundation, palm, rise, long) $\mathcal{F}_K$(长) = 长, 加, 大(growth, increase, increase) $\mathcal{F}_C$(长) = 胀, 增, 膨, 速, 涨, 长, 加, 快(swell, increase, inflate, speed, rise, grow, plus, fast)

H.3 English Adversarial Examples

Table 17: English Adversarial Examples Generated by `SemAttack` for BERT-based Classifier using $\mathcal{F}_T$.

Input (red = Modified character, **bold** = original character.)
Original English Text: I went to AAA **for** their travel service. They could not help me at all with my trip to Belize. They have zilch information and resources. This is a prime destination of American tourists. I was disappointed. **Adversarial English Text:** I went to AAA tor their travel service. They could not help me at all with my trip to Belize. They have zilch information and resources. This is a prime destination of American tourists. I was disappointed. **Model Prediction:** 1-star (most negative) → 5-star (most positive)
Original English Text: I called numerous times and noted that they are going to deliver at a work address between 9 am to 5 pm. They attempted delivery three times after 5 pm. I **got** ups to pick up my parcel and got it delivered on time. **Adversarial English Text:** I called numerous times and noted that they are going to deliver at a work address between 9 am to 5 pm. They attempted delivery three times after 5 pm. I hot ups to pick up my parcel and got it delivered on time. **Model Prediction:** 1-star (most negative) → 5-star (most positive)
Original English Text: Mercedes does the **best** mani and pedi! You really have to go in at least once to see what I mean. **Adversarial English Text:** Mercedes does the bet mani and pedi! You really have to go in at least once to see what I mean. **Model Prediction:** 5-star (most positive) → 1-star (most negative)
Original English Text: I was charged $ 200 to **add** 6 lbs of Freon to my air conditioning. I went to amazon.com and 25 lbs cost $ 120 including shipping. That should be approx $ 29 **for** 6 lbs of Freon. So labor which was 20 min, transportation, and equipment up - keep for john, the service person who came, was $ 171. I feel that's somewhat unreasonable. Just fair warning for the next customer. Update: after listening to my complaint, the owner offered to refund my payment. That was quite reasonable of them. Therefore, I switch my review to 4 stars. **Adversarial English Text:** I was charged $ 200 to ad 6 lbs of Freon to my air conditioning. I went to amazon.com and 25 lbs cost $ 120 including shipping. That should be approx $ 29 fog 6 lbs of Freon. So labor which was 20 min, transportation, and equipment up - keep for john, the service person who came, was $ 171. I feel that's somewhat unreasonable. Just fair warning for the next customer. Update: after listening to my complaint, the owner offered to refund my payment. That was quite reasonable of them. Therefore, I switch my review to 4 stars. **Model Prediction:** 4-star (positive) → 1-star (most negative)
Original English Text: **Liked** how they were open late and also had happy hour specials after 10 pm. We really **liked** the bulgogi and korean prime kalbi. They were marinated very flavor-fully . the mushroom medley and sweet corn were also very good. Would definitely keep this place on my list of late night eats or when iia just craving korean barbecue. **Adversarial English Text:** Lied how they were open late and also had happy hour specials after 10 pm. We really lied the bulgogi and korean prime kalbi. They were marinated very flavor-fully . the mushroom medley and sweet corn were also very good. Would definitely keep this place on my list of late night eats or when iia just craving korean barbecue. **Model Prediction:** 4-star (positive) → 1-star (most negative)

Table 18: English Adversarial Examples Generated by `SemAttack` for BERT-based Classifier using $\mathcal{F}_K$.

Input (red = Modified character, **bold** = original character.)
Original English Text: Like the others below, I had a similar bad experience with this company. I also forgot to check here before I bought the living social deal. I am having some **issues** getting it refunded as well. Maid affordable was a no show, will not **call** back, and does not answer the phone or emails. Definitely take your business to someone else. **Adversarial English Text:** Like the others below, I had a similar bad experience with this company. I also forgot to check here before I bought the living social deal. I am having some topic getting it refunded as well. Maid affordable was a no show, will not shout back, and does not answer the phone or emails. Definitely take your business to someone else. **Model Prediction:** 1-star (most negative) → 5-star (most positive)
Original English Text: Just another reason why I will never bank with chase.... so now you can't deposit any amount of cash without **showing** your id..... so much for just running to the bank quick. **Adversarial English Text:** Just another reason why I will never bank with chase.... so now you can't deposit any amount of cash without usher your id..... so much for just running to the bank quick. **Model Prediction:** 1-star (most negative) → 5-star (most positive)
Original English Text: My 2017 camry got a check engine light and my car had a strong odor of gasoline after service closed, I asked the receptionist if there was anyway they could get me a rental and she said they were closed so she recommended me to come in bright and early at 7am on monday so they could look at my car so I told her I left for work at 6am cause I work in north scottsdale so I told her I didn't not want to drive my car to scottsdale and back because I was afraid my car would blow up or something from the strong odor of gasoline and she put me on hold to talk to a manager. When she came back on the phone she said her manager was going to get a hold of the rental manager to see if someone could come in tomorrow (today now) to get me a rental and I left my name and number and no one has **reached** out to me. It's great to know they don't care if their customer's car blows up on the freeway cause it's not a sale! Thanks avondale toyota you guys rock ! ! ! ! The dealership I work at teaches their receptionist to hand out rentals cause they know stuff like this happens, you guys might want to look into that ! **Adversarial English Text:** My 2017 camry got a check engine light and my car had a strong odor of gasoline after service closed, I asked the receptionist if there was anyway they could get me a rental and she said they were closed so she recommended me to come in bright and early at 7am on monday so they could look at my car so I told her I left for work at 6am cause I work in north scottsdale so I told her I didn't not want to drive my car to scottsdale and back because I was afraid my car would blow up or something from the strong odor of gasoline and she put me on hold to talk to a manager. When she came back on the phone she said her manager was going to get a hold of the rental manager to see if someone could come in tomorrow (today now) to get me a rental and I left my name and number and no one has achieve out to me. It's great to know they don't care if their customer's car blows up on the freeway cause it's not a sale! Thanks avondale toyota you guys rock ! ! ! ! The dealership I work at teaches their receptionist to hand out rentals cause they know stuff like this happens, you guys might want to look into that ! **Model Prediction:** 1-star (most negative) → 5-star (most positive)
Original English Text: I called numerous times and noted that they are going to deliver at a work address between 9 am to 5 pm. They attempted delivery three **times** after 5 pm. I got up to pick up my parcel and got it delivered on time . **Adversarial English Text:** I called numerous times and noted that they are going to deliver at a work address between 9 am to 5 pm. They attempted delivery three meter after 5 pm. I got up to pick up my parcel and got it delivered on time . **Model Prediction:** 1-star (most negative) → 5-star (most positive)

Table 19: English Adversarial Examples Generated by `SemAttack` for BERT-based Classifier using $\mathcal{F}_C$.

Input (red = Modified character, **bold** = original character.)

Original English Text: If you **think** Las Vegas is getting too white trash, don't go near here. This place is like a Steinbeck novel come to life. I kept expecting to see donkeys and chickens walking around. woo - pig - soooeeee this place is awful ! ! !

Adversarial English Text: If you senses Las Vegas is getting too white trash, don't go near here. This place is like a Steinbeck novel come to life. I kept expecting to see donkeys and chickens walking around. woo - pig - soooeeee this place is awful ! ! !

Model Prediction: 1-star (most negative) → 5-star (most positive)

Model Prediction: 1-star (most negative) → 5-star (most positive)

Original English Text: I have used this company twice. The first time they were great. We spent over 5,000 for installation of a new ac unit on a rental property. Since they did an **excellent** job, we had them do a redesign of ac system in our home to improve the cooling in our house. It was one of the most frustrating customer service experiences I've had with a contractor in the 25 years I have lived in phoenix. They didn't complete the job in the time frame they promised. They damaged the faux ceiling in the kitchen, they drilled holes and didn't repair them in the bedroom. They left marks on the ceiling in the **living** room, where they marked to cut a hole and then didn't. Which told me they installers were not skilled or professional. After waiting for 2 months for them to repair the mistake in the kitchen, we gave up and paid to have it repaired. I heard a lot of promises, no solution. I would never use this contractor again.

Adversarial English Text: I have used this company twice. The first time they were great. We spent over 5,000 for installation of a new ac unit on a rental property. Model Prediction: 1-star (most negative) → 5-star (most positive)

Original English Text: There's so many choices of food in Las vegas. Don't choose this place. It is no exaggeration that mcdonalds and arby's have better hash browns, eggs, and bacon. Missed items in the dishes we ordered. All around **disappointment** to the las vegas allure.

Adversarial English Text: There's so many choices of food in Las vegas. Don't choose this place. It is no exaggeration that mcdonalds and arby's have better hash browns, eggs, and bacon. Missed items in the dishes we ordered. All around sorrow to the las vegas allure.

Model Prediction: 1-star (most negative) → 5-star (most positive)

Table 20: English Adversarial Examples Generated by `SemAttack` for BERT-based Classifier using all perturbation functions.

Input (red = Modified character, **bold** = original character.)
Original English Text: I went to AAA for their travel service. They could not help me at all with my **trip** to Belize. They have zilch information and resources. This is a prime destination of American tourists. I was disappointed. **Adversarial English Text:** I went to AAA for their travel service. They could not help me at all with my voyage to Belize. They have zilch information and resources. This is a prime destination of American tourists. I was disappointed. **Model Prediction:** 1-star (most negative) → 5-star (most positive)
Original English Text: My wife and I have been to this location multiple times, and have only had 1 **bad** experience where the people in the check out area were a little brain dead that day. (they told us that the rug we purchased wasn't in stock, then it was, then wasn't, then was again...) Other than that, we are always **helped** right away, and checking out goes quickly. They also have free self serve Starbucks coffee which I always help myself to. **Adversarial English Text:** My wife and I have been to this location multiple times, and have only had 1 worst experience where the people in the check out area were a little brain dead that day. (they told us that the rug we purchased wasn't in stock, then it was, then wasn't, then was again...) Other than that, we are always served right away, and checking out goes quickly. they also have free self serve Starbucks coffee which I always help myself to. **Model Prediction:** 4-star (positive) → 1-star (most negative)
Original English Text: I love shopping at buffalo exchange but when it comes to selling I prefer selling to the phoenix location because the employees are a lot more genuine, there's less of a hipster pretentious vibe there, and I usually sell more there **too**. Not to mention the tempe location usually turns the music off at 8:30, which gives an unwanted feeling to their guests. I am giving two stars for the sake of finding things at all locations. Go phoenix location! **Adversarial English Text:** I love shopping at buffalo exchange but when it comes to selling I prefer selling to the phoenix location because the employees are a lot more genuine, there's less of a hipster pretentious vibe there, and I usually sell more there anyway. Not to mention the tempe location usually turns the music off at 8:30, which gives an unwanted feeling to their guests. I am giving two stars for the sake of finding things at all locations. Go phoenix location! **Model Prediction:** 2-star (negative) → 5-star (most positive)
Original English Text: There' s so many choices of food in Las Vegas. Don't choose this place. It is no exaggeration that mcdonalds and arby's have **better** hash browns, eggs, and bacon. Missed items in the dishes we ordered. All around disappointment to the Las Vegas allure. **Adversarial English Text:** There's so many choices of food in Las Vegas. Don't choose this place. It is no exaggeration that mcdonalds and arby's have delicious hash browns, eggs, and bacon. Missed items in the dishes we ordered. All around disappointment to the Las Vegas allure. **Model Prediction:** 1-star (most negative) → 5-star (most positive)
Original English Text: Not only is this place in my neighborhood, it is exactly what I'm looking for. I have pale skin, green eyes, and freckles yet I have been **cheated** out of having naturally red hair by mother nature!! Therefore I have been a fake redhead for at least a decade. You can imagine the cost and damage to my hair I have endured. Fringe has a new dye that is ammonia free! It's basically just a oil and water dying process! I've gone twice in a row and my hair has never been in such good condition. I'm paying the same amount for hair dying as my old salon except here I get a better cut and style and it's not frying my hair! Also Chanel (who dyes my hair) is a totally cool chic and always has interesting things to talk about! This is my new go to salon! **Adversarial English Text:** Not only is this place in my neighborhood, it is exactly what I'm looking for. I have pale skin, green eyes, and freckles yet I have been humiliated out of having naturally red hair by mother nature!! Therefore I have been a fake redhead for at least a decade. You can imagine the cost and damage to my hair I have endured. Fringe has a new dye that is ammonia free! It's basically just a oil and water dying process! I've gone twice in a row and my hair has never been in such good condition. I'm paying the same amount for hair dying as my old salon except here I get a better cut and style and it's not frying my hair! Also Chanel (who dyes my hair) is a totally cool chic and always has interesting things to talk about! This is my new go to salon! **Model Prediction:** 5-star (most positive) → 1-star (most negative)

Table 21: English Adversarial Examples Generated by `SemAttack` for BERT-based Classifier on SNLI Dataset using all perturbation functions.

Input (red = Modified character, **bold** = original character.)
Original Premise: Four boys are about to be **hit** by an approaching wave. **Adversarial Premise:** Four boys are about to be smashed by an approaching wave. **Hypothesis:** The wave missed the boys. **Model Prediction:** contradiction → entailment
Original Premise: A yellow race car **sliding** through a corner as spectators watch. **Adversarial Premise:** A yellow race car slipping through a corner as spectators watch. **Hypothesis:** A NASCAR is being watched. **Model Prediction:** neutral → entailment
Original Premise: A group of people on the bark, brightly lighten street, while one man with a gray hat holds a large colorful sign with **arrows**. **Adversarial Premise:** A group of people on the bark, brightly lighten street, while one man with a gray hat holds a large colorful sign with swords. **Hypothesis:** The people are walking down the street. **Model Prediction:** entailment → contradiction
Original Premise: A man takes a **drink** in the doorway of a home. **Adversarial Premise:** A man takes a drinking in the doorway of a home. **Hypothesis:** A man is looking out onto his front lawn from the doorway of his home. **Model Prediction:** neutral → contradiction
Original Premise: A dog **attacking** a man wearing protective gear. **Adversarial Premise:** A dog hurting a man wearing protective gear. **Hypothesis:** He was training a police dog. **Model Prediction:** neutral → entailment
Original Premise: A white man in a **red** shirt riding a bike. **Adversarial Premise:** A white man in a golden shirt riding a bike. **Hypothesis:** An old guy wears a shirt on a bike. **Model Prediction:** neutral → entailment
Original Premise: A child in a blue and white striped shirt crosses his arms and smiles while standing on red carpeted **stairs**. **Adversarial Premise:** A child in a blue and white striped shirt crosses his arms and smiles while standing on red carpeted terraces. **Hypothesis:** A child is smiling as he watches a clown. **Model Prediction:** neutral → contradiction
Original Premise: This man, with a red & white shirt has **water** bottles on this white truck. **Adversarial Premise:** This man, with a red & white shirt has beer bottles on this white truck. **Hypothesis:** The guy has bottles on the truck for me. **Model Prediction:** neutral → entailment
Original Premise: Three people are riding a carriage **pulled** by four horses. **Adversarial Premise:** Three people are riding a carriage hauled by four horses. **Hypothesis:** The oxen are pulling the carriage. **Model Prediction:** contradiction → entailment

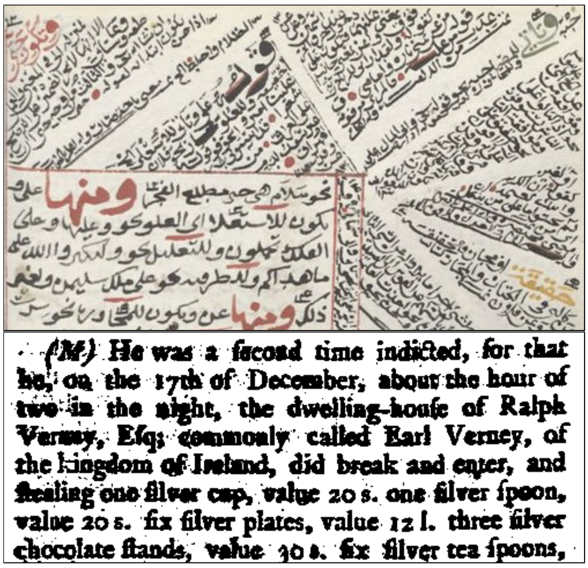
Abstract

We present a self-supervised pre-training approach for learning rich visual language representations for both handwritten and printed historical document transcription. After supervised fine-tuning of our pre-trained encoder representations for low-resource document transcription on two languages, (1) a heterogeneous set of handwritten Islamicate manuscript images and (2) early modern English printed documents, we show a meaningful improvement in recognition accuracy over the same supervised model trained from scratch with as few as 30 line image transcriptions for training. Our masked language model-style pre-training strategy, where the model is trained to be able to identify the true masked visual representation from distractors sampled from within the same line, encourages learning robust contextualized language representations invariant to scribal writing style and printing noise present across documents.

1 Introduction

Document transcription is the task of converting images of handwritten or printed text into a symbolic form suitable for indexing, searching, and computational analysis.[1] Historical documents, whether they were (re)produced via handwriting or the early printing press, confound current statistical document transcription models due to (1) extremely varied style and content across domains, (2) the presence of noise, and (3) a dearth of labeled data.



(M) He was a ſecond time indicted, for that he, on the 17th of December, about the hour of two in the night, the dwelling-houſe of Ralph Verney, Eſq; commonly called Earl Verney, of the kingdom of Ireland, did break and enter, and ſtealing one ſilver cup, value 20 s. one ſilver ſpoon, value 20 s. ſix ſilver plates, value 12 l. three ſilver chocolate ſtands, value 30 s. ſix ſilver tea ſpoons,

Figure 1: Example page image crops from an Islamicate manuscript dated to 1842 (**Top**, ref: Leiden Or. 669), showcasing its dense, visual complexity with extensive marginalia, and printed proceedings of London's Old Bailey Courthouse (**Bottom**, c. 18th century) (Shoemaker, 2005).

First, historical printed documents, such as books produced from early modern England (c. 16th–18th centuries; bottom of Fig. 1), use non-standardized spacing and fonts (Shoemaker, 2005) and can contain code-switching that confuses language models (Garrette et al., 2015). However, this variation pales in comparison to their handwritten counterparts. For instance, pre-modern Islamicate manuscripts (i.e., Persian and Arabic

---

[1] We use the generic term *document transcription* to refer to both the task of optical character recognition (OCR), which is typically reserved for *printed* documents, and handwritten text recognition (HTR) for manuscripts.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 206 - 216
July 10-15, 2022 ©2022 Association for Computational Linguistics

handwritten documents from c. 7th–19th centuries; top of Fig. 1), differ in script family, scribal handwriting style, and symbol inventory/vocabulary. As a result, a large degradation in performance is observed when evaluating HTR models on unseen manuscripts (Jaramillo et al., 2018).

Production and imaging noise also present a problem for historical document transcription models. Whether it be uneven inking from a printing press, inconsistent text baselines, or holes resulting from insect damage to ancient pages, techniques must be designed to cope with the noise (Berg-Kirkpatrick and Klein, 2014; Goyal et al., 2020).

While neural networks have a demonstrated capability to model complex data distributions, they typically require large amounts of supervised training data to do so, which is infeasible for historical documents. Unsupervised, non-neural transcription models with fewer parameters alleviate the need to create labeled data (Berg-Kirkpatrick et al., 2013), but struggle with complex handwriting variation. For Islamicate manuscripts, ground truth transcription often requires paleography experts to decipher the ancient writing systems as they appear in each scribal writing style.

In this paper, we propose a self-supervised learning framework designed to overcome these three challenges presented by historical documents. Inspired by the astounding success of self-supervised pre-training techniques for masked language modeling (MLM) in NLP (Devlin et al., 2019), visual models (Chen et al., 2020; Radford et al., 2021), and speech recognition (Baevski et al., 2020), our approach pre-trains a neural text line-image encoder by learning to distinguish masked regions of unlabeled line images from other distractor regions. Specifically, our contribution is the following:

- we show that the recent pre-train/fine-tune paradigm is particularly advantageous for low-resource historical document transcription, obtaining large improvements in both printed and handwritten documents in both English and Arabic-script languages.
- we motivate the self-supervised contrastive loss for document transcription through the lens of "lacuna reconstruction", where blank parts of a document called lacuna must be inferred by human readers.

In doing so, we argue that our approach to pre-training implicitly incentivizes the model to discover and encode discrete character classes in its internal representations, while ignoring style differences occurring in lines using different fonts or languages, or authored by other scribes.

2 Related Work

Masked Pre-training Our approach to self-supervised pre-training follows a growing body of work in both NLP and speech that leverages mask-predict objectives for learning useful, task-agnostic language representations from unlabeled data. In the self-supervised pre-train/supervised fine-tune paradigm, these representations can then be updated on the task of interest using in-domain labeled data. Past work covers learning representations for NLP from monolingual and multilingual text (Devlin et al., 2019; Yang et al., 2019), speech (Baevski et al., 2019; Jiang et al., 2019; Song et al., 2020; Wang et al., 2020), and images grounded with text (Radford et al., 2021). Representations can be learned through either reconstruction-type objectives (Jiang et al., 2019; Song et al., 2020; Wang et al., 2020) or probabilistic contrastive loss functions (Oord et al., 2018; Baevski et al., 2019, 2020). Most similar to our work is the speech recognition system wav2vec2.0 (Baevski et al., 2020), which uses the same two phase training setup with a self-supervised contrastive loss during pre-training and Connectionist Temporal Classification (CTC) loss on transcribed speech data during fine-tuning. Talnikar et al. (2020) presents that the self-supervised loss regularizes the supervised loss during joint learning of both objectives. Follow up work has shown the usefulness of the pre-trained speech representations for exploring speech variation (Bartelds et al., 2020). In this paper, we show that the same learning paradigm can also be successfully applied to very low resource document transcription settings.

Islamicate HTR While machine recognition of handwritten, historic English/German documents can range from 5–12% character error rate (CER) on a sufficient amount of in-sample manuscript training data (Sánchez et al., 2019), performance on Arabic-script languages is much more challenging, leading to substantially higher

CER. Pre-modern Islamicate manuscripts (i.e., Persian and Arabic handwritten documents from c. 7th–19th centuries), often differ in script family, scribal handwriting style, and symbol inventory/vocabulary. In the top of Figure 1, we present an extreme example of some of the problematic visual variation that can be observed. Even a model trained in a supervised fashion on such a complex document sees a large degradation in performance when evaluating HTR models on unseen manuscripts (Jaramillo et al., 2018) . Until recently, OCR performance on Arabic-script *printed* texts was still poor, typically above 25% CER (Alghamdi and Teahan, 2017), which is too high for downstream users (i.e., researchers and librarians).

Recent studies involving Islamicate manuscripts found that state-of-the-art systems are only able to achieve 40 to mid-20% CER using proprietary software (e.g., Google Cloud Vision, RDI, Transkribus) (Clausner et al., 2018; Keinan-Schoonbaert, 2020, 2019). However, results from these studies only report in-domain performance—an unrealistic scenario where considerable amounts of labeled data can be obtained to enable both training and testing on the same manuscript. In contrast, out-of-domain performance tends to suffer considerably, supported by Romanov et al. (2017)'s study of neural OCR for printed Arabic-script documents. Our work aims to address such performance issues for both in-domain and out-of-domain Islamicate HTR settings by learning general, content-rich pre-trained language representations from large amounts of heterogeneous unlabeled data.

Historical OCR Closely related to manuscript transcription, OCR is another task involving language recognition from images. However, OCR operates on documents that have been printed by a machine with regular, re-used character fonts exhibiting much less superficial glyph variation than human handwriting. OCR is far from a solved problem in the case of documents printed on early modern (c. 16th–18th centuries; see bottom of Fig. 1), movable-type printing presses, where humans would manually set metal type casts with non-standard spacing and fonts (Shoemaker, 2005). In this setting, inking noise and historical font shapes confuse OCR models trained on modern, computer-generated documents (Arlitsch and Herbert, 2004). Berg-Kirkpatrick et al. (2013)'s Ocular explicitly uses a generative probabilistic model inspired by historical printing processes to model such noise. Later work has extended it to handle more typesetting noise (Garrette et al., 2015), and produce both diplomatic and normalized transcriptions (Garrette and Alpert-Abrams, 2016). Separately, OCR post-correction models have been proposed to resolve OCR outputs in historical documents (Hämäläinen and Hengchen, 2019; Dong and Smith, 2018) and other low-resource settings (Rijhwani et al., 2020, 2021). In contrast, our approach pre-trains the visual language recognition model's encoder, which produces better contextualized representations in order to reduce the amount of errors the model itself makes. Unlike Ocular, our proposed method does not use a language model and is not fully unsupervised as we require 1–3 pages of transcribed data for learning to transcribe during fine-tuning.

3 Approach

When human readers encounter a lacuna, a blank information gap in a portion of a book or manuscript, they must infer its latent meaning using nearby context like in a cloze test (Taylor, 1953). We argue that the most useful information for inference lies in the ability to reason about the identities of the missing characters in the lacuna using the identities of the surrounding characters. Indeed, MLM-style pre-training techniques are also motivated by the idea of the cloze test, and recent research indicates that language representations learned through the prediction of missing content using surrounding sentential context are useful for many downstream tasks (Devlin et al., 2019; Clark et al., 2019, 2020). Our approach combines the ideas of lacuna inference and masked pre-training to provide a useful learning signal for downstream historical document transcription, a setting with massive digitized collections but few transcribed examples.

Specifically, we introduce a self-supervised pre-training method that randomly masks lacuna-like regions of document line images and learns to reconstruct them by distinguishing them from nearby line image segments, or foils. While lacuna can be reconstructed in a generative way, we find that a discriminative contrastive loss works better in practice. By leveraging a diverse set of unlabeled data

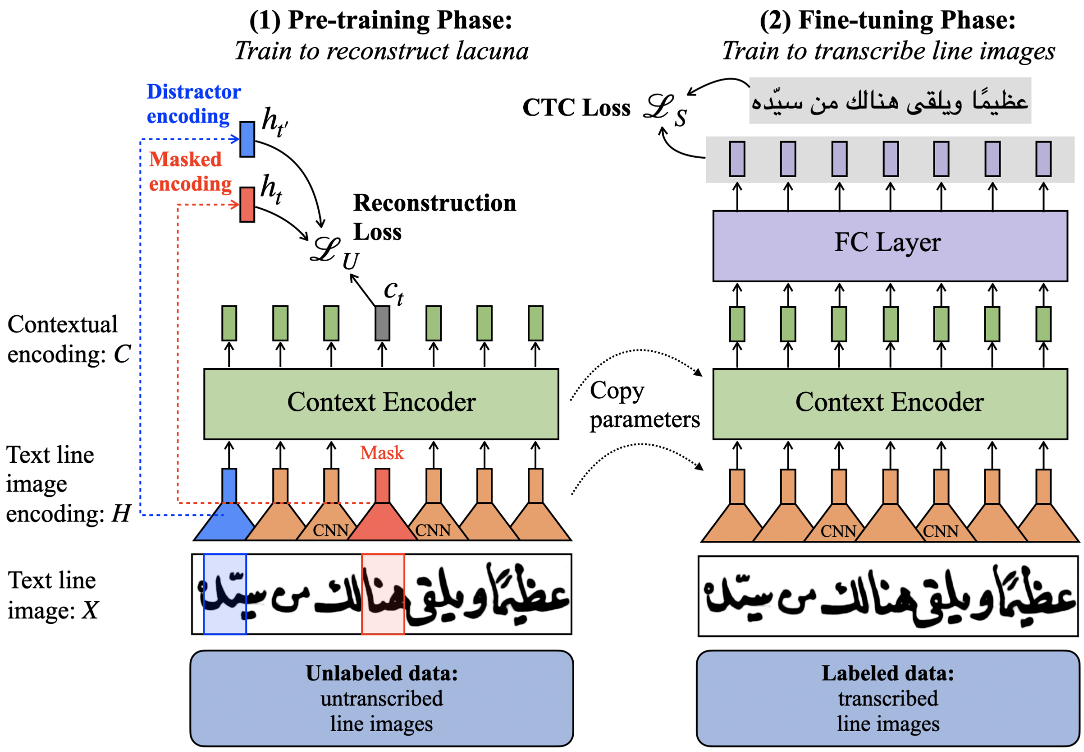


Figure 2: Our proposed two-stage approach for low-resource document transcription first pre-trains a line image encoder using a self-supervised contrastive loss on unlabeled data (left), followed by a fine-tuning phase, in which the pre-trained encoder learns to transcribe 1–3 pages of supervised data using a CTC loss (right).

for pre-training, the model is forced to infer the identities of masked text regions in the presence of scribal writing variation or typesetting noise ubiquitous in historical documents. In the next sections, we describe our model/masking strategy in detail.

3.1 Model

In Figure 2, we show our two-stage pre-train/fine-tune modeling approach. First, we describe the document line image encoder that is shared between stages. For simplicity of description, we assume that each document line image, X, is n pixels tall and m pixels wide, and that pixels are binary-valued. Thus, the space of input text line images can be denoted as $\mathcal{X} = \{0,1\}^{n \times m}$. We first process the input with a **convolutional feature extractor**, $f : \mathcal{X} \mapsto \mathcal{H}$, that maps the input, X, to an encoding matrix, H, using a deep convolutional neural network followed by a reshaping of the image height dimension into the channels dimension. Next, a **contextual encoder**, $g : \mathcal{H} \mapsto \mathcal{C}$, computes a contextualized representation matrix, C, from H using a neural sequence model, parameterized by a bidirectional LSTM (Hochreiter and Schmidhuber, 1997). We describe both the design of f, which determines the output size of the convolutional encoding space $\mathcal{H}$, and g in Section 5.1. Together, both the convolutional and contextual layers form the encoder of text line images used for downstream document transcription. Ideally, f will capture the underlying visual appearance of distinct character classes, while g will discover linguistic correlations between these classes.

3.2 Masking

During pre-training, we replace randomly sampled, non-overlapping segments of H with a learned mask embedding vector prior to computing contextualized representation matrix C. We train the model to distinguish the masked region from a foil using the contrastive loss presented in Section 3.3.

3.3 Pre-training Objective

We use the following self-supervised contrastive loss whose variants have demonstrated success in self-supervised representation learning (Oord et al., 2018; Baevski et al., 2020):

$$\mathcal{L}_U(c_t) = -\log \frac{\exp\left(s(c_t, h_t)\right)}{\sum_{t'} \exp\left(s(c_t, h_{t'})\right)}$$

Here, c_t (depicted in Figure 2) is the contextual encoder's output representation of the *masked* line image at position t. Similarly, h_t (also depicted in Figure 2) is the *convolutional* encoder's output representation of the *masked region itself*. Further, $s(c, h)$ represents a scoring function that computes the similarity between representation vectors c and h. We use the cosine similarity similar to Baevski et al. (2020), but compute it using only raw vectors, instead of the raw vectors and quantized vectors. The cross-entropy loss requires the model to distinguish the representation of the true masked region, h_t, from distractor representations: the convolutional encodings of other segments, $h_{t'}$ with $t' \neq t$.

3.4 Fine-tuning Objective

After learning pre-trained representations, we add the randomly initialized, fully connected character vocabulary projection layer to the top of our context encoder network (top right of Fig. 2) and perform supervised training using the Connectionist Temporal Classification (CTC) objective (Graves et al., 2006; Graves, 2012; Baevski et al., 2020) with transcribed data. CTC is a commonly used loss function for supervised training in speech and handwriting recognition systems. In this case, CTC is used to marginalize over all monotonic alignments between the sequence of input visual representations and the observed ground truth output sequence of characters.

4 Datasets

In this section, we describe the unlabeled pre-training and labeled fine-tuning/testing datasets used in our experiments. Representative line images from five of the datasets are exhibited in Figure 3.

4.1 Islamicate Manuscripts

First, we introduce a variety of pre-modern Islamicate manuscript datasets (i.e., Persian and Arabic handwritten documents from c. 7th–19th centuries) selected for both their uniquely different domain content (e.g., scientific to legal to religious) and their visually distinct scribal handwriting style. All but the first pre-train dataset are professionally transcribed by Islamicate manuscript scholars.

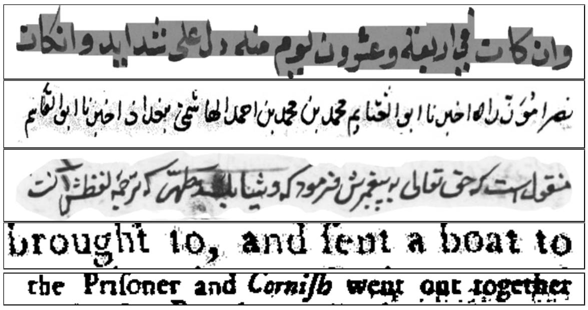

Figure 3: Assortment of cropped, grayscale line images from a selection of our datasets, as extracted by annotators. From top to bottom, RASM 2019 (Keinan-Schoonbaert, 2020), Attar-Mubhij, Ḥuliyya, Trove (Holley, 2010), Old Bailey (Shoemaker, 2005). The Islamicate line images are shown pre-binarization, while the English line images come binarized.

HMML Pre-train Through a collaboration with the Hill Museum and Manuscript Library (HMML), we obtain about 100 early modern, mostly Syrian, naskh[2] manuscripts dating from 1600–1775 with some voweling, but with ornamentally voweled texts excluded (i.e., texts in which every single vowel and orthographic feature is included, usually for ornamental reasons). We filter out manuscripts with extensive marginalia, figures, or tables, though some marginal notes and other elements (e.g., seals, interlinears) are still present. This results in a dataset containing roughly 750,000 *unlabeled* line images.

HMML Fine-tune We obtain transcriptions for 115 line images from a 4-page held-out subset of the HMML Pre-train dataset. This dataset is designed for in-domain fine-tuning/testing experiments with our pre-trained models.

RASM 2019 For the ICDAR 2019 Competition on Recognition of Historical Arabic Scientific Manuscripts, the British Library released 2,164 transcribed line images from scientific manuscripts written in various scribal hands (Keinan-Schoonbaert, 2020). RASM 2019 has become a popular benchmark for Arabic-script

---

[2] `https://en.wikipedia.org/wiki/Naskh_(script)`

handwriting recognition due to its relatively large amount of supervised data for the task.

Attar-Mubhij An Arabic-language legal text with 190 transcribed line images obtained from OpenITI.[3]

Ḥuliyya A 229-line Persian, nastaʼlīq[4] devotional text written by an early modern scholar containing mostly prayers (also obtained from OpenITI).

4.2 Early Modern English Printed Works

Next, we describe several English book and newspaper datasets used in our experiments that were originally printed in early modern England and Australia.

EEBO Pre-train We harvest 750,000 unlabeled line images from a randomly sampled collection of document images from Early English Books Online (EEBO),[5] which contains "almost every work printed in the British Isles and North America, as well as works in English printed elsewhere from 1470-1700."

Trove A dataset of historic Australian newspapers (c. 1803–1954) from the National Library of Australia (Holley, 2010). We use the manually transcribed version totaling 450 lines (Berg-Kirkpatrick et al., 2013).

Old Bailey A manually transcribed set of 20 documents printed 1716–1906, consisting of 30 lines per document, taken from Berg-Kirkpatrick and Klein (2014). Shoemaker (2005) compiled the documents, which describe proceedings of London's Old Bailey Courthouse.

4.3 Line Extraction

Since our model processes individual line images of a document, we use Kiessling (2020)'s line extraction method to automatically segment page images into their component text line images for at-scale collection of the pre-training datasets. We find and discard poorly extracted line images outside an empirically determined pixel width-to-height ratio range of 6–23.

5 Experiments

In this section, we describe our experimental setup, including architectural details and hyperparameters for the neural line image encoder, pre-train/fine-tune specifics, dataset splits, and the baseline systems we compare against.

5.1 Experimental Details

Encoder For all experiments, we binarize the line images and scale them to a height of 96 pixels, but allow them to vary in width. We base our CNN architecture on the Kraken OCR system (Kiessling, 2019): two rectangular 4×2 kernels first process the input image, each followed by a Leaky ReLU activation and Group Norm. Two max pooling operations are applied, one before and one after the final 3×3 convolutional layer kernel, with kernel sizes/strides of $4 \times 2/1 \times 2$ for both. The first kernel uses a stride of 4×2 and the final two both use 1×1. The convolutional hidden dimensions are 64, 128, and 256. We use a 3-layer BiLSTM for our contextual encoder with a hidden size of 512. This results in 6,408,000 trainable parameters. Models are implemented in PyTorch (Paszke et al., 2019) and Fairseq (Ott et al., 2019). Code is available at `https://github.com/nvog/lacuna`.

Pre-training During pre-training, we perform a grid search over masking probability and length using 75k lines of data and select the best model based on lowest fine-tuned CER on HMML Fine-tune. We determine $p = 0.5/p = 0.65$ to perform best for Islamicate manuscript/English print with a non-overlapping segment length of 12 time steps. We ensure that 8 time steps are between each non-overlapping segment. A maximum of 100 time steps are sampled and used as foils in the denominator of the loss from Sec. 3.3. We use the same learning rate scheduler and Adam optimizer from Baevski et al. (2020) that warms up for the first 8% of updates to a learning rate of 5e-4 and linearly decays it afterwards. Models are pre-trained for 3–5 days on 4 RTX 2080 Ti cards.

Fine-tuning During fine-tuning, we use a tri-stage learning rate schedule with the Adam optimizer, which warms up the learning rate to 5e-4 during the first 10% of updates and decays it linearly by a factor of 0.05 for the final 50% of training. We only update the fully connected layer for

Table 1: Document transcription results on Islamicate manuscripts. Character error rate (CER) is reported on held-out test sets introduced in Section 4.1. For baselines, we compare against the current Google Cloud OCR via the API, and the state-of-the-art, neural network-based architecture from Kraken (Kiessling, 2019), which does not use self-supervised pre-training (i.e., 0 lines pre-train). With access to the same amount of 30 and 90 lines of supervised fine-tuning data as this system, our proposed self-supervised pre-training regime (using 75k and 750k lines of unlabeled manuscript data) shows a large improvement across all datasets.

the first 200 epochs of training and then proceed to update the contextual encoder as well. These optimization choices are inspired by Baevski et al. (2020). We use a small batch size of 8 and train for a maximum of 700 epochs with the CTC loss (Sec. 3.4). We use greedy decoding after removing the CTC's blank token and do not use any external language model. For Islamicate manuscript experiments we perform NFD unicode normalization. Character Error Rate (CER) is computed using Kraken OCR (Kiessling, 2019).

5.2 Fine-tune/Test Splits

For Islamicate manuscript datasets, we hold out 10% of RASM 2019 for testing and the final page each of HMML Fine-tune, Attar-Mubhij, and Ḥuliyya. For English print datasets, we use the same test splits as Berg-Kirkpatrick and Klein (2014) for fair comparison and fine-tune on the validation set of each dataset.

5.3 Baselines

For our first baseline, we use the proprietary Google Cloud OCR API (Fujii et al., 2017; Ingle et al., 2019), which provides state-of-the-art results on multilingual handwritten and printed *modern* documents. In contrast to our system's unlabeled pre-training procedure for *historical* documents, this system uses synthesized handwriting strokes and data perturbation to obtain more supervised data for improved performance.

For our second baseline, we use the popular, state-of-the-art open-source Kraken OCR (Kiessling, 2019), which consists of a CNN-LSTM encoder trained in a supervised fashion with the same segmentation-free Connectionist Temporal Classification (Graves et al., 2006) loss function we use during our method's fine-tuning stage. We provide the encoder's implementation details in Section 5.1.

For early modern English print experiments, we also compare to the fully unsupervised Ocular (Berg-Kirkpatrick et al., 2013), which is a generative probabilistic model purpose-built for the historical printing process, yet unable to handle complex glyph variation observed in handwriting.

6 Results

In this section, we present document transcription results for both Islamicate manuscripts and early modern English works introduced in Section 4. We compare performance against supervised and unsupervised prior work, and investigate the impact of pre-training/fine-tuning dataset sizes.

6.1 Islamicate Manuscripts

In Table 1, we present single-run supervised fine-tuning results on in-domain subsets of each dataset limited to 30 and 90 lines for low-resource setting evaluation. These two settings are roughly equivalent to 1 and 3 pages of transcribed data for each manuscript. Each row represents a dif-

Baselines		
	Test Dataset CER (↓)	
System	Trove	Old Bailey

30 Lines for Supervised Fine-tuning		
	Test Dataset CER (↓)	
# Lines Pre-train	Trove	Old Bailey
0	70.5	60.0
75k	20.3	26.5
750k	**19.6**	**12.2**
90 Lines for Supervised Fine-tuning		
	Test Dataset CER (↓)	
# Lines Pre-train	Trove	Old Bailey
0	38.7	28.6
75k	12.2	9.4
750k	**10.4**	**7.6**

Table 2: Document transcription results on early modern English printed works. Character error rate (CER) is reported on held-out test sets introduced in Section 4.2. First 5 baselines are taken from Berg-Kirkpatrick and Klein (2014). Similar to Table 1, supervised data is limited to 30 and 90 line settings.

ferent set of encoder parameters, which we use to initialize the fine-tuning experiments. The *0 # lines pre-train* row represents a randomly initialized Kraken-style encoder, while *75k* and *750k* settings use the encoder parameters pre-trained with our lacuna reconstruction objective on different orders of magnitude of unlabeled HMML Pre-train line images. We also compare to the Google Cloud OCR introduced in Section 5.3.

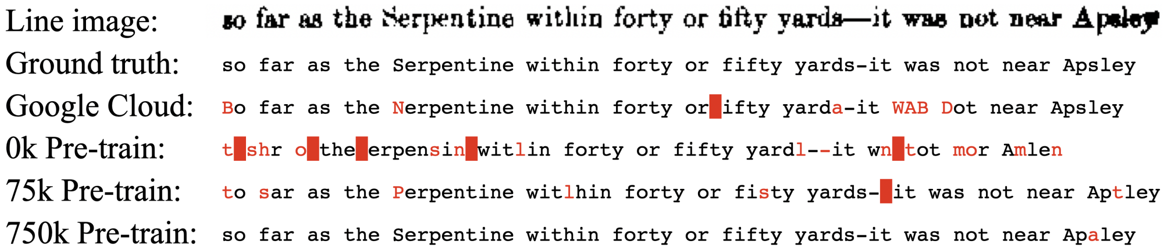
The first thing we can observe is the extremely high character error rates for both the commercial Google Cloud OCR system and the randomly initialized 0k pre-train models, especially in the 30-line setting. Access to about 2 more pages of data (in the 90-line setting) improves results for this setting in the Arabic-language legal text Attar-Mubhij, but does not seem to help much for RASM 2019, a larger collection of scientific manuscripts. This is probably due to the higher amount of diversity in content and style in this benchmark dataset for Arabic-language HTR. Seemingly, without any signal from pre-training and only tens of lines of transcribed data, the model is unable to learn a sufficient visual encoder for the large variety of scribal hands and scripts observed in the manuscripts (examples shown in Fig. 3). Pre-training on just 75k lines halves the error rate for Attar-Mubhij in the 30-line setting. Furthermore, 750k pre-train reduces the Attar-Mubhij CER from 60.4 to 23.7.

The HMML Fine-tune dataset (HMML-F in Table 1) has the largest relative error rate difference between the pre-trained models and models without pre-training. Errors are reduced by about 55% for 75k-30, 70% for 750k-30, 58% for 75k-90, and 73% for 750k-90, which is at least 10 points higher than other datasets on average. Since manuscripts in HMML-F are sourced from the same library as the HMML Pre-train dataset, the results suggest that in-domain pre-training data provides an advantage over the other documents from different collections. Regardless, our approach's improved performance on 30-line settings compared to the supervised 90-line results trained from scratch across all datasets is impressive and shows promising generalization ability.

6.2 Early Modern English Printed Works

In Table 2, we present supervised fine-tuning results on in-domain subsets of each dataset limited to the same 30 and 90 line settings as in the Islamicate manuscript experiments. Our first observation is that the randomly initialized encoder from the 0-line pre-train setting sees a much larger improvement from 30 to 90 lines of supervised fine-tuning data than the Islamicate manuscript experiments. We speculate this is due to the more similar and repeated glyph shapes on printed data compared to handwritten data, which makes learning of the visual encoder easier. Still, pre-training the visual encoder cuts CER across both datasets, though we do see a slightly bigger relative error rate reduction when fine-tuning on Trove versus Old Bailey.

In Figures 4 & 5, we show comparisons across predicted transcriptions from different systems and datasets for illustrative purposes. First, we observe



Line image:	so far as the Serpentine within forty or fifty yards—it was not near Apsley
Ground truth:	`so far as the Serpentine within forty or fifty yards-it was not near Apsley`
Google Cloud:	`Bo far as the Nerpentine within forty or█ifty yarda-it WAB Dot near Apsley`

75k Pre-train:	`sale ars given by the Sportsmon█'s█Special`
750k Pre-train:	`sale are given by the Sportsmon'█s "█Special`

Figure 5: Comparison of results on the Trove test set with errors highlighted. Pre-trained results are from the 90-line fine-tuning setting.

that Google Cloud OCR, the best baseline system on Old Bailey, consistently struggles with inking variation. For example, the bleeding ink on the initial '`s`' of each line image is mistaken for a '`B`', the '`n`' in '`not`' in Fig. 4 is mistaken for a '`D`' due to the subtle connection of the glyph's legs from overinking, and the '`m`' in '`Sportsman`' in Fig 5 is confused for the characters '`in`' because of underinking. However, the 0k pre-train baseline clearly makes the most insertion/deletion/substitution errors since it must learn how to transcribe noisy line images from a randomly initialized encoder using only 90 transcribed line images for supervised parameter learning. Initializing the visual encoder with parameters learned from our self-supervised regime on 75k unlabeled line images from EEBO reduces a lot of these nonsensical errors to only superficial glyph recognition issues. By increasing the pre-training amount by an order of magnitude to 750k, we obtain our best results. Future work could integrate a language model during decoding to address the unlikely sequences of characters/words still output by our best system, like the words '`Apaley`' and '`Sportsmon`'.

7 Conclusion

In this paper, we proposed a two-phase pre-train/fine-tune approach for document transcription and applied it to historical documents in low-resource settings. Our pre-training strategy, inspired by reconstructing missing information, or lacuna, in documents uses hundreds of thousands of unlabeled line images to learn rich visual language representations. After supervised fine-tuning on tens of transcribed line images, we showed large character error rate reduction on Islamicate manuscripts exhibiting major script and style variation and we improved over several state-of-the-art OCR systems on early modern English printed works. We estimate that our approach could save human annotators significant amounts of time and enable more distant readings of library collections.

Ethical Considerations

While more accurate transcription of printed and handwritten documents in low-resource settings can expand research access for language and history scholars, it could also potentially facilitate government surveillance of marginalized communities. Separately, bad actors could more easily scan and digitize document images containing sensitive information and use them for nefarious purposes.

FreeTransfer-X: Safe and Label-Free Cross-Lingual Transfer from Off-the-Shelf Models

`{guo.yinpeng, liliangyou, jiang.xin, qun.liu}@huawei.com`

Abstract

Cross-lingual transfer (CLT) is of various applications. However, labeled cross-lingual corpus is expensive or even inaccessible, especially in the fields where labels are private, such as diagnostic results of symptoms in medicine and user profiles in business. Although being lack of labels, there are off-the-shelf models in these sensitive fields. Instead of pursuing the original labels, a workaround for CLT is to transfer knowledge from the off-the-shelf models without labels. To this end, we define a novel CLT problem named *FreeTransfer-X* that aims to achieve knowledge transfer from the off-the-shelf models in rich-resource languages. To address the problem, we propose a 2-step knowledge distillation (KD, Hinton et al., 2015) framework based on multilingual pre-trained language models (mPLM)[1]. The significant improvement over strong neural machine translation (NMT) baselines demonstrates the effectiveness of the proposed method. In addition to reducing annotation cost and protecting private labels, the proposed method is compatible with different networks and easy to be deployed. Finally, a range of analyses indicate the great potential of the proposed method.

1 Introduction

Cross-lingual transfer (CLT) is a critical topic for natural language processing due to the data imbalance between languages. While models of rich-resource languages (e.g. English) have been applied on various real-world tasks, the progress on poor-resource languages lags behind. CLT researches enable the knowledge transfer from the rich-resource languages to the poor-resource languages.

Although the application of CLT is valuable, data labels are expensive or even inaccessible in private and sensitive domains, such as medicine and business. For example, the diagnostic results of a user's symptoms are private and a company's internal description of users are confidential. Since short of labels for CLT, even though there are excellent applications in rich-resource languages, it is difficult to benefit the people using poor-resource languages. Previous CLT researches have not well studied how to leverage knowledge of rich-resource languages without labels. To define and tackle this problem will benefit both the community and the industry.

In order to reduce the demand of labels, existing works mainly fall into two paradigms as follows. One paradigm focuses on learning language-agnostic representation and model parameters. CLT is realized by either aligning parameters of monolingual models or sharing parameters among different languages (Liu et al., 2019; Devlin et al., 2019b; Conneau et al., 2020; Wang et al., 2020). The objective is to build a unified representation, which is used by downstream tasks, for all the languages. In this paradigm, although the demand of labels is reduced, it still requires a certain number of labels to adapt the model to a particular language and task. Besides, models in this paradigm are usually large-scale Transformers (Vaswani et al., 2017) based on mPLMs, which limits their deployment in real-world. Another paradigm is to leverage machine translation (MT) systems to generate training or testing pseudo-corpus for a specific language (Conneau et al., 2018). For simplicity, we take English as the rich-resource languages in this paper. `Translate-train` translates annotated training corpus from English to other languages. Gold labels are directly applied to the translated data. Although labels in poor-resource languages are not required, gold labels in English are still necessary. On the contrary, `Translate-test` translates testing corpus from poor-resource languages to English. This method can directly lever-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 217 - 228
July 10-15, 2022

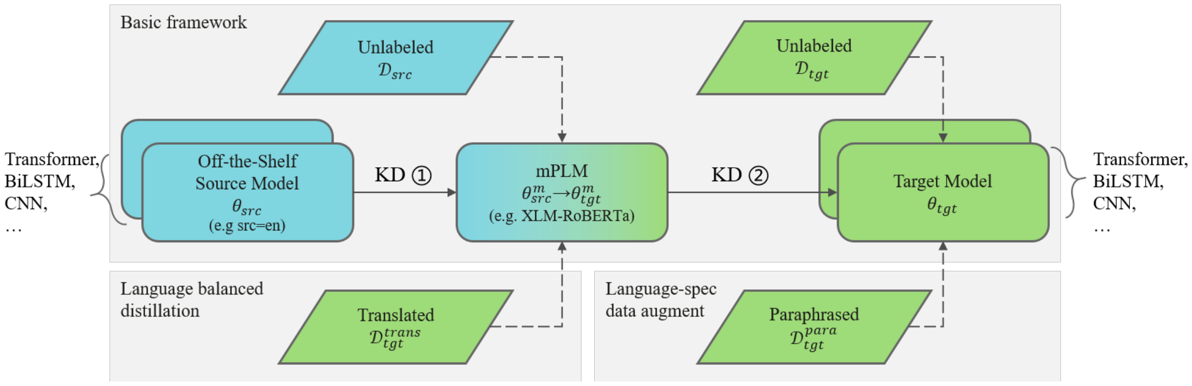

Figure 1: Overview of the proposed 2-step knowledge distillation (KD) framework. KD-(1) distills knowledge from the off-the-shelf English model to the mPLM. KD-(2) distills knowledge from the mPLM to the model in the target language. Blue modules: in the source language src, green modules: in the target language tgt.

age off-the-shelf English models, but it runs a 2-pass inference which highly limits its efficiency. Both the two CLT paradigms mentioned above require language-specific and task-specific labels, except for the 2-pass `Translate-test`. The demand of labels highly limits the reuse of the English knowledge in private and sensitive domains. Then a question comes up: *Is it possible to perform CLT totally without labels?*

In this paper, we define a novel problem: *safe and label-free cross-lingual transfer from off-the-shelf models (FreeTransfer-X)*. The FreeTransfer-X asks researchers to achieve CLT only with off-the-shelf English models but any labels, as formally defined in Section 2.1. To the best knowledge of the authors, it's the first time that the FreeTransfer-X is clearly defined.

To address the FreeTransfer-X, we propose a 2-step knowledge distillation (KD, Hinton et al., 2015) framework based on mPLM, as shown in Figure 1. Given an off-the-shelf model θ_{src} in the source language (e.g. English), first we take θ_{src} as the teacher and an mPLM model θ^m_{src} as the student, then train θ^m_{src} on unlabeled corpus $\mathcal{D}_{src}$. Second, we take θ^m_{tgt} as the teacher and train a student θ_{tgt} on unlabeled corpus $\mathcal{D}_{tgt}$. This cross-lingual transfer framework is label-free and applicable for any model architecture. Experimental results demonstrate the effectiveness of the proposed framework on both sentence classification and sequence tagging.

In short, the major contributions of this work include:

- A novel cross-lingual transfer problem FreeTransfer-X is defined. The FreeTransfer-X asks researchers to achieve CLT from off-the-shelf models without using labels. It reduces the labeling cost and protects the labels in private domains such as medicine and business.
- We propose a 2-step knowledge distillation framework based on mPLMs, e.g. XLM-RoBERTa (Conneau et al., 2020), to address the FreeTransfer-X. It significantly outperforms the NMT baselines on sentence classification and sequence tagging tasks. Besides, it's compatible with heterogeneous networks.
- Further analysis indicates abundant research potentials of the proposed framework. To improve the two distillation steps and the mPLM may benefit the framework.

2 Methodology

2.1 Problem Definition

Denote the source language and the target language as src and tgt respectively. Given an off-the-shelf model θ_{src} (e.g. English intent classifier), unlabeled in-domain corpus $\mathcal{D}_{src}$ and unlabeled in-domain corpus $\mathcal{D}_{tgt}$, the objective is to output a model θ_{tgt} in the target language tgt. For simplicity in this paper, we constrain the target model θ_{tgt} to be of the same network architecture to the off-the-shelf source model θ_{src}.

2.2 Basic Framework

We propose to adopt knowledge distillation (KD, Hinton et al., 2015) to address the FreeTransfer-X, since it can transfer knowledge from teacher models without knowing original labels. In addition, knowledge distillation is free from network architectures and can be applied between heterogeneous networks, which benefits the deployment in various environment.

2.2.1 Two-Step Knowledge Distillation

For a specific natural language processing (NLP) task, given a model θ_{src} and the unlabeled data $\mathcal{D}_{src}$ in the source language src and the unlabeled data $\mathcal{D}_{tgt}$ in the target language tgt. As shown in Figure 1, we propose to train a model θ_{tgt} in the target language tgt via 2 KD steps:

1. Leverage the NLP capability of the off-the-shelf model θ_{src}, e.g. an English sentence classifier $\theta_{en,cls}$. We distill knowledge from the teacher θ_{src} to the student mPLM θ^{m}_{src} on data $\mathcal{D}_{src}$.

2. Due to the zero-shot cross-lingual transfer capability of the mPLMs, θ^{m}_{src} implicitly achieve the NLP capability on the target language θ^{m}_{tgt}. Then similar to the step 1, we distill knowledge from the teacher θ^{m}_{tgt} to the student θ_{tgt} in the target language tgt on data $\mathcal{D}_{tgt}$.

The proposed framework works for arbitrary network including but not limited to Transformers (Vaswani et al., 2017), BiLSTM (Schuster and Paliwal, 1997) and CNN (Kim, 2014).

2.2.2 Training Objectives

The training is purely based on KD that no other training objectives is included. We only apply KD between the classification distribution $P_T(\cdot)$ and $P_S(\cdot)$ of the teacher and the student respectively, which is compatible to arbitrary model architecture. Freezing the parameters of the teacher, we train the student by minimizing the Kullback-Leibler Divergence (Div_{KL}, Joyce, 2011) between them. Denote the prediction category as $\mathcal{C} = [c_0, c_1, ..., c_k]$, then the Div_{KL} can be formalized as,

$$\begin{aligned} & Div_{KL}(P_T(\mathcal{C}|\cdot) \| P_S(\mathcal{C}|\cdot) \\ & = \sum_{c_i \in \mathcal{C}} P_T(c_i|\cdot) \log\left(\frac{P_T(c_i|\cdot)}{P_S(c_i|\cdot)}\right) \end{aligned} \tag{1}$$

However, KD objectives of different NLU tasks varies a lot. We classify NLU tasks into two categories: 1) sentence-level tasks like sentence classification, 2) word-level tasks like sequence tagging. Given an input example $\mathcal{X} \in \mathcal{D}$ as a sequence of words $\mathcal{X} = [x_0, x_1, ..., x_n]$. For sentence-level tasks, $\mathcal{X}$'s sentence-level category is $\mathcal{C}_{\mathcal{X}}$. The teacher model and student model respectively output sentence-level prediction distribution $P_T(\mathcal{C}_{\mathcal{X}}|\mathcal{X})$ and $P_S(\mathcal{C}_{\mathcal{X}}|\mathcal{X})$. For word-level tasks, $\mathcal{X}$'s word-level category is $\mathcal{C}_{x_i}, i \in [0, n]$. Then the KD objective can be written as,

$$\begin{aligned} & \mathcal{L} = Div_{KL}(P_T(\mathcal{C}|\mathcal{X}) \| P_S(\mathcal{C}|\mathcal{X})) \\ & \text{where } \mathcal{C} = \begin{cases} \mathcal{C}_{\mathcal{X}} & \text{, sentence-level} \\ \mathcal{C}_{x_i} & \text{, word-level} \end{cases} \end{aligned} \tag{2}$$

It's worth noting that word-level Div_{KL} cannot be directly applied for heterogeneous teacher and student models since their tokenizations are different. In order to align the predictions of teacher and student, we only adopt the prediction on the first sub-word of each word.

2.3 Enhanced Cross-Lingual Distillation

To explore the potentials of improving the two KD steps, we propose to enhance them with machine translation (MT) and paraphrase generation (PG).

2.3.1 Language Balanced Distillation

During the first KD step that training the mPLM from an English (i.e. the source language) classifier, to leverage the cross-lingual transferarability of mPLM, the conventional method is to train the mPLM only on the English corpus. However, in our preliminary experiments, we notice that the mPLM's accuracy gap between English and the target languages are very huge. It's over 5% between the English target model (94.0) and the average of all target models (88.4), as reported by *2-step KD* in Table 7, Appendix A.

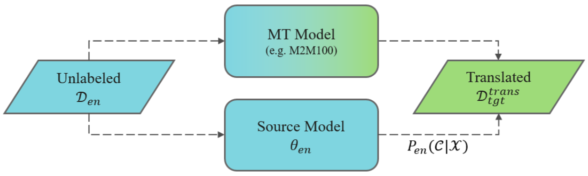

Figure 2: Language balanced distillation. Leverage the MT model to translate unlabeled English $\mathcal{D}_{en}$ into target languages $\mathcal{D}^{trans}_{tgt}$. Perform KD on the translated $\mathcal{D}^{trans}_{tgt}$ with θ_{en}'s predicted distribution $P_{en}(\mathcal{C}|\mathcal{X})$.

Hence, we propose to translate the unlabeled English corpus $\mathcal{D}_{en}$ to target languages $\mathcal{D}^{trans}_{tgt}$, as depicted by Figure 2. Since $\mathcal{D}_{en}$ and $\mathcal{D}^{trans}_{tgt}$ are aligned, source English model's predicted distribution $P_{en}(\mathcal{C}|\mathcal{X})$ of $\mathcal{D}_{en}$ can be directly applied to $\mathcal{D}^{trans}_{tgt}$. In this way, KD is able to be performed on not only the source language but also the target languages.

As shown in the lower left of Figure 1, the translated $\mathcal{D}_{tgt}^{trans}$ is incorporated in the training of KD step one.

2.3.2 Language-Specific Data Augmentation

Inspired by data augmentation for KD (Jiao et al., 2020) and multilingual paraphrase generation (Guo et al., 2019), we augment the unlabeled target corpus $\mathcal{D}_{tgt}$ via paraphrasing.

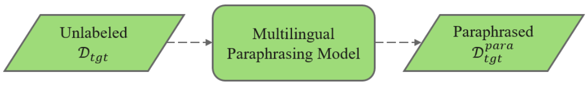

Figure 3: Language-specific data augmentation. We paraphrase the target corpus $\mathcal{D}_{tgt}$ into $\mathcal{D}_{tgt}^{para}$ as the augmented training data. KD is then performed on the mixture of $\mathcal{D}_{tgt}$ and $\mathcal{D}_{tgt}^{para}$.

3 Experiments

3.1 Datasets and Preprocessing

MultiATIS++ (Xu et al., 2020) extends the Multilingual ATIS corpus (Upadhyay et al., 2018) to 9 languages across 4 language families, including Indo-European (English, Spanish, German, French, Portuguese and Hindi), Sino-Tibetan (Chinese), Japonic (Japanese) and Altaic (Turkish). It provides annotations for intent recognition (sentence classification) and slot filling (sequence tagging) for each languages. The utterances are professionally translated from English and manually annotated. MultiATIS++ includes 37,084 training examples and 7,859 testing examples.

MTOP (Li et al., 2021) is a recently released multilingual NLU dataset covering 6 languages: English, German, French, Spanish, Hindi, Thai. It's also manually annotated for intent recognition (sentence classification) and slot filling (sequence tagging). MTOP provides a larger corpus consisting of 104,445 examples, of which 10% is validation set and 20% is testing set.

For each language, we randomly split both MultiATIS++ and MTOP into two balanced parts: *annotated* and *unannotated*. The annotated parts are used to train and simulate the off-the-shelf source models while the unannotated parts are used for training the baselines and the proposed 2-step distillation model. We tokenize Chinese, Japanese and Thai utterances using Jieba[2], MeCab[3] and pythainlp[4] respectively.

3.2 Baselines

Translate-Test (Conneau et al., 2018) is a machine translation based method. It performs two-pass inferences to tackle the FreeTransfer-X problem: 1) translate the testing utterances into English (i.e. the source language) from the target language, 2) predict on the translated English utterances with the off-the-shelf English model.

Translate-Train-Pseudo is also based on machine translation. It's a variant of the **Translate-Train** (Conneau et al., 2018), which translates English training examples into target languages and applies English annotations to the translated examples. However, annotations are not provided in the FreeTransfer-X problem. Hence, Translate-Train-Pseudo utilizes the prediction of the off-the-shelf English model to pseudoly annotates the translated examples.

Gold-Supervised is for reference since it's trained with annotations. It replaces the first distillation step of the proposed framework with gold-supervised training, in other words, the mPLM is supervised by gold annotations instead of the off-the-shelf English model. It's supposed to be very strong.

3.3 Experiment Settings

3.3.1 Model Architectures

We experiment with three mainstream NLU model architectures to verify the universality of the proposed framework. They are used as the backbones of the off-the-shelf models θ_{src} and the output models θ_{tgt} in target language.

Transformer encoder (Vaswani et al., 2017) models input sequences fully with Attention mechanism. We follow the language modeling method of BERT (Devlin et al., 2019a). We adopt absolute positional encoding. The contextual representation vector of the first word is used for sentence classification. Sequence tagging is based on the contextual representation of each word.

Bidirectional LSTM (BiLSTM) (Schuster and Paliwal, 1997) models input sequences via leveraging two stacked LSTM layers respectively from backward and forward directions. We take the representation vector of the last word for sentence classification. Word-level representation is used for sequence tagging like Transformer.

Table 1: Classification accuracy averaged over target languages. MTOP: de, es, fr, hi, th. MultiATIS++: de, es, fr, hi, ja, pt, tr, zh. For simplicity, the architecture of a target model is identical to its corresponding English source model.

Convolutional Neural Networks (CNN) (Kim, 2014) encodes input sequences with CNN modules. We adopt three kind of 1-D kernels with kernel size of 3, 4 and 5. Output vectors from all kernels and channels are concatenated as the representation for sentence classification. Dilated CNN (Strubell et al., 2017) is adopted for sequence tagging.

3.3.2 Training Details

English is regarded as the source language in all the experiments. Off-the-shelf English models are trained on the hold-out annotated English corpus as described in Section 3.1. All the experimented models are controlled in comparable model scale. AdamW (Loshchilov and Hutter, 2019) is adopted as the optimizer with $\epsilon = 1e - 8$. We train the models for 50 epochs and take the checkpoint of the best validation accuracy as the final model. Table 2 reports the hyper-parameters of the model architectures.

Model	Embed size	Hidden size	#Layers	#Params
Transformer	256	256	4	5.3M
BiLSTM	256	512	2	5.3M
CNN	256	768	2	5.0M

Table 2: Hyper-parameters of the experimented models.

Initial learning rate is decided based on a gradient-based searching heuristics proposed by Smith (2015), since in our preliminary experiments Smith (2015) stably finds better learning rates than manual searching. We build vocabularies of 10k words for each language via Byte Pair Encoding (BPE) Sennrich et al. (2016). Experiments are implemented with PyTorch (Paszke et al., 2019) and conducted on a single Nvidia V100 32GB GPU.

3.3.3 Auxiliary Models

M2M-100 (Fan et al., 2021) is adopted as the MT system in our experiments. We apply the 418M model checkpoint from Huggingface[5].

XLM-RoBERTa (Conneau et al., 2020) is adopted as the mPLM in the proposed 2-step distillation framework.

3.4 Results

Average accuracy across languages and models is given in Table 1 and Table 3. Language-wise results are provided in Appendix A.

3.4.1 Sentence Classification

As shown in Table 1, the proposed 2-step KD framework significantly outperforms the MT baselines on most model architectures, except for the CNN of *Translate-test*. Although *Translate-test* is strong in a very few cases, it requires 2-pass inference (MT and classification) that results in a high latency. On the contrary, the proposed framework directly produces classification models in the target languages, which is more efficient. In addition, the *language-balanced distillation* and *language-specific data augmentation* further enhance our model to a large extent, +2.3% and +1.1% respectively. Language-wise results in Table 7 demonstrate the robustness of our method across various languages.

To our surprise, the naive *2-step KD* model even performs on par with the *Gold-supervised* reference on average. We guess it's due to the regularization effects of knowledge distillation that brings a good generalizability to the proposed model. It implies the proposed framework may be a annotation-free alternative to current zero-shot cross-lingual transfer framework.

	+ Balanced distillation		92.8	93.2	92.9	92.4	91.8	91.6	93.2	89.2	92.9	92.2

Table 4: Classification accuracy of the finetuned mPLM models, i.e. XLM-RoBERTa. Evaluated on MultiATIS++. *Gold-supervised* is trained with gold annotations. **Bold languages** is not in the Indo-European language family as English.

However, comparing the results of the English source model and those of the target models in Table 7, the cross-lingual transferred models still lag far behind the original English models. There is a great potential of the proposed framework.

3.4.2 Sequence Tagging

On the sequence tagging task, the proposed model beats the baselines by a wide margin. The MT-based baselines perform very poor on this task due to the error from word-level annotation alignment. Also because of the alignment error, we do not apply *language balanced distillation* and *language-specific data augmentation* on this task.

As to the comparison with the *Gold-supervised* reference, our model performs slightly worse than it. It may due to the insufficient knowledge distillation from the teacher to the student, which comes from the discrepancy between teacher's and student's tokenizations. Although, as described in Section 2.2.2, we perfectly align their prediction at word-level, only the first subword of each word is used for distillation. More informative subword-level aligning and distillation methods can be explored. We leave this problem for the future research. Besides, similar to sentence classification, gap between the English source model and the transferred target models is huge, as shown in Table 3.

In sum, both experimental results on sentence classification and sequence tagging demonstrate that the proposed model is significantly stronger than MT-based cross-lingual transfer methods. Furthermore, the proposed model only slightly lags behind or even performs on par with the strong *Gold-supervised* reference, which is not able to address the FreeTransfer-X problem.

4 Further Analysis

In order to explore the potential of the proposed framework, we analyze it in more details. For simplicity, experiments in this Section are conducted only on the MultiATIS++ sentence classification task.

4.1 Effects of the Distillation

Table 4 reports the accuracy of the XLM-RoBERTa finetuned from gold annotations, Transformer teacher, BiLSTM teacher and CNN teacher.

First, compare the *Original* with the *Naive KD Finetuned* of each model respectively. It's very interesting that the accuracy of the student mPLM is consistently higher than its teacher. The XLM-RoBERTa students gain 2.8%, 2.4% and 2.0% improvement from the *Original* teachers as Transformer, BiLSTM and CNN respectively. The phenomenon implies the general effectiveness of language modeling of mPLMs. We conjecture the improvement comes from two aspects: 1) mPLMs'

Models		Original	Finetuned	Zero-Shot Cross-Lingual Transfer								
		en	en	de	es	fr	hi	ja	pt	tr	zh	Avg
Transformer	XLM-RoBERTa	94.4	97.2	96.9	96.8	96.2	90.8	90.1	95.6	84.3	91.3	92.8
	mBERT		96.9	88.4	92.4	93.8	81.1	85.7	94.0	73.7	83.2	86.5

	mBERT		92.3	80.4	87.5	82.5	79.2	79.4	82.3	76.5	75.0	80.3
CNN	XLM-RoBERTa	92.7	94.7	91.8	94.1	93.2	90.3	90.9	94.2	83.5	90.3	91.0
	mBERT		93.3	82.6	86.9	87.9	78.1	78.7	88.2	72.9	80.9	82.0

Table 5: Classification accuracy of XLM-RoBERTa and mBERT. *Step-1 KD*: off-the-shelf English model -> mPLM. The mPLMs are finetuned and evaluated on MultiATIS++.

Models		Original	Transferred	Transferred Target Languages									
		en	en	de	es	fr	hi	ja	pt	tr	zh	Avg	Δ
Transformer	XLM-RoBERTa	94.4	94.0	94.4	93.3	90.8	85.7	81.3	92.4	76.5	87.1	87.7	-5.1
	mBERT		95.6	86.2	91.8	92.8	79.8	81.7	90.9	72.9	80.3	84.6	-1.9
BiLSTM	XLM-RoBERTa	90.8	89.8	89.8	89.7	89.5	84.1	78.1	84.9	71.5	83.1	83.8	-4.9
	mBERT		89.6	80.9	82.9	81.0	78.5	76.0	83.7	71.7	78.6	79.2	-1.1
CNN	XLM-RoBERTa	92.7	90.7	87.9	88.1	87.8	85.0	83.2	86.3	75.2	86.7	85.0	-6.0
	mBERT		89.1	79.4	82.9	81.5	76.0	78.2	82.4	72.0	79.5	79.0	-3.0

Table 6: Classification accuracy of the target models, distilled from XLM-RoBERTa and mBERT respectively. *Step-2 KD*: mPLM -> target model. Δ: changes w.r.t Table 5. The target models are transferred and evaluated on MultiATIS++.

generalizability learn from the large-scale pre-training, 2) the large model scale of mPLMs, which enhances its NLU capability. Besides, the improvement with respect to the *Original* varies across model architectures. Especially when compare Transformer (+2.8%) to CNN (+2.0%), although the Transformer's student XLM-RoBERTa performs much closer to the *Gold-supervised*, it still improves greater than the CNN's student. Since the XLM-RoBERTa is Transformer-based network, it implies that the knowledge distillation performs better if the architectures of the teacher and the student are more similar.

Second, under the cross-lingual transfer condition, although the *Gold-supervised* outperforms the *Naive KD* on most target languages, it performs weaker on Turkish (tr). It demonstrates the better generalizability and few-shot performance of the *Naive KD*, since Turkish is a low-resource language in MultiATIS++. The number of training examples of Turkish (578) is less than other languages (4488).

Third, the effectiveness of the proposed *language balanced distillation* is very clear. In the comparison between the *Naive KD* and *+ Balanced distillation*, the accuracy is highly boosted almost on all the target languages. This improvement is particularly significant on the languages that is not in the same family of English: Hindi (hi), Japanese (ja), Turkish (tr) and Chinese (zh). A future research topic is to improve *language balanced distillation* on the languages similar to the source language, e.g. European languages to English. Data selection algorithms may have potentials.

In sum, the proposed framework and distillation method is effective and of strong generalizability. Future researches on heterogeneous distillation and data selection may benefit the proposed framework.

4.2 Effects of mPLM Models

Table 5 and Table 6 respectively reports accuracy of the step-1 KD and step-2 KD in the proposed framework. According to Table 6, the choice of mPLM is critical to the target models' performance. Performance with XLM-RoBERTa as the mPLM is stronger than with mBERT. However, there are interesting observations we should notice.

First, observe the performance changes (Δ) of the *Step-2 KD*: from the mPLM teacher to the target model student. We notice that the performance drop of mBERT is slighter than the XLM-RoBERTa's, based on the results of the average score in Table 6 minus those in Table 5. It implies that as the capability of mPLM increases, the KD dissipation tends to increase as well. Similar to the analysis in Section 4.1, the KD dissipation may come from: 1) the pre-trained language model that the target models lack of, 2) discrepancy between the model size of the mPLM and the target models. Hence, performance based on XLM-RoBERTa drops more due to its gap to the target models is greater than mBERT's in both the two aspects of discrepancy. To reduce the KD dissipation, researches should focus on how to reduce the model discrepancy between mPLM and the target model, e.g. improve the language modeling capability of the target model. Besides, the performance difference among model architectures is consistent, either based on XLM-RoBERTa or mBERT. It further evidences that the proposed framework is general and works well for different model architectures.

4.3 Cross-Architecture Transfer

To analyze the proposed framework in a more general setting, we free the architecture ties of the off-the-shelf English models and the target models to be heterogeneous, that the source and target models can be different.

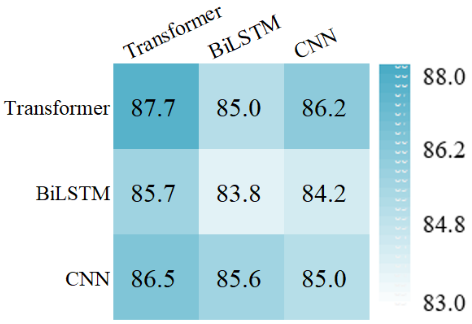

Figure 4: Classification accuracy of the target models via cross-architecture transfer, averaged over all target languages. Transfer from rows to columns. *Row*: architectures of source English models, *Column*: architectures of the target models. Experimented on MultiATIS++.

As depicted in Figure 4, the transfer performs the best when taking Transformer as both the source and target models. The worst comes to the transfer between BiLSTM models. On one side, the advantage of the Transformer architecture may be a reason. On the other side, it reconfirms the observation that the more similar teacher and student models are, the better transfer performance comes.

Besides, taking the BiLSTM as the source or target model consistently result in lower accuracy, no matter what the corresponding target or source models are. Hence, we guess the architecture similarity between BiLSTM and the Transformer-based mPLM is lower than that between CNN and the mPLM. We leave this for future work.

In addition, we study the accuracy drop from the source English models to the target models, as shown in Figure 5. From the perspective of the source model, the drop is the least when BiLSTM is the source. From the perspective of the target model, the drop is the least when Transformer is the target. It reveals an asymmetry between the two KD steps with respect to the mPLM. To reduce the KD dissipation to the largest extent, it seems mPLM should be distilled from a weaker teacher architecture (e.g. BiLSTM) before teaching a stronger student architecture (e.g. Transformer).

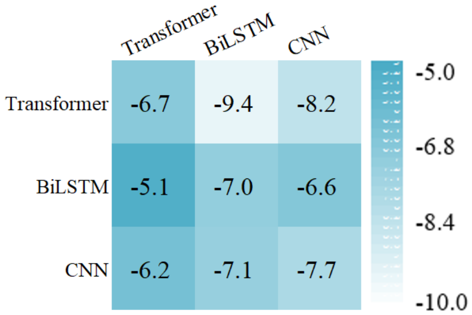

Figure 5: Accuracy drop from the source English models to the target models, averaged over all target languages. Transfer from rows to columns. *Row*: architectures of source English models, *Column*: architectures of the target models. Experimented on MultiATIS++.

In brief, the proposed framework works for heterogeneous cross-lingual transfer. The future work may focus on how to define the similarity between model architectures and how to evaluate the source-target model pairs.

5 Conclusions

In this paper, we define a novel cross-lingual transfer (CLT) problem - FreeTransfer-X, especially for CLT in private scenarios such as medical and business. The FreeTransfer-X is defined to transfer knowledge from off-the-shelf models in rich-resource languages to poor-resource languages, without labeled corpora. To address the FreeTransfer-X, we propose a 2-step knowledge distillation (2-step KD) framework based on multilingual pre-trained language models. In addition, two data augmentation methods for cross-lingual KD are proposed to boost the performance of the 2-step KD framework. Experimental results clearly demonstrate the effectiveness of the proposed framework. It's worth noting that the proposed KD framework can be applied between heterogeneous models, which benefits the deployment in different environment. Further analyses point out various research directions for future work.

FreeTransfer-X: Safe and Label-Free Cross-Lingual Transfer from Off-the-Shelf Models

Huawei Noah's Ark Lab
{guo.yinpeng, liliangyou, jiang.xin, qun.liu}@huawei.com

Abstract

Cross-lingual transfer (CLT) is of various applications. However, labeled cross-lingual corpus is expensive or even inaccessible, especially in the fields where labels are private, such as diagnostic results of symptoms in medicine and user profiles in business. Although being lack of labels, there are off-the-shelf models in these sensitive fields. Instead of pursuing the original labels, a workaround for CLT is to transfer knowledge from the off-the-shelf models without labels. To this end, we define a novel CLT problem named *FreeTransfer-X* that aims to achieve knowledge transfer from the off-the-shelf models in rich-resource languages. To address the problem, we propose a 2-step knowledge distillation (KD, Hinton et al., 2015) framework based on multilingual pre-trained language models (mPLM)[1]. The significant improvement over strong neural machine translation (NMT) baselines demonstrates the effectiveness of the proposed method. In addition to reducing annotation cost and protecting private labels, the proposed method is compatible with different networks and easy to be deployed. Finally, a range of analyses indicate the great potential of the proposed method.

1 Introduction

Cross-lingual transfer (CLT) is a critical topic for natural language processing due to the data imbalance between languages. While models of rich-resource languages (e.g. English) have been applied on various real-world tasks, the progress on poor-resource languages lags behind. CLT researches enable the knowledge transfer from the rich-resource languages to the poor-resource languages.

Although the application of CLT is valuable, data labels are expensive or even inaccessible in private and sensitive domains, such as medicine and business. For example, the diagnostic results of a user's symptoms are private and a company's internal description of users are confidential. Since short of labels for CLT, even though there are excellent applications in rich-resource languages, it is difficult to benefit the people using poor-resource languages. Previous CLT researches have not well studied how to leverage knowledge of rich-resource languages without labels. To define and tackle this problem will benefit both the community and the industry.

In order to reduce the demand of labels, existing works mainly fall into two paradigms as follows. One paradigm focuses on learning language-agnostic representation and model parameters. CLT is realized by either aligning parameters of monolingual models or sharing parameters among different languages (Liu et al., 2019; Devlin et al., 2019b; Conneau et al., 2020; Wang et al., 2020). The objective is to build a unified representation, which is used by downstream tasks, for all the languages. In this paradigm, although the demand of labels is reduced, it still requires a certain number of labels to adapt the model to a particular language and task. Besides, models in this paradigm are usually large-scale Transformers (Vaswani et al., 2017) based on mPLMs, which limits their deployment in real-world. Another paradigm is to leverage machine translation (MT) systems to generate training or testing pseudo-corpus for a specific language (Conneau et al., 2018). For simplicity, we take English as the rich-resource languages in this paper. `Translate-train` translates annotated training corpus from English to other languages. Gold labels are directly applied to the translated data. Although labels in poor-resource languages are not required, gold labels in English are still necessary. On the contrary, `Translate-test` translates testing corpus from poor-resource languages to English. This method can directly lever-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 229 - 240
July 10-15, 2022

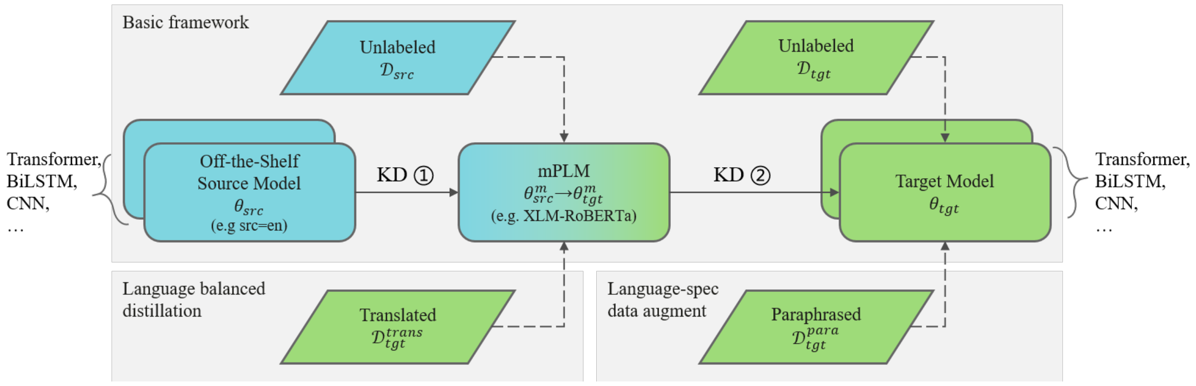

Figure 1: Overview of the proposed 2-step knowledge distillation (KD) framework. KD-(1) distills knowledge from the off-the-shelf English model to the mPLM. KD-(2) distills knowledge from the mPLM to the model in the target language. Blue modules: in the source language src, green modules: in the target language tgt.

age off-the-shelf English models, but it runs a 2-pass inference which highly limits its efficiency. Both the two CLT paradigms mentioned above require language-specific and task-specific labels, except for the 2-pass `Translate-test`. The demand of labels highly limits the reuse of the English knowledge in private and sensitive domains. Then a question comes up: *Is it possible to perform CLT totally without labels?*

In this paper, we define a novel problem: *safe and label-free cross-lingual transfer from off-the-shelf models (FreeTransfer-X)*. The FreeTransfer-X asks researchers to achieve CLT only with off-the-shelf English models but any labels, as formally defined in Section 2.1. To the best knowledge of the authors, it's the first time that the FreeTransfer-X is clearly defined.

To address the FreeTransfer-X, we propose a 2-step knowledge distillation (KD, Hinton et al., 2015) framework based on mPLM, as shown in Figure 1. Given an off-the-shelf model θ_{src} in the source language (e.g. English), first we take θ_{src} as the teacher and an mPLM model θ^m_{src} as the student, then train θ^m_{src} on unlabeled corpus $\mathcal{D}_{src}$. Second, we take θ^m_{tgt} as the teacher and train a student θ_{tgt} on unlabeled corpus $\mathcal{D}_{tgt}$. This cross-lingual transfer framework is label-free and applicable for any model architecture. Experimental results demonstrate the effectiveness of the proposed framework on both sentence classification and sequence tagging.

In short, the major contributions of this work include:

- A novel cross-lingual transfer problem FreeTransfer-X is defined. The FreeTransfer-X asks researchers to achieve CLT from off-the-shelf models without using labels. It reduces the labeling cost and protects the labels in private domains such as medicine and business.
- We propose a 2-step knowledge distillation framework based on mPLMs, e.g. XLM-RoBERTa (Conneau et al., 2020), to address the FreeTransfer-X. It significantly outperforms the NMT baselines on sentence classification and sequence tagging tasks. Besides, it's compatible with heterogeneous networks.
- Further analysis indicates abundant research potentials of the proposed framework. To improve the two distillation steps and the mPLM may benefit the framework.

2 Methodology

2.1 Problem Definition

Denote the source language and the target language as src and tgt respectively. Given an off-the-shelf model θ_{src} (e.g. English intent classifier), unlabeled in-domain corpus $\mathcal{D}_{src}$ and unlabeled in-domain corpus $\mathcal{D}_{tgt}$, the objective is to output a model θ_{tgt} in the target language tgt. For simplicity in this paper, we constrain the target model θ_{tgt} to be of the same network architecture to the off-the-shelf source model θ_{src}.

2.2 Basic Framework

We propose to adopt knowledge distillation (KD, Hinton et al., 2015) to address the FreeTransfer-X, since it can transfer knowledge from teacher models without knowing original labels. In addition, knowledge distillation is free from network architectures and can be applied between heterogeneous networks, which benefits the deployment in various environment.

2.2.1 Two-Step Knowledge Distillation

For a specific natural language processing (NLP) task, given a model θ_{src} and the unlabeled data $\mathcal{D}_{src}$ in the source language src and the unlabeled data $\mathcal{D}_{tgt}$ in the target language tgt. As shown in Figure 1, we propose to train a model θ_{tgt} in the target language tgt via 2 KD steps:

1. Leverage the NLP capability of the off-the-shelf model θ_{src}, e.g. an English sentence classifier $\theta_{en,cls}$. We distill knowledge from the teacher θ_{src} to the student mPLM θ^{m}_{src} on data $\mathcal{D}_{src}$.

2. Due to the zero-shot cross-lingual transfer capability of the mPLMs, θ^{m}_{src} implicitly achieve the NLP capability on the target language θ^{m}_{tgt}. Then similar to the step 1, we distill knowledge from the teacher θ^{m}_{tgt} to the student θ_{tgt} in the target language tgt on data $\mathcal{D}_{tgt}$.

The proposed framework works for arbitrary network including but not limited to Transformers (Vaswani et al., 2017), BiLSTM (Schuster and Paliwal, 1997) and CNN (Kim, 2014).

2.2.2 Training Objectives

The training is purely based on KD that no other training objectives is included. We only apply KD between the classification distribution $P_T(\cdot)$ and $P_S(\cdot)$ of the teacher and the student respectively, which is compatible to arbitrary model architecture. Freezing the parameters of the teacher, we train the student by minimizing the Kullback-Leibler Divergence (Div_{KL}, Joyce, 2011) between them. Denote the prediction category as $\mathcal{C} = [c_0, c_1, ..., c_k]$, then the Div_{KL} can be formalized as,

$$\begin{aligned} & Div_{KL}(P_T(\mathcal{C}|\cdot) \| P_S(\mathcal{C}|\cdot) \\ & = \sum_{c_i \in \mathcal{C}} P_T(c_i|\cdot) \log\left(\frac{P_T(c_i|\cdot)}{P_S(c_i|\cdot)}\right) \end{aligned} \tag{1}$$

However, KD objectives of different NLU tasks varies a lot. We classify NLU tasks into two categories: 1) sentence-level tasks like sentence classification, 2) word-level tasks like sequence tagging. Given an input example $\mathcal{X} \in \mathcal{D}$ as a sequence of words $\mathcal{X} = [x_0, x_1, ..., x_n]$. For sentence-level tasks, $\mathcal{X}$'s sentence-level category is $\mathcal{C}_{\mathcal{X}}$. The teacher model and student model respectively output sentence-level prediction distribution $P_T(\mathcal{C}_{\mathcal{X}}|\mathcal{X})$ and $P_S(\mathcal{C}_{\mathcal{X}}|\mathcal{X})$. For word-level tasks, $\mathcal{X}$'s word-level category is $\mathcal{C}_{x_i}, i \in [0, n]$. Then the KD objective can be written as,

$$\begin{aligned} & \mathcal{L} = Div_{KL}(P_T(\mathcal{C}|\mathcal{X}) \| P_S(\mathcal{C}|\mathcal{X})) \\ & \text{where } \mathcal{C} = \begin{cases} \mathcal{C}_{\mathcal{X}} & \text{, sentence-level} \\ \mathcal{C}_{x_i} & \text{, word-level} \end{cases} \end{aligned} \tag{2}$$

It's worth noting that word-level Div_{KL} cannot be directly applied for heterogeneous teacher and student models since their tokenizations are different. In order to align the predictions of teacher and student, we only adopt the prediction on the first sub-word of each word.

2.3 Enhanced Cross-Lingual Distillation

To explore the potentials of improving the two KD steps, we propose to enhance them with machine translation (MT) and paraphrase generation (PG).

2.3.1 Language Balanced Distillation

During the first KD step that training the mPLM from an English (i.e. the source language) classifier, to leverage the cross-lingual transferarability of mPLM, the conventional method is to train the mPLM only on the English corpus. However, in our preliminary experiments, we notice that the mPLM's accuracy gap between English and the target languages are very huge. It's over 5% between the English target model (94.0) and the average of all target models (88.4), as reported by *2-step KD* in Table 7, Appendix A.

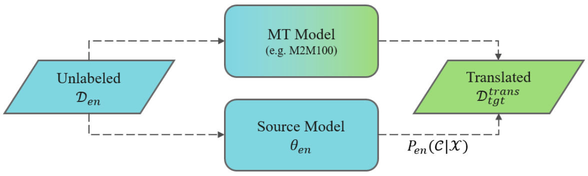

Figure 2: Language balanced distillation. Leverage the MT model to translate unlabeled English $\mathcal{D}_{en}$ into target languages $\mathcal{D}^{trans}_{tgt}$. Perform KD on the translated $\mathcal{D}^{trans}_{tgt}$ with θ_{en}'s predicted distribution $P_{en}(\mathcal{C}|\mathcal{X})$.

Hence, we propose to translate the unlabeled English corpus $\mathcal{D}_{en}$ to target languages $\mathcal{D}^{trans}_{tgt}$, as depicted by Figure 2. Since $\mathcal{D}_{en}$ and $\mathcal{D}^{trans}_{tgt}$ are aligned, source English model's predicted distribution $P_{en}(\mathcal{C}|\mathcal{X})$ of $\mathcal{D}_{en}$ can be directly applied to $\mathcal{D}^{trans}_{tgt}$. In this way, KD is able to be performed on not only the source language but also the target languages.

As shown in the lower left of Figure 1, the translated $\mathcal{D}_{tgt}^{trans}$ is incorporated in the training of KD step one.

2.3.2 Language-Specific Data Augmentation

Inspired by data augmentation for KD (Jiao et al., 2020) and multilingual paraphrase generation (Guo et al., 2019), we augment the unlabeled target corpus $\mathcal{D}_{tgt}$ via paraphrasing.

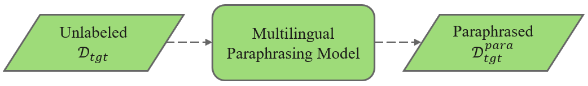

Figure 3: Language-specific data augmentation. We paraphrase the target corpus $\mathcal{D}_{tgt}$ into $\mathcal{D}_{tgt}^{para}$ as the augmented training data. KD is then performed on the mixture of $\mathcal{D}_{tgt}$ and $\mathcal{D}_{tgt}^{para}$.

3 Experiments

3.1 Datasets and Preprocessing

MultiATIS++ (Xu et al., 2020) extends the Multilingual ATIS corpus (Upadhyay et al., 2018) to 9 languages across 4 language families, including Indo-European (English, Spanish, German, French, Portuguese and Hindi), Sino-Tibetan (Chinese), Japonic (Japanese) and Altaic (Turkish). It provides annotations for intent recognition (sentence classification) and slot filling (sequence tagging) for each languages. The utterances are professionally translated from English and manually annotated. MultiATIS++ includes 37,084 training examples and 7,859 testing examples.

MTOP (Li et al., 2021) is a recently released multilingual NLU dataset covering 6 languages: English, German, French, Spanish, Hindi, Thai. It's also manually annotated for intent recognition (sentence classification) and slot filling (sequence tagging). MTOP provides a larger corpus consisting of 104,445 examples, of which 10% is validation set and 20% is testing set.

For each language, we randomly split both MultiATIS++ and MTOP into two balanced parts: *annotated* and *unannotated*. The annotated parts are used to train and simulate the off-the-shelf source models while the unannotated parts are used for training the baselines and the proposed 2-step distillation model. We tokenize Chinese, Japanese and Thai utterances using Jieba[2], MeCab[3] and pythainlp[4] respectively.

3.2 Baselines

Translate-Test (Conneau et al., 2018) is a machine translation based method. It performs two-pass inferences to tackle the FreeTransfer-X problem: 1) translate the testing utterances into English (i.e. the source language) from the target language, 2) predict on the translated English utterances with the off-the-shelf English model.

Translate-Train-Pseudo is also based on machine translation. It's a variant of the **Translate-Train** (Conneau et al., 2018), which translates English training examples into target languages and applies English annotations to the translated examples. However, annotations are not provided in the FreeTransfer-X problem. Hence, Translate-Train-Pseudo utilizes the prediction of the off-the-shelf English model to pseudoly annotates the translated examples.

Gold-Supervised is for reference since it's trained with annotations. It replaces the first distillation step of the proposed framework with gold-supervised training, in other words, the mPLM is supervised by gold annotations instead of the off-the-shelf English model. It's supposed to be very strong.

3.3 Experiment Settings

3.3.1 Model Architectures

We experiment with three mainstream NLU model architectures to verify the universality of the proposed framework. They are used as the backbones of the off-the-shelf models θ_{src} and the output models θ_{tgt} in target language.

Transformer encoder (Vaswani et al., 2017) models input sequences fully with Attention mechanism. We follow the language modeling method of BERT (Devlin et al., 2019a). We adopt absolute positional encoding. The contextual representation vector of the first word is used for sentence classification. Sequence tagging is based on the contextual representation of each word.

Bidirectional LSTM (BiLSTM) (Schuster and Paliwal, 1997) models input sequences via leveraging two stacked LSTM layers respectively from backward and forward directions. We take the representation vector of the last word for sentence classification. Word-level representation is used for sequence tagging like Transformer.

	+ Data augmentation	**79.6**	**79.1**	**78.8**	88.7	**86.4**	**86.9**	**83.3**

Table 1: Classification accuracy averaged over target languages. MTOP: de, es, fr, hi, th. MultiATIS++: de, es, fr, hi, ja, pt, tr, zh. For simplicity, the architecture of a target model is identical to its corresponding English source model.

Convolutional Neural Networks (CNN) (Kim, 2014) encodes input sequences with CNN modules. We adopt three kind of 1-D kernels with kernel size of 3, 4 and 5. Output vectors from all kernels and channels are concatenated as the representation for sentence classification. Dilated CNN (Strubell et al., 2017) is adopted for sequence tagging.

3.3.2 Training Details

English is regarded as the source language in all the experiments. Off-the-shelf English models are trained on the hold-out annotated English corpus as described in Section 3.1. All the experimented models are controlled in comparable model scale. AdamW (Loshchilov and Hutter, 2019) is adopted as the optimizer with $\epsilon = 1e-8$. We train the models for 50 epochs and take the checkpoint of the best validation accuracy as the final model. Table 2 reports the hyper-parameters of the model architectures.

Model	Embed size	Hidden size	#Layers	#Params
Transformer	256	256	4	5.3M
BiLSTM	256	512	2	5.3M
CNN	256	768	2	5.0M

Table 2: Hyper-parameters of the experimented models.

Initial learning rate is decided based on a gradient-based searching heuristics proposed by Smith (2015), since in our preliminary experiments Smith (2015) stably finds better learning rates than manual searching. We build vocabularies of 10k words for each language via Byte Pair Encoding (BPE) Sennrich et al. (2016). Experiments are implemented with PyTorch (Paszke et al., 2019) and conducted on a single Nvidia V100 32GB GPU.

3.3.3 Auxiliary Models

M2M-100 (Fan et al., 2021) is adopted as the MT system in our experiments. We apply the 418M model checkpoint from Huggingface[5].

XLM-RoBERTa (Conneau et al., 2020) is adopted as the mPLM in the proposed 2-step distillation framework.

3.4 Results

Average accuracy across languages and models is given in Table 1 and Table 3. Language-wise results are provided in Appendix A.

3.4.1 Sentence Classification

As shown in Table 1, the proposed 2-step KD framework significantly outperforms the MT baselines on most model architectures, except for the CNN of *Translate-test*. Although *Translate-test* is strong in a very few cases, it requires 2-pass inference (MT and classification) that results in a high latency. On the contrary, the proposed framework directly produces classification models in the target languages, which is more efficient. In addition, the *language-balanced distillation* and *language-specific data augmentation* further enhance our model to a large extent, +2.3% and +1.1% respectively. Language-wise results in Table 7 demonstrate the robustness of our method across various languages.

To our surprise, the naive *2-step KD* model even performs on par with the *Gold-supervised* reference on average. We guess it's due to the regularization effects of knowledge distillation that brings a good generalizability to the proposed model. It implies the proposed framework may be a annotation-free alternative to current zero-shot cross-lingual transfer framework.

	+ Balanced distillation		92.8	93.2	92.9	92.4	91.8	91.6	93.2	89.2	92.9	92.2

Table 4: Classification accuracy of the finetuned mPLM models, i.e. XLM-RoBERTa. Evaluated on MultiATIS++. *Gold-supervised* is trained with gold annotations. **Bold languages** is not in the Indo-European language family as English.

However, comparing the results of the English source model and those of the target models in Table 7, the cross-lingual transferred models still lag far behind the original English models. There is a great potential of the proposed framework.

3.4.2 Sequence Tagging

On the sequence tagging task, the proposed model beats the baselines by a wide margin. The MT-based baselines perform very poor on this task due to the error from word-level annotation alignment. Also because of the alignment error, we do not apply *language balanced distillation* and *language-specific data augmentation* on this task.

As to the comparison with the *Gold-supervised* reference, our model performs slightly worse than it. It may due to the insufficient knowledge distillation from the teacher to the student, which comes from the discrepancy between teacher's and student's tokenizations. Although, as described in Section 2.2.2, we perfectly align their prediction at word-level, only the first subword of each word is used for distillation. More informative subword-level aligning and distillation methods can be explored. We leave this problem for the future research. Besides, similar to sentence classification, gap between the English source model and the transferred target models is huge, as shown in Table 3.

In sum, both experimental results on sentence classification and sequence tagging demonstrate that the proposed model is significantly stronger than MT-based cross-lingual transfer methods. Furthermore, the proposed model only slightly lags behind or even performs on par with the strong *Gold-supervised* reference, which is not able to address the FreeTransfer-X problem.

4 Further Analysis

In order to explore the potential of the proposed framework, we analyze it in more details. For simplicity, experiments in this Section are conducted only on the MultiATIS++ sentence classification task.

4.1 Effects of the Distillation

Table 4 reports the accuracy of the XLM-RoBERTa finetuned from gold annotations, Transformer teacher, BiLSTM teacher and CNN teacher.

First, compare the *Original* with the *Naive KD Finetuned* of each model respectively. It's very interesting that the accuracy of the student mPLM is consistently higher than its teacher. The XLM-RoBERTa students gain 2.8%, 2.4% and 2.0% improvement from the *Original* teachers as Transformer, BiLSTM and CNN respectively. The phenomenon implies the general effectiveness of language modeling of mPLMs. We conjecture the improvement comes from two aspects: 1) mPLMs'

Models		Original	Finetuned	Zero-Shot Cross-Lingual Transfer

Table 6: Classification accuracy of the target models, distilled from XLM-RoBERTa and mBERT respectively. *Step-2 KD*: mPLM -> target model. Δ: changes w.r.t Table 5. The target models are transferred and evaluated on MultiATIS++.

generalizability learn from the large-scale pre-training, 2) the large model scale of mPLMs, which enhances its NLU capability. Besides, the improvement with respect to the *Original* varies across model architectures. Especially when compare Transformer (+2.8%) to CNN (+2.0%), although the Transformer's student XLM-RoBERTa performs much closer to the *Gold-supervised*, it still improves greater than the CNN's student. Since the XLM-RoBERTa is Transformer-based network, it implies that the knowledge distillation performs better if the architectures of the teacher and the student are more similar.

Second, under the cross-lingual transfer condition, although the *Gold-supervised* outperforms the *Naive KD* on most target languages, it performs weaker on Turkish (tr). It demonstrates the better generalizability and few-shot performance of the *Naive KD*, since Turkish is a low-resource language in MultiATIS++. The number of training examples of Turkish (578) is less than other languages (4488).

Third, the effectiveness of the proposed *language balanced distillation* is very clear. In the comparison between the *Naive KD* and + *Balanced distillation*, the accuracy is highly boosted almost on all the target languages. This improvement is particularly significant on the languages that is not in the same family of English: Hindi (hi), Japanese (ja), Turkish (tr) and Chinese (zh). A future research topic is to improve *language balanced distillation* on the languages similar to the source language, e.g. European languages to English. Data selection algorithms may have potentials.

In sum, the proposed framework and distillation method is effective and of strong generalizability. Future researches on heterogeneous distillation and data selection may benefit the proposed framework.

4.2 Effects of mPLM Models

Table 5 and Table 6 respectively reports accuracy of the step-1 KD and step-2 KD in the proposed framework. According to Table 6, the choice of mPLM is critical to the target models' performance. Performance with XLM-RoBERTa as the mPLM is stronger than with mBERT. However, there are interesting observations we should notice.

First, observe the performance changes (Δ) of the *Step-2 KD*: from the mPLM teacher to the target model student. We notice that the performance drop of mBERT is slighter than the XLM-RoBERTa's, based on the results of the average score in Table 6 minus those in Table 5. It implies that as the capability of mPLM increases, the KD dissipation tends to increase as well. Similar to the analysis in Section 4.1, the KD dissipation may come from: 1) the pre-trained language model that the target models lack of, 2) discrepancy between the model size of the mPLM and the target models. Hence, performance based on XLM-RoBERTa drops more due to its gap to the target models is greater than mBERT's in both the two aspects of discrepancy. To reduce the KD dissipation, researches should focus on how to reduce the model discrepancy between mPLM and the target model, e.g. improve the language modeling capability of the target model. Besides, the performance difference among model architectures is consistent, either based on XLM-RoBERTa or mBERT. It further evidences that the proposed framework is general and works well for different model architectures.

4.3 Cross-Architecture Transfer

To analyze the proposed framework in a more general setting, we free the architecture ties of the off-the-shelf English models and the target models to be heterogeneous, that the source and target models can be different.

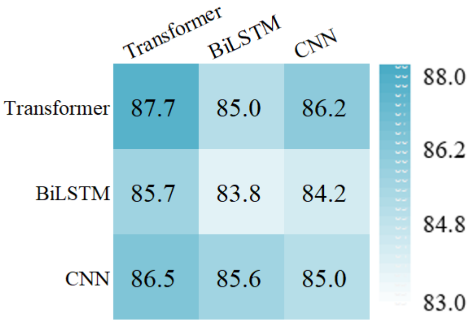

Figure 4: Classification accuracy of the target models via cross-architecture transfer, averaged over all target languages. Transfer from rows to columns. *Row*: architectures of source English models, *Column*: architectures of the target models. Experimented on MultiATIS++.

As depicted in Figure 4, the transfer performs the best when taking Transformer as both the source and target models. The worst comes to the transfer between BiLSTM models. On one side, the advantage of the Transformer architecture may be a reason. On the other side, it reconfirms the observation that the more similar teacher and student models are, the better transfer performance comes.

Besides, taking the BiLSTM as the source or target model consistently result in lower accuracy, no matter what the corresponding target or source models are. Hence, we guess the architecture similarity between BiLSTM and the Transformer-based mPLM is lower than that between CNN and the mPLM. We leave this for future work.

In addition, we study the accuracy drop from the source English models to the target models, as shown in Figure 5. From the perspective of the source model, the drop is the least when BiLSTM is the source. From the perspective of the target model, the drop is the least when Transformer is the target. It reveals an asymmetry between the two KD steps with respect to the mPLM. To reduce the KD dissipation to the largest extent, it seems mPLM should be distilled from a weaker teacher architecture (e.g. BiLSTM) before teaching a stronger student architecture (e.g. Transformer).

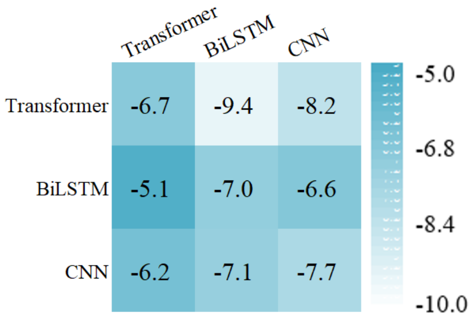

Figure 5: Accuracy drop from the source English models to the target models, averaged over all target languages. Transfer from rows to columns. *Row*: architectures of source English models, *Column*: architectures of the target models. Experimented on MultiATIS++.

In brief, the proposed framework works for heterogeneous cross-lingual transfer. The future work may focus on how to define the similarity between model architectures and how to evaluate the source-target model pairs.

5 Conclusions

In this paper, we define a novel cross-lingual transfer (CLT) problem - FreeTransfer-X, especially for CLT in private scenarios such as medical and business. The FreeTransfer-X is defined to transfer knowledge from off-the-shelf models in rich-resource languages to poor-resource languages, without labeled corpora. To address the FreeTransfer-X, we propose a 2-step knowledge distillation (2-step KD) framework based on multilingual pre-trained language models. In addition, two data augmentation methods for cross-lingual KD are proposed to boost the performance of the 2-step KD framework. Experimental results clearly demonstrate the effectiveness of the proposed framework. It's worth noting that the proposed KD framework can be applied between heterogeneous models, which benefits the deployment in different environment. Further analyses point out various research directions for future work.

Abstract

Back translation (BT) is one of the most significant technologies in NMT research fields. Existing attempts on BT share a common characteristic: they employ either beam search or random sampling to generate synthetic data with a backward model but seldom work studies the role of synthetic data in the performance of BT. This motivates us to ask a fundamental question: *what kind of synthetic data contributes to BT performance?* Through both theoretical and empirical studies, we identify two key factors on synthetic data controlling the back-translation NMT performance, which are quality and importance. Furthermore, based on our findings, we propose a simple yet effective method to generate synthetic data to better trade off both factors so as to yield a better performance for BT. We run extensive experiments on WMT14 DE-EN, EN-DE, and RU-EN benchmark tasks. By employing our proposed method to generate synthetic data, our BT model significantly outperforms the standard BT baselines (i.e., beam and sampling based methods for data generation), which proves the effectiveness of our proposed methods.

1 Introduction

Since the birth of neural machine translation (NMT) (Bahdanau et al., 2014; Sutskever et al., 2014) back translation (BT) (Sennrich et al., 2016a) has quickly become one of the most significant technologies in natural language processing (NLP) research field. This is because 1) it provides a simple yet effective approach to advance the supervised NMT by leveraging monolingual data (Edunov et al., 2018) and it also serves as a key learning objective in unsupervised NMT (Artetxe et al., 2018; Lample et al., 2018); 2) back translation even plays a significant role in other NLP research fields beyond translation such as paraphrasing (Mallinson et al., 2017) and style transfer (Prabhumoye et al., 2018; Zhang et al., 2018).

Back translation consists of two steps, namely synthetic corpus generation with a backward model and parameter optimization for the forward model. Various contributions have been made on improving back translation, for instance, iterative back translation (Hoang et al., 2018), tagged back translation (Caswell et al., 2019), confidence weighting (Wang et al., 2019), data diversification (Nguyen et al., 2020). Although these efforts differ in some aspects, all of them share a common characteristic: they employ a default way to generate synthetic data in the first step of BT which is either beam search or random sampling with a backward model. Seldom work studies the consequences of synthetic corpus to back translation and hence it is unclear how synthetic data influences the final performance of BT.

The early study empirically suggests the quality of the synthetic corpus is vital for BT performance (Sennrich et al., 2016a). However, recent studies illustrate better test performance can be achieved by low quality synthetic corpus (Edunov et al., 2018). This contradictory observation indicates the quality of synthetic data is not the only element that affects the BT performance. Hence, this fact naturally raises a fundamental question: *what kind of synthetic data contributes to back translation performance?*

In this paper, we attempt to take a step forward toward the above fundamental question. To this end, we start from a critical objective in semi-supervised learning, which is defined by the marginal distribution of a target language. Then we derive an approximate lower bound of the objective function, which is closely related to the objective of back translation. Corresponding to this lower bound, we theoretically find two related elements for maximizing such a lower bound: quality of syn-

July 10-15, 2022

thetic bilingual data and importance weight of its source. Since both elements are mutually exclusive to some extent, it may induce contradictory observation if one judges the BT performance according to a single element. In addition, such a theoretical explanation is supported by our empirical experiments. Furthermore, based on our findings, we propose a new heuristic approach to generate synthetic data whose both elements are better balanced so as to yield improvements over both sampling and beam search based methods. Extensive experiments on three WMT14 tasks show that our BT consistently outperforms the standard sampling and beam search based baselines by a significant margin.

Our contributions are three folds:

1. We point out that importance weight and quality of synthetic candidates are two key factors that affect the NMT performance.
2. We propose a simple yet effective method for synthetic corpus generation, which could better balance the quality and importance of synthetic data.
3. Our experiments prove the effectiveness of the aforementioned strategy, it outperforms beam or sampling decoding methods on three benchmark tasks.

2 Revisiting Back Translation

NMT builds a probabilistic model $p(y|x;\theta)$ with neural networks parameterized by θ, which is used to translate a sentence x in source language $\mathcal{X}$ to a sentence y in target language $\mathcal{Y}$. The standard wisdom to train the model is to minimize the following objective function over a given bilingual corpus $\mathcal{B} = \{(x_i, y_i)\}$:

$$\ell(\mathcal{B};\theta) = \sum_{(x_i,y_i)\in\mathcal{B}} \log p(y_i|x_i;\theta) \tag{1}$$

Recently Sennrich et al. (2016a) propose a remarkable method called **Back Translation (BT)** to improve NMT by using a monolingual corpus $\mathcal{M}$ in target language $\mathcal{Y}$ besides $\mathcal{B}$ and back translation becomes one of the most successful techniques in NMT (Fadaee and Monz, 2018; Edunov et al., 2018). At a high level, back translation can be considered as a semi-supervised method because it leverages both labeled and unlabeled data. Suppose $p(x|y;\pi)$ is the backward translation model whose parameter π is optimized over $\mathcal{B}$, the key idea of back translation can be summarized as the following two steps:

- **Synthetic Corpus Generation:** It firstly back-translates each target sentence $y \in \mathcal{M}$ to $\hat{x}$ obtain a synthetic bilingual corpus $\{(\hat{x}, y) \mid y \in \mathcal{M}\}$ by $p(x|y;\pi)$.
- **Parameter Optimization:** It combines both authentic corpus $\mathcal{B}$ and the synthetic corpus and then optimizes the parameter θ by minimizing the loss

$$\ell(\mathcal{B};\theta) + \sum_{y\in\mathcal{M}} \log p(y|\hat{x};\theta) \tag{2}$$

To make BT more efficient, the standard configuration is widely adopted: each sentence y is required to generate a single source $\hat{x}$ and both two steps are performed for a single pass. We follow this standard in this paper for generality but our idea in this paper is straightforward to apply to other configurations such as (Graça et al., 2019; Hoang et al., 2018; Nguyen et al., 2020).

In the first step, there are two main strategies to generate the synthetic corpus, i.e., deterministically decoding and randomly sampling with $p(x|y;\pi)$. The first strategy aims to search the best candidate as follows,

$$\hat{x}^b = \arg\max p(\hat{x}|y;\pi) \tag{3}$$

The above optimization is achieved by the beam search decoding, which can be regarded as a degenerated shortest path problem with respect to the $\log p(\hat{x}|y;\pi)$ with limited routing attempts. The alternative strategy is random sampling: it randomly samples a token with respect to the distribution estimated by a back-translation model at each decoding step. Such a process can be modelled by,

$$\hat{x}^s = \mathtt{rand}\{p(\hat{x}|y;\pi)\} \tag{4}$$

Research Question Prior work points out (Sennrich et al., 2016a) that the synthetic corpus with high quality is beneficial to the final performance of back translation. However, the recent studies (Edunov et al., 2018) find that NMT models with unsatisfactory BLEU score corpus, for instance, the corpus generated by sampling based strategy, also establish the state-of-the-art (SOTA) achievement among back-translation NMT models.

This contradictory fact indicates that the quality of synthetic corpus is not the sole element for back translation. This motivates us to study a fundamental question for back translation: *what kind of synthetic corpus is beneficial to back translation?*

3 Understanding Synthetic Data by Two Factors

To answer the fundamental question presented in the previous section, we first start from the marginal likelihood objective defined on the target language $\mathcal{Y}$, and then we theoretically explain two factors (i.e., quality and importance) that are highly related to the training objective of back translation. Finally, we empirically explain why synthetic corpus with low quality may lead to better performance than synthetic corpus with high quality by measuring both factors.

3.1 Theoretical Explanation

Maximizing marginal likelihood is an important principle to leverage unlabeled data. Therefore, we rethink back translation from this principle because it makes use of target monolingual corpus $\mathcal{M}$. For each $y \in \mathcal{M}$, the marginal likelihood objective can be derived by the Bayesian Equation (5), Jansen Inequality (6), and importance sampling (7) as follows:

$$\begin{aligned}
\log p(y;\theta) &= \log \sum_x p(x)p(y|x;\theta) && (5)\\
&\geq \sum_x p(x)\log p(y|x;\theta) && (6)\\
&= \sum_x p(x|y)\frac{p(x)}{p(x|y)}\log p(y|x;\theta) &&\\
&= \mathbb{E}_{\hat{x}\sim p(\cdot|y)}\left\{\frac{p(\hat{x})}{p(\hat{x}|y)}\log p(y|\hat{x};\theta)\right\} &&\\
&\approx \frac{p(\hat{x})}{p(\hat{x}|y)}\log p(y|\hat{x};\theta) && (7)
\end{aligned}$$

where $p(x)$ is a language model on source language $\mathcal{X}$, $p(x|y)$ is a backward translation model from $\mathcal{Y}$ to $\mathcal{X}$ which serves as the proposal distribution for importance sampling, and $\hat{x}$ is sampled from $p(x|y)$. If $p(x|y)$ is set as the backward model $p(x|y;\pi)$ optimized on $\mathcal{B}$, the last term in Equation 7 is the same as the second term in BT loss (i.e., $\log p(y|\hat{x})$ in Eq. 2), and the unique difference is the multiplicative term called *importance* weight:

$$\mathrm{Imp}(\hat{x};y) = \frac{p(\hat{x})}{p(\hat{x}|y)} \qquad (8)$$

The denominator is the candidate conditional probability to target, and the numerator is the candidate distribution on source language distribution. Since $\mathrm{Imp}(\hat{x};y)$ is constant with respect to the parameter θ, maximizing $\log p(y|\hat{x};\theta)$ in BT loss implicitly maximizes $\mathrm{Imp}(\hat{x};y)\log p(y|\hat{x})$, which indicates that back translation aims to implicitly maximize the marginal likelihood objective. More importantly, according to Equation 7 we can find that the following two factors are critical to influence the marginal likelihood $\log p(y;\theta)$:

- **Factor 1:** The quality of $\hat{x}$ as a translation of y corresponding to the $\log p(y|\hat{x};\theta)$ in Eq. 7.
- **Factor 2:** The importance of $\hat{x}$ as a translation of y corresponding to $\mathrm{Imp}(\hat{x};y)$ in Eq. 7.

Theoretically, if $\hat{x}$ is of higher quality and contains more semantic information in y, $p(y|\hat{x};\theta)$ would be higher and thus it would lead to a higher $\log p(y;\theta)$, which is well acknowledged by prior work (Sennrich et al., 2016a; Wang et al., 2019). In particular, if $\hat{x}$ is with higher importance weight, maximizing $\log p(y|\hat{x};\theta)$ is more helpful to maximize $\log p(y;\theta)$. On the contrary, if $\mathrm{Imp}(\hat{x};y)$ is very small, it needs to avoid such a sample $\hat{x}$ from $p(x|y)$, which is essentially the rejection control strategy in importance sampling theory (Liu et al., 1998; Liu and Liu, 2001).

Unfortunately, in practice, both factors are mutually exclusive to some extent: if $\hat{x}$ is with high quality, $p(\hat{x}|y;\theta)$ would be higher as well leading to lower importance weight. This fact can explain the contradictory observation in Sec 2 that BT with high-quality synthetic data sometimes leads to better testing performance, while it may deliver worse performance at other times, which will be later justified in Sec 3.2.

Estimating Two Factors To measure the quality of $\hat{x}$ for each y, it is natural to use the evaluation metric such as BLEU if the reference translation x of y is available. Otherwise, as a surrogate, we use the log likelihood $\log p(\hat{x}|y;\pi)$ of the backward translation model π which is trained on the authentic data $\mathcal{B}$. Similarly, in order to estimate the importance of $\hat{x}$, we train an additional language model $p(x;\omega)$ with GPT (Radford et al., 2018) on a large monolingual corpus for $\mathcal{X}$. In this way, the importance weight is estimated by

$$\mathrm{Imp}(\hat{x}) \approx \frac{p(\hat{x};\omega)}{p(\hat{x}|y;\pi)}$$

Systems	BLEU($\hat{x}$)	$\log p(\hat{x}\|y, \pi)$	Imp.	Test BLEU
beam	**27.20**	**-15.65**	-95.13	32.7
sampling	7.70	-157.62	**-41.86**	34.1
beam*	**18.50**	**-26.66**	-95.07	31.6

* The checkpoint of the backward model for generating synthetic corpus are only trained for 1 epoch. However, its $\log p(\hat{x}|y, \pi)$ is still measured by a standard backward model π.

Table 1: Testing BLEU (on test set), quality (measured by both BLEU and $\log p(\hat{x}|y; \pi)$) and importance (Imp.) estimation of synthetic data (on dev set) with beam search or random sampling on WMT14 DE-EN task.

Systems	BLEU($\hat{x}$)	$\log p(\hat{x}\|y, \pi)$	Imp.	Test BLEU
en-de(en)_beam	**31.90**	**-15.29**	-91.07	29.7
en-de(en)_sampling	10.90	-139.71	**-46.88**	30.0
ru-en(ru)_beam	**33.10**	**-15.49**	-89.71	35.9
ru-en(ru)_sampling	9.50	-155.82	**-47.47**	35.6

Table 2: Testing BLEU (on test set), quality (measured by both BLEU and $\log p(\hat{x}|y; \pi)$) and importance (Imp.) estimation of synthetic data (on development set) with beam search or random sampling on WMT14 EN-DE and RU-EN tasks.

3.2 Empirical Justification

In this subsection, we aim to justify the following statements: 1) encouraging the quality of synthetic corpus may to some extent hurt the performance of BT due to the decrease of importance; 2) judging the testing performance in terms of quality only may be dangerous while it would be meaningful to judge the testing performance by taking into account both factors rather than either factor. To this end, we run some quick experiments on WMT14 datasets whose settings will be shown in Sec 5 later.

We set up two back translation systems with two different options (i.e., beam search and sampling) to generate synthetic corpus by using the best checkpoint of $p(\hat{x}|y; \pi)$ tuned on the development set. Both beam search and sampling based BT systems are denoted by beam and sampling. In addition, we pick another checkpoint of $p(\hat{x}|y; \pi)$ which is trained for only 1 epoch, and we use this weak checkpoint to set up another beam search based BT system, which is denoted as beam*. Table 1 shows BLEU on test dataset, the quality and importance on the development set according to three systems on WMT14 DE-EN task.

In Table 1, beam is better than sampling in the quality of synthetic corpus but its testing performance is worse. This is meaningful because the former relies on the synthetic corpus with lower importance weight according to our theoretical explanation. In addition, when comparing beam with beam*, we can find that beam delivers better testing performance because its quality is better meanwhile its importance weight is almost similar to that of beam*. Table 2 consistently demonstrates that it is meaningless to take into account quality only when evaluating BT. These facts justify our statements and provide an answer to the fundamental question in section 2.

4 Improving Synthetic Data for BT

As shown in the previous section, both importance and quality of synthetic corpus are beneficial to the overall testing performance of back translation. It is a natural idea to promote both factors when generating synthetic corpus such that running BT on such corpus leads to better testing performance. However, this is difficult because both factors are mutually exclusive as discussed in Section 3. In this section, we instead propose two methods (namely data manipulation and gamma score) to trade off both factors in the hope to yield better BT performance.

4.1 Data Manipulation

Since the synthetic data in sampling based BT is of high importance yet low quality whereas the case for the synthetic data in beam search based BT is opposite, we propose a data manipulation method to trade off importance and quality by combining both synthetic datasets. Through balancing the ratio between beam and sampling based synthetic corpora, we expect to find an optimized beam/sampling ratio to further improve NMT model performance.

Specifically, we randomly shuffle $\mathcal{M}$ and divide it into two parts with the first part accounting for γ ($0 < \gamma < 1$); then we generate translations for the first part with beam search while generating translations for the second part with sampling. Formally, we use the following corpus $\mathcal{M}^c$ as the synthetic corpus for BT:

$$\mathcal{M}^c = \{(\hat{x}_i^b, y_i)_{i=0}^{k}\} \cup \{(\hat{x}_j^s, y_j)_{j=k}^{|\mathcal{M}|}\}$$
$$k = \lfloor \gamma |\mathcal{M}| \rfloor$$

Where $\hat{x}^b$ denotes a translation of y generated by $p(x|y; \pi)$ with beam search and $\hat{x}^s$ is a translation with sampling, $|\cdot|$ means the size of the corpus, and γ is the combination ratio for beam and sampling synthetic corpora. By tuning γ here, one can modify the weightage for the number of beam and sampling sentences, to improve back-translation performance by training models on a combined synthetic corpus.

Although this method is easy to implement, its limitation is obvious. Since each $\hat{x}$ is either from beam search or from sampling, the quality of $\mathcal{M}^c$ is generally worse than that of beam search and its importance weight is generally worse than that of sampling. Consequently, we propose an alternative method in the next part of this section.

4.2 Gamma Score

The key idea to the alternative method is that it employs a score that balances both quality and importance to generate a translation $\hat{x}$ for each $y \in \mathcal{M}$. A natural choice of such a score is defined by the interpolation score as follows:

$$\gamma \log \mathrm{Imp}(\hat{x}; \omega, \pi) + (1-\gamma) \log p(\hat{x}|y; \pi)$$

where γ is used to trade off both factors as in corpus manipulation. With the help of this score, one may optimize the $\hat{x}$ by beam search whose interpolation score is the best among all possible translations of $y \in \mathcal{M}$. Unfortunately, such an implementation leads to limited performance in our preliminary experiments, due to two major challenges.

On one hand, the estimations of quality and importance weight of $\hat{x}$ are not well calibrated, and in particular, quality and importance are mutually exclusive as mentioned before. As a result, beam search with the interpolation score over the exponential space can not guarantee a desirable translation $\hat{x}$ for each y. On the other hand, quality and importance weight of $\hat{x}$ are not at the same scale for different y, it is difficult to balance both factors with a fixed γ in the interpolation score for different y.

To alleviate these issues, we propose a simple method as follows. Specifically, firstly, instead of beam search with the interpolation score, we simply utilize the backward translation $p(x|y;\pi)$ to randomly sample a set of candidate translations which is denoted by $A(y) = \{\hat{x}_i\}_i^N$ ($N = 50$ in this paper as it works well). [1] Then we pick a $\hat{x}_j$ among $A(y)$ according to the balancing score. Secondly, for each $\hat{x}$, we normalize the log values of importance and quality of each candidate by its sequence length, then normalize these values with respect to all N candidates as follows:

$$\tilde{\mathcal{F}}(\hat{x}_i) = \frac{\log\big(\mathcal{F}(\hat{x}_i)\big)/\mathtt{len}(\hat{x}_i) - \mu_{\mathcal{F}}}{\sigma_{\mathcal{F}}} \quad (9)$$

where $\mathcal{F}$ is either importance weight or quality estimations, and $\mu_{\mathcal{F}} = \frac{1}{N}\sum_i \log \mathcal{F}(\hat{x}_i)$ and $\sigma_{\mathcal{F}} = \frac{\sum_i (\log \mathcal{F}(\hat{x}_i) - \mu_{\mathcal{F}})^2}{N-1}$ are mean and variance of N sampled candidates with length normalized. Finally, the Gamma score is defined on the normalized values of importance and quality as follows:

$$\Gamma(\hat{x}_i; \omega, \pi) = \frac{\exp\big(\gamma \tilde{\mathrm{Imp}}(\hat{x}_i; \omega, \pi) + (1-\gamma)\tilde{p}(\hat{x}_i|y,\pi)\big)}{\sum_j \exp\big(\gamma \tilde{\mathrm{Imp}}(\hat{x}_j; \omega, \pi) + (1-\gamma)\tilde{p}(\hat{x}_j|y,\pi)\big)} \quad (10)$$

where $\tilde{\mathrm{Imp}}$ and $\tilde{p}$ are the normalized log value of importance weight and backward translation model $p(\hat{x}|y,\pi)$ as defined in Equation 9.

Once the gamma score in Equation 10 is computed, there are two methods to select $\hat{x}$ from $A(y)$, which are deterministic and stochastic methods. For deterministic selection, we simply select the candidates with maximum gamma score among N translation candidates; and for sampling, we sample a candidate according to its gamma score distribution. These two methods are called gamma selection and gamma sampling in our experiments.

5 Experiments

5.1 Settings

We run all the experiments by using fairseq (Ott et al., 2019) framework. For dataset settings, since datasets WMT14 EN-DE and DE-EN are widely used (Li et al., 2019b; Zhu et al., 2020; Li et al., 2020; Fan et al., 2021; Le et al., 2021), we follow both standard benchmarks and additionally we employ WMT14 RU-EN as the third dataset to validate the effectiveness of the proposed methods. For back translation experiment, we use an equal scale monolingual corpus randomly sampled from Newscrawl 2020 (Barrault et al., 2019) comprising 4.5 million monolingual sentences for DE-EN language pair and 2.5 million for RU-EN direction, thus total 9 million sentences for DE-EN pair and 5 million for RU-EN direction are used. We tokenize the parallel corpus using Mose tokenizer (Koehn et al., 2007), and learn a source and target shared Byte-Pair-Encoding (BPE) (Sennrich et al., 2016b)

---

[1] N-best decoding strategy with $p(x|y;\pi)$ to generate N candidates may be another solution which remains as future work.

Systems	DE-EN

with 32K types. We develop on newstest2013 and report the results on newstest2014.

As for model architecture, we employ all the translation models using architecture `transformer_wmt_en_de_big`, which is a Big Transformer architecture with 6 blocks in the encoder and decoder, and is widely used as a standard backbone on various NMT research studies. We use the same hyperparameter settings across all the experiments, i.e., 1024 word representation size, 4096 inner dimensions of feed-forward layers, and dropout is set to 0.3 for all the experiments. In addition, for monolingual models, we apply `transformer_lm_gpt` architecture (Radford et al., 2018) on source language side of the corpus without any extra corpus. [2] The detailed hyperparameters used for training translation and language models are shown in Appendix.

For baseline models, we train them for 400K updating steps, and train the models with back-translation data for 1.6M updating steps. We save the checkpoints every 100k updating intervals, and only select the checkpoints with highest develop set performance. As for the back-translation data, we study beam decoding and sampling decoding as baselines since they are the common practice for BT research (Roberts et al., 2020; Wang et al., 2019). We use baseline models' checkpoints at 400K updating steps to generate default beam5 decoding and sampling decoding synthetic corpus without any penalty. For monolingual models, we only select the checkpoints with the best develop set performance. When tuning γ on dev sets for data manipulation methods we select it from $\{0, 1/4, 1/2, 3/4, 1\}$ and the optimal is $\gamma = 1/2$. For the Gamma Score method, γ is tuned among $\{0.1, 0.2, 0.3, 0.4, 0.5\}$ and it is set $\gamma = 0.2$ for all three tasks.

All the experiments are conducted using 8 Nvidia V100-32GB graphic cards without any gradient accumulation or bitext upsampling, and the results in this paper are measured in case-sensitive detokenized BLEU with SacreBLEU[3] by Post (2018).

5.2 Main Results

5.2.1 Results on DE-EN

Data Manipulation We conduct two experiments to study the data manipulation for back-translation NMT model performance using aforementioned corpus with and without authentic corpus.

Table 3 show the data manipulation results compared with baseline. Firstly, for synthetic corpus experiment, we find that even if only monolingual corpus is used, the performance of back-translation NMT model can still be significantly improved to 31.3 from 29.2 by sampling or 27.6 by beam, and it is only 0.7 lower than bitext baseline by BLEU score measure. Secondly, for the experiments with bitext, the best performance by data manipulation only helps the back-translation NMT model achieves almost the same performance with sampling BT. This means data manipulation methods cannot achieve a higher BLEU score than sampling or beam.

Gamma Score In this paragraph, we conduct the experiments based on gamma score method. We conduct both of the methods in this experiment: we select the candidate with highest gamma score for the deterministic method whereas sample the candi-

---

[2] Note that we do not use the pre-trained language models such as GPT-3 or T5 to exclude our gains from large scale monolingual data.

[3] We use the fairseq default shell script `sacrebleu.sh`, with WMT14/full testsets to evaluate the model checkpoints. The sacrebleu output format is BLEU + case.mixed + lang.de-en + numrefs.1 + smooth.exp + test.wmt14/full + tok.13a + version.1.4.13.

Table 5: SacreBLEU score on WMT14 EN-DE and RU-EN testsets. Gamma criterion based methods outperform beam search based and sampling based back-translation NMT models. The result marked with * denotes that it is significantly better than both sampling and beam based BT with $p < 0.001$.

date by gamma score distribution for the stochastic method.

Once again, we use synthetic gamma corpus combined with bitext to train the back-translation NMT models on each corpus, the results are listed in 4. From the table, we can see that our proposed gamma sampling significantly outperforms the sampling based and beam search based back-translation baselines by 0.9 and 2.3 BLEU scores in terms of SacreBLEU. And our two proposed gamma score based methods outperform the data manipulation method as well.

In the rest of the experiments, we report results for both gamma selection and gamma sampling as the proposed methods and their hyperparameter γ for other tasks is fixed to 0.2.

5.3 Results on other Datasets

We conduct the experiments on WMT14 EN-DE and RU-EN for both gamma selection and gamma sampling as well, and table 5 shows that our proposed gamma based methods significantly outperform beam and sampling based back-translation methods on both en-de and ru-en translation for almost 1 and 0.4 BLEU score respectively. Recently, Edunov et al. (2020) point out that BLEU might overlook the contributions from back translation since it poorly correlates with human evaluation on the data generated in back translation scenario. Follow their suggestions, to better reflect the scenario of back translation, we also evaluate our experiment using COMET metric suggested by Rei et al. (2020). The results are shown in table 6 and we can see that the proposed methods perform well in terms of COMET.

Discussion on Efficiency Since our method requires to run sampling with size of 50 to generate synthetic data, its efficiency is about 10x slower than that of beam BT with size of 5 and 50x slower than that of sampling BT with size 1. Luckily, because the bottleneck of BT is not the synthetic data generation but the parameter optimization on both synthetic and authentic data, our overall overhead is less than 0.5x slower than sampling BT. In addition, since decoding is very easy to be parallelized on GPU or CPU machines, the cost of decoding is not a serious issue for our method, which makes it possible to run our method on a large scale dataset.

5.4 Analysis on Synthetic Corpus

In this subsection, we analyze the synthetic corpus of proposed gamma score methods on both sentence level and token level.

Sentence Level We evaluate the back-translation synthetic source sentences by their sentence representations. We use the baseline model to generate the hidden representations at the end-of-speech token as the sentence representation. Here, we compute the singular value spectrum of the representations for different back-translation corpora. [4]

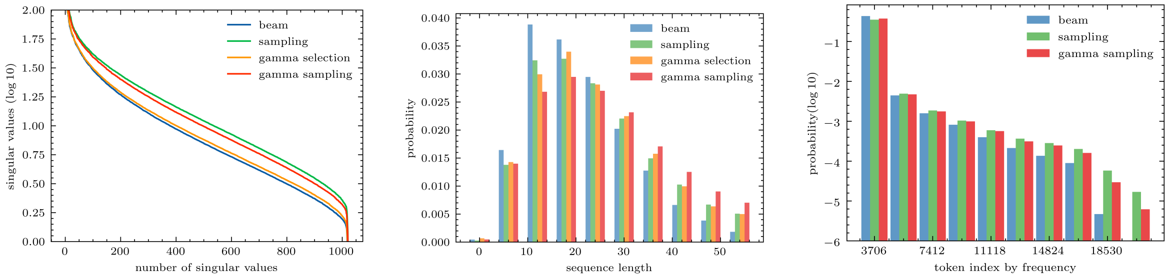
The spectrum is shown in figure 1(a). From the spectrum, sampling has a more uniform distribution whereas beam has the worst variety. Our proposed methods have moderate variety between sampling and beam, and gamma sampling consists of higher linguistic information richness compared with gamma selection.

Figure 1(b) shows the sequence length of the synthetic corpora of different generation methods. Beam generates the shortest synthetic sentences and gamma sampling generates the longest synthetic sentences on average. Between them, sampling and gamma selection generate almost the same sequence length, which means gamma selection candidates provide more learning signals than random sampling under the same length.

Token Level Figure 1(c) is the token frequency histogram, which shows beam has higher probability to decode high frequency tokens while sampling

---

[4] Singular value spectrum analysis is a widely used method to measure the representation distribution. Gao et al. (2019) firstly introduces this method to measure the isotropy of representation, and Wang et al. (2019) directly employ spectrum control for better NMT performance. The idea is, representations of high linguistic variety usually are more isotropic, thus having a relatively uniform singular value distribution. We employ this method here to measure the variety of sentence-level information.



(a) Spectrum (b) Sequence Length (c) Token frequency

System	DE-EN	EN-DE	RU-EN
Transformer	51.66	53.35	54.55
Beam BT	49.35	54.61	55.12
Sampling BT	52.71	56.01	54.34
Gamma Selection BT	53.83	**58.22**	**57.03**
Gamma Sampling BT	**53.97**	58.18	56.69

Table 6: COMET metric evaluation results on WMT14 DE-EN, EN-DE and RU-EN datasets. The testset results are in accordance with BLEU metric.

prefers more low frequency tokens.

We also measure the vocabulary size, finding that the proposed gamma sampling shares the same vocabulary size as sampling method. This could be the reason that gamma sampling is based on random sampling for candidates generation.

6 Related Work

This section describes prior arts in back-translation for NMT, data augmentation, and semi-supervised machine translation.

Back-translation NMT Bojar and Tamchyna (2011) firstly proposed back-translation, then Bertoldi and Federico (2009); Lambert et al. (2011) apply back translation to solve the domain adaptation problems in phrase-based NMT systems. Sennrich et al. (2016a) further extend the back translation for training NMT models integrally.

For understanding the back-translation synthetic corpus, Currey et al. (2017) use a copy of target as a pseudo source, and find that NMT model performance can still be improved under the low resource settings. Caswell et al. (2019) propose tagged back-translation to indicate to the model that the given source is synthetic. To further find an optimum back-translation corpus decoding method, Imamura et al. (2018) firstly use sampling based synthetic corpus and find such a stochastic decoding method outperforms beam search on boosting NMT model performance, and Edunov et al. (2018) broaden the investigation of a number of back-translation generation methods for synthetic source sentences. Their contribution shows that sampling or noisy synthetic data gives a much stronger training signal. Graça et al. (2019) reformulate back-translation in the context of optimization and clarifying to improve sampling based decoding method search space, thus proposing N best list sampling. Recently, Nguyen et al. (2020) diversify the training data by multiple forward and backward models translations and combine them with the original datasets.

Data Augmentation for NMT NMT researchers are the pioneers of data augmentation studies since back-translation is a natural type of data augmentation method. (Sennrich et al., 2016a; Norouzi et al., 2016; Zhang and Zong, 2016; Bi et al., 2021). To balance the token frequency in NMT corpus, Fadaee et al. (2017) create new sentences contain low-frequency words. However, as observed by Wang et al. (2018), the improvement across different translation tasks is not consistent, and they invent SwitchOut data augmentation policy. Recht et al. (2018, 2019); Werpachowski et al. (2019) also observe such an inconsistency of variance between training corpus and testing set as well as in the generation tasks. Recently, Li et al. (2019a) try to understand data augmentation from input sensitivity and prediction margin, thus obtaining relatively low variance in generation.

Semi-supervised Machine Translation However, as high quality bitext is always limited and costly to collect, Gulcehre et al. (2015) study methods for effectively leveraging monolingual data in

NMT systems. He et al. (2016) develop a dual-learning mechanism, under such a learning objective, a NMT system is able to automatically learn from unlabeled data, thus improving NMT performance iteratively. Based on iterative learning, Lample et al. (2018) investigates how to learn NMT systems when only large monolingual corpora can be used in each language.

For supervision of models, Gulcehre et al. (2017) employ the target language model hidden states into NMT decoder to further improve performance. Edunov et al. (2020) show that back-translation improves translation quality of both naturally occurring text and translationese according to professional human translators. For supervision of learning corpus, Wu et al. (2019) study both the source-side and target-side monolingual data for NMT.

7 Conclusion

In this work, we answer a fundamental question about synthetic data for back translation. We theoretically and empirically show two key factors namely quality and importance weight of synthetic data play an important role in back translation, and then we propose a new method to generate synthetic data which better balances both factors so as to boost the back-translation performance. For future work, we think it would be of significance to apply our synthetic data generation method to other BT methods or even to more broad NLP tasks such as paraphrasing and style transfer.

A Model Details

The models are optimized using Adam optimizer (Kingma and Ba, 2015), with $\beta_1 = 0.9, \beta_2 = 0.98$. We use the same learning rate schedular as (Vaswani et al., 2017) with maximum learning rate 7×10^{-4}, and 4000 warmup updates. We use the fairseq 10.2 as the framework and the training command as well as the model hyperparameters are listed below,

```
 fairseq-train \
--arch transformer_wmt_en_de_big
--share-all-embeddings
--dropout 0.3
--weight-decay 0.0
--criterion
    label_smoothed_cross_entropy
```

```
--label-smoothing 0.1
--optimizer adam
--adam-betas '(0.9, 0.98)'
--clip-norm 0.0
--lr-scheduler inverse_sqrt
--warmup-updates 4000
--max-tokens 4096
--max-update 1600000
--validate-interval-updates 10000
--save-interval-updates 100000
--lr 7e-4
--upsample-primary 1
```

And the GPT model we employ is only trained on source side of bitext corpus, without extra datasets. The training command line and core settings are listed below.

```
 fairseq-train \
--task language_modeling
--arch transformer_lm_gpt
--share-decoder-input-output-embed
--dropout 0.1
--optimizer adam
--adam-betas '(0.9, 0.98)'
--weight-decay 0.01
--clip-norm 0.0
--lr 7e-5
--lr-scheduler inverse_sqrt
--warmup-updates 8000
--tokens-per-sample 512
--sample-break-mode none
--max-tokens 4096
--update-freq 1
--max-update 1000000
--keep-last-epochs 5
--validate-interval-updates 10000
--save-interval-updates 10000
```

PERKGQA: Question Answering over Personalized Knowledge Graphs

Abstract

Previous studies on question answering over knowledge graphs have typically operated over a single knowledge graph (KG). This KG is assumed to be known a priori and is leveraged similarly for all users' queries during inference. However, such an assumption is not applicable to real-world settings, such as healthcare, where one needs to handle queries of new users over unseen KGs during inference. Furthermore, privacy concerns and high computational costs render it infeasible to query the single KG that has information about all users while answering a specific user's query. The above concerns motivate our question answering setting over personalized knowledge graphs (PERKGQA) where each user has restricted access to their KG. We observe that current state-of-the-art KGQA methods that require learning prior node representations fare poorly. We propose two complementary approaches, PATHCBR and PATHRGCN for PERKGQA. The former is a simple non-parametric technique that employs case-based reasoning, while the latter is a parametric approach using graph neural networks. Our proposed methods circumvent learning prior representations, can generalize to unseen KGs, and outperform strong baselines on an academic and an internal dataset by 6.5% and 10.5%.

1 Introduction

The task of Question Answering over Knowledge Graphs (KGQA), involves answering a natural language question by querying a predefined knowledge graph (KG), such as WikiData or Freebase. Progress in KGQA research has addressed several challenges, such as answering complex questions, multi-hop reasoning, (Lan and Jiang, 2020; Ren et al., 2021), conversational KGQA (Kacupaj et al., 2021), and multi-lingual KGQA (Zhou et al., 2021), and has also found applications in tax, insurance, and healthcare (Lüdemann et al., 2020; Huang et al., 2021; Park et al., 2020).

Most KGQA research has focused on generalizable or generic knowledge, which assumes there is a predefined global KG for all queries. This assumes that nodes used during inference were already defined in the KG during training and holds for cases that focus on generalizable knowledge. This work proposes approaches that circumvent the need to make such an assumption.

Furthermore, using a single global KG to handle queries of different users raises additional concerns, especially when a user's query requires situated knowledge such as personal information.

- **Scalability:** The massive size of the global KG makes it computationally expensive to apply sophisticated neural architectures over it.
- **Privacy:** The unfettered access to information of all individuals raises ethical or legal concerns.

In this paper, we formulate PERKGQA or question answering over personalized knowledge graphs. Here the user has access to their specific KG, a subset of the global KG that contains only the information relevant to the user. We are restricted to the user's KG to answer their queries during training and inference. Such a setting addresses the challenges above of scalability, privacy, and generalizing over unseen KGs.

PERKGQA appears deceivingly simple in conception since we afford access to a subset of the larger global KG. One can claim that our setting is similar to the KGQA subtask where subgraphs and questions are predefined, and thus, traditional KGQA methods are applicable. However, information retrieval based KGQA methods employ knowledge graph completion techniques like TransE (Bordes et al., 2013) to learn node representations over the global KG and reuse them during inference. Alternately, other approaches leverage additional information such as semantic parses, logical forms, and query graphs to answer queries.

July 10-15, 2022 ©2022 Association for Computational Linguistics

This sets PerKGQA apart because we lack access to any prior information, be it text, semantic parses, or prior representations of KG nodes. Our setting requires learning node representations from scratch for each KG to handle unknown entities during inference. Moreover, other challenges prevalent in KGQA settings, namely multi-hop reasoning or answering complex/constraint-based questions, are also applicable to PerKGQA. To the best of our knowledge, we are the first to address the challenges of KGQA over unseen KGs in the absence of any additional information.

We propose two approaches, PathCBR and PathRGCN, that are well-suited to these settings. PathCBR is a simple non-parametric case-based reasoning approach that encodes path information of past queries to answer a new query. PathRGCN is a parametric approach that employs graph neural networks, path information, and the KG's structure to extract answers. These approaches circumvent the need for learning prior node representations and can be readily applied to unseen KGs.

Contributions of the paper:

- We formulate PerKGQA, a new setting for KGQA where we operate over unseen KGs in the absence of any additional information. We observe that SOTA methods that need to learn underlying node embeddings fare poorly.
- To encourage research, we modify an existing academic dataset (Yih et al., 2016) and make it available for research (as Mod-WebQSP).
- We propose PathCBR and PathRGCN, which outperform baselines on Mod-WebQSP and an internal dataset by 6.5% and 10.5% respectively.

2 Preliminaries

2.1 Task Formulation

A Knowledge Graph (KG) is represented as $\mathcal{K} = (\mathcal{V}, \mathcal{E}, \mathcal{R})$, where $\mathcal{V}$ is the set of entities, $\mathcal{R}$ is the set of relations, and $\mathcal{E}$ is the set of triplets. (e_1, r, e_2), $e_1, e_2 \in \mathcal{V}$, and $r \in \mathcal{R}$. Thus $\mathcal{E} \subset (\mathcal{V} \times \mathcal{R} \times \mathcal{V})$. Given a natural language question q, the objective of KGQA is to retrieve answer entities from $\mathcal{V}$.

For PerKGQA, we treat each question as posed by a separate user, and each question is associated with its corresponding knowledge graph, $\mathcal{K}_q$. A given $\mathcal{K}_q$ has a subset of nodes, $\mathcal{V}_q$ and relations, $\mathcal{R}_q$. Two knowledge graphs, $\mathcal{K}_q$ and $\mathcal{K}_{q^*}$ associated with questions q and q^* can have a varying degree of overlap, even being distinctly different.

2.2 Running Example

We now demonstrate the applicability of PerKGQA for a cloud service provider (e.g. Microsoft Azure) in Figure 1. Here, users (blue and red) can create cloud resources (yellow), and index them using a unique system identifier. These resources have a corresponding user-specific tag (green), are located in a specific region (orange), and have predefined services deployed on them (purple). The entire system can be envisioned as a knowledge graph (CloudKG) where nodes represent concepts (users and services), and edges define the relations between concepts. Due to confidentiality, user names are replaced with anonymous identifiers, while concept and relation names in CloudKG are modified. The underlying schema is unchanged.

Deploying a chatbot-based assistant that performs QA over CloudKG would facilitate use, especially by novice users. It would enable users to navigate the system and glean information by posing natural language questions. In Figure 1, when User 101 asks "Which resources have nlp-serv and demo_1 tags?", the system is expected to answer "res_1, res_3". We refer to Figure 1 as a running example in subsequent sections. As new users become a part of CloudKG, the QA system should accommodate their requests over the corresponding KG without any training. KGQA approaches that operate upon the entire CloudKG would be computationally infeasible due to the massive size of the user-base [1]. Moreover, the approach should be privacy-preserving wherein a given user's information is not revealed to another.

3 Datasets

We operate on two datasets: an internal dataset, CloudKGQA, built on top of CloudKG, and an academic dataset called Mod-WebQSP designed to mimic our setting. An instance in either dataset follows the same task formulation in Section 2, namely, for each question q, there exists a corresponding KG, K_q, which contains all the necessary information. Also, each question q is associated with one or more source entities; these correspond to nodes in the K_q linked through salient mentions of entities in q. E.g., the source entity for, "Who was responsible for Lincoln's assassination?" is the node corresponding to Abraham Lincoln.

---

[1] https://www.statista.com/statistics/321215/global-consumer-cloud-computing-users/

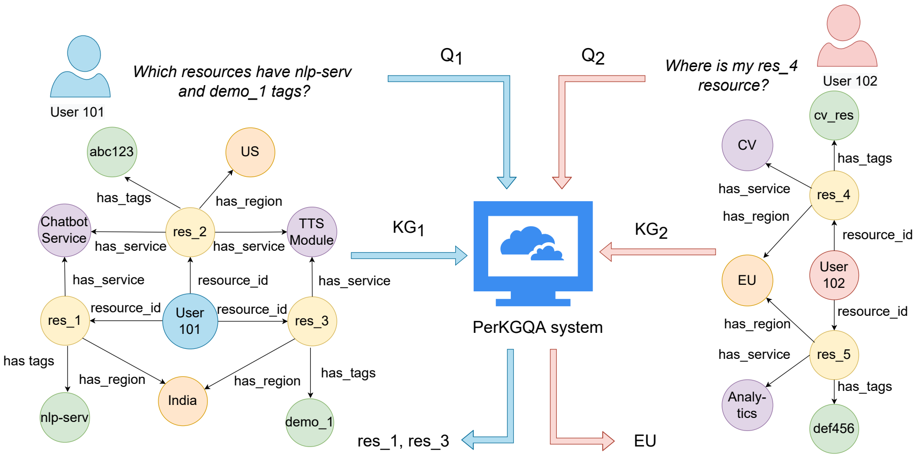

Figure 1: PERKGQA for a cloud service provider setting. The two users (in blue and red) create cloud resources (in yellow) in specific regions (in orange), and deploy services e.g. *Chatbot service*, or *Analytics* (in purple) on them. The users assign customized tags (in green) to the resources. Each user has their unique KG. The system should scale to support queries of new users over unseen KGs without any retraining or additional knowledge.

3.1 CloudKGQA

The internal dataset, which we refer to as CloudKGQA, entails question-answering of a customer's queries on their respective cloud resources. We refer the readers to Figure 1 as we present examples that outline the key characteristics of CloudKGQA.

- **Multiple Answers:** A question can have one or more correct answers.
- **Varying Complexity:** A question can either be simple or complex.
  (i) **Simple:** The question can be answered by a single-hop relation, e.g. "Which resource has the tag nlp_serv?"
  (ii) **Complex :** The question involves logical operations like union or intersection, e.g."Show me resources in US and India" or contains multiple constraints, e.g. "Which resource has the TTS and MongoDB service and is located in US?" has three constraints, TTS, MongoDB, and US.
- **Multi-Hop distance:** The distance between the source entities and the answers is variable (e.g., the number of hops for "Show me tags for resources in US" is 2 in Figure 1).
- **Variable graph size:** The size of the KG varies in terms of the number of nodes, edges, and relations for each question.
- **Unseen nodes:** Nodes that appear in the KG during inference might not be seen while training.

3.2 Modified WebQSP (Mod-WebQSP)

We also operate on the publicly-available WebQSP dataset (Yih et al., 2016), built over Freebase ($\mathcal{F}$). We chose WebQSP since it shares similar characteristics of CloudKGQA, namely the presence of multi-answer, multi-hop, simple and complex questions. To completely mimic our setting, we construct a KG, $\mathcal{F}_q$ for each question q, with the caveat that a significant fraction of nodes remains unseen during inference. We describe our process for creating individual KG in the Appendix A. Our modification achieves a low overlap of 4.0% between entities across training and test splits, implying that 96% of entities remain unseen.

3.3 Differences between the datasets

We present the descriptive statistics of the two datasets in Table 1 corresponding to the mean number of nodes, edges, relations, answers, and hops for a KG. We also depict the degree of overlap between nodes in training and test splits. The number of instances in CloudKGQA and Mod-WebQSP are 800 and 4468, respectively. Moreover, we split the data into train, development, and test for both datasets in the ratio of 8:1:1.

We observe that CloudKGQA is comparatively smaller in size, had significantly fewer relations, but had longer reasoning chains. Moreover, CloudKGQA had more complex questions in terms of logical operations and multiple-constraints. Specifically, CloudKGQA had one or more source entities for each question, q, whereas Mod-WebQSP had only one source entity. The KGs in CloudKGQA had a similar underlying schema; different KGs had the same set of relations but different entities. However, the questions in the test data had distinct question templates from those during training, as

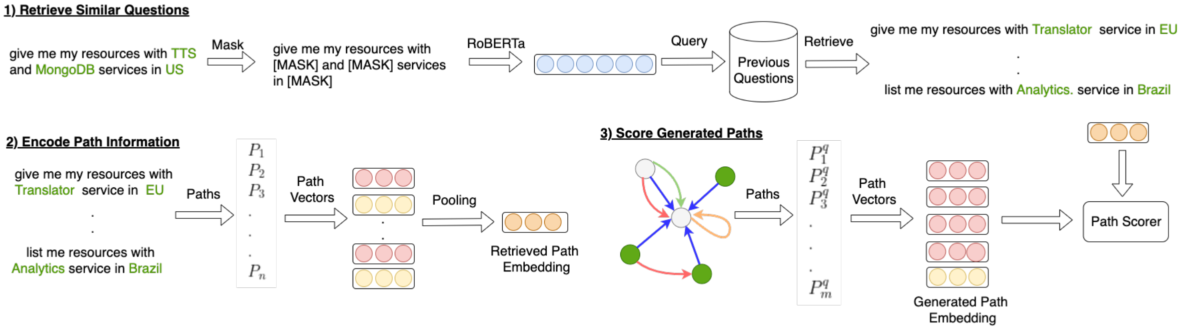

Figure 2: PATHCBR Overview: (1) Retrieve questions similar to a given query template from set of questions; (2) Encode path information as a path embedding; (3) Score generated paths using the retrieved path embedding.

seen in Figure 2. The Mod-WebQSP dataset, on the other hand, had KGs with different relations, but questions in the test data were similar to those asked during training. We chose these two datasets because they capture two different scenarios.

Dataset	CloudKGQA	Mod-WebQSP
Nodes	23.39	518.21
Edges	35.59	1334.10
Relations	8.00	36.20
Answers	1.99	4.94
Hops	1.75	1.36
Overlap	3.21%	4.01%

Table 1: An overview of the statistics of the two datasets, CloudKGQA and Mod-WebQSP. We present the mean number of nodes, edges, relations, answers, and hops, and the overlap between nodes during test and train.

4 Methodology

4.1 PATHCBR

PATHCBR is a non-parametric approach that employs case-based reasoning to retrieve queries without any training . Given a question q, the corresponding knowledge graph $\mathcal{K}_q$ and the source entities, $s_1, s_2, \cdots, s_k$, PATHCBR (Figure 2) performs the following steps:

(i) **Query Retrieval:** For a query, q, we first retrieve similar questions from the available training set. We consider a question to be similar if they share similar answer types with the query rather than the entities (Das et al., 2020). We perform Named Entity Recognition (NER) to identify text-spans that correspond to source entities $s_1, s_2, \cdots, s_k$ in K_q (Sun et al., 2019; Wang et al., 2020b). We substitute the extracted text spans with a special [MASK] token, yielding the masked query template $q_{\textsc{Mask}}$. We hypothesize that masking entities can help us learn the association of the entity with the template and could generalize to unseen entities. We employ a pretrained language model, such as RoBERTa, to create a contextualized embedding of $q_{\textsc{Mask}}$ and call it v_q. We then retrieve the top n questions ($q_1, \cdots, q_n$) and their respective KGs, $(\mathcal{K}_{q_1}, \cdots, \mathcal{K}_{q_n})$ ranked by decreasing cosine similarity between v_q and v_{q_i}. The v_{q_i} are created in the same manner as v_q. We represent the steps of masking and retrieving below:

$$\begin{aligned} q_{\textsc{Mask}} &\leftarrow \textsc{Mask}(q) \\ v_q &\leftarrow \textsc{RoBERTa}(q_{\textsc{Mask}}) \\ (q_1, \mathcal{K}_{q_1}), \cdots, (q_n, \mathcal{K}_{q_n}) &\leftarrow \textsc{Retrieve}(v_q) \end{aligned}$$

(ii) **Encoding path information:** We now construct the answer paths for the retrieved KGs $\mathcal{K}_{q_i}$. An answer path $p_{s_{ij},a_{ik}}$ comprises a sequence of relations, starting from a source s_{ij} entity to the answer entity a_{ik} in $\mathcal{K}_{q_i}$. There can be multiple answer paths between the source and the answer, but for simplicity we consider only the shortest paths, similar to Srivastava et al. (2021). We represent an answer path, either explicitly as a sequence of relations $(r_{i1}, r_{i2}, ..r_{im})$ leading from s_{ij} to a_{ik}, or by pooling over its constituent relation embeddings $(v_{r_{i1}}, v_{r_{i2}}, ..v_{r_{im}})$. We describe different approaches to obtain the relation embedding v_{r_i} in Section 5. Once we have embeddings for individual paths, we pool across all possible answer paths over the retrieved KGs, $\mathcal{K}_q$ to obtain the retrieved path embedding, v^q_P for q. We describe the steps to encode the path information below:

$$\begin{aligned} p_{s_{ij},a_{ik}} &\leftarrow [r_{i1}, r_{i2}, \cdots, r_{im}] \\ v_{p_{s_{ij},a_{ik}}} &\leftarrow \textsc{Max-Pool}([v_{r_{i1}}, v_{r_{i2}}, \cdots, v_{r_{im}}]) \\ v^q_P &\leftarrow \textsc{Max-Pool}([\forall v_{p_{s_{ij},a_{ik}}}]) \end{aligned}$$

(iii) **Scoring generated paths:** For the given query q, we generate all possible paths of a certain length,

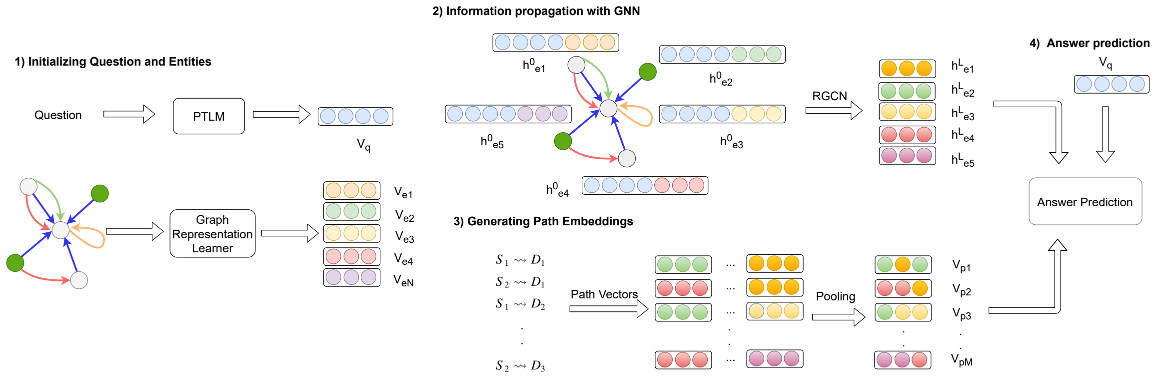

Figure 3: PATHRGCN Overview: (1) Initialize the question using a pretrained language model (PTLM) and the nodes in the corresponding KG; (2) Perform information propagation using RGCN to update node embeddings; (3) Encode path information from the source entities (shown in green) to all possible target nodes by pooling over the constituent node embeddings; (4) Perform answer prediction at both the path and node level.

arising from $s_1, s_2, \cdots, s_k$. The length of the path is determined by the maximum length of the answer path encountered during retrieval. These generated paths (say p_j) constitute a sequence of relations arising from the source node (say $r_1, r_2, \cdots, r_m$), similar to the retrieved paths. We encode them by pooling over the constituent relation embeddings to obtain v_{p_j}, the generated path embedding. We finally score the generated path embedding against the retrieved path embedding v_P^q; a higher similarity implies that the generated path is more likely to lead to an answer. However, if we store the path information explicitly as a sequence of relations, then the nodes we reach by traversing the retrieved sequences are answers for q. The equations follow:

$$\begin{aligned} p_j &\leftarrow [r_1, \cdots, r_{im}] \\ v_{p_j} &\leftarrow \textsc{Max-Pool}([v_{r_1}, ..., v_{r_m}]) \\ score(v_{p_j}) &\leftarrow \textsc{sim}(v_{p_j}, v_P^q). \end{aligned}$$

4.2 PATHRGCN

We now propose our parametric PATHRGCN model that can encode and fine-tune path embeddings for KGQA. Given a question q, the corresponding knowledge graph $\mathcal{K}_q$ and the source entities, $s_1, s_2, \cdots, s_k$, PATHRGCN (Figure 3), encompass the following steps during training:

(i) **Initialization:** We encode q using a pretrained language model (PTLM) such as RoBERTa (Liu et al., 2019), to obtain the corresponding representation, v_q. We use unsupervised graph representation learning techniques like Node2Vec (Grover and Leskovec, 2016) and Walklet (Perozzi et al., 2017), that leverage the neighbourhood information of nodes in $\mathcal{K}_q$ to obtain the corresponding embeddings: $v_{e_1}, v_{e_2}, \cdots, v_{e_N}$ for the N nodes $e_1, e_2, \cdots, e_N$ in $\mathcal{K}_q$. Unlike Wang et al. (2020a,b), we do not use pretrained word embeddings since user-provided names can be arbitrary.

$$\begin{aligned} v_q &\leftarrow \textsc{RoBERTa}(q) \\ v_{e_1}, v_{e_2}, ..., v_{e_N} &\leftarrow \textsc{Walklet}(\mathcal{K}_q). \end{aligned}$$

(ii) **Information propagation using GNN:** We employ graph neural networks (GNN) to update the node representations of $\mathcal{K}_q$. We modify $\mathcal{K}_q$ by adding the inverse-relations between nodes and self-loops to facilitate information propagation across both directions similar to Wang et al. (2020a,b). We concatenate v_{e_i} with v_q and a binary value of b_i. b_i has a value of 1 or 0, corresponding to whether e_i is a source entity. The resultant representation, $h_{e_i}^0 = [v_q, v_{e_i}, b_i]$, is then passed as input to the first GNN layer, and the representations of all nodes are updated. We perform such updates L times, where L denotes the number of GNN layers, resulting in the final representation of $h_{e_i}^L$. We use softmax as the non-linear activation and add dropout for regularization between updates. We use the RGCN model (Schlichtkrull et al., 2018) to account for different relationships between nodes.

$$\begin{aligned} h_{e_i}^0 &\leftarrow v_q \oplus v_{e_i} \oplus b_i \\ h_{e_i}^{j+1} &\leftarrow \text{RGCN}(h_{e_i}^j) \end{aligned}$$

(iii) **Path embedding generation:** We construct all possible paths $p_1, p_2, ...p_m$ upto a fixed distance from the source entities, and generate their corresponding path embeddings. The embeddings for path p_j or v_{p_j} is obtained by pooling over the updated representations of the nodes that constitutes p_j. We hypothesize that learning the path structure can provide intermediate supervision (Srivastava et al., 2021) and can help prune-out nodes that are unlikely to be reached from the source.

$$v_{p_j} \leftarrow \textsc{Max-Pool}(h_{e_i}^L)\ \forall e_i \in p_j$$

(iv) **Answer prediction:** We perform answer prediction both at the node and path level. We concatenate the updated representation for node e_i as $h_{e_i}^L$, with the question-embedding v_q, and pass it through a linear layer with sigmoid activation. to obtain $\hat{y}_{e_i}$). This represents the probability of e_i being an answer and is trained against the ground truth value of y_{e_i}. We perform the same procedure at the path level to obtain the probability of path p_j that leads to e_i as ($\hat{y_{p_j,e_i}}$). We use binary cross-entropy loss for answer prediction at the node level (NL) and path level (PL) and minimize these losses jointly during training. Specifically :

$$\begin{aligned}
\hat{y}_{e_i} &\leftarrow \sigma(\text{FFN}(h_{e_i}^L \oplus v_q)) \\
\hat{y}_{p_j,e_i} &\leftarrow \sigma(\text{FFN}(v_{p_j} \oplus v_q)) \\
\text{NL} &= -\sum_{e_i \in \mathcal{K}_q} y_{e_i} \cdot log(\hat{y}_{e_i}) \\
\text{PL} &= -\sum_{e_i} \sum_{\forall p_j \rightsquigarrow e_i} y_{e_i} \cdot log(\hat{y}_{p_j,e_i})
\end{aligned}$$

Inference: During inference, given a question q^* and its corresponding sub-graph $\mathcal{K}_{q^*}$, the learnt PATHRGCN models outputs (i) probability that the node $e_1, e_2, \cdots, e_N$ is an answer and (ii) probability that the paths $p_1, p_2, \cdots, p_m$ leads to an answer. Thus for a given entity, e_i, we compute the maximum probability amongst all paths that end in e_i. We compute the mean of this probability alongside the probability of e_i being an answer.

5 Experiments

5.1 Baselines

We choose GNN-based retrieval models as our baselines since they have achieved high performance across different KGQA datasets without additional information (query-answer paths or semantic parses). We experiment with three relevant KGQA retrieval techniques, namely, **Embed-KGQA** (Saxena et al., 2020), **Rel-GCN** (Wang et al., 2020a), and **GlobalGraph** (Wang et al., 2020b). We do not use baselines that require additional textual information to generate the heterogeneous graph, such as GraftNet (Sun et al., 2018) or PullNet (Sun et al., 2019) since this information is not available to us. We present a detailed description of the baselines in the Appendix B.1.

5.2 Experimental Details

PATHCBR: We experiment with how masking entities impact QA performance. For CloudKGQA, we identify entities by performing string-match over text spans in the question to their corresponding nodes in the KG. For Mod-WebQSP, we use the publicly available SpaCy NER[2]. We also experiment with SpaCy's POS-Tagger to mask proper nouns. The masked query is encoded using the [CLS] token of RoBERTa-BASE (Liu et al., 2019). We experiment with different ways to encode relations, either as a one-hot vector or using RoBERTa-BASE to encode the text. We perform max-pooling over the constituent relation embedding to obtain the resultant path-embedding. Likewise, max-pooling over the resultant path-embeddings yields the retrieved path-embedding. We also experimented with mean-pooling, but max-pooling fared consistently better. The generated paths are similarly encoded during inference. We compute cosine-similarity between a generated and retrieved path embedding. We retrieve the top 5 questions in descending order of their similarity for a given query.

PATHRGCN: For PATHRGCN, we use RoBERTa-BASE to encode the question text, and Walklet (Perozzi et al., 2017) to generate the unsupervised node-representations for the KG corresponding to the question. We use Walklet instead of Node2Vec since it exhibits the highest performance over several node classification tasks (Rozemberczki and Sarkar, 2020). Moreover, it does not require any additional features to generate the embeddings and is computationally fast; Walklet was ≈ 20 times faster than Node2Vec.

Baselines: We defer the reader to Appendix B.2 for the exact hyper-parameter settings and experimental details of the baselines.

5.3 Evaluation Metrics

We evaluate the performance of the baselines and our proposed approaches across two metrics commonly used in KGQA, namely, Hits@1 and Accuracy. For a given question, Hits@1 has a value of 100 if the highest-scoring candidate is a correct

Table 3: Mean performance of PathCBR across different settings for entity masking and encoding path information, as a sequence of relations (Path Sequence), as a One-Hot Vector, or as a Text Embedding using a PTLM. The best performance is highlighted in bold and the second best is underlined.

answer; else, it is 0. Accuracy denotes the fraction of answers predicted correctly amongst the top K candidates (as a percentage). We also measure Hits@K for a question, for which the value is 100 if the answer is present amongst the top K candidates; else it is 0. For both Accuracy and Hits@K, K is the number of correct answers. We carry out experiment for five random seeds and report the mean and standard deviation. We perform statistical significance using the paired bootstrapped test of Berg-Kirkpatrick et al. (2012) in Dror et al. (2018).

6 Results

In this section, we pose the following research questions (RQs) and attempt to answer the same. We present instances of preprocessed questions that serve as input to the model.

RQ1. How do our proposed approaches fare on PerKGQA compared to KGQA baselines?

We observe that both PathCBR and PathRGCN, yield the highest performance on CloudKGQA, outperforming the existing baselines by over 100% for Hits@1 and Accuracy in Table 2. We attribute the poor performance of prior KGQA techniques to their inability to (i) learn global node embeddings over the large base KG or (ii) update the embeddings during training.

For Mod-WebQSP, PathRGCN achieves the highest performance outperforming preexisting baselines significantly (p-value $\leq$ 0.001). However, PathCBR achieves performance comparable to the baselines, and can answer questions corresponding to templates encountered during training, for instance, *"who plays ken barlow in coronation"*. We attribute the low performance of PathCBR to:

(i) The underlying global KG for Mod-WebQSP is more complex and dense. There are 572 possible relations as opposed to 8 for CloudKGQA . Moreover, there can be multiple relations between two entities, (e.g. *'location.country.capital'* and *'location.contained_by'* are both valid relations between Tokyo and Japan), a characteristic absent in CloudKGQA. The possible paths increase exponentially with hops, and additional supervision afforded by GNNs helps answer these questions with long-range dependencies (Wang et al., 2020b).

(ii) Not all possible relations encountered during inference were available during training. E.g., the most relevant question retrieved for *"what was wayne gretzky 's first team"* was *"what team does plaxico burress play for"*, because the relation corresponding to *"first team"* was absent during training. At times, the pretrained language model could

	CloudKGQA			Mod-WebQSP		
Method	Hits@1	Hits@K	Accuracy	Hits@1	Hits@K	Accuracy
Rel-GCN + TransE	44.9 ± 8.7	52.5 ± 6.1	41.4 ± 6.3	49.4 ± 2.3	59.6 ± 1.2	48.5 ± 1.8
GlobalGraph + TransE	46.6 ± 3.6	56.1 ± 1.9	43.6 ± 2.5	48.4 ± 0.6	59.1 ± 0.7	48.3 ± 0.9
PathRGCN + TransE	51.4 ± 4.8	68.4 ± 2.6	57.0 ± 4.4	53.1 ± 0.9	62.6 ± 0.7	52.0 ± 0.8
Rel-GCN + Walklet	79.1 ± 3.9	79.8 ± 4.2	79.3 ± 4.0	63.0 ± 1.1	71.3 ± 0.8	63.0 ± 1.2
GlobalGraph + Walklet	86.3 ± 3.8	87.2 ± 4.0	86.5 ± 3.9	64.4 ± 0.9	72.6 ± 0.9	64.6 ± 0.8
PathRGCN + Walklet	**90.4 ± 2.1**	**91.3 ± 1.5**	**90.7 ± 1.5**	**68.6 ± 0.2**	**75.2 ± 0.4**	**68.5 ± 0.3**
PathRGCN + Walklet - NL	90.3 ± 7.1	91.1 ± 6.9	90.6 ± 6.8	65.7 ± 1.0	73.0 ± 1.1	65.8 ± 1.0

Table 4: Performance of the baselines and PathRGCN when initialized with different node embeddings. We report the mean and standard deviation across 5 runs. The best performance is highlighted. NL stands for Node Loss.

not infer the query's semantic meaning. E.g, the most relevant question for *"what town was martin luther king assassinated in"* was *"what town was abe lincoln born in"*, despite the occurrence of questions like *"where was huey newton killed"*. Thus if the templates are widely different, it is not sufficient to encode the question using a PTLM; rather, we need to fine-tune the questions to learn meaningful representation.

We further inspect the capabilities of our techniques to address the individual characteristics of PerKGQA, namely multiple answers, variable hop distance, multiple constraints, and variable KG size. Our approaches outperform baselines consistently and significantly on all such fronts.

A thorough analysis of our proposed approaches to the different properties of these two datasets reveals their complementary strengths. We note PathRGCN has a better performance on larger KG size, more answers, longer hops, and additional constraints, and vice-versa for PathCBR. We defer the reader to Appendix C for these results.

RQ2. What is the impact of entity masking and encoding different path-information strategies on PathCBR's performance?

We observe that masking entities using NER, or proper nouns using a POS Tagger improves performance in Table 3. The only exception is for CloudKGQA where due to arbitrary naming conventions (e.g. "abc123"), entities were not detected as proper nouns creating inconsistent templates. We observe that encoding relations as a one-hot vector yields better performance than a text embedding, especially when the relation-names exhibit high lexical overlap as in Mod-WebQSP. Moreover, representing the path information as a sequence of relations cannot deal with unseen templates as in CloudKGQA. We highlight instances that substantiate our claim in Appendix C.

RQ3. What role does graph structure and path-information play on PerKGQA?

We investigate the benefits of unsupervised graph representation learning techniques to initialize node embeddings. In particular, we compare the efficacy of Walklet and TransE embeddings, when applied to Rel-GCN, GlobalGraph, and PathRGCN. We see significant improvements for all models when TransE embeddings are substituted with Walklet in Table 4.

Since we operate for individual KGs, TransE does not have sufficient information to generate meaningful node representations. Walklet leverages the neighbourhood information and thus can capture the structural representation for each KG. PathRGCN significantly outperforms the baselines on both fronts, when all three models are initialized with Walklet or when all three models are initialized with TransE embeddings.

We also investigate the importance of incorporating node loss (NL in Table 2) for additional supervision. This aids Mod-WebQSP, where multiple relations between entities give rise to several possible paths between source and answer, most of which are spurious. Since multiple paths do not exist for CloudKGQA, removing the node loss does not deteriorate performance.

7 Related Work

The task of KGQA has evolved from a simple-classification setting (Mohammed et al., 2018) to an information retrieval paradigm (Wang et al., 2020b; Saxena et al., 2020; Yasunaga et al., 2021; Sun et al., 2019; Xiong et al., 2019) that can tackle multi-hop relations or complex questions. Other approaches include semantic parsing (Lan and Jiang, 2020; Ding et al., 2019; Maheshwari et al., 2019;

Zhu et al., 2020; Ren et al., 2021) and reinforcement learning (Das et al., 2018; Lin et al., 2018; Saha et al., 2019; Ansari et al., 2019). We investigate graph-based information retrieval methods in this work since they achieve SOTA performance without any additional information like logical forms or semantic parses. This sets us apart from recent work on KGQA generalizability (Gu et al., 2021; Chen et al., 2021) which requires such logical forms during training; information often unavailable for real-world data settings. Our work also differs from Sidiropoulos et al. (2020) which is more focused on entity-linking and relation prediction for unseen domains and leverages existing web resources, which is not applicable to us.

Most KGQA approaches that operate in an information retrieval setting over predefined (or base) knowledge graphs follow a similar procedure to make the problem computationally feasible. (Sun et al., 2018, 2019; Wang et al., 2020b,a). They first construct a smaller sub-graph for each question from the base graph, using the Personalized PageRank algorithm (Haveliwala, 2003). then re-use the base graph's node representation to initialize the nodes in the sub-graph. Thus during inference, they already have prior representation of the nodes. However, in our setting, we encounter new KG during inference, and thus we need to learn the representations of those unseen nodes from scratch.

Our PATHCBR approach is closely related to Das et al. (2020), which performs relation linking such as (Delhi, capital_of, _?_). They first retrieve entities similar to the query entity and the corresponding reasoning paths that lead to an answer for those retrieved entities. They then apply reasoning paths to the query entity. PATHCBR differs in two ways; (i) We operate upon complex or compositional questions and retrieve similar templates rather than entities, and (ii) We do not use a rule-based framework to generate reasoning paths. Rather, we encode the retrieved path information as an embedding and use it to score paths generated during inference to ensure generalization. In a similar vein, Das et al. (2021) uses a neuro-symbolic case-based reasoning approach for answering complex, multi-hop questions. However, their approach cannot be applied to our setting since it requires logical forms (SPARQL queries). We circumvent this requirement by designing PATHRGCN that leverages GNNs, KGs' structure, and path information between source and answers.

8 Conclusion and Future Work

We propose PERKGQA, a realistic setting for performing question answering over knowledge graphs; for each user's question, we have their corresponding KG but no additional information. Such a setting addresses the challenges of unseen nodes during inference, and prevents access to information of other users while being computationally feasible. However, state-of-the-art KGQA techniques that require learning node representations a priori fare poorly. We propose two approaches, a simple non-parametric case-based-reasoning model and a supervised neural architecture, harness path information for QA. Our approaches improve upon the baselines by 6.5% on an academic dataset and 10.5% on an internal dataset.

Having demonstrated the applicability of PERKGQA in the cloud service provider domain, we aim to explore other scenarios involving personalized or sensitive information, like healthcare. Prior work in medical NLP has focused predominately on generic or ontological knowledge such as UMLS. A personalized KG, constructed over a patient's health records, will encode information specifically for the individual and not the general population, e.g. whether the patient is allergic to certain medications. We plan to collaborate with medical professionals and create personalized KG in the healthcare domain to assist patients.

Furthermore, we seek to address certain limitations of our current approach, namely their inability to tackle spurious paths. We plan to rectify it either by explicitly providing the correct path information or incorporating some learning paradigm to detect them (He et al., 2021). Moreover, for PATHCBR, the retrieval phase is a bottleneck since one needs to compare a given query with all possible training questions and requires better indexing schemes like FAISS (Johnson et al., 2019). Likewise, the inference time for both approaches increases as the number and the length of the paths increase. However, PATHRGCN can adapt to longer paths since the node embeddings provide some degree of additional supervision. Nevertheless, we plan to explore techniques beyond embedding-based approaches, namely semantic parsing or query-graph generation, to alleviate the path-based constraint and adapt them to our PERKGQA. In the absence of gold logical forms, we plan to learn semantic parses through a weakly-supervised or distantly-supervised setting similar to Cheng et al. (2019).

Supplementary Material

A Constructing Mod-WebQSP

We also mimic our setting on the publicly-available WebQSP dataset (Yih et al., 2016), which operates on the Freebase KG, $\mathcal{F}$ [1] . We use the pruned version of the dataset provided by Saxena et al. (2020). To completely mimic our setting, we construct a graph $\mathcal{F}_q$ associated with each question q with the caveat that a significant fraction of nodes we encounter during inference are not observed during training.

Each question is associated with a source entity, as noted in the dataset of Saxena et al. (2020). The question's corresponding KG, comprises all nodes, a distance of k-hop from the source entity, where k is the shortest distance between the source and the answer. We limit ourselves to k=2, similar to Saxena et al. (2020). Furthermore, to constrain the size of $\mathcal{F}_q$, we randomly sample 1000 paths at a k-hop distance from the source entity; these are inclusive of all paths that lead from the source to an answer.

We observe a small fraction of questions ($\approx 5\%$), which have $\geq$ 100 answers; these correspond to simple 1-hop questions like *"What did Roald Dahl write?"*, or *"Who are famous people from Spain?"*. We remove such questions to constrain the size of the KG. Since our objective was to retrieve all possible answers in the KG for a given question, there are no missing answers in the KG corresponding to the question in the Mod-WebQSP.

To achieve low overlap between nodes we encountered during training and inference, we modify them by assigning new identifiers. For example, a node, "m.0gzh" corresponding to "Abraham Lincoln", was modified to "**KG_i**_m.0gzh" and "**KG_j**_m.0gzh" for questions q_i and q_j in their respective KG $\mathcal{F}_{q_i}$ and $\mathcal{F}_{q_j}$. Although these nodes have the same underlying entity name in the original KG, $\mathcal{F}$, their node representations are different in these two questions. We rank all relations in $\mathcal{F}$, based on the decreasing order of frequency, and chose the top 39 relations that occur in 95% of all triplets in $\mathcal{F}$. We modify only those nodes which are associated with these 39 relations.

We added the graph-identifiers to the most frequent relations to ensure a small degree of overlap between the training and the test sets, similar to the CloudKGQA dataset, where certain entities were universal, like names of regions (India, USA). This would facilitate prior KGQA techniques, like EmbedKGQA, that perform KGC on the individual KGs to share embeddings and perform better. However, our proposed approaches, PATHCBR, and PATHRGCN remain agnostic to the degree of overlap. They do not keep track of any prior entities. Specifically PATHCBR masks these entities in the question, whereas PATHRGCN learns these entity representations from scratch for each KG.

B Experiments

In this section, we present the baselines in detail and our experimental settings.

B.1 Baselines

EmbedKGQA: The EmbedKGQA model (Saxena et al., 2020) performs Knowledge Graph Completion (KGC) on an existing knowledge graph, to learn node representations. They use ComplEx (Trouillon et al., 2016) to generate node embeddings, to account for the anti-symmetric nature of the relations between nodes. Furthermore, they use RoBERTa (Liu et al., 2019) as the Pre-Trained Language Model (PTLM) to encode the question. They learn an objective function to select answers based on the similarity between question and node embeddings and further perform pruning based on the relation type to prevent over-generation of candidates. EmbedKGQA can perform arbitrary multi-hop reasoning, is not restricted to a specific neighbourhood, and can effectively handle incomplete links/edges. To ensure EmbedKGQA can be applied in our setting, we carried out KGC on the KG associated with the question instead of the entire Freebase KG. This ensures that the entity representations are distinct for each individual KG.

Rel-GCN: The Rel-GCN approach of Wang et al. (2020a) first constructs a smaller sub-graph $\mathcal{K}_q$ for a given question, using PPR (Haveliwala, 2003) from the large base knowledge-graph, $\mathcal{K}$. They encode the question q using PTLM as v_q, and use TransE (Bordes et al., 2013) on $\mathcal{K}$ to obtain the node representations v_{e_i} for node e_i in $\mathcal{K}$. They concatenate the node embedding with the question-embedding e_q, and then perform RGCN on $\mathcal{K}_q$ to obtain their updated representations. These updated representations are used to score whether a given node is an answer or not. For PERKGQAsetting we perform TransE not on the

---

[1] `https://developers.google.com/freebase/data`

original graph, $\mathcal{K}$, but on each sub-graph $\mathcal{K}_q$.

GlobalGraph: The GlobalGraph technique of Wang et al. (2020b) is similar in conception to Rel-GCN, having the same steps, (i) sub-graph construction, (ii) encoding representations of question and nodes, (iii) running RGCN to update the node representations. Moreover, to capture long-dependencies between nodes, the model leverages the set of incoming and outgoing relations to assign a global type for each node. They also identify nodes that are correlated with the question and construct a dynamic graph connecting such similar nodes. GCN over this dynamic graph yields updated representations for such nodes. Once again, for PERKGQA, we perform TransE on the individual KG associated with the question $\mathcal{K}_q$.

B.2 Experimental Details

We describe the hyper-parameters we employ for the parametric models, namely PATHRGCN and the baselines.

PATHRGCN: For PATHRGCN, we use RoBERTa-BASE to encode the question text, and Walklet (Perozzi et al., 2017) during initialization to generate the unsupervised node-representations for each KG. The embedding sizes for the question, nodes, and GNN layers was set to 768, 128, and 200, respectively. We fix L, the number of GNN layers to 1. For Path-RGCN, the length of an answer-path is chosen based on the maximum distance between a source entity and an answer entity encountered during training. This corresponds to a distance of 3 for CloudKGQA and a distance of 2 for Mod-WebQSP. We used Adam optimizer with a low learning rate of 2e-5, a decay of 5e-4, and patience of 30, and trained for 100 epochs. Each model took around 3 hours to complete on a p3.8x large EC2 instance.

Baselines: For Rel-GCN (Wang et al., 2020a), and GlobalGraph (Wang et al., 2020b), we use RoBERTa-BASE (Liu et al., 2019) to encode the question, and TransE embeddings to initialize the nodes (Bordes et al., 2013). We use the publicly available PyTorch-Geometric library (Fey and Lenssen, 2019) to implement RGCN (Schlichtkrull et al., 2018) for these two baselines. The embedding dimensions for our question, node, and GNN layers are 768, 128, and 200 respectively. The number of GNN layers, was set to 2 and 1 for Rel-GCN and GlobalGraph respectively, as specified in their papers. For EmbedKGQA, we use the publicly available code of Saxena et al. (2020) along with the default hyper-parameters for training. We use the publicly-available, LibKGE (Broscheit et al., 2020) library to generate Complex embeddings for each KG.

C Analysis

RQ1. What is the impact of entity masking and encoding different path-information strategies on PATHCBR's performance?

We investigate the impact of different strategies for masking entities and encoding path information on the performance of the PERKGQAtask for the two datasets and report them in Table 3.

(i) **Entity-masking:** For Mod-WebQSP, entity masking using either a publicly-available NER or a POS Tagger, shows a huge boost in performance as seen in Table 3. Masking entities facilitates retrieving relevant questions which share similar answer types rather than similar entity names in the query. For example, for "What county is *greeley colorado* in ?", the most relevant question retrieved after masking is "What county is *novato california* in?", as opposed to "What college is in *greeley colorado*?". We observe a similar trend for CloudKGQA when we mask entities linked to nodes in the KG. However, the performance drops substantially when we use a POS-Tagger. Since the naming convention for nodes is arbitrary, like *"abc123"*, they are not detected as proper nouns; this creates inconsistent templates, and irrelevant questions appear higher in the ranked list.

(ii) **Encoding path information:** We observe that encoding relations as one-hot vectors fare just as well, if not better than encoding the relation-text using a PTLM. This is especially true for Mod-WebQSP where relation-names have high lexical overlap and thus exhibit high similarity. For example, for *"where is jamarcus russell from"*, the correct relation is **"people.person.place_of_birth"**, but the relation predicted, was **"people.person.date_of_birth"**. Encoding relations as one-hot-vectors circumvents this issue. Encoding the path-information, as a sequence of relations works well for Mod-WebQSP but not for our CloudKGQA, since the questions encountered during inference have different templates.

RQ2. How does our proposed approaches fare against the baselines for different KGQA prop-

Figure 4: Performance of the different techniques on the CloudKGQA dataset and the Mod-WebQSP dataset across different properties of the dataset. For CloudKGQA, we investigate the difference in performance based on the number of hops, head-nodes, logical constraints, and KG size. For Mod-WebQSP, we observe the difference in performance based on the number of hops and the size of the subgraph.

erties?

We investigate the performance of the different methods (accuracy) on the PERKGQA task for different properties of the dataset. The methods we investigated were (i) PATHRGCN (ii) PATHCBR (iii) GlobalGraph initialized with Walklet (iv) PATHRGCN initialized with TransE, and (v) GlobalGraph initialized with TransE, the best baseline without any modifications. We investigate the following dataset properties.

(i) Variable number of answers: We observe the performance for variable number of answers, for CloudKGQA in Figure 4a and for Mod-WebQSP in Figure 4b.

(ii) Variable size of the graph: We note the effect of for varying graph size on different methods for CloudKGQA in Figure 4c and for Mod-WebQSP in Figure 4d.

(iii) Variable Hop Distance: We investigate the performance for varying number of hops for the CloudKGQA in Figure 4e and for Mod-WebQSP in Figure 4f.

(iv) Complex Questions: We observe specifically for CloudKGQA how the accuracy across methods varies for complex questions, based on the varying number of head-nodes in Figure 4g and the number of logical constraints in Figure 4h. This information was available to us for our internal dataset but not for Mod-WebQSP.

For CloudKGQA, we observe that our non-parametric PATHCBR approach achieves the highest performance when the number of answers is few (≤ 3), the subgraph is comparatively smaller (# edges ≤ 50), the number of hops is few (≤ 2), and when there are fewer constraints, (number of logical constraints ≤ 2, and number of source entities ≤ 3). PATHRGCN boasts a comparative higher performance for the converse scenarios, i.e., greater answers, a larger size of the KG, more hops, and additional constraints. This observation highlights the trade-off between model complexity and the complexity of the question itself. The only exception lies for the 2-hop cases wherein PATHCBR achieves a score of 1.0 because the questions seen during training had a similar template, and answers were found within two hops. Nevertheless, across all sub-cases, we see that our proposed architectures, PATHRGCN or PATHCBR, boasts the highest performance, while the GlobalGraph + TransE, the best performing baseline, achieve the lowest performance. The baseline fares are consistently poorer than the PATHRGCN + TransE, which shows that incorporating the path information was beneficial across all stages.

For Mod-WebQSP, we see that our PATHRGCN model consistently boasts the highest accuracy across all sub-cases. The trend is similar to Cloud-KGQA, where the PATHRGCN model can handle a larger KG size and more considerable hop distance. The only difference is the higher performance of PATHCBR when there are more answers, which is justifiable since the mean number of answers for Mod-WebQSP is five instead of two.

D Ethical Risks

In this paper, we propose PERKGQA, a realistic setting for performing question answering over knowledge graphs; for each user's question, we have their corresponding KG, but no additional information, and we have to perform QA using that limited information. We acknowledge that our setting could be applicable in scenarios involving personalized or sensitive information, like healthcare or insurance providers. Our settings is explicitly designed to deter access to another user's information when a given user poses a query. However, the model might provide different answers to different users despite the same query because the underlying KG is different. We acknowledge that our proposed idea is still in its infancy and requires more research to deem it suitable for real-world applications.

Zero-shot Cross-lingual Conversational Semantic Role Labeling

Abstract

While conversational semantic role labeling (CSRL) has shown its usefulness on Chinese conversational tasks, it is still under-explored in non-Chinese languages due to the lack of multilingual CSRL annotations for the parser training. To avoid expensive data collection and error-propagation of translation-based methods, we present a simple but effective approach to perform zero-shot cross-lingual CSRL. Our model implicitly learns language-agnostic, conversational structure-aware and semantically rich representations with the hierarchical encoders and elaborately designed pre-training objectives. Experimental results show that our model outperforms all baselines by large margins on two newly collected English CSRL test sets. More importantly, we confirm the usefulness of CSRL to non-Chinese conversational tasks such as the question-in-context rewriting task in English and the multi-turn dialogue response generation tasks in English, German and Japanese by incorporating the CSRL information into the downstream conversation-based models. We believe this finding is significant and will facilitate the research of non-Chinese dialogue tasks which suffer the problems of ellipsis and anaphora.

1 Introduction

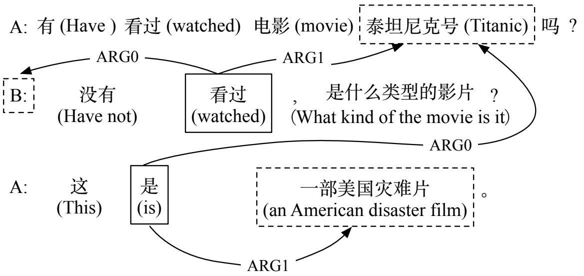

Figure 1: An example of CSRL parsing.

Conversational Semantic Role Labeling (CSRL) (Xu et al., 2021) is a recently proposed dialogue understanding task, which aims to extract predicate-argument pairs from the entire conversation. Figure 1 illustrates a CSRL example where a CSRL parser is required to identify "《泰坦尼克号》(Titanic)" as the `ARG1` argument of the predicate "看过 (watched)" and the `ARG0` argument of the predicate "是 (is)". We can see that in the original conversation, "《泰坦尼克号》(Titanic)" is omitted in the second turn and referred as "这 (this)" in the last turn. By recovering the dropped and referred components in conversation, CSRL has shown its usefulness to a set of Chinese dialogue tasks, including multi-turn dialogue rewriting (Su et al., 2019) and response generation (Wu et al., 2019). However, there remains a paucity of evidence on its effectiveness towards non-Chinese languages owing to the lack of multilingual CSRL models. To adapt a model into new languages, previous solutions can be divided into three categories: 1) manually annotating a new dataset in the target language (Daza and Frank, 2020) 2) borrowing machine translation and word alignment techniques to transfer the dataset from the source language into the target language (Daza and Frank, 2019; Fei et al., 2020a) 3) zero-shot transfer learning with multilingual pre-trained language model (Rijhwani et al., 2019; Sherborne and Lapata, 2021). Due to the fact that manually collecting annotations is costly and translation-based methods might introduce translation or word alignment errors, zero-shot cross-lingual transfer learning is more practical to the NLP community.

Recent works have witnessed prominent performances of multilingual pre-trained language models (PrLMs) (Devlin et al., 2019; Conneau et al., 2020) on cross-lingual tasks, including machine translation (Lin et al., 2020; Chen et al., 2021), semantic role labeling (SRL) (Conia and Navigli, 2020; Conia et al., 2021) and semantic parsing (Fei et al., 2020b; Sherborne and Lapata, 2021). How-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 269 - 281
July 10-15, 2022

ever, cross-lingual CSRL, as a combination of three challenging tasks (i.e., cross-lingual task, dialogue task and SRL task), suffers three outstanding difficulties: 1) **latent space alignment** - how to map word representations of different languages into an overlapping space; 2) **conversation structure encoding** - how to capture high-level dialogue features such as speaker dependency and temporal dependency; and 3) **semantic arguments identification** - how to highlight the relations between the predicate and its arguments, wherein PrLMs can only partially encode multilingual inputs to an overlapping vector space. Although there are some success that can separately achieve structural conversation encoding (Mehri et al., 2019; Zhang and Zhao, 2021) and semantic arguments identification (Wu et al., 2021a), a unified method for jointly solving these problems is still under-explored, especially in a cross-lingual scenario.

In this work, we summarize our contributions as follows: **(1)** We propose a simple but effective model which consists of three modules, namely cross-lingual language model (CLM), structure-aware conversation encoder (SA-Encoder) and predicate-argument encoder (PA-Encoder), and five well-designed pre-training objectives. Our model implicitly learns language-agnostic, conversational structure-aware and semantically rich representations to perform zero-shot cross-lingual CSRL. **(2)** Experiments show that our method achieves impressive cross-lingual performance on the language pair (Zh→En) , and outperforms all baselines on the two newly collected English CSRL test sets. **(3)** We confirm the usefulness of CSRL to the question-in-context rewriting task in English and multi-turn response generation tasks in English, German and Japanese. We believe this finding is important and will facilitate the research of non-Chinese dialogue tasks that suffer from ellipsis and anaphora. **(4)** We release our code, the new annotated English CSRL test sets and checkpoints of our best models to facilitate the further research at `https://github.com/hahahawu/Zero-Shot-XCSRL`.

2 Related Work

Zero-shot cross-lingual transfer learning. Recently, thanks to the rapid development of multilingual pre-trained language models such as multilingual BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020), a number of approaches have been proposed for zero-shot cross-lingual transfer learning on various downstream tasks, including semantic parsing (Sherborne and Lapata, 2021), natural language generation (Shen et al., 2018) and understanding (Liu et al., 2019; Lauscher et al., 2020). In this work, we claim our method is zero-shot because no non-Chinese CSRL annotations are seen during the CSRL training stage. For decoding, we directly use the cross-lingual CSRL model trained on Chinese CSRL data to analyze conversations in other languages. To our best knowledge, our work is the first step to cross-lingual CSRL.

Conversational semantic role labeling. While ellipsis and anaphora frequently occur in dialogues, Xu et al. (2021) observed that most of the dropped or referred components can be found in dialogue histories. Following this observation, they proposed conversational semantic role labeling (CSRL) which required the model to find predicate-argument structures over the entire conversation instead of a single sentence. In this way, when analyzing a predicate in the latest utterance, a CSRL model needs to consider both the current turn and previous turns to search potential arguments, and thus might recover the omitted components. Furthermore, Xu et al. (2020, 2021) also confirmed the usefulness of CSRL to Chinese dialogue tasks by applying CSRL information into downstream dialogue tasks. However, there are still two main problems to be solved for CSRL task: (1) the performance of current state-of-the-art CSRL model (Xu et al., 2021) is still far from satisfactory due to the lack of high-level conversational and semantic features modeling; (2) the usefulness of CSRL to conversational tasks in non-Chinese languages has not been confirmed yet due to the lack of cross-lingual CSRL models. In this work, we primarily focus on the latter problem and propose a simple but effective model to perform cross-lingual CSRL. We would like to distinguish our work from the work (Wu et al., 2021b) which purely focuses on improving the monolingual CSRL performance where they try to model predicate-aware representations. This solution could benefit to monolingual CSRL task, but hurt the cross-lingual performance, because the relative positions of the predicates may differ from language to language.

3 Methodology

Following Xu et al. (2021), we solve the CSRL task as a sequence labeling problem. Formally, given a dialogue $C = \{u_1, u_2, ..., u_N\}$ of N utter-

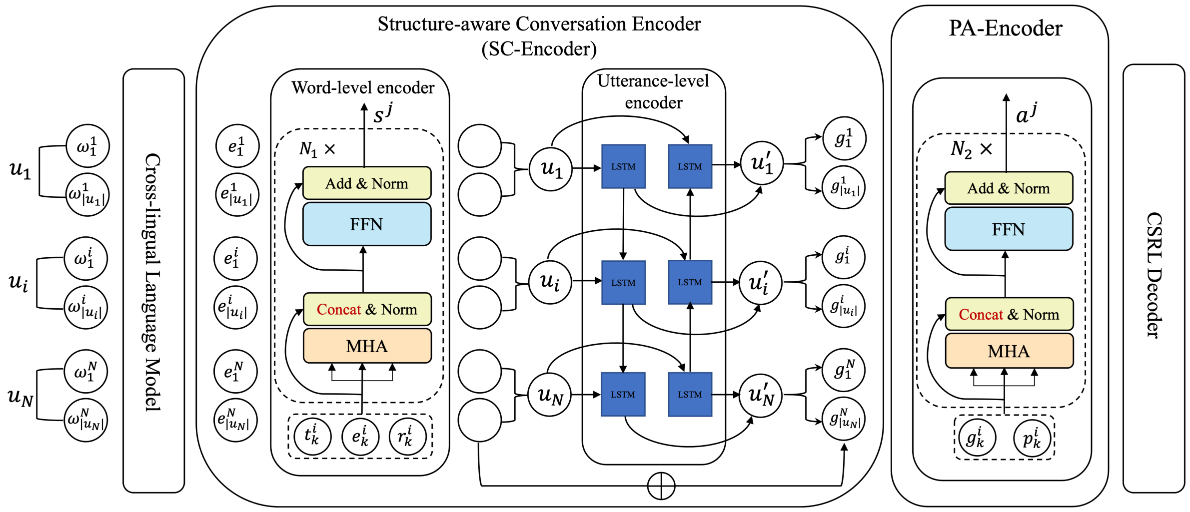

Figure 2: Overall model architecture.

ances, where $u_i = \{w^i_1, w^i_2, ..., w^i_{|u_i|}\}$ consisting of a sequence of words, and a predicate indicator $p = (p^1_1, ..., p^i_k, ..., p^N_{|u_N|})$ used to identify whether a word is the predicate or not, our goal is to assign each word with a semantic role label $l \in L$ where L is the label set. We also incorporate speaker role indicator r to distinguish speakers, and dialogue turn indicator t to distinguish dialogue turns.

3.1 Architecture

Cross-lingual Language Model (CLM) We concatenate all utterances into a sequence and then use a pre-trained cross-lingual language model such as XLM-R (Conneau et al., 2020) or mBERT (Devlin et al., 2019) to capture the syntactic and semantic characteristics. Following Conia et al. (2021), we obtain word representations $\mathbf{e} \in \mathbb{R}^{|S| \times d}$ by concatenating the hidden states of the four top-most layers of the language model, where $|S|$ is the sequence length and d is the dimension of the hidden state.

Structure-aware Conversation Encoder (SC-Encoder) Different from standard SRL(Carreras and Màrquez, 2005), CSRL requires the models to find arguments from not only the current turn, but also previous turns, thus bringing more challenges of dialogue modeling. To address this problem, we propose a universal structure-aware conversation encoder which comprises of two parts, i.e., word-level encoder and utterance-level encoder. Formally, with the speaker role embedding $\boldsymbol{r} \in \mathbb{R}^{|S| \times d}$ and dialogue turn embedding $\boldsymbol{t} \in \mathbb{R}^{|S| \times d}$, the word-level encoder computes a sequence of timestep encodings $\boldsymbol{s} \in \mathbb{R}^{|S| \times d}$ as follows:

$$\boldsymbol{s}^j_{(i,k)} = \begin{cases} \boldsymbol{e}^i_k \oplus \boldsymbol{t}^i_k \oplus \boldsymbol{r}^i_k & \text{if } j = 0 \\ \boldsymbol{s}^{j-1}_{(i,k)} \oplus \mathrm{MT{\small RANS}}^j(\boldsymbol{s}^{j-1}_{(i,k)}) & \text{otherwise} \end{cases} \qquad (1)$$

where $\boldsymbol{s}^j_{(i,k)}$ is the timestep encoding of k-th token in i-th utterance from j-th word-level encoder layer while $j \in (0, \ldots, N_1)$, $\oplus$ represents vector concatenation, and MTRANS is the **M**odified **Trans**former encoder layer. Concretely, we replace the `[Add]` operation in the first residual connection layer with `[Concat]` because we argue that concatenation is a superior approach to preserve the information from previous layers[1].

We obtain utterance representations $\boldsymbol{u} \in \mathbb{R}^{N \times d}$ by max-pooling over words in the same utterance. Then we pass the resulting utterance representations $\boldsymbol{u}$ through a stack of Bi-LSTM (Hochreiter and Schmidhuber, 1997) layers to obtain the sequentially encoded utterance representations $\boldsymbol{u}' \in \mathbb{R}^{N \times d}$. Finally, we combine the utterance-level feature $\boldsymbol{u}'$ with the word-level feature $\boldsymbol{s}$ to obtain structure-aware dialogue context representations $\boldsymbol{g} \in \mathbb{R}^{|S| \times d}$ as follows:

$$\boldsymbol{g}^i_k = \mathrm{Swish}(\mathbf{W}^g[\boldsymbol{s}^{N_1}_{(i,k)} \oplus \boldsymbol{u}'_i] + \mathbf{b}^g) \qquad (2)$$

where $\mathrm{Swish}(x) = x \cdot \mathrm{sigmoid}(x)$ is a non-linear activation function, $\boldsymbol{s}^{N_1}_{i,k}$ is the encoding of k-th token in i-th utterance from the last layer of the word-level encoder. $\mathbf{W}^g$ and $\mathbf{b}^g$ are trainable parameters.

Predicate-Argument Encoder (PA-Encoder) We introduce the third module (i.e., predicate-argument encoder) whose goal is to capture the

---

Figure 4: Illustration of pre-training objectives for conversation structure encoding.

relations between each predicate-argument couple that appears in the conversation. Similar with the word-level encoder, we use a stack of MTRANS layers to implement this encoder. Formally, with the predicate embedding $\boldsymbol{p} \in \mathbb{R}^{|S| \times d}$, the model calculates the predicate-specific argument encodings $\boldsymbol{a} \in \mathbb{R}^{|S| \times d}$ as follows:

$$\boldsymbol{a}^j_{(i,k)} = \begin{cases} \boldsymbol{g}^i_k \oplus \boldsymbol{p}^i_k & \text{if } j = 0 \\ \boldsymbol{a}^{j-1}_{(i,k)} \oplus \text{MTRANS}^j(\boldsymbol{a}^{j-1}_{(i,k)}) & \text{otherwise} \end{cases} \quad (3)$$

where $\boldsymbol{a}^j_{(i,k)}$ is the argument encoding of k-th token in i-th utterance from j-th encoder layer while $j \in (0, \ldots, N_2)$. Finally, we obtain the semantic role encoding $\boldsymbol{l}$ using the resulting argument encodings from the last layer of the predicate-argument encoder:

$$\boldsymbol{l}^i_k = \text{Swish}(\mathbf{W}^l \boldsymbol{a}^{N_2}_{(i,k)} + \mathbf{b}^l) \quad (4)$$

In particular, our proposed model is mostly language-agnostic since we do not explicitly introduce any language-specific knowledge such as word order, part-of-speech tags or dependent relations, and only introduce the predicate indicator that might contain some language-specific information in the semantic module, which would not affect latent space alignment and dialogue modeling.

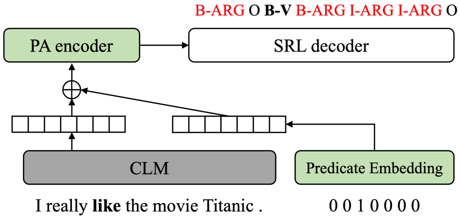

Figure 5: Illustration of pre-training objectives for semantic argument identification.

3.2 Pre-training Objectives

Besides the universal model, we also elaborately design five pre-training objectives to model task-specific but language-agnostic features for better cross-lingual performance. In this section, we divide our pre-training objectives into three groups according to the challenges to be solved.

Latent space alignment In cross-lingual language module, we use mBERT or XLM-R to align the latent space of different languages. Although mBERT and XLM-R have exhibited good alignment ability, even both of them are trained with unpaired data, we may further improve it when we have access to parallel data.

We first use translation language model (TLM) (Conneau and Lample, 2019) to learn word-level alignment ability. Concretely, we concatenate parallel sentences as a single consecutive token sequence with special tokens separating them and then perform masked language modeling (MLM) (Devlin et al., 2019) on the concatenated sequence. Besides, we also attempt to improve sentence-level alignment ability using hard parallel sentence identification (HPSI). Specifically, we select a pair of parallel or non-parallel sentences from the training set with equal probability. Then the model is required to predict whether the sampled sentence pair is parallel or not. Different from the standard PSI (Dou and Neubig, 2021), we sample the non-parallel sentence upon the n-gram similarity or construct it by text perturbation (details in Appendix A) instead of in a random manner. Figure 3 illustrates the workflows of TLM and HPSI. We pre-train the CLM using the combination of TLM and HPSI, finally achieving latent space alignment.

Conversation structure encoding Although there are a number of pre-training objectives proposed to learn dialogue context representations (Mehri et al., 2019) and structural representations (Zhang and Zhao, 2021), we tend to explicitly model speaker dependency and temporal depen-

Dataset	language	#dialogue	#utterance	#predicate	#tokens per utterance	cross ratio
DuConv	ZH	3,000	27,198	33,673	10.56	21.89%
Persona-Chat	EN	50	2,669	477	17.96	17.74%
CMU-DoG	EN	50	3,217	450	12.57	7.41%

Table 1: Statistics of the annotations on DuConv, NewsDialog and PersonalDialog.

dency in the conversation, both of which have been proven to be critical to CSRL task (Xu et al., 2021).

We first propose speaker role identification (SPI) to learn speaker dependency in the conversation. Specifically, we randomly sample $K_1\%$ utterances and replace their speaker indicators with special mask tags. To make the task harder and effective, we split the utterances into clauses if only two interlocutors utter in turn in a conversation. The goal of SPI is to predict the masked speaker roles according to the corrupted speaker indicators and context. Secondly, we borrow utterance order permutation (UOR) to encourage the model to be aware of temporal connections among utterances in the context. Concretely, given a set of utterances, we randomly shuffle the last $K_2\%$ utterances and require the model to organize them into a coherent context. Figure 4 illustrates the workflows of SPI and UOR. We pre-train the SC-Encoder using the combination of SPI and UOR.

Semantic arguments identification The core of all SRL-related tasks is to recognize the predicate-argument pairs from the input. Therefore, we propose semantic arguments identification (SAI) objective to strengthen the correlations between the predicate and its arguments with the help of external standard SRL corpus, i.e., CoNLL-2012. Specifically, for each SRL sample, we only focus on those arguments, including ARG0-4, ARG-LOC, ARG-TMP and ARG-PRP, all of which are defined in both SRL and CSRL tasks. The model is encouraged to find the textual spans of these arguments with the given predicate. We believe this objective would benefit to boundary detection, especially for location and temporal arguments. Figure 5 illustrates the workflow of SAI. We drop the SC-Encoder to fit in standard SRL samples which do not have any conversational characteristics.

3.3 Training

Hierarchical Pre-training The pre-training is hierarchically conducted according to different modules, and the pre-training of the upper module is based on the pre-trained lower modules. Specifically, we first train CLM module with TLM and HPSI; then we train SC-Encoder with SPI and UOR while keeping the weights of pre-trained CLM module unchanged; finally we train PA-Encoder with SAI while freezing the weights of pre-trained CLM and SC-Encoder modules. Hopefully, we expect that each module could acquire different knowledge with specific pre-training objectives.

CSRL training We initialize the specific modules, including CLM, SC-Encoder and PA-Encoder, from the pre-trained checkpoints. The CSRL model is trained only using Chinese CSRL annotations and no additional data is introduced during the CSRL training stage. We train our model to minimize the cross-entropy error for a training sample with label y based on the semantic role encoding $\boldsymbol{l}$,

$$p = \mathrm{softmax}(\boldsymbol{l}_t) \quad \mathcal{L}_{CSRL} = -\sum_{l=1}^{L} y \log p \quad (5)$$

4 Experiments

4.1 Datasets

CSRL data We use the same split as Xu et al. (2021) where DuConv annotations are splitted into 80%/10%/10% as train/dev/in-domain test set. Furthermore, we manually collect two CSRL test sets for cross-lingual evaluation based on Persona-Chat(Zhang et al., 2018) and CMU-DoG(Zhou et al., 2018), both of which are English conversation datasets. The CSRL data annotation is difficult because it needs great expertise in SRL and dialogue. So we only explore cross-lingual CSRL on Chinese→English (Zh→En) here, and we leave other languages for future work.

Following the instructions in Xu et al. (2021), we manually collect two out-of-domain CSRL test sets based on English dialogue datasets Persona-Chat and CMU-DoG. Specifically, we also annotate the arguments ARG0-4, ARG-TMP, ARG-LOC and ARG-PRP and require that the labeled arguments can only appear in the current turn or the previous turns. We employ three annotators who have studied Chinese CSRL annotations for a period time before this annotation. The first two annotators are

Table 2: Evaluation results on the DuConv, Persona-Chat and CMU-DoG datasets.

required to label all cases and any disagreements between them are solved by the third annotator. The statistics of the datasets are listed in Table 1.

Pre-training data For TLM and HPSI objectives which requires parallel data to enhance alignment ability, we choose IWSLT'14 English↔Chinese (En↔Zh) translations[2]. For SPI and UOR objectives whose goal is to model high-level conversational features, we select samples from Chinese conversation dataset (i.e., DuConv) and English conversation datasets (i.e., Persona-Chat and CMU-DoG) with equal probability. For SAI, we borrow the Chinese and English SRL annotations from CoNLL-2012(Pradhan et al., 2012).

We stress that by **keeping the sampling balance** of Chinese and English data for every pre-training objective and **sharing all parameters across the languages**, our model would capture task-specific but language-agnostic features.

4.2 Experimental Setup

Following previous work(Xu et al., 2021), we evaluate our system on micro-average $F1_{all}$, $F1_{cross}$ and $F1_{intra}$ over the (predicate, argument, label) tuples, wherein we calculate $F1_{cross}$ and $F1_{intra}$ over the arguments in the different, or same turn as the predicate. We refer these two types of arguments as *cross*-arguments and *intra*-arguments. For language in-domain evaluation, we compare to *SimpleBERT* (Shi and Lin, 2019), *CSRL-BERT* (Xu et al., 2021) and *CSAGN* (Wu et al., 2021b), all of which employ the Chinese pre-trained language model as the backbone. For cross-lingual evaluation, we compare to *SimpleXLMR*, *CSRL-XLMR* and *CSAGN-XLMR* by simply replacing the BERT backbones of those models with XLM-R. Additionally, we also compare to the back-translation baselines, i.e., Translate-test and Translate-train. Specifically, Translate-test means that the English test data is translated and projected to Chinese annotations using Google Translate (Wu et al., 2016) and the state-of-the-art word alignment toolkit Awesome-align(Dou and Neubig, 2021). Similarly, Translate-train means the Chinese training data is translated and projected to English annotations for training. We feed the translated samples into CSAGN/CSAGN-XLMR to obtain the back-translation results.

4.3 Main Results

Table 2 summarized the results of all compared methods on DuConv, Persona-Chat and CMU-DoG datasets. Firstly, we can see that our method achieves competitive performance over all datasets, especially in cross-lingual scenario where our method outperforms the baselines by large margins no matter fine-tuning or freezing the language model during the CSRL training stage. Although CSAGN exceeds our method on DuConv test set, it fails to work well in cross-lingual scenario. We think this is because it heavily relies on the rich features from the Chinese pre-trained language model and it is overfitting on the predicate-aware information. Superior to CSAGN, our model with the

Table 3: Ablation studies on pre-training objectives and different modules.

multilingual backbone achieves outstanding performance on both language in-domain and cross-lingual datasets. This observation is expected because (1) our model is language-agnostic which makes the cross-lingual transfer easier; (2) our model captures high-level conversational features in SC-Encoder, thus enhancing the capacities of the model to recognize cross-arguments; (3) rich semantic features are modeled by PA-Encoder, which would improve the capacities of the model to recognize intra-arguments.

Secondly, although our model has achieved good performance over all datasets, further improvements can be observed after incorporating the proposed pre-training objectives, especially when freezing the parameters of the language model. Exceptionally, we find that the performance on the CMU-DoG dataset heavily drops after introducing the pre-training objectives, especially in terms of F1_{intra}. We think this is because the semantic argument spans in CoNLL-2012 are relatively different from those in CMU-DoG, thus leading to the vague boundary detection and performance drop. To verify this assumption, we conduct an ablation study by removing SAI from the pre-training stage. Interestingly, we observe substantial improvements over F1_{all} and F1_{intra}, suggesting that pre-training on CoNLL-2012 does hurt the performance on CMU-DoG. Furthermore, we also find that fine-tuning all parameters leads to slightly better performance than freezing the language model during the CSRL training stage. This finding is consistent with the previous work (Conia et al., 2021).

Table 3 presents the results of ablation studies on pre-training objectives and different modules.

U1	how many games did the colts win?
U2	the $\text{Colts}_{\textbf{ARG0}}$ finished with a 12-2 record.
Question	who did they $\text{play}_{\textbf{predicate}}$ in the playoffs?
Question′	who did the Colts play in the playoffs?

Table 4: An example of question-in-context rewriting.

For the pre-training objectives, we found that (1) removing TLM & HPSI objective hurts the performance consistently but slightly; (2) SPI & UOR objectives help the model to better identify the cross-arguments; (3) SAI objective helps to find intra-arguments on DuConv and Persona-Chat, but might hurt the F1_{intra} score on CMU-DoG; (4) hierarchical pre-training is superior to end-to-end pre-training which simultaneously optimizes all auxiliary objectives. We think this is because the end2end pre-training is extremely unstable and confuses the optimization process of the model.

For model components, we found that only removing one of the SC-Encoder, PA-Encoder or MTRANS slightly affect the performance. However, the performance heavily decreases when SC-Encoder and PA-Encoder are both removed. We think the reason is that at least one module is needed to capture the high-level features on the top of the language model. We preserve these two modules in our model since they essentially learn different abilities, i.e., the ability of dialogue modeling and semantics modeling, which also makes our model more explainable.

4.4 Applications

Xu et al. (2021) has confirmed the usefulness of CSRL by applying CSRL parsing results to two Chinese dialogue tasks, including dialogue context rewriting and dialogue response generation. In the

Method	Persona-Chat (en)			BConTrast (de)		BSD (ja)

Table 6: Evaluation results on the dataset of CANARD.

same vein, we also explore whether CSRL could benefit to the same non-Chinese dialogue tasks.

Question-in-context Rewriting *Question-in-context rewriting* (Elgohary et al., 2019) is a challenging task which requires the model to resolve the conversational dependencies between the question and the context, and then rewrite the original question into independent one. This is an example in Table 4. The question “who did they play in the playoffs?" cannot be independently understood without knowing “they” refer to, but it can be resolved with the given context.

Since the CSRL models can identify the predicate-argument structures from the entire conversation, we believe that it can help this rewriting task by searching the dropped or referred components from the context. For example, in Table 4, our CSRL parser can find that the ARG0 of the predicate “play" is “the Colts". Motivated by this observation, we attempt to borrow CSRL to help the question rewriting with the context. We first employ the pre-trained cross-lingual CSRL parser (Ours$_{\text{XLM-R + pre-train}}$) to extract predicate-argument pairs from conversations. We adopt the model proposed in (Xu et al., 2020) to achieve the rewriting. More details about the model are in Appendix E.

Since the rewriting datasets are only available in Chinese and English, we hereby only evaluate on CANARD (Elgohary et al., 2019) which is a widely used English question rewriting dataset, and report the BLEU scores. Table 6 lists the evaluation results on CANARD. We can see that our implementation with CSRL achieves competitive performance against the state-of-the-art rewriting models, i.e., SARG (Huang et al., 2020) and RUN (Liu et al., 2020a), and significantly outperforms the baseline method (Bahdanau et al., 2014). Note that, in this part, we are more focused on the improvements after introducing CSRL information. We find that the scores across all metrics are improved with the aid of CSRL. To figure out the reasons of these improvements, we investigate which type of questions could benefit from CSRL information most. By comparing the rewritten questions of different methods, we find that the questions that require information completion, especially those containing referred components (around 15% cases), benefit from CSRL most. This observation is in line with our expectation that our CSRL parser could consistently offer essential guidance by recovering the dropped or referred text components.

Multi-turn Dialogue Response Generation Besides the rewriting task that is heavily affected by omitted components, we also explore the usefulness of CSRL to *multi-turn dialogue response generation*, one of the main challenges in dialogue community. In contrast to single-turn dialogue response generation, multi-turn dialogues suffer more frequently occurred ellipsis and anaphora, which leads to vague context representations. To this end, we attempt to employ CSRL to build better context representations. In specific, we highlight the words picked up by the CSRL parser, and then teach the model to pay more attention on those words which would hold more semantic features.

We evaluate on three dialogue datasets in different languages, including **Persona-Chat** (Zhang et al., 2018) in English, **BConTrast** (Farajian et al., 2020) in German and **BSD** (Rikters et al., 2019) in Japanese. We report BLEU-1/2 and Distinct-1/2 scores for the comparison. We employ the pre-trained cross-lingual CSRL parser (Ours$_{\text{XLM-R}}$) to analyze the latest utterance, and obtain the predicate-argument pairs. Then the concatenated sequence of the extracted pairs and the context is fed into our model for response generation. We adopt the UniLM (Dong et al., 2019) or mBART (Liu et al., 2020b) as our generation model. More implementation details are in Appendix E.

Table 5 summarizes the results on three datasets. We can see that the models with different backbones can consistently benefit from the additional introduced CSRL information. While substantial gains from CSRL information are obtained on English and Japanese dialogues, smaller improvements are observed on the German dialogue task. We think this is because English is well-represented in pre-trained multilingual models and Japanese is more similar to Chinese while German accounts for none of both. Apart from automatic evaluation criteria, we also conduct human evaluation on the English dataset. Specifically, we randomly select 200 generated responses for each method, and then recruit three annotators to evaluate the coherence and informativeness of the response against the conversation context by giving a score ranging from 1(worst) to 5(best). We find that the method with CSRL wins in 35% cases, and ties with the vanilla model in around 55% cases. With more careful analysis, we find that the responses that contains entities mentioned in histories benefit from CSRL information most. We think this is because none-phrases are more likely to be recognized as semantic arguments by CSRL parser, and then receive more attentions during encoding.

5 Conclusion

In this work, we propose a simple but effective model with five pre-training objectives to perform zero-shot cross-lingual CSRL, and also confirm the usefulness of CSRL to non-Chinese dialogue tasks.

A Hard Parallel Sentence Identification Sampling

Following previous work (Robinson et al., 2020; Wei et al., 2020) which suggests that contrastive learning of representations benefits from hard negative samples, we also try to select hard negative samples for PSI task based on n-gram similarity and text perturbation. Specifically, for each sentence, we calculate its n-gram similarity scores to other sentences, where $n = 1, 2, 3, 4$, and then we select the sentence with the highest score at each gram as the candidate sentence; additionally, we construct the corrupted sentence as the candidate by token deletion, token replacement and token order permutation. Finally, we sample from the candidate set created by n-gram similarity at 40% time and from the candidate set created by text perturbation at 60% time.

B Modified Transformer Encoder Layer

To overcome the information forgetting of hierarchical models, we attempt to modify the standard Transformer to better reserve the information from the previous layers. In specific, we try following variants:

- **MTRANS**. Replacing the `[Add]` operation in the **first** residual connection layer with `[Concat]`.
- **LATER-MTRANS**. Replacing the `[Add]` operation in the **second** residual connection layer with `[Concat]`.
- **BOTH-MTRANS**. Replacing the `[Add]` operations in **both** the first and second residual connection layers with `[Concat]`.

Our intuition of substituting the summation with concatenation is that the residual layer with concatenation would introduce additional parameters, and we expect these additional parameters to retain more history information. As shown in Table 2, we obtain some gains while using MTRANS. Additionally, we also report the F1$_{all}$ scores on DuConv/Persona-Chat/CMU-DoG datasets while using LATER-MTRANS and BOTH-MTRANS here. LATER-MTRANS achieves 88.18/65.32/58.44 points, and BOTH-MTRANS achieves 88.40/66.12/59.72 points against the standard Transformer achieving 88.25/65.27/58.58 points. Although BOTH-MTRANS achieves the best performance, we finally choose MTRANS since BOTH-MTRANS brings a large volume of additional parameters which leads to a huge model size while the increasing of model parameters caused by MTRANS is acceptable.

C Experimental settings

We implement the model in PyTorch(Paszke et al., 2019), and use the pre-trained language model of multilingual BERT (mBERT) or XLM-RoBERTa (XLM-R) made available by the Transformer library (Wolf et al., 2020) as the backbone. We train the model using AdamW(Loshchilov and Hutter, 2018) with a linear learning rate schedule. For each model, we run five different random seeds and report the average score. More details and hyper-parameters are listed in Table 7.

D Baselines

We compare to following baseline models,

1. **SimpleBERT/SimpleXLMR** (Shi and Lin, 2019). It uses the Chinese BERT or XLM-R as the backbone and simply concatenates the entire dialogue context with the predicate.
2. **CSRL- BERT/XLMR** (Xu et al., 2021). It uses the Chinese BERT or XLM-R as the backbone but attempts to encode the conversation structural information by integrating the dialogue turn and speaker embeddings in the input embedding layer.
3. **CSAGN/CSAGN-XLMR** (Wu et al., 2021b). It uses the Chinese BERT or XLM-R as the backbone and employ the relational graph neural network to model predicate- and speaker-aware dependencies. We implement this baseline based on the code `https://github.com/hahahawu/CSAGN`.

E Application Models

Rewriting Model. We adopt the model proposed in (Xu et al., 2020) which directly concatenates the predicate-argument structures, the conversation context and the question as a sequence, and then feeds them into the model with special attention masks. During decoding, the model takes CSRL pairs and the context to generate the rewritten question word by word. The input representation, attention strategies and loss function of our model are same as (Xu et al., 2020)'s. We initialize the model using the base BERT model and use AdamW with a linear learning rate schedule to update parameters.

Note that we only attempt to introduce the CSRL information as a condition into our generation-based model. We did not include the CSRL information into the state-of-the-art rewriting models, i.e., SARG and RUN because these models rewrite the sentence by learning a text editing matrix instead of directly learning the distributions of the target words. Unfortunately, there are no straightforward ways to include our CSRL information into these models to help the matrix learning.

Response Generation Model. Our model for response generation is directly borrowed from UniLM (Dong et al., 2019) or mBART (Liu et al., 2020b). For UniLM, the generation process is same with the rewriting task, wherein the extracted semantic pairs, the context and the response are concatenated into a sequence and encoded with the special mask. For mBART, we just concatenate the extracted predicate-argument pairs with the context into a sequence, and then feed the sequence into the encoder for training; during decoding, our model takes semantic information and the context as input to generate the response word by word. The input representation, attention strategies for CSRL structures and loss function are same as the rewriter model's. We initialize the model using the base multilingual BERT or mBART and use AdamW with a linear learning rate schedule to update parameters.

F Hyper-parameters

We list the hyper-parameters of CSRL experiments (Table 7), rewriting experiments (Table 8) and response experiments (Table 9) below.

Name	Value
Language model	xlm-roberta-base
Hidden state size	512
Word-level encoder layers	2
Pred.-arg encoder layers	1
Batch size per GPU	24
Max learning rate	5e-5
Min learning rate	1e-5
Max *lr* for LM fine-tuning	1e-5
Min *lr* for Lm fine-tuning	1e-6
Max sequence length	512
Max training epochs	50
Max training steps	15000
Early-stop patience	10

Abstract

Systems like Voice-command based conversational agents are characterized by a pre-defined set of skills or intents to perform user specified tasks. In the course of time, newer intents may emerge requiring retraining. However, the newer intents may not be explicitly announced and need to be inferred dynamically. Thus, there are two important tasks at hand (a). identifying emerging new intents, (b). annotating data of the new intents so that the underlying classifier can be retrained efficiently. The tasks become specially challenging when a large number of new intents emerge simultaneously and there is a limited budget of manual annotation. In this paper, we propose **MNID** (**M**ultiple **N**ovel **I**ntent **D**etection) which is a cluster based framework to detect multiple novel intents with budgeted human annotation cost. Empirical results on various benchmark datasets (of different sizes) demonstrate that MNID, by intelligently using the budget for annotation, outperforms the baseline methods in terms of accuracy and F1-score.

1 Introduction

The conversational agents such as Amazon Alexa, Apple Siri are characterised by the skill of understanding *intents* which help them to efficiently handle a user's query. For example, the query **'Will it be colder in Ohio'** requires getting the weather updates for the city 'Ohio' and would be associated to the intent *GetWeather*. The agents are trained with a pre-defined set of intents such as {*GetWeather*, *RateBook*, *BookRestaurant*} so as to perform the goal-oriented user tasks. But with the passage of time, a user may be interested in performing newer tasks adding hitherto unknown intents. For example, **'Play some music from 1954'** would be associated to the intent *PlayMusic* that may not be a part of the set of pre-defined intents.

Emergence of novel intent detection has been periodically checked by different models in the last decade. There are works on incremental learning in dynamic environment for evolving new classes (Zhou and Chen, 2002; Kuzborskij et al., 2013; Scheirer et al., 2012). There are also several approaches (Sun et al., 2016; Masud et al., 2010; Haque et al., 2016; Wang et al., 2020; Mu et al., 2017b,a) to detect new classes in the form of outlier detection but they do not distinguish among multiple new class labels so are not effective in novel multi-class detection. Xia et al. (2018); Siddique et al. (2021) detect user intents using zero-shot generalized intent detection framework. However, they assume that the unseen intent class LABELS are already known, while in our case neither the number of unseen intent classes, nor the corresponding class labels are known. The other line of works (Xia et al., 2021; Halder et al., 2020) supply the system with new intents, albeit with a limited amount of tagged data per class and then have an efficient algorithm to incrementally learn new classes. These models work on the assumption that some instances of these new classes would be provided for model building. However, in a realistic setting, the system may not have any knowledge of the number and types of new intents appearing, it may at most understand that some new out-of-domain samples are generated. So, the problem statement is to probe the incoming data wisely and **use minimum human intervention to identify all types of novel intents emerging and intelligently tag a limited set of data covering all discovered intents**, which can be be fed into a model for retraining.

More concretely the system is at first trained with an initial set of known intents; side-by-side an out-of-distribution (OOD) detector classifier is also trained to identify datapoints which do not fit the known intents. When substantial amount of

such points are detected, the task is to (a) identify whether the points are originating from introduction of a single novel intent or multiple and (b) choose (a limited number of) samples to annotate so that the classifier can be retrained efficiently.

In order to determine the number of novel intents present in the OOD data, we undertake a clustering based approach with the idea that each cluster would represent a novel intent. By increasing the cluster number progressively, we can make a highly accurate estimate of the number of novel intents. If sample points of an intent mainly correspond to a well formed cluster, the implication is that without much probing we can shortlist enough training samples (through silver tagging) for that class. On the other hand, if the sample points of an intent tend to intertwine with other intent points in the feature space, these can be considered as uncertain points and require human intervention for tagging (gold tagging). With this intuition in place, we design a mix of silver and gold tagging to produce high-quality training samples which can be used to retrain the classifier.

Our proposed framework of Multiple Novel Intent Detection (**MNID**) is compared with competitive baselines and evaluated across several standard public datasets in NLU domain where it performs substantially better. We use datasets with different number of intent classes. SNIPS (Coucke et al., 2018) and ATIS (Tur et al., 2010) are smaller datasets, consisting of less number intent classes - 7 and 21, respectively. HWU (Liu et al., 2019a), BANKING (Casanueva et al., 2020) and CLINC (Larson et al., 2019) consist of large number of intent classes - 64, 77 and 150, respectively.

The paper is organized as follows. We discuss the Problem Setting and solution overview in Section 2. Our algorithmic framework is described in Section 3. We present the datasets with experimental statistics and data pre-processing in Section 4. In Section 5, we discuss the experimental design and baselines. Detail evaluation results with different algorithmic variations are in Section 6. We conclude with a summary in Section 7[1].

2 Problem Setting and Solution Overview

Problem Setting: To formally describe the problem setting, let there be a dataset W containing overall N classes. However, the value of N is not known apriori. Let $T \in W$ be the test set and $W - T = D$ be the rest of the dataset, out of which $|D_{init}|$ ($<< |D|$) labelled data of N_{init} ($< N$)

Algorithm 1 Multiple Novel Intent Detection (**MNID**)

Return ($\mathcal{L}$)
```

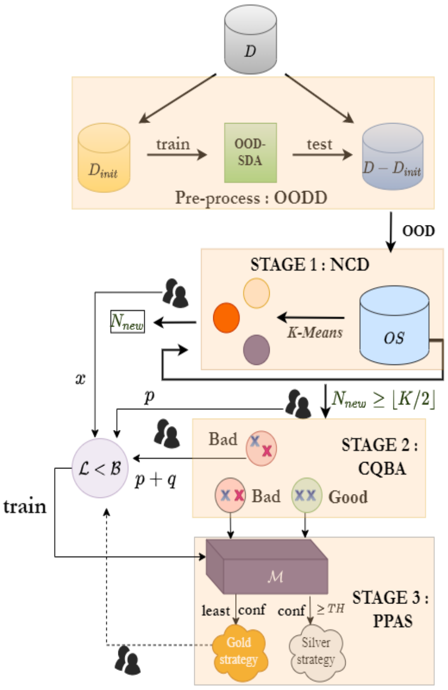

Figure 1: End-to-end architecture of MNID: Multiple Novel Intent Detection

classes is initially provided, while the rest of the data is unlabelled. The task is to design an algorithm to (a). detect all the remaining $N - N_{init}$ classes and (b). spent a limited budget (B - $|D_{init}|$) to annotate high fidelitous new datapoints, so that the classifier can achieve high accuracy when retraining.

Solution Overview: The solution steps are as follows: (a) Identify the OOD (out of distribution) datapoints which do not belong to the initial N_{init} classes. This can be considered as a preprocessing step. (b) Use a part of the allotted budget to annotate a portion of these OOD datapoints. These points (for annotation) are selected by repeatedly running a clustering algorithm with increasing number of clusters as input, and choosing cluster centre points to identify the unknown classes. **Rationale:** The intuition/expectation is that each cluster hosts a separate intent, hence annotating the cluster centres would lead to discovery of maximum number of novel intents. (c) Further identify the classes which are well clustered in feature space and which are not. Use another portion of the budget to increase the annotations of not-so well formed clusters and then build up a classifier with all the classes. **Rationale:** If a cluster is well-formed, most likely it is hosting a single class, hence there is no need to annotate further points there, rather annotate more points in not-so-well-formed clusters. (d) Use the classifier to classify points from the clusters. Identify low-confidence points from the bad clusters and annotate them. High-confidence points from good clusters are silver annotated. **Rationale:** The low-confidence points in the bad clusters are the most uncertain points, hence annotating them helps in increasing classifier accuracy. Similarly high-confident points in the good clusters almost surely will belong to that particular cluster, hence silver annotation is pursued. (e). Retrain the classifier.

The overall MNID framework with different algorithmic modules is shown in Fig. 1.

3 MNID: Solution Detail

The proposed framework for Multiple Novel Intent Detection (MNID) is explained through Algorithm 1. As highlighted in the overview, the algorithm consists of data pre-processing step, followed by three stages, each of them are discussed below. The total budget of (gold) annotation is B. Besides the system can undertake unlimited silver annotation. The advantage of silver strategy is that it is free as no human probing is required. However, it is also likely to bring in noise if used indiscriminately.

Pre-process: OOD Detection (OODD): For the dataset (D), this module (Algorithm 2) takes the initial labelled data (D_{init}) as input and predicts the Out-of-Domain (OOD) samples on the remaining data, ($D - D_{init}$). We call the set of OOD samples predicted as $\mathcal{OS}$. This is a part of the data pre-processing.

Stage 1. Novel Class detection (NCD): In this sub-module (Algorithm 3), we aim at finding all the new classes, N_{new}. On the OOD samples ($\mathcal{OS}$), obtained in the previous sub-module (Algorithm 2), we do clustering using K-Means. We start the algorithm with $K = 1$ and number of new classes, N_{new} = 0. We perform - (i) K-Means clustering. (ii) Annotate x points from each cluster, add those points to $\mathcal{L}$ and identify n' new classes. (iii) Increase new class count (N_{new}+ n'). (iv) Double the number of cluster count (we compare N_{new} with $K/2$). We execute the above steps until cluster count exceeds the new intent count. The algorithm returns current annotations ($\mathcal{L}$), newly discovered class count (N_{new}) and newly formed clusters ($\mathcal{CL}$). The budget spent in this step is B_1.

Stage 2. Cluster Quality Based Annotation (CQBA): In this step (Algorithm 4), we evaluate the quality of each of the clusters obtained by the previous algorithm. We annotate p points from each of these clusters and if all the p points belong to the same class, we term it as a *good cluster* or else a *bad cluster*. An example of a *bad cluster* in BANKING would be the one containing data points from multiple classes, which may have high similarity, such as: *declined_cash_withdrawal* and *pending_cash_withdrawal*. For the *bad clusters*, we annotate q more points. All these annotated points are then added to the labelled data, $\mathcal{L}$. The budget spent in this step is B_2. Hence the remaining budget B - (B_1 + B_2) is used in the next step.

Stage 3. Post Processing Annotation Strategy (PPAS): In this step (Algorithm 5), we add more data to the labelled set, $\mathcal{L}$, through gold annotation (*gold strategy*), as well as silver-annotated data (*silver strategy*). To select these data points, we first train a classifier ($\mathcal{M}$) with the labelled set, $\mathcal{L}$ as obtained in the last step (CBQA), and consider the clusters $\mathcal{CL}$. We predict on the remaining points of the clusters to get the confidence of the datapoints. We perform silver strategy based on confidence score (CS) and gold strategy in round-robin way to operate on each cluster one after another.

Gold Strategy: Least confident data-points are annotated from the bad clusters (if present) or else from the good clusters. Gold strategy is performed in a round-robin way to retrieve data points with the least score for each cluster until our budget exhausts.

Silver strategy: If the confidence score (CS) of a datapoint from a cluster is greater than a predefined threshold ($\mathcal{TH}$), we measure the average cosine similarity of points annotated within that cluster with this point. If similarity is above a predefined threshold (τ), we label this point with class label of that cluster. The predefined threshold (τ) is required to choose good samples selectively instead of choosing all the points. Silver strategy does not require human intervention therefore there is no extra addition to the annotation cost, but the multiple conditions are checked to prevent noise in the training set.

Final Step: We again train the neural model $\mathcal{M}$ on $\mathcal{L}$ and test on $\mathcal{T}$ to find out Accuracy and F1.

4 Dataset and Pre-Processing

We perform our experiments on a variety of datasets, which are widely used as benchmarks for Natural Language Understanding tasks. The datasets are SNIPS (Coucke et al., 2018), ATIS (Tur et al., 2010), HWU (Liu et al., 2019a), BANKING (Casanueva et al., 2020) and CLINC (Larson et al., 2019). SNIPS (7) and ATIS (21) are smaller datasets consisting of less number of intents (in bracket) where HWU (64), BANKING (77) and CLINC (150) are larger datasets with many intents. ATIS is the most imbalanced, skewed dataset. In BANKING data - several intents are highly similar among themselves. The detailed statistics of these datasets including our experimental framework are shown in Table 1. Since the datasets are already fully labelled, annotation essentially means utilizing the already available labels. Hence, we

Table 2: Accuracy (A) and F1-Score in (%) of various OODD algorithms to detect OOD points from different datasets. **Bold** denotes the best for each dataset.

In the pre-processing step, we filter the out-of-domain samples. We consider four algorithms for detecting out-of-domain samples. i) Softmax Prediction Probability (MSP) (Hendrycks and Gimpel, 2018) predicts out-of-domain samples based on a threshold on the softmax prediction scores. ii) Deep Open Classification (DOC) (Shu et al., 2017) method builds a multi-class classifier with one vs rest layer of sigmoids. iii) Large Margin Cosine Loss (LMCL) (Lin and Xu, 2019) trains a network with margin loss and predictions are then fed into an algorithm called Local Outlier Factor (LOF) for outlier detection. iv) Few-shot OOD (FS-OOD) (Tan et al., 2019) uses a Proto-Typical Network to detect OOD examples and classifying in-domain examples with few-shot examples from the in-domain class. We fine-tune BERT embeddings using all these out of domain sample detection algorithms. We use bert-base-uncased for these methods. We set the threshold for MSP as 0.5 as in Lin and Xu (2019), Xu et al. (2020). The results of all these algorithms are shown in Table 2. FS-OOD (Tan et al., 2019) provides us the best accuracy and F1 for detecting OOD samples ($\mathcal{OS}$). Only DOC performs better in case of SNIPS but overall FS-OOD outperforms other approaches so we use FS-OOD produced out-of-sample data.[2]

5 Experimental Setup

The efficacy of the algorithm needs to be tested on two aspects. (a). The number of unknown intents identified. (b). The accuracy achieved when the data is annotated by our algorithm, MNID. To test the accuracy, we use state-of-the-art several classification algorithms used for intent detection.

Different Neural Models: We explore different neural models to evaluate **MNID** as discussed next:

1. IFSTC (Xia et al., 2021): This finetunes a trained model on few shot data of new classes using an entailment and hybrid strategy. We use the hybrid strategy (best performing in their case).

2. PolyAI (Casanueva et al., 2020): It performs intent classification task based on dual sentence encoders - Universal Sentence Encoders (USE) (Cer et al., 2018) and ConveRT. Since authors have taken down the ConveRT model, we apply USE only. [3]

Along with the above two, we also consider other standard models, **3. BERT ('bert-base-uncased')** (Devlin et al., 2019) and **4. RoBERTa ('roberta-base-uncased')** (Liu et al., 2019b) for evaluation on these datasets. We finetune these pre-trained language models for 15 epochs for the smaller datasets (SNIPS, ATIS) 50 epochs for the larger datasets (HWU, BANKING, CLINC) and with a learning rate of 2e-05 and Adam optimizer[4]. Early stopping was employed to stop training. For all methods, we provide the same number of gold annotated data obtained using our pipeline and report its performance.

Baselines: We compare the performance of our method using two annotation techniques for choosing $B - \|D_{init}\|$ data points: 1) Gl_F: This is the ideal scenario where we are given F (=10) data points for each of the new classes - $Gold_{Few}$, abbreviated as 'Gl_F'. 2) Rn_F : Here, we randomly choose $B - \|D_{init}\|$ data points from the unlabelled data - $Random_{Few}$, abbreviated as 'Rn_F'.

Clustering Algorithms: One of the building blocks of **MNID** is to cluster datapoints, so the efficacy of **MNID** depends on employing an efficient clustering algorithm. We do a detailed study by employing several unsupervised and semi-supervised clustering algorithms and choose the best.

The unsupervised algorithms are: (i) **K-Means (KM)** (MacQueen et al., 1967) (ii) **Agglomera-**

Table 3: Overall Accuracy (A) and Macro F1 in (%) across all datasets for different scenarios - ideal (Gl_F), random (Rn_F) and MNID (The best outcomes among three scenarios in **Bold**). *Casanueva et al. (2020) report accuracy of 90.15 with OOS and 92.14 without OOS.

tive Clustering (AG) (Gowda and Krishna, 1978) (iii) **Deep Clustering Network (DCN)** (Yang et al., 2017) and (iv) **Deep Embedded Clustering (DEC)** (Xie et al., 2016) which uses the stacked autoencoder based reconstruction loss. The semi-supervised algorithms are: (i) **DeepAligned (DAL)** (Zhang et al., 2021) which uses limited data for pre-training and cluster assignments as pseudo labels for cluster refinement. (ii) **DTC** (Han et al., 2019) develops on the DCN algorithm by scaling it to the transfer learning setting and can estimate the number of known classes in unlabelled data. It is however highly dependent on availability of labelled data (iii) **KCL** (Hsu et al., 2017) which transfers the knowledge to target dataset considering KL-divergence based distance loss (iv) **MCL** (Hsu et al., 2019) which uses meta-classification based likelihood criterion for pairwise similarity evaluation (v) **CDAC+** (Lin et al., 2020) which uses prior data to refine the clustering process and KL-divergence based loss [5].

Other than KM and AG, all the other unsupervised methods along with some of the semi-supervised methods such as DTC and CDAC need the information of the ground truth number of clusters for training and we provide them so (it is an extra advantage for them). For semi-supervised methods such as KCL, MCL, DTC and DAL, we start with double the number of ground truth clusters and let the method determine the number of clusters.

Hyper-parameters and Settings: For Post-Processing annotation strategy of MNID, we set the cosine similarity threshold, τ as 0.8 and the confidence threshold, $\mathcal{TH}$ as 0.5 [6]. For all datasets, we use a setting similar to κ-shot with κ = 10. For N intents, we define our total budget $B = \kappa \times N$. We use same budget for all our experiments. We experiment on NVIDIA Tesla K40m GPU with 12 GB RAM, 6 Gbps clock cycle and GDDR5 memory. All the methods took less than 8 GPU hours for training.

6 Experimental Results

In this section, we discuss the experimental outcomes for MNID and competing baselines. We also show results of different clustering algorithms and variations of distinct components of MNID.

(A) Class Discovery: MNID is very effective in identifying almost all new intents. For HWU, BANKING and CLINC, 54 out of 54 (100%), 66 out of 67 (98.5%) and 139 out of 140 (99.3%) new intents from the unknown intent set were discovered, respectively. For SNIPS and ATIS, we could discover 2 out of 2 (100%) and 7 out of 8 (87.5%) new intent classes, respectively. Due to data skewness (ATIS) and high intent similarity (BANKING, CLINC) MNID misses one intent.

(B) Performance of MNID: Table 3 shows the performance of different models - IFSTC, PolyAI, BERT and RoBERTa when trained with datasets provided by MNID. In order to maintain the fairness, MNID, Rn_F and Gl_F use the (overall) same number of gold-annotated data points. Besides MNID uses silver-annotated data points, while the others do not have any way of creating high quality silver annotated data. Each cell in the table consists of values from Gl_F, Rn_F and MNID. As expected, Rn_F performs the worst across all settings. However, except two scenarios, we observe that MNID consistently performs better than the Gl_F dataset. For all these four different settings across five datasets, MNID improvements over Gl_F predictions are statistically significant ($p < 0.05$) as

---

[5] Code: `https://github.com/thuiar/TEXTOIR`

[6] This combination of τ and $\mathcal{TH}$ provides the best results among different experimented results.

per McNemar's Test. It is observed that our approach also works well on the highly imbalanced ATIS dataset in which some of the classes have less than 10 data points and highly similar BANKING dataset in which the intents are closely related eg., ‘top-up-reverted’ and ‘top-up-failed’. This is because although Gl_F chooses uniformly across all classes, MNID selectively labels datapoints having high uncertainty thus providing the classifier with the right ingredient to perform better. In IFSTC on SNIPS dataset, MNID underperforms as compared to Gl_F but with a very small margin. This happens because in the case of SNIPS dataset, the number of new classes is very less, hence Gl_F can choose ideal candidates. The best performance of MNID as well as the two baselines is in the PolyAI setting when it is used with Universal Sentence Encoders (USE). Since PolyAI performs the best, all our subsequent results are provided on PolyAI (USE).

(C) Distribution of gold annotated points: Fig 2 shows the count of the gold annotated points ($Y-axis$) for new classes (class indices on $X-axis$). The dotted line is at the frequency of 10, corresponding to the average annotations per class. For 76.2% (HWU), 81.5% (BANKING) and 67.3% (CLINC) classes in good clusters require ‘$\leq$ 10’ annotations. More than 10 annotations are needed for 65.4% (HWU), 68.5% (BANKING) and 54.5% (CLINC) classes in bad clusters.

(D) Budgets: For novel intent class discovery, a minimum number of human annotation is necessary. For NCD to work, at least 4 shot, 6-shot and 7-shot annotations are required for HWU, BANKING and CLINC datasets respectively.

Different Variations of MNID

MNID consists of three steps (a). novel class detection (NCD), (b). cluster quality based annotation (CQBA) and (c). post-processing annotation strategy (PPAS). In each of these steps, certain parameters can be varied. We systematically discuss the impact of these parameters on MNID performance.

Variations at NCD

(a) Performance of Clustering Algorithms: We explore different unsupervised and semi-supervised clustering algorithms in our **MNID** framework. Overall accuracy and F1-Score for open intent discovery by different approaches are shown in Table 4. From Table 4, it is seen that unsupervised approaches perform better than semi-supervised models. The semi-supervised techniques get biased by the initial seed and fail to discover diverse clusters needed to detect all the new intent classes. K-Means (KM) performs the best across all datasets in terms of accuracy and F1 score except for HWU dataset where DEC and DTC (F1 only) outperforms it. This is most probably due to its robustness and absence of any outlier in the dataset. So we use K-Means as the clustering algorithm for MNID.

(b) Class Discovery with number of clusters: From Fig 3a, we observe an increasing trend in the number of classes discovered with increasing number of clusters which show that classes get evenly distributed across clusters as the number of clusters increases. The rate at which new classes are discovered is linear with the new clusters until significant classes are detected. The horizontal lines represent the gold number of new intents.

(c) Effect of number of points (x) used in clustering: Fig 3b shows that the accuracy on all datasets drops as we increase the number of points used for new class discovery in clustering beyond $x = 2$. This is because most of the budget gets exhausted while clustering and we have a very small budget to annotate low-confidence points in the next steps. Note that at least two points from a cluster need to be annotated for new class discovery.

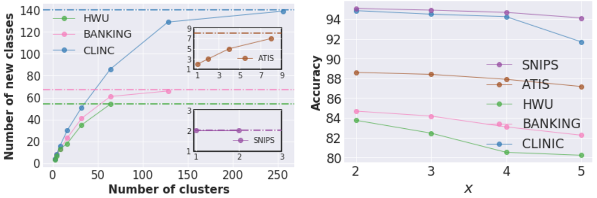
Table 6: Accuracy (%) based on point selections from Good and Bad clusters



(a) Class discovery with number of clusters

(b) Accuracy vs points annotated (x) for clustering

Figure 3: Variations of NCD

Variations at CQBA

(a) Effect of number of points selected from Good and Bad clusters: We experiment with different values of point selection (p, q) for the module CQBA (Algo 4) and observe how accuracy changes for three larger datasets - HWU, BANKING and CLINC. We get the best accuracy for (p, q) = (3, 2) i.e 3 (p) points from good cluster and 5 ($p + q$) points from bad cluster as shown in Table 6. Since, we perform gold annotation strategy on the bad clusters, a higher number of point selection is required to identify classes.

(b) Distribution of good and bad clusters: For CLINC, BANKING and HWU we obtain 256, 128 and 64 clusters respectively by NCD. The percentage of good clusters obtained for CLINC, BANKING and HWU are 70.70% (181 out of 256), 46.88% (60 out of 128) 56.25 % (36 out of 64), respectively. For BANKING, since the entire dataset is from a single domain with multiple intents being similar among themselves, we obtain more bad clusters than the good clusters. For SNIPS and ATIS, however, all the clusters are good clusters.

Variations at PPAS

(a) Different Variations of Gold and Silver Strategies: The results for different variations of MNID methods (based on Silver and Gold Strategy applications) for all the datasets are provided in Table 5. We observe that the best result is obtained on MNID-9, i.e., choosing high confidence points from the good clusters for silver strategy and low confidence points from the bad clusters (if detected or else from the good clusters) only for gold strategy. This strategy ensures that during silver annotation we choose points with high fidelity and side by side for gold annotation choose points with high uncertainty, both of which help in developing a highly accurate classifier. Silver strategy on

high confidence points from good cluster (7 vs 9) and gold strategy on low confidence points from bad cluster (4 vs 9) alone enhances ∼1- 3% accuracy and F1 for the three large datasets.MNID-9 corresponds to our proposed approach, MNID.

(b) Silver Strategy Analysis: We inspect silver strategy based on cosine similarity, confidence score and strategy accuracy.

(i) Effect of Cosine Similarity and Confidence Score (CS): We study the effect of cosine similarity of silver strategy for MNID. From Fig. 4a, we observe that the best results are always obtained using a higher threshold of 0.8 cosine similarity. In case of BANKING, HWU and ATIS accuracy drops at 0.9 whereas for other datasets it remains almost identical. Fig. 4b shows how accuracy varies for different confidence scores. We observe that for all the datasets the best results are obtained at a threshold of 0.5. This is because a lower threshold allows more diverse datapoints to be selected using cosine similarity and this in turn improves the model performance. In both the cases if the cosine similarity or the threshold is increased beyond the optimal point, that results in selection of too less datapoints which is not enough for the classifier to do a meaningful learning. Hence accuracy drops. So we choose the parameters - cosine similarity = 0.8 and τ = 0.5 - while choosing *high confidence* point to be annotated by silver strategy.

(ii) Strategy Accuracy: The accuracy of data point selection by silver strategy for different MNID variations is shown in Table 7. We see the strategy of choosing high-confidence points from good clusters produce points with high fidelity. Table 7 also shows the average number of points per class as selected by this strategy for various datasets. Here we see that enough number of silver points are annotated even after considering a very strict criterion. Note, average points per intent class count is the highest for BANKING because multiple intents are very similar to each other and hence more points qualify the cosine similarity threshold, τ.

.

7 Conclusion

We have developed MNID (**M**ultiple **N**ovel **I**ntent **D**etection), an end-to-end framework to identify multiple novel intents within a fixed annotation cost. The algorithm intelligently uses the concept of clusters to first discover the classes and then estimate the nature in which datapoints of a class is distributed, that is, whether the datapoints of a class congregate strongly within themselves and separate from other classes or are entangled with datapoints of other classes. In the two types of situations, we propose two different strategies, silver strategy to take advantage of the clusters so that we can annotate many points without any extra human cost and gold strategy to annotate highly uncertain points. This two-pronged approach helps us to annotate highly precise points automatically while annotating the most uncertain (with respect to the class it belongs) points using human assistance. We have done a very rigorous analysis/experimentation to establish the core idea of our algorithm. We observe that the accuracy of classifiers when fed with the dataset created by MNID can beat the standard best few-shot setting where it is assumed that 'κ' instances of each class are provided and annotated by human whereas in our case we have to first discover the classes and then have to find the instances of each class.

One limitation of MNID is that it is not able to detect intents where classes are very similar to each other. For example, the query "Can you explain why my payment is still pending?" in BANKING dataset is from the "pending transfer" category but our system detects as "pending card payment" intent as both intents are quite similar. We shall try to address this issue in future. We have presently worked on a setting where novel intents appear in one step, we would strive to extend this framework to explore the dynamics of periodically evolving intents.

Abstract

It is challenging to train a good intent classifier for a task-oriented dialogue system with only a few annotations. Recent studies have shown that fine-tuning pre-trained language models with a small amount of labeled utterances from public benchmarks in a supervised manner is extremely helpful. However, we find that supervised pre-training yields an anisotropic feature space, which may suppress the expressive power of the semantic representations. Inspired by recent research in isotropization, we propose to improve supervised pre-training by regularizing the feature space towards isotropy. We propose two regularizers based on contrastive learning and correlation matrix respectively, and demonstrate their effectiveness through extensive experiments. Our main finding is that it is promising to regularize supervised pre-training with isotropization to further improve the performance of few-shot intent detection. The source code can be found at `https://github.com/fanolabs/isoIntentBert-main`.

1 Introduction

Intent detection is a core module of task-oriented dialogue systems. Training a well-performing intent classifier with only a few annotations, i.e., few-shot intent detection, is of great practical value. Recently, this problem has attracted considerable attention (Vulić et al., 2021; Zhang et al., b; Dopierre et al., b) but remains a challenge.

To tackle few-shot intent detection, earlier works employ induction network (Geng et al., 2019), generation-based methods (Xia et al., a), metric learning (Nguyen et al., 2020), and self-training (Dopierre et al., b), to design sophisticated algorithms. Recently, pre-trained language models (PLMs) have emerged as a simple yet promising solution to a wide spectrum of natural language processing (NLP) tasks, triggering the surge of PLM-based solutions for few-shot intent detection (Wu et al., 2020; Zhang et al., a,b; Vulić et al., 2021; Zhang et al., b), which typically fine-tune PLMs on conversation data.

A PLM-based fine-tuning method (Zhang et al., a), called IntentBERT, utilizes a small amount of labeled utterances from public intent datasets to fine-tune PLMs with a standard classification task, which is referred to as *supervised pre-training*. Despite its simplicity, supervised pre-training has been shown extremely useful for few-shot intent detection even when the target data and the data used for fine-tuning are very different in semantics. However, as will be shown in Section 3.2, IntentBERT suffers from severe anisotropy, an undesirable property of PLMs (Gao et al., a; Ethayarajh, 2019; Li et al., 2020).

Anisotropy is a geometric property that semantic vectors fall into a narrow cone. It has been identified as a crucial factor for the sub-optimal performance of PLMs on a variety of downstream tasks (Gao et al., a; Arora et al., b; Cai et al., 2020; Ethayarajh, 2019), which is also known as the representation degeneration problem (Gao et al., a). Fortunately, isotropization techniques can be applied to adjust the embedding space and yield significant performance improvement in many tasks (Su et al., 2021; Rajaee and Pilehvar, 2021a).

Hence, this paper aims to answer the question:

- Can we improve supervised pre-training via *isotropization* for few-shot intent detection?

Many isotropization techniques have been developed based on transformation (Su et al., 2021; Huang et al., 2021), contrastive learning (Gao et al., b), and top principal components elimination (Mu and Viswanath, 2018). However, these methods are designed for off-the-shelf PLMs. When applied on PLMs that have been fine-tuned on some NLP task such as semantic textual similarity or intent classification, they may introduce an adverse effect,

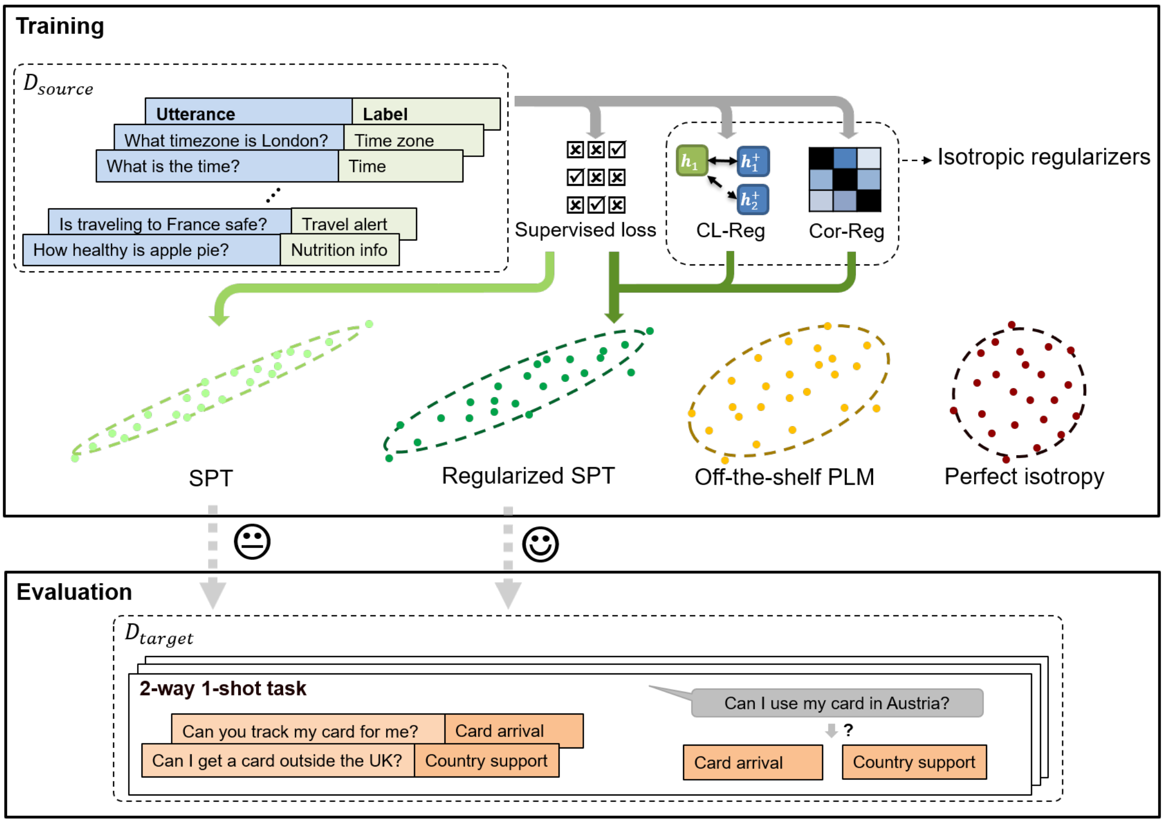

Figure 1: Illustration of our proposed regularized supervised pre-training. SPT denotes supervised pre-training (fine-tuning an off-the-shelf PLM on a set of labeled utterances), which makes the feature space more anisotropic. CL-Reg and Cor-Reg are designed to regularize SPT and increase the isotropy of the feature space, which leads to better performance on few-shot intent detection.

as observed in Rajaee and Pilehvar (2021c) and our pilot experiments.

In this work, we propose to regularize supervised pre-training with isotropic regularizers. As shown in Fig. 1, we devise two regularizers, a contrastive-learning-based regularizer (CL-Reg) and a correlation-matrix-based regularizer (Cor-Reg), each of which can increase the isotropy of the feature space during supervised training. Our empirical study shows that the regularizers can significantly improve the performance of standard supervised training, and better performance can often be achieved when they are combined.

The contributions of this work are three-fold:

- We present the first study on the isotropy property of PLMs for few-shot intent detection, shedding light on the interaction of supervised pre-training and isotropization.
- We improve supervised pre-training by devising two simple yet effective regularizers to increase the isotropy of the feature space.
- We conduct a comprehensive evaluation and analysis to validate the effectiveness of the proposed approach.

2 Related Works

2.1 Few-shot Intent Detection

With a surge of interest in few-shot learning (Finn et al., 2017; Vinyals et al., 2016; Snell et al., 2017), few-shot intent detection has started to receive attention. Earlier works mainly focus on model design, using capsule network (Geng et al., 2019), variational autoencoder (Xia et al., a), or metric functions (Yu et al., 2018; Nguyen et al., 2020). Recently, PLMs-based methods have shown promising performance in a variety of NLP tasks and become the model of choice for few-shot intent detection. Zhang et al. (c) cast few-shot intent detection into a natural language inference (NLI) problem and fine-tune PLMs on NLI datasets. Zhang et al. (b) propose to fine-tune PLMs on unlabeled utterances by contrastive learning. Zhang et al. (a) leverage a small set of public annotated intent detection benchmarks to fine-tune PLMs with standard supervised training and observe promising performance on cross-domain few-shot intent detection. Meanwhile, the study of few-shot intent detection has been extended to other settings including semi-supervised learning (Dopierre et al., b,a), generalized setting (Nguyen et al., 2020), multi-label classification (Hou et al., 2021), and incremental learning (Xia et al., b). In this work, we consider standard few-shot intent detection, following the setup of Zhang et al. (a) and aiming to improve supervised pre-training with isotropization.

2.2 Further Pre-training PLMs with Dialogue Corpora

Recent works have shown that further pre-training off-the-shelf PLMs using dialogue corpora (Henderson et al., b; Peng et al., 2020, 2021) are beneficial for task-oriented downstream tasks such as intent detection. Specifically, TOD-BERT (Wu et al., 2020) conducts self-supervised learning on diverse task-oriented dialogue corpora. ConvBERT (Mehri et al., 2020) is pre-trained on a 700 million open-domain dialogue corpus. Vulić et al. (2021) propose a two-stage procedure: adaptive conversational fine-tuning followed by task-tailored conversational fine-tuning. In this work, we follow Zhang et al. (a) to further pre-train PLMs using a small amount of labeled utterances from public intent detection benchmarks.

2.3 Anisotropy of PLMs

Isotropy is a key geometric property of the semantic space of PLMs. Recent studies identify the anisotropy problem of PLMs (Cai et al., 2020; Ethayarajh, 2019; Mu and Viswanath, 2018; Rajaee and Pilehvar, 2021c), which is also known as the representation degeneration problem (Gao et al., a): word embeddings occupy a narrow cone, which suppresses the expressiveness of PLMs. To resolve the problem, various methods have been proposed, including spectrum control (Wang et al., 2019), flow-based mapping (Li et al., 2020), whitening transformation (Su et al., 2021; Huang et al., 2021), contrastive learning (Gao et al., b), and cluster-based methods (Rajaee and Pilehvar, 2021a). Despite their effectiveness, these methods are designed for off-the-shelf PLMs. The interaction between isotropization and fine-tuning PLMs remains under-explored. A most recent work by Rajaee and Pilehvar shows that there might be a conflict between the two operations for the semantic textual similarity (STS) task. On the other hand, Zhou et al. (2021) propose to fine-tune PLMs with isotropic batch normalization on some supervised tasks, but it requires a large amount of training data. In this work, we study the interaction between isotropization and supervised pre-training (fine-tuning) PLMs on intent detection tasks.

Dataset	BERT	IntentBERT
BANKING	.96	$.71_{(.04)}$
HINT3	.95	$.72_{(.03)}$
HWU64	.96	$.72_{(.04)}$

Table 1: The impact of fine-tuning on isotropy. Fine-tuning renders the semantic space notably more anisotropic. The mean and standard deviation of 5 runs with different random seeds are reported.

3 Pilot Study

Before introducing our approach, we present pilot experiments to gain some insights into the interaction between isotropization and fine-tuning PLMs.

3.1 Measuring isotropy

Following Mu and Viswanath (2018); Biś et al. (2021), we adopt the following measurement of isotropy:

$$\mathrm{I}(\mathbf{V}) = \frac{\min_{\mathbf{c}\,\in\,C} \mathrm{Z}(\mathbf{c},\mathbf{V})}{\max_{\mathbf{c}\,\in\,C} \mathrm{Z}(\mathbf{c},\mathbf{V})}, \tag{1}$$

where $\mathbf{V} \in \mathbb{R}^{N\times d}$ is the matrix of stacked embeddings of N utterances (note that the embeddings have zero mean), C is the set of unit eigenvectors of $\mathbf{V}^\top\mathbf{V}$, and $\mathrm{Z}(\mathbf{c},\mathbf{V})$ is the partition function (Arora et al., b) defined as:

$$\mathrm{Z}(\mathbf{c},\mathbf{V}) = \sum_{i=1}^{N} \exp\left(\mathbf{c}^\top\mathbf{v}_i\right), \tag{2}$$

where $\mathbf{v}_i$ is the i_{th} row of $\mathbf{V}$. $\mathrm{I}(\mathbf{V}) \in [0,1]$, and 1 indicates perfect isotropy.

3.2 Fine-tuning Leads to Anisotropy

To observe the impact of fine-tuning on isotropy, we follow IntentBERT (Zhang et al., a) to fine-tune BERT (Devlin et al., 2019) with standard supervised training on a small set of an intent detection benchmark OOS (Larson et al., 2019) (details are given in Section 4.1). We then compare the isotropy of the original embedding space (BERT) and the embedding space after fine-tuning (IntentBERT) on target datasets. As shown in Table 1, after fine-tuning, the isotropy of the embedding space is notably decreased on all datasets. Hence, it can be seen that *fine-tuning may render the feature space more anisotropic*.

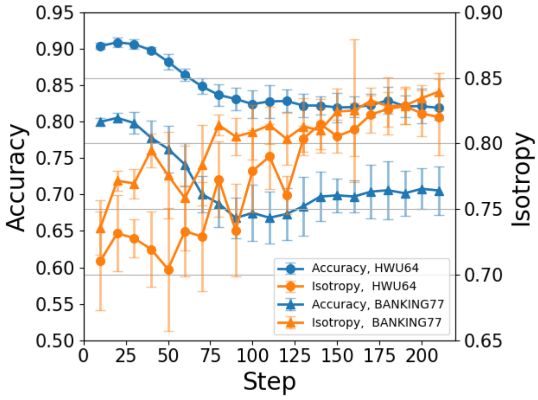

Figure 2: The impact of contrastive learning on IntentBERT with experiments on HWU64 and BANKING77 datasets. The performance (blue) drops while the isotropy (orange) increases.

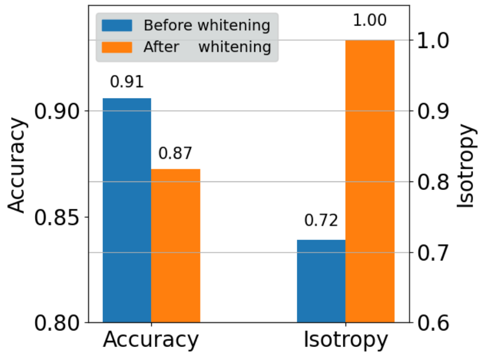
3.3 Isotropization after Fine-tuning May Have an Adverse Effect

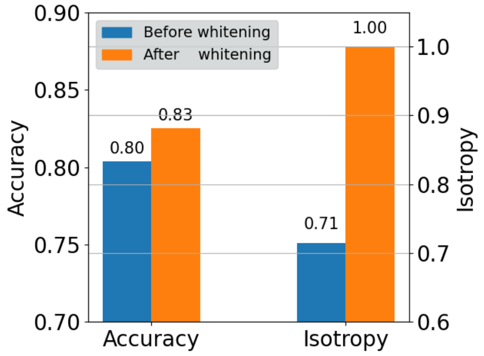
To examine the effect of isotropization on a fine-tuned model, we apply two strong isotropization techniques to IntentBERT: dropout-based contrastive learning (Gao et al., b) and whitening transformation (Su et al., 2021). The former fine-tunes PLMs in a contrastive learning manner[1], while the latter transforms the semantic feature space into an isotropic space via matrix transformation. These methods have been demonstrated highly effective (Gao et al., b; Su et al., 2021) when applied to off-the-shelf PLMs, but things are different when they are applied to fine-tuned models. As shown in Fig. 2, contrastive learning improves isotropy, but it significantly lowers the performance on two benchmarks. As for whitening transformation, it has inconsistent effects on the two datasets, as shown in Fig. 3. It hurts the performance on HWU64 (Fig. 3a) but yields better results on BANKING77 (Fig. 3b), while producing nearly perfect isotropy on both. The above observations indicate that *isotropization may hurt fine-tuned models*, which echoes the recent finding of Rajaee and Pilehvar.

4 Method

The pilot experiments reveal the anisotropy of a PLM fine-tuned on intent detection tasks and the challenge of applying isotropization techiniques on the fine-tuned model. In this section, we propose a joint fine-tuning and isotropization framework. Specifically, we propose two regularizers to make the feature space more isotropic during fine-tuning. Before presenting our method, we first introduce supervised pre-training.



(a) HWU64.



(b) BANKING77.

Figure 3: The impact of whitening on IntentBERT with experiments on HWU64 and BANKING77 datasets. Whitening transformation leads to perfect isotropy but has inconsistent effects on the performance.

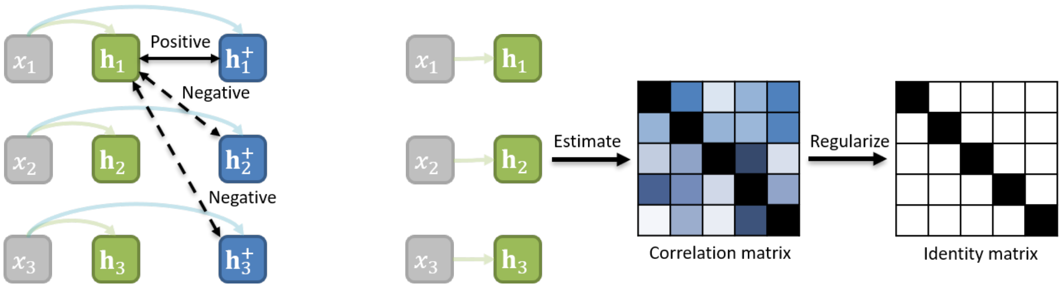
4.1 Supervised Pre-training for Few-shot Intent Detection

Few-shot intent detection targets to train a good intent classifier with only a few labeled data $\mathcal{D}_{\text{target}} = \{(x_i, y_i)\}_{N_t}$, where N_t is the number of labeled samples in the target dataset, x_i denotes the i_{th} utterance, and y_i is the label.

To tackle the problem, Zhang et al. (a) propose to learn intent detection skills (fine-tune a PLM) on a small subset of public intent detection benchmarks by supervised pre-training. Denote by $\mathcal{D}_{\text{source}} = \{(x_i, y_i)\}_{N_s}$ the source data used for pre-training, where N_s is the number of examples. The fine-tuned PLM can be directly used on the target dataset. It has been shown that this method

---

[1] We refer the reader to the original paper for details.



(a) CL-Reg.

(b) Cor-Reg.

Figure 4: Illustration of CL-Reg (contrastive-learning-based regularizer) and Cor-Reg (correlation-matrix-based regularizer). x_i is the i_{th} utterance in a batch of size 3. In (a), x_i is fed to the PLM twice with built-in dropout to produce two different representations of x_i: $\mathbf{h}_i$ and $\mathbf{h}_i^+$. Positive and negative pairs are then constructed for each x_i. For example, $\mathbf{h}_1$ and $\mathbf{h}_1^+$ form a positive pair for x_1, while $\mathbf{h}_1$ and $\mathbf{h}_2^+$, and $\mathbf{h}_1$ and $\mathbf{h}_3^+$, form negative pairs for x_1. In (b), the correlation matrix is estimated from $\mathbf{h}_i$, feature vectors generated by the PLM, and is regularized towards the identity matrix.

can work well when the label spaces of $\mathcal{D}_{\text{source}}$ and $\mathcal{D}_{\text{target}}$ are disjoint.

Specifically, the pre-training is conducted by attaching a linear layer (as the classifier) on top of the utterance representation generated by the PLM:

$$\mathrm{p}(y|\mathbf{h}_i) = \operatorname{softmax}\left(\mathbf{W}\mathbf{h}_i + \mathbf{b}\right) \in \mathbb{R}^L, \quad (3)$$

where $\mathbf{h}_i \in \mathbb{R}^d$ is the representation of the i_{th} utterance in $\mathcal{D}_{\text{source}}$, $\mathbf{W} \in \mathbb{R}^{L\times d}$ and $\mathbf{b} \in \mathbb{R}^L$ are the parameters of the linear layer, and L is the number of classes. The model parameters $\theta = \{\phi, \mathbf{W}, \mathbf{b}\}$, with ϕ being the parameters of the PLM, are trained on $\mathcal{D}_{\text{source}}$ with a cross-entropy loss:

$$\theta = \arg\min_{\theta} \mathcal{L}_{\text{ce}}\left(\mathcal{D}_{\text{source}}; \theta\right). \quad (4)$$

After supervised pre-training, the linear layer is removed, and the PLM can be immediately used as a feature extractor for few-shot intent classification on target data. As shown in Zhang et al. (a), a parametric classifier such as logistic regression can be trained with only a few labeled samples to achieve good performance.

However, our analysis in Section 3.2 shows the limitation of supervised pre-training, which yields a anisotropic feature space.

4.2 Regularizing Supervised Pre-training with Isotropization

To mitigate the anisotropy of the PLM fine-tuned by supervised pre-training, we propose a joint training objective by adding a regularization term $\mathcal{L}_{\text{reg}}$ for isotropization:

$$\mathcal{L} = \mathcal{L}_{\text{ce}}(\mathcal{D}_{\text{source}}; \theta) + \lambda\mathcal{L}_{\text{reg}}(\mathcal{D}_{\text{source}}; \theta), \quad (5)$$

where λ is a weight parameter. The aim is to learn intent detection skills while maintaining an appropriate degree of isotropy. We devise two different regularizers introduced as follows.

Contrastive-learning-based Regularizer. Inspired by the recent success of contrastive learning in mitigating anisotropy (Yan et al., 2021; Gao et al., b), we employ the dropout-based contrastive learning loss used in Gao et al. (b) as the regularizer:

$$\mathcal{L}_{\text{reg}} = -\frac{1}{N_b}\sum_{i}^{N_b}\log\frac{e^{\operatorname{sim}(\mathbf{h}_i,\mathbf{h}_i^+)/\tau}}{\sum_{j=1}^{N_b} e^{\operatorname{sim}(\mathbf{h}_i,\mathbf{h}_j^+)/\tau}}. \quad (6)$$

In particular, $\mathbf{h}_i \in \mathbb{R}^d$ and $\mathbf{h}_i^+ \in \mathbb{R}^d$ are two different representations of utterance x_i generated by the PLM with built-in standard dropout (Srivastava et al., 2014), i.e., x_i is passed to the PLM twice with different dropout masks to produce $\mathbf{h}_i$ and $\mathbf{h}_i^+$. $\operatorname{sim}(\mathbf{h}_1, \mathbf{h}_2)$ denotes the cosine similarity between $\mathbf{h}_1$ and $\mathbf{h}_2$. τ is the temperature parameter. N_b is the batch size. Since $\mathbf{h}_i$ and $\mathbf{h}_i^+$ represent the same utterance, they form a positive pair. Similarly, $\mathbf{h}_i$ and $\mathbf{h}_j^+$ form a negative pair, since they represent different utterances. An example is given in Fig. 4a. By minimizing the contrastive loss, positive pairs are pulled together while negative pairs are pushed away, which in theory enforces an isotropic feature space (Gao et al., b). In Gao et al. (b), the contrastive loss is used as the single objective to fine-tune off-the-shelf PLMs in an unsupervised manner, while in this work we use it jointly with supervised pre-training to fine-tune PLMs for few-shot learning.

Correlation-matrix-based Regularizer. The above regularizer enforces isotropization implicitly.

Here, we propose a new regularizer that explicitly enforces isotropization. The perfect isotropy is characterized by zero covariance and uniform variance (Su et al., 2021; Zhou et al., 2021), i.e., a covariance matrix with uniform diagonal elements and zero non-diagonal elements. Isotropization can be achieved by endowing the feature space with such statistical property. However, as will be shown in Section 5.3, it is difficult to determine the appropriate scale of variance. Therefore, we base the regularizer on *correlation matrix* :

$$\mathcal{L}_{\text{reg}} = \|\mathbf{\Sigma} - \mathbf{I}\|, \tag{7}$$

where $\|\cdot\|$ denotes Frobenius norm, $\mathbf{I} \in \mathbb{R}^{d \times d}$ is the identity matrix, $\mathbf{\Sigma} \in \mathbb{R}^{d \times d}$ is the correlation matrix with $\mathbf{\Sigma}_{ij}$ being the Pearson correlation coefficient between the i_{th} dimension and the j_{th} dimension. As shown in Fig. 4b, $\mathbf{\Sigma}$ is estimated with utterances in the current batch. By pushing the correlation matrix towards the identity matrix during training, we can learn a more isotropic feature space.

Moreover, the proposed two regularizers can be used together as follows:

$$\begin{aligned} \mathcal{L} = \mathcal{L}_{\text{ce}}(\mathcal{D}_{\text{source}}; \theta) + \lambda_1 \mathcal{L}_{\text{cl}}(\mathcal{D}_{\text{source}}; \theta) \\ + \lambda_2 \mathcal{L}_{\text{cor}}(\mathcal{D}_{\text{source}}; \theta), \end{aligned} \tag{8}$$

where λ_1 and λ_2 are the weight parameters, and $\mathcal{L}_{\text{cl}}$ and $\mathcal{L}_{\text{cor}}$ denote CL-Reg and Cor-Reg, respectively. Our experiments show that better performance is often observed when they are used together.

5 Experiments

To validate the effectiveness of the approach, we conduct extensive experiments.

5.1 Experimental Setup

Datasets. To perform supervised pre-training, we follow Zhang et al. to use the OOS dataset (Larson et al., 2019) which contains diverse semantics of 10 domains. Also following Zhang et al., we exclude the domains “Banking” and “Credit Cards” since they are similar in semantics to one of the test dataset BANKING77. We then use 6 domains for training and 2 for validation, as shown in Table 2. For evaluation, we employ three datasets: **BANKING77** (Casanueva et al., 2020) is an intent detection dataset for banking service. **HINT3** (Arora et al., a) covers 3 domains, “Mattress Products Retail”, “Fitness Supplements Retail”, and “Online Gaming”. **HWU64** (Liu et al., 2019a) is a large-scale dataset containing 21 domains. Dataset statistics are summarized in Table 3.

Training	Validation
“Utility”, “Auto commute”, “Work”, “Home”, “Meta”, “Small talk”	“Travel”, “Kitchen dining”

Table 2: Split of domains in OOS.

Dataset	#domain	#intent	#data
OOS	10	150	22500
BANKING77	1	77	13083
HINT3	3	51	2011
HWU64	21	64	10030

Table 3: Dataset statistics.

Our Method. Our method can be applied to fine-tune any PLM. We conduct experiments on two popular PLMs, BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019b). For both of them, the embedding of $[CLS]$ is used as the utterance representation in Eq. 3. We employ logistic regression as the classifier. We select the hyperparameters $\lambda, \lambda_1, \lambda_2$, and τ by validation. The best hyperparameters are provided in Table 4.

Method	Hyperparameter
CL-Reg	$\lambda = 1.7, \tau = 0.05$
Cor-Reg	$\lambda = 0.04$
CL-Reg + Cor-Reg	$\lambda_1 = 1.7, \lambda_2 = 0.04, \tau = 0.05$

(a) BERT-based.

Method	Hyperparameter
CL-Reg	$\lambda = 2.9, \tau = 0.05$
Cor-Reg	$\lambda = 0.06$
CL-Reg + Cor-Reg	$\lambda_1 = 2.9, \lambda_2 = 0.13, \tau = 0.05$

(b) RoBERTa-based.

Table 4: Hyperparameters selected via validation.

Baselines. We compare our method to the following baselines. First, for BERT-based methods, **BERT-Freeze** freezes BERT; **CONVBERT** (Mehri et al., 2020), **TOD-BERT** (Wu et al., 2020), and **DNNC-BERT** (Zhang et al., c) further pre-train BERT on conversational corpus or natural language inference tasks. **USE-ConveRT** (Henderson et al., a; Casanueva et al., 2020) is a transformer-based dual-encoder pre-trained on conversational corpus. **CPFT-BERT** is the re-implemented version of CPFT (Zhang

Table 6: 5-way few-shot intent detection using RoBERTa. We report the mean and standard deviation of our methods and IntentBERT variants. CL-Reg, Cor-Reg, and CL-Reg + CorReg denote supervised pre-training regularized by the corresponding regularizer. The top 3 results are highlighted.

et al., b), by further pre-training BERT in an unsupervised manner with mask-based contrastive learning and masked language modeling on the same training data as ours. **IntentBERT** (Zhang et al., a) further pre-trains BERT via supervised pre-training described in Section 4.1. To guarantee a fair comparison, we provide **IntentBERT-ReImp**, the re-implemented version of IntentBERT, which uses the same random seed, training data, and validation data as our methods. Second, for RoBERTa-based baselines, **RoBERTa-Freeze** freezes the model. **WikiHowRoBERTa** (Zhang et al., d) further pre-trains RoBERTa on synthesized intent detection data. **DNNC-RoBERTa** and **CPFT-RoBERTa** are similar to DNNC-BERT and CPFT-BERT except the PLM. **IntentRoBERTa** is the re-implemented version of IntentBERT based on RoBERTa, with uses the same random seed, training data, and validation data as our method. Finally, to show the superiority of the joint fine-tuning and isotropization, we compare our method against whitening transformation (Su et al., 2021). **BERT-White** and **RoBERTa-White** apply the transformation to BERT and RoBERTa, respectively. **IntentBERT-White** and **IntentRoBERTa-White** apply the transformation to IntentBERT-ReImp and IntentRoBERTa, respectively.

All baselines use logistic regression as classifier except DNNC-BERT and DNNC-RoBERTa, wherein we follow the original work[2] to train a pairwise encoder for nearest neighbor classification.

Training Details. We use PyTorch library and Python to build our model. We employ Hugging Face implementation[3] of *bert-base-uncased* and *roberta-base*. We use Adam (Kingma and Ba,

---

[2] https://github.com/salesforce/DNNC-few-shot-intent

[3] https://github.com/huggingface/transformers

2015) as the optimizer with learning rate of $2e-05$ and weight decay of $1e-03$. The model is trained with Nvidia RTX 3090 GPUs. The training is early stopped if no improvement in validation accuracy is observed for 100 steps. The same set of random seeds, $\{1, 2, 3, 4, 5\}$, is used for IntentBERT-ReImp, IntentRoBERTa, and our method.

Evaluation. The baselines and our method are evaluated on C-way K-shot tasks. For each task, we randomly sample C classes and K examples per class. The $C \times K$ labeled examples are used to train the logistic regression classifier. Note that we do not further fine-tune the PLM using the labeled data of the task. We then sample another 5 examples per class as queries. Fig. 1 gives an example with $C = 2$ and $K = 1$. We report the averaged accuracy of 500 tasks randomly sampled from $\mathcal{D}_{\text{target}}$.

5.2 Main Results

The main results are provided in Table 5 (BERT-based) and Table 6 (RoBERTa-based). The following observations can be made. First, our proposed regularized supervised pre-training, with either CL-Reg or Cor-Reg, consistently outperforms all the baselines by a notable margin in most cases, indicating the effectiveness of our method. Our method also outperforms whitening transformation, demonstrating the superiority of the proposed joint fine-tuning and isotropization framework. Second, Cor-Reg slightly outperforms CL-Reg in most cases, showing the advantage of enforcing isotropy explicitly with the correlation matrix. Finally, CL-Reg and Cor-Reg show a complementary effect in many cases, especially on BANKING77. The above observations are consistent for both BERT and RoBERTa. It can be also seen that higher performance is often attained with RoBERTa.

IntentBERT-ReImp	.71(.04)	.72(.03)	.72(.03)
SPT+CL-Reg	.77(.01)	.78(.01)	.75(.03)
SPT+Cor-Reg	.79(.01)	.76(.06)	.80(.03)
SPT+CL-Reg+Cor-Reg	.79(.01)	.76(.05)	.80(.02)

Table 7: Impact of the proposed regularizers on isotropy. The results are obtained with BERT. SPT denotes supervised pre-training.

The observed improvement in performance comes with an improvement in isotropy. We report the change in isotropy by the proposed regularizers in Table 7. It can be seen that both regularizers and their combination make the feature space more isotropic compared to IntentBERT-ReImp that only uses supervised pre-training. In addition, in general, Cor-Reg can achieve better isotropy than CL-Reg.

5.3 Ablation Study and Analysis

Moderate isotropy is helpful. To investigate the relation between the isotropy of the feature space and the performance of few-shot intent detection, we tune the weight parameter λ of Cor-Reg to increase the isotropy and examine the performance. As shown in Fig. 5, a common pattern is observed: the best performance is achieved when the isotropy is moderate. This observation indicates that it is important to find an appropriate trade-off between learning intent detection skills and learning an isotropic feature space. In our method, we select the appropriate λ by validation.

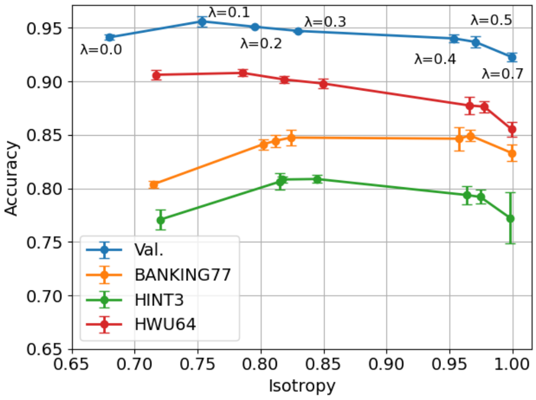

Figure 5: Relation between performance and isotropy. The results are obtained with BERT on 5-way 2-shot tasks.

Correlation matrix is better than covariance matrix as regularizer. In the design of Cor-Reg (Section 4.2), we use the correlation matrix, rather than the covariance matrix, to characterize isotropy, although the latter contains more information – variance. The reason is that it is difficult to determine the proper scale of the variances. Here, we conduct experiments using the covariance matrix, by pushing the non-diagonal elements (covariances) towards 0 and the diagonal elements (variances) towards 1, 0.5, or the mean value, which are denoted by Cov-Reg-1, Cov-Reg-0.5, and Cov-Reg-mean respectively in Table 8. It can be seen that all the variants perform worse than Cor-Reg.

Our method is complementary with batch normalization. Batch normalization (Ioffe and Szegedy, 2015) can potentially mitigate the

Table 9: Effect of combining batch normalization and our method. The experiments are conducted with BERT and evaluated on 5-way 2-shot tasks. SPT denotes supervised pre-training. BN denotes batch normalization.

The performance gain is not from the reduction in model variance. Regularization techniques such as L1 regularization (Tibshirani, 1996) and L2 regularization (Hoerl and Kennard, 1970) are often used to improve model performance by reducing model variance. Here, we show that the performance gain of our method is ascribed to the improved isotropy (Table 7) rather than the reduction in model variance. To this end, we compare our method against L2 regularization with a wide range of weights, and it is observed that reducing model variance cannot achieve comparable performance to our method, as shown in Fig. 6.

The computational overhead is small. To analyze the computational overheads incurred by CL-Reg and Cor-Reg, we decompose the duration of one epoch of our method using the two regularizers jointly. As shown in Fig. 7, the overheads of CL-Reg and Cor-Reg are small, only taking up a small portion of the time.

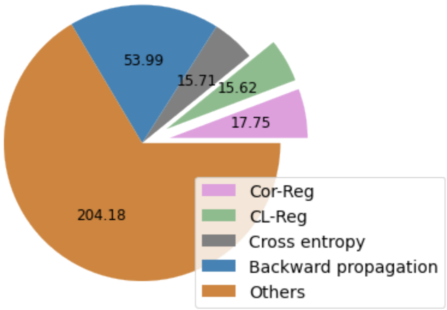

Figure 7: Run time decomposition of a single epoch. The unit is second.

6 Conclusion

In this work, we have identified and analyzed the anisotropy of the feature space of a PLM fine-tuned on intent detection tasks. Further, we have proposed a joint training framework and designed two regularizers based on contrastive learning and correlation matrix respectively to increase the insotropy of the feature space during fine-tuning, which leads to notably improved performance on few-shot intent detection. Our findings and solutions may have broader implications for solving other natural language understanding tasks with PLM-based models.

Exploring the Value of Multi-View Learning for Session-Aware Query Representation

Abstract

Recent years have witnessed a growing interest towards learning distributed query representations that are able to capture search intent semantics. Most existing approaches learn query embeddings using relevance supervision making them suited only to document ranking tasks. Besides, they generally consider either user's query reformulations or system's rankings whereas previous findings show that user's query behavior and knowledge change depending on the system's results, intertwine and affect each other during the completion of a search task. In this paper, we explore the value of multi-view learning for generic and unsupervised session-aware query representation learning. First, single-view query embeddings are obtained in separate spaces from query reformulations and document ranking representations using transformers. Then, we investigate the use of linear (CCA) and non linear (UMAP) multi-view learning methods, to align those spaces with the aim of revealing similarity traits in the multi-view shared space. Experimental evaluation is carried out in a query classification and session-based retrieval downstream tasks using respectively the KDD and TREC session datasets. The results show that multi-view learning is an effective and controllable approach for unsupervised learning of generic query representations and can reflect search behavior patterns.

1 Introduction

Understanding user's search intent is central in information retrieval (IR). Modeling user's intent inevitably requires to capture search context. Search history is arguably the most salient facet of context that has been widely captured and used in previous work (Teevan et al., 2005; Dehghani et al., 2017; Aloteibi and Clark, 2020; Zhou et al., 2020). It mainly includes the following: (1) the previous user's queries, generally recorded into physical sessions (also called time-based sessions (Lucchese et al., 2011)) or task-based sessions (also called missions (Hagen et al., 2013)); (2) the retrieved documents that the user subsequently selects (e.g., based on clicks), among those retrieved by the IR system in response to her queries. Mining user's search intent from search history is challenging because of phenomena such as vocabulary mismatch between the query and documents, ambiguity issues since two queries even with slight lexical variations may underline different intents (Steiner, 2019; Sanderson, 2008), and topic change in user's search behavior which is particularly prominent while completing complex search tasks (e.g., exploratory and multi-step tasks (Hassan Awadallah et al., 2014; He and Yilmaz, 2017). To address these challenges, recent years have witnessed a growing interest in learning query representations to capture hidden syntactic and semantic relationships (Zamani and Croft, 2016; Grbovic et al., 2016; Bing et al., 2018; Zhang et al., 2019; Zhou et al., 2020). However, learning context-aware query embeddings faces two main issues: (1) user's query formulations included in the search sessions bring word contexts that do not extensively occur at the training phase in web search data (Keller and Lapata, 2003); (2) queries do not exhibit a clear structure as sentences. In most of previous work, query embeddings are learned based on search session contexts modeled from relevant or pseudo-relevant documents returned by the system (Zamani and Croft, 2016, 2017; Zhang et al., 2019). These methods are suited to supervised relevance ranking tasks with sufficient training data. Other methods learn distributed query representations based on user's query reformulations in the search session (Grbovic et al., 2016; Sen et al., 2018; Zhou et al., 2020). These methods are rather unsupervised and applicable to a wide range of downstream language processing tasks making them *generic*.

In this work, we explore the unsupervised problem of learning generic distributed query representa-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 304 - 315
July 10-15, 2022

tions, able to support a wide range of downstream search tasks. As outlined recently, unsupervised representation learning for IR has not received much attention yet (Lin, 2021). This paper attempts to fill this gap by following a query oriented fashion. Specifically, we argue that by considering only one facet of the search session (i.e., documents vs. query reformulations) as done in Sen et al. (2018); Grbovic et al. (2016); Zamani and Croft (2016); Zhang et al. (2019); Zhou et al. (2020), or by considering them both but without relating the semantics underlying between the user's search intent and the system's document results (Bing et al., 2018), we lose valuable mutual information about the *interactive intentions* (Xie, 2002) that could act as a soft supervision during the search task. Based on previous findings (Eickhoff et al., 2014; Liu et al., 2019a) showing how user's query behavior and knowledge change from system's results during the search session, we propose a framework for Session-aware Query rEpresentation learning based on multi-View Learning (SaQuEViL).

SaQuEViL is a two-step architecture that consists of two single-view query encoders, namely user-view and system-view query encoders, and a multi-view query encoder. Each single-view query encoder is based on a bidirectional transformer (Vaswani et al., 2017) at the session level. By investigating the use of unsupervised multi-view based learning algorithms, namely Cross-modal Factor Analysis (CFA) and Uniform Manifold Approximation and Projection (UMAP), the multi-view encoder takes as input the two single-view query embeddings related to the same query and provides a multi-view query representation. The underlying objective functions aim to maximize the alignment of features between both views which leans to reveal the underlying manifold. In the multi-view embedding space, similar queries formulated in the context of similar tasks have spatially close representations.

Our key contributions are: 1) we model generic session-aware query representation as an unsupervised multi-view learning task using a two-step framework architecture, SaQuEViL; 2) we experimentally show the effectiveness of multi-view based representations in query classification and session-retrieval as downstream tasks; 3) we conduct quantitative and qualitative analyses showing the potential of SaQuEViL in understanding user's search behavior.

2 Related Work

2.1 Distributed query representation

A common problem in IR is that queries –the pivotal parts of a retrieval process– are under-specified which is prone to the vocabulary mismatch and thereby, the poor performance of search-related tasks. Recently, much attention has been paid to learning distributed query representations. Previous work following this approach can be organized based on the facet of query context and type of supervision used to learn the distributed representations. In the first line of work, both query context and supervision include user's relevance signals on documents (Zamani and Croft, 2016, 2017; Zhang et al., 2019). The underlying assumption is that the more queries share the same relevant or pseudo-relevant documents among those selected by the retrieval system, the more they have semantically close intent leading to similar embeddings in the latent representation space. Using a probabilistic framework, Zamani and Croft (2016) propose to learn relevance-based query representations based on the embeddings of the query words. Then, the closeness between the probability distribution of the query representation, based on similarity metrics of word embeddings, and the query language model is maximised. Zhang et al. (2019) propose the GEN Encoder which learns distributed representations of queries in two stages. The first stage captures user's intent based on document clicks by using the assumption that queries with similar clicks underline similar intent. The second stage denoises the representations and enhances their generalizability by leveraging human paraphrase labeling in a multi-task learning setting. The second line of work relies on query context held by the search history through query reformulations recorded into physical sessions (Grbovic et al., 2016) or task-based sessions (Mehrotra and Yilmaz, 2017; Sen et al., 2018). Query embeddings are learned based on the assumption that lexically similar queries formulated in similar search sessions across users are semantically related leading to close representations in the embedding space. Mehrotra and Yilmaz (2017) propose task-aware query embeddings by applying the skip-gram model on sequences of queries belonging to the same task-based session. These query representations learned in an unsupervised manner are expected to be generic, thought their evaluation has been limited to specific downstream tasks such as query expansion in sponsored search (Grbovic et al., 2016) and search task extraction (Sen et al., 2018). A recent line of work uses context built up on query reformulation in a session and documents (Bing et al., 2018; Zhou et al., 2020). For instance, Bing et al. (2018) model a unified graph information where vertices consist of queries in the session, clicked documents and corresponding websites; and edges reflect undifferentiated semantic relationships. The authors propose a supervised model based on an objective function that aims at optimizing, over session data, the log-likelihood of reaching a leaf (i.e., query, URL) in the corresponding Huffman tree.

In contrast to most all the aforementioned works that model query representation as supervised text representation learning based on the core idea of "query sentence", we model query representation as multi-view learning of manifold underlying queries and document results based on the core idea of *interactive intentions* (Xie, 2002) that provide soft supervision during the search session.

2.2 Session-aware query reformulation

Session-aware query reformulation is involved in retrieval-based interactive systems, including dynamic IR systems (Yang et al., 2016), multi-turn Question Answering (QA) (Mensio et al., 2018), and dialogue systems (Cui et al., 2019). Several works studied the connections between search sessions, intentions in query reformulation, and search behavior (Lu et al., 2017; Liu et al., 2019b; Tamine et al., 2020). Among the major findings, we particularly mention the following: (1) query reformulation patterns can be observed in search sessions providing insights on the search process characteristics such as underlying search task stage (Tamine et al., 2020; Eickhoff et al., 2014) and success (Odijk et al., 2015); (2) during the session search, system's results often lead to a change in both user's knowledge and the complexity of subsequent queries (Eickhoff et al., 2014; Liu et al., 2019a); (3) user search process runs into sequential phases, specialization, and intent shift. As user's search intents are gradually satisfied based on system's results, their subsequent queries lean to topically shift (Chen et al., 2021).

The main findings that have been drawn from the literature review strengthen our motivation toward learning single-view query embeddings that capture hidden session-related patterns from the two perspectives of user's sequence of query reformulations in the one hand and system's results in the other hand, and then identify mutual information that can reveal similarities across users' search intents.

3 Background

3.1 Multi-view representation learning

Multi-view representation learning (Li et al., 2019) aims to recover a meaningful latent representation of a target object using data provided by one or multiple sources. The *views* correspond to measurement modalities from such different sources, such as text and images of the same scene (Hwang and Grauman, 2012) but may also be multiple information from the same source such as document text and hyperlinks (Bickel and Scheffer, 2004). Potential applications of multi-view learning include cross-modal retrieval (Hwang and Grauman, 2012; Li et al., 2003) and machine translation (Faruqui and Dyer, 2014). SOTA methods for multi-view feature learning are the Canonical Correlation Analysis (CCA) (Dhillon et al., 2011) and Cross-modal Factor Analysis (CFA) (Li et al., 2003) whose primary goal is to maximize the correlations of features among multiple different views. These methods generally admit global solutions and ignore the non-linearities of multi-view data (Viinikanoja et al., 2010). Unlikely, k-neighbor based manifold learning methods such as Laplacian Eigenmaps (Belkin and Niyogi, 2003), IsoMap (Tenenbaum et al., 2000), and Uniform Manifold Approximation and Projection (UMAP) (McInnes et al., 2018) recover non-linear dependencies between views. The core of these methods relies upon optimization over a graphical representation of different data sets that are characterized by the same underlying manifold where edges in the graph are computed to preserve the topological structure of this manifold. This optimization yields a shared low-dimensional space where the latent representations of semantically similar data are spatially close to one another. Recently, several proposed methods for multi-view representation learning are based on deep neural networks. For instance, Deep CCA aims to learn complex nonlinear transformations of two views in a shared space (Andrew et al., 2013).

3.2 Definitions and notations

We introduce here some key definitions. Note that we refer the term of *embedding* to either the user-view query vector or system-view query vector and refer the term of *representation* as the final multi-view query vector.

Definition 1. *Search session.* In the literature review, there are two main definitions of search sessions: (1) a *physical session* (Hagen et al., 2013) is a set of consecutive queries automatically delimited using a time-out threshold on user's activities; (2) a *task-based session* which targets an atomic information need through a set of queries that are possibly neither consecutive nor within the same time-based session. SaQuEViL can be readily applied to both definitions of search sessions.

Formally, let $\mathcal{S}$ be the set of users' search sessions. A user's search session $S \subset \mathcal{S}$ consists of: (1) all on-session user's queries $q_{1,S}, q_{2,S}, \ldots, q_{k,S}$ ordered by time where each query $q_{m,S}$, consists of K_m words $q_{m,S} = \{w_{m1}, w_{m2} \ldots, w_{mK_m}\}$; (2) the sets of N top documents returned by the retrieval system as an answer to each query $q_{m,S}$, denoted as $\mathcal{D}^N_{m,S}$.

Definition 2. *User-view query embedding.* Each on-session query $q_{m,S}$ is embedded as a d_1-dimensional user-view query embedding, denoted as $\mathbf{q}^u_{m,S} \in \mathbb{R}^{d_1}$, that captures the user's formulation of his search intent. $\mathbf{q}^u_{m,S}$ is encoded based on its formulation $\{w_{m1}, w_{m2} \ldots, w_{mK_m}\}$ as well as all the formulations of the previous queries in the session $\{q_{m-1,S}, q_{m-2,S} \ldots, q_{1,S}\}$.

Definition 3. *System-view query embedding.* Each on-session query $q_{m,S}$ is embedded as a d_2-dimensional system-view query embedding, denoted as $\mathbf{q}^s_{m,S} \in \mathbb{R}^{d_2}$, that captures the system's understanding of the user's search intent. $\mathbf{q}^s_{m,S}$ is encoded based on document results obtained from the concatenation of the query $q_{m,S}$ along with previous queries in the session.

4 Session-Aware Query Representation By Multi-View Learning

4.1 Problem statement

Let $\mathcal{S} = \{S_1, \ldots, S_K\}$ be a set of sessions such as $S_i = \{q_{1,i}, q_{2,i}, \ldots, q_{ki,i}\}$, including a total of n on-session queries $q_{m,i}$ with $n = (\sum ki)_{i=1}^{i=K}$. The objective of SaQuEViL is twofold: (1) encoding $\Sigma^1 \in \mathbb{R}^{n \times d_1}$ (resp. $\Sigma^2 \in \mathbb{R}^{n \times d_2}$) the vector space embedding and user-view query embeddings $\mathbf{q}^u_{m,i}$ (resp. system-view query embeddings $\mathbf{q}^s_{m,i}$); (2) learn a multi-view latent space $\Sigma^* \in \mathbb{R}^{n \times d}$ (with $d \leq min(d_1, d_2)$) and query representations $\hat{\mathbf{q}}_{m,i} \in \Sigma^*$ by jointly achieving pairwise alignments between the user-view embedding $\mathbf{q}^u_{m,i}$ and system-view embedding $\mathbf{q}^s_{m,i}$ and recovering an optimal alignment of manifolds over all the query representations $\hat{\mathbf{q}}_{m,i}$. Final representations are picked to match the downstream task, either when *document* matching is required or session-aware *query* is required.

The two key assumptions of multi-view learning are satisfied (Blum and Mitchell, 1998; Foster et al., 2008): (1) each of the user-view and system-view are independent conditionally to the sessions; and (2) the two single views provide a redundant estimate of the session.

4.2 Multi-view query representation learning

4.2.1 Framework overview

Figure 1 presents an overview of the SaQuEViL framework. For encoding the single-view query embeddings $\mathbf{q}^u_{m,i}$, $\mathbf{q}^s_{m,i}$, we opted for BERT (Devlin et al., 2019) as transformer embedding and followed the standard CLS encoding strategy (BERT$_{CLS}$). So, $\mathbf{q}^u_{m,i}$ (resp. $\mathbf{q}^s_{m,i}$) is obtained by applying $\Gamma($BERT$_{CLS}([CLS]q_{m,i}))$ (resp. $\otimes_{j=1}^{j=N}$BERT$_{CLS}([CLS]head(d^j_{m,i})))$, where $\otimes$ is a vector concatenation operator, $head(\cdot)$ is a function that returns the title and first tokens of a given document, and Γ is an expansion function such as broadcast used to match the dimensions.

Following, we detail the key principles of multi-view query representation learning $\hat{\mathbf{q}}_{m,i}$ using linear (CFA (Dhillon et al., 2011)) and non-linear (UMAP (McInnes et al., 2018)) methods.

4.2.2 CFA-based representation learning

Given the two mean centered matrices $\mathcal{Q}^u \in \mathbb{R}^{d_1 \times n}$ and $\mathcal{Q}^s \in \mathbb{R}^{d_2 \times n}$, where columns refer respectively to the user-view embeddings $\mathbf{q}^u_{m,i}$ and system-view embedding $\mathbf{q}^s_{m,i}$, CFA learns two linear and orthogonal transformations $A \in \mathbb{R}^{d_1 \times d}$ and $B \in \mathbb{R}^{d_2 \times d}$ such that the distance between $A^\intercal \mathcal{Q}^u$ and $B^\intercal \mathcal{Q}^s$ is minimized. The CFA objective is:

$$A^*, B^* = argmin_{A,B}(\| A^\intercal \mathcal{Q}^u - B^\intercal \mathcal{Q}^s \|_F) \quad (1)$$

where $A^\intercal A = I$ and $B^\intercal B = I$ and $\| \cdot \|_F$ is the Frobenius norm. The solution of Equation (1) is obtained through the Singular Value Decomposition (SVD) of $Z = (\mathcal{Q}^u)^\intercal \mathcal{Q}^s$, such as $Z = S_z V_z D_z$ and $A^* = S_z, B^* = D_z$ (Krzanowski, 1988). Thus, we obtain the multi-view query representations $\mathbf{q}^u$ and $\mathbf{q}^s$ as the rows of the user-view or

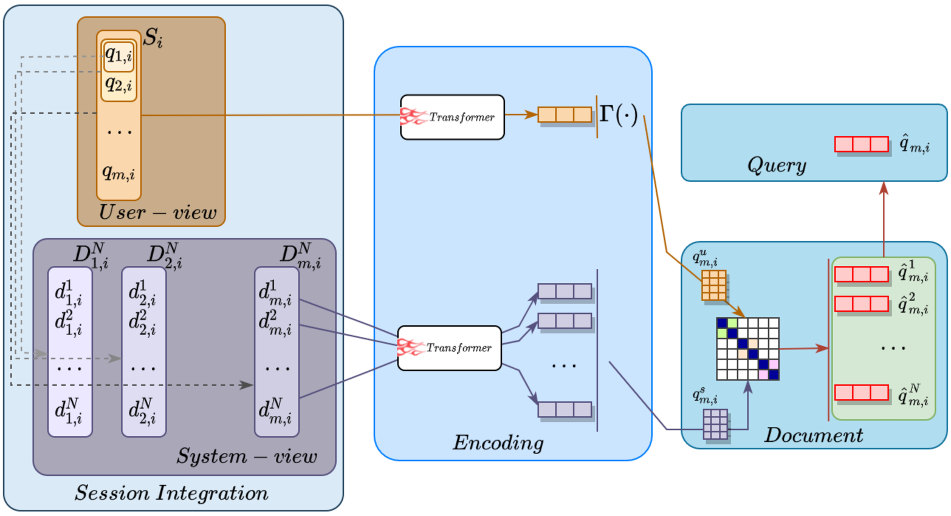

Figure 1: Overview of the SaQuEViL framework.

system-view transformations $\hat{\mathcal{Q}}^u = (\mathcal{Q}^u)^\intercal A^*$ and $\hat{\mathcal{Q}}^s = (\mathcal{Q}^s)^\intercal B^*$ respectively.

4.2.3 UMAP-based representation learning

Let $G(\mathcal{V}, \xi)$ be the graph where the vertices $\mathcal{V}$ correspond to queries $q_m \in \cup(S_i)_{i=1}^K$ and ξ the edges that reflect a weighted neighborhood relationship $\mathbf{q}_m \sim \mathbf{q}_{m'}$ defined in matrix $\mathcal{W}$ such as $\mathcal{W}(m, m') > 0$ if $\mathbf{q}_m, \mathbf{q}_{m'}$ are neighbors. The two key differences between SOTA graph-based manifold learning algorithms (Belkin and Niyogi, 2003; Tenenbaum et al., 2000) lie in the construction of the k-neighbor edges ξ and the choice of the weights $\mathcal{W}(i, j)$. Specifically, in the multi-view setting of the UMAP method, for each query q_m, there are two induced local graphs: (1) the user graph $G^u_m(\mathcal{V}^u, \xi^u_m)$ where $\mathcal{V}^u$ is the set of k-nearest neighbors of $\mathbf{q}^u_m$ denoted as $Fset^u(q_m)$ and ξ_m is the set of outgoing edges directed from q_m to its set k-nearest neighbors q^u_{mj} thereby inducing the similarity relationship $\mathbf{q}^u_m \sim \mathbf{q}^u_{mj}$ defined in matrix $\mathcal{W}^u(n, n)$; (2) the system graph $G^s_m(\mathcal{V}^s, \xi^s_m)$ where $\mathcal{V}^s$ is the set of k-nearest neighbors of $\mathbf{q}^s_m$ denoted as $Fset^s(q_m)$ and ξ^s_m is the set of outgoing edges directed from q_m to its set k-nearest neighbors $\mathbf{q}^s_{mj}$ thereby inducing the similarity relationship $\mathbf{q}^s_m \sim \mathbf{q}^s_{mj}$ defined in matrix $\mathcal{W}^s(n, n)$. Pairwise alignment between the user-view and system-view of query q_m is ensured by building the graph $G(\mathcal{V}, \xi)$ as a graph intersection between user graph $G^u_m(\mathcal{V}^u, \xi^u_m)$ and system graph $G^s_m(\mathcal{V}^s, \xi^s_m)$ for each query $q_m \in \cup(S_i)_{i=1}^K$. This intersection builds the weighting matrix $\mathcal{W}(n, n)$ based on the weighting matrices $\mathcal{W}^u$ and $\mathcal{W}^s$. Spectral optimization of the multi-view query representations is then achieved by functions $\mathbf{f} : \mathcal{V} \mapsto \mathbb{R}$ that recover the optimal alignment of manifolds underlying queries $q_m \in \cup(S_i)_{i=1}^K$ through the minimization of a cost on graph $G(\mathcal{V}, \xi)$, defined as (McInnes et al., 2018):

$$\mathcal{L}(f) = \sum_{S\in\mathcal{S};q_m,q'_m\in S} \frac{1}{2}(f_m - f'_m)^2 \mathcal{W}(m, m') \tag{2}$$

subject to scale and translation constraints $f^T f = 1$ *and* $f^T e = 0$.

The optimization process of UMAP is detailed in Belkin and Niyogi (2003); McInnes et al. (2018).

5 Experimental Setting

We address the following research questions:
RQ1) How does the SaQuEViL framework perform in query classification and session-based retrieval as downstream tasks?
RQ2) To what extent the SaQuEViL embedding space preserves the similarities of each of the single-view embedding spaces?
RQ3) Can we use SaQuEViL framework to understand user's search behavior?

5.1 Downstream tasks

5.1.1 Query classification

The goal of query classification consists in assigning an incoming query the most appropriate topic labels (categories). Labels are pre-defined and search-related data are available to train each label. ***Data.*** As previously done by Zamani and Croft (2016); Zamani et al. (2017) to evaluate query embedding performances, we used the KDD 2005 dataset (Li et al., 2005). The dataset consists of 800 queries recorded from MSN search log. The dataset also includes 43 categories -that act as candidate task-based sessions- labeled by human assessors. Accordingly, we assume that the set of queries belonging to each target category c represents a session S_c. To solely measure the quality of the query representations and ensure comparability across query representations, we opted for the classification strategy proposed in Zamani and Croft (2016); Zamani et al. (2017). We first compute the probability of each category (session) $p(Sc_i/q) = \frac{\delta(\vec{Sc_i},\vec{q})}{\sum_j \delta(\vec{Sc_j},\vec{q})}$ where $\vec{q}$ is a query vector, $\vec{Sc_i}$ is the centroid vector of category (session) Sc_i. $\vec{Sc_i}$ is computed by averaging the query vectors $\vec{q_{ki}}$ of queries q_{ki} belonging to session Sc_i. Then we select the N top sessions with the highest probabilities as the more likely ones to be assigned to query q.

Evaluation metrics. We consider the evaluation metrics used in the KDD challenge (Li et al., 2005), Recall and F1 measures, and carefully followed their description to implement our evaluation script. Statistical tests are performed using two-tailed paired t-test. We depict a significant increase for p < 0.05 as *.

Baselines and scenarios. We reported traditional SOTA pre-trained embeddings as query encoders *GloVe* (Pennington et al., 2014), *Word2vec* (Mikolov et al., 2013) and *BERT* (Devlin et al., 2019), as well as *RPE* (Zamani and Croft, 2016; Zamani et al., 2017), a SOTA relevance-based query representation model. To show the impact of user-view and system-view alignment, we also compared our multi-view CFA-based and UMAP-based query representations $\hat{\mathbf{q}}$ to the representation vector obtained by concatenation of $\mathbf{q}^u$ and $\mathbf{q}^s$ vectors. The latter scenario is denoted *w/o Align*.

Training and inference. We performed a 5-fold cross-validation over the queries and used the document rankings provided by the ClueWeb12[1] corpus to learn the SaQuEViL multi-view query representations. The ClueWeb12 corpus was indexed using the respective default configuration of Anserini[2] while the retrieval was done using the default configuration of Pyserini[3] search. With respect to Figure 1, projected $\hat{\mathbf{q}}$ vectors are averaged in order to obtain a unique vector per query. The number of labels assigned to each query was tuned on the training set from 1 to 5.

5.1.2 Session-based retrieval

The goal of session-based retrieval consists in evaluating document rankings over user sessions rather than isolated queries (Carterette et al., 2016).

Data. We use the TREC 2014 session track (Carterette et al., 2016) which provides the following: (1) 1,257 full sessions among which 1,021 of these have at least one reformulation. On average there are 4.33 queries per session, among which the final query in the session is referred to as the *current query*; (2) the ranked list of documents for each past query; and (3) human annotations about type of search for 54 sessions; the latter are labeled using 4 categories of user search behavior w.r.t. the classification designed by Li and Belkin (2008): *known-item*, *interpretive*, *known-subject*, and *exploratory*.

It is worth noting that we did not use the users' clicks in our experiments since they are considered as weak supervision. The corpus used is the ClueWeb12 collection. The relevance of a document was judged for the results of the current query but judgment is based on the whole session.

Evaluation metrics. We use the TREC session track's official metrics. These are: nDCG@10, ERR@10, nERR@10, and PC@10. All runs are evaluated using the official evaluation script[4].

Baselines and scenarios. We used classical baselines including *Current* and *Aggregated query*. The latter is a concatenation of all the session's queries as suggested in Van Gysel et al. (2016).

Training and inference. In contrary to query classification, projected $\hat{\mathbf{q}}$ vectors are not aggregated as each is used for document ranking. We first compute a neural score by calculating the cosine similarity between the session vector $\sum_{j=1}^{m-1} \hat{\mathbf{q}}_{j,S}$ and the document vector $\hat{\mathbf{q}}_{m,S}^{d^l_{m,S}}$ in the SaQuEViL space. Then we obtain the final score used for document ranking by linearly combining the neural score with the BM25 score as commonly done in neural IR (MacAvaney, 2020).

Table 1: Performance of SaQuEViL query representations and baselines (GloVe (Pennington et al., 2014), Word2vec (Mikolov et al., 2013), BERT (Devlin et al., 2019), and RPE (Zamani and Croft, 2017)) in query classification. The improvements over each baseline of our best scenario, SaQuEViL CFA, are reported in brackets. The highest values are highlighted in bold. Improvement significance w.r.t. BERT is indicated by the superscript '*'.

6 Results and Analysis

6.1 RQ1: Effectiveness evaluation of SaQuEViL in downstream tasks

6.1.1 Query classification

Table 1 presents the performance results in terms of Precision and F1. Note that one strong baseline is obtained by encoding the query with BERT (0.4143) which clearly outperforms a supervised alternative (0.3961), e.g., RPE which is trained on relevance signals (Zamani and Croft, 2017). It can be explained as RPE do not use contextualized embeddings as BERT. We can interestingly see that SaQuEViL, even trained without supervision, outperforms (0.443) both unsupervised (GloVe, Word2vec, and BERT) and supervised encoders (RPE model). This result clearly indicates the value of the alignment to identify relevant mutual information between user's view through query reformulation and system's view through document rankings to enhance the query representation. We can also see that even without alignment, SaQuEViL (0.4274) outperforms BERT (0.4143) indicating that each view information is helpful on this task. Finally, our best scenario corresponds to the SaQuEViL CFA setup that achieves a minimum improvement of 7 % in terms of Precision and F1 w.r.t. reported baselines. This result leads us to consider that linear dependencies are revealed from session-based query reformulations and corresponding documents.

Model	NDCG@10	ERR@10	nERR@10	PC@10
Current	0.1659	0.1639	0.2332	0.3190
Aggregated	0.1834	0.1952	0.2645	0.3460
SaQuEViL				
w/o Align	0.1841	**0.2021**	**0.2749**	0.3340
CFA	**0.1843**	0.1950	0.2646	**0.3473**
UMAP	0.1835	0.1951	0.2644	0.3450

Table 2: Performance of SaQuEViL query representations and baselines (Aggregated (Van Gysel et al., 2016)) in session-based retrieval. Best results are highlighted in bold.

6.1.2 Session-based retrieval

Table 2 presents the performance scores of SaQuEViL scenarios and baselines in the session-based retrieval downstream task. As expected, including session information outperforms (0.1834) the use of the single query (0.1659) in terms of NDCG@10, but also for all the other metrics. Moreover, we can notice that SaQuEViL slightly improves the Aggregated (Van Gysel et al., 2016) results but none scenario shows a clear wining. SaQuEViL w/o Align setup outperforms in terms of ERR@10 (0.2021) and nERR@10 (0.2749) but SaQuEViL CFA obtains the best scores for NDCG@10 (0.1843) and PC@10 (0.3473). Nevertheless, the improvements for the session-based retrieval downstream task are modest[5]. We can also notice that CFA and UMAP methods exhibit the same performance trend.

6.2 RQ2: Analysis of the SaQuEViL multi-View embedding space

Our main objective here is to analyse to what extent the SaQuEViL framework builds a shared embedding space that preserves the structure of the single-view spaces. Grounded with the results obtained above (Section 6.2), we achieve this goal by analyzing the discrepancies between the single-view spaces and the shared space obtained with SaQuEViL using the query representations learned in query classification. For each target query q, we consider the k-neighbors of $\hat{\mathbf{q}}$ in the SaQuEViL shared space as the gold standard and the plurality vote of the k-neighbors in each of the single-view spaces, namely, $\mathbf{q}^u$ and $\mathbf{q}^s$, as the prediction. We used the cosine similarity to find neighbors and then compute Precision, Recall and F-measure metrics under a multi-label setup, where each query

---

[5] Note that stronger results on the TREC session 2014 dataset are reported by Aloteibi and Clark (2020), but we only focused on an extrinsic use of SaQuEViL and integration to task specific models is out of the scope of the paper.

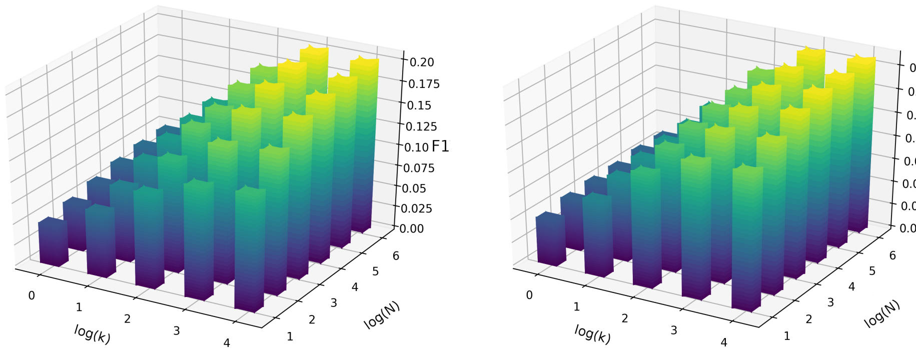

Figure 2: F1 performances when comparing SaQuEViL CFA (left) / UMAP (right) multi-view space and the concatenation of both views embedding. Number of neighbors and ranked documents are in *log* scale. Better in color as brighter color indicates higher values.

Model	**First k queries into the session**				
	1	3	6	9	all
Aggregated	0.373	**0.573**	0.553	0.535	0.535
SaQuEViL					
w/o Align	0.462	0.571	0.607	0.589	0.589
CFA	**0.516**	0.569	**0.625**	**0.625**	**0.625**
UMAP	0.498	0.571	**0.625**	0.589	0.589

Table 3: F1-micro performances of SaQuEViL and baseline (Aggregated (Van Gysel et al., 2016)) encoders in search type classification using TREC session 2014. Highest values of F1-measure are highlighted in bold.

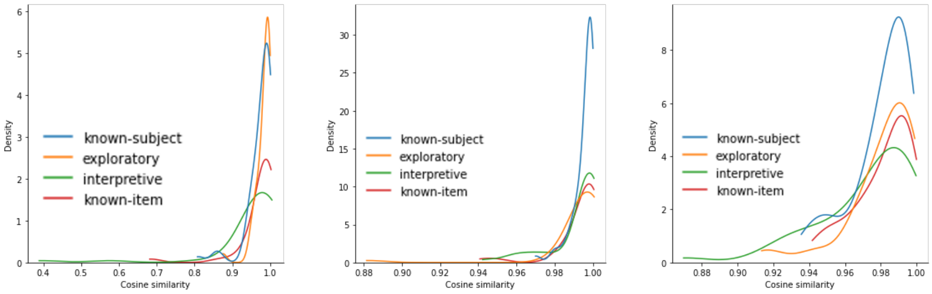
identifier is considered as a target class. In particular, we analyze the impact of two key parameters of the SaQuEViL framework: number of neighbors (k) and number of top documents (N) used to learn the query representations. Results for different values of k (1, 2, 4, 8, and 16) and N (2, 4, 8, 16, 32, and 64) in *log* scale are presented in Figure 2. Three main conclusions can be grasped from Figure 2: (1) increasing the number of neighbors increases the similarity between the spaces until 8-16 neighbors then it stabilizes for both methods (CFA and UMAP) in terms of F1; (2) adding extra documents impacts in the same way, e.g., positive at early increments and then stabilizes, but for the two multi-view learning methods; (3) a higher preservation of original similarities in SaQuEViL spaces correlates with higher performances on the downstream task as SaQuEViL CFA obtains a maximum score close to 0.20 of F1 while UMAP is 0.06 points behind (0.14 of F1)[6]. These results might shed light on possible controllable room of improvements of a wide range of downstream tasks including, but not limited to session-based retrieval.

6.3 RQ3: Search behavior understanding

Our aim here is to understand in what extent the SaQuEViL representation space helps understanding behaviors in user session. To do so, we used the *type of search* annotations provided in the TREC session 2014 dataset (*known-item*, *interpretive*, *known-subject*, and *exploratory*). A standard 5-cross fold setup with k-nearest neighbor classifier is used to draw the intrinsic capabilities of the encoders to distinguish user search behavior types. Average results of F1-micro across the 5 folds are presented in Table 3. To perform the classification at the test stage, we used as context the first k queries of sessions (columns 1, 3, 6 and 9) as well as the full session (column *all*). As can be seen from Table 3, SaQuEViL CFA encoder (0.625) clearly outperforms the proposed alternatives, the BERT encoder for the Aggregated queries (0.535) and the SaQuEViL w/o Align (0.589) when considering the full session. Looking at the impact of context length (k) in the classification, we can note that the Aggregated query representation starts with a low performance (0.373) and, when up to 3 queries are used in the session, it achieves the maximal performance (0.573). However, the SaQuEViL w/o Align encoder starts in a higher performance (0.462) and achieves the maximal performance when up to 6 queries are used from the session (0.607). In both cases, the performance drops when the size of the session increases. This also points an advantage of SaQuEViL CFA encoder as it shows a more stable performance (0.516 to 0.625) regardless the number of used queries.
To further our analysis, we plot in Figure 3 distributions of distances between adjacent query pairs for each session w.r.t. corresponding search type and by using different query encoders: GloVe, SaQuE-

---

[6] Note that this correlation must have an upper limit lower than 1.0 (F1) as exactly similar spaces may lay on similar performances to our strategy w/o align in downstream tasks.



(a) (b) (c)

Figure 3: Distribution of cosine similarities for (a) GloVe, (b) SaQuEViL-w/o Align, and (c) SaQuEViL CFA between adjacent queries per session categorized by search type *known-item*, *interpretive*, *known-subject*, and *exploratory*.

ViL w/o Align, and SaQuEViL CFA[7]. We can see that the distribution of CFA encoder significantly differs from the other encoders. Interestingly, we note that CFA better separates the four search types and gradually differentiates the trends of query similarities based on the two dimensions of search namely "goal-quality" and "product" of the search. Indeed, the curves with more spread query similarity values (0.87-0.99) correspond to *interpretive* and *exploratory* sessions which reflect non-factual task products with either specific or amorphous goals leading to issue semantically different queries along the sessions. Unlikely, the curves with high density of narrow and relatively high similarity values (0.93-0.99) reflect factual search as characterized in *known-subject* and *known-item* search.

7 Conclusion

The paper presented SaQuEViL, a framework that learns query representations that reflect users' intents within a session-based search. By relying on the key finding that system's results affects user's query behavior and knowledge, we advocate the use of unsupervised multi-view learning to capture manifolds in a shared distributed representation space. Through experimental evaluation in two downstream tasks, we show the effectiveness of SaQuEViL over supervised and unsupervised pretrained encoders, though improvements are limited in session-based retrieval that inherently requires relevance supervision. A series of experiments and qualitative analyses also show the potential of SaQuEViL to control the representation space through key parameters that directly influence performance of downstream tasks and additionally, to clearly separate user behavior patterns in search sessions. We believe that this work opens avenues of research in the design of unsupervised distributed representations able to support search tasks, which has not received much attention yet.

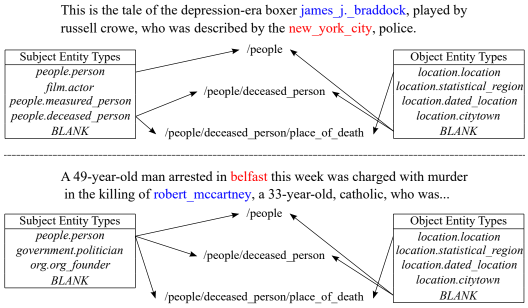
Abstract

Distant supervision uses triple facts in knowledge graphs to label a corpus for relation extraction, leading to wrong labeling and long-tail problems. Some works use the hierarchy of relations for knowledge transfer to long-tail relations. However, a coarse-grained relation often implies only an attribute (e.g., domain or topic) of the distant fact, making it hard to discriminate relations based solely on sentence semantics. One solution is resorting to entity types, but open questions remain about how to fully leverage the information of entity types and how to align multi-granular entity types with sentences. In this work, we propose a novel model to enrich distantly-supervised sentences with entity types. It consists of (1) a pairwise type-enriched sentence encoding module injecting both context-free and -related backgrounds to alleviate sentence-level wrong labeling, and (2) a hierarchical type-sentence alignment module enriching a sentence with the triple fact's basic attributes to support long-tail relations. Our model achieves new state-of-the-art results in overall and long-tail performance on benchmarks.

1 Introduction

Human-curated knowledge graphs (KGs), play a critical role in many downstream tasks but suffer from the incompleteness (Xiong et al., 2018; Yao et al., 2019). As a remedy, relation extraction is to distinguish the relation between two entities according to their semantics in text, but a major obstacle is a lack of sufficient labeled corpus. Fortunately, distant supervision can be used to annotate a raw text corpus via KGs for relation extraction, a.k.a. distantly supervised relation extraction (DSRE). This is based on a strong assumption that a sentence containing two entities will express the semantics of their relation in a KG (Riedel et al., 2010).

The assumption cannot always hold, leading to the wrong labeling problem. For example, both "*Jobs founded Apple*" and "*Jobs ate Apple*" are labeled with "/BUSINESS/COMPANY/FOUNDERS" according to a KG triple fact (*Steven Jobs*, /BUSINESS/COMPANY/FOUNDERS, *Apple Inc*). A basic technique for this problem is selective attention (Zeng et al., 2015; Lin et al., 2016; Ji et al., 2017) under multi-instance learning framework (Riedel et al., 2010; Hoffmann et al., 2011). Given a bag of sentences with the same entity pair, it learns to select correct one(s) by an end-to-end attention. The other major challenge is known as the long-tail problem, caused by domain mismatching during distant supervision. That is, many relation labels correspond only to a limited number of training sentences in the corpus (Ye et al., 2019). For example, in a DSRE benchmark, the distant supervision is an encyclopedic KG (i.e., Freebase (Bollacker et al., 2008)) while the corpus is news articles from the New York Times (NYT), so relations, like "/PEOPLE/PERSON/RELIGION", scarcely appear. As illustrated by Li et al. (2020b) and Zhang et al. (2019), more than 70% of relation labels in NYT can be regarded as *long-tail relations*.



This is the tale of the depression-era boxer james_j._braddock, played by russell crowe, who was described by the new_york_city, police.

Figure 1: Two sentences with the same long-tail relation. For each sentence, multi-granular relations from top to bottom are pointed by its best pairwise types, which indicates not all pairwise types provide the same contribution. Blue is subject entity, and red is object entity. The 1st sentence relies on the direct pairwise types due to its relation-irrelevant semantics while the 2nd sentence integrates its relation-relevant semantics and pairwise types to enhance its representation.

To mitigate the long-tail problem, some works

Findings of the Association for Computational Linguistics: NAACL 2022, pages 316 - 326
July 10-15, 2022 ©2022 Association for Computational Linguistics

(Han et al., 2018; Zhang et al., 2019; Li et al., 2020b) resort to the hierarchy of relations for knowledge transfer from data-rich relations to the long-tail ones since the relations have coarse-grained overlap. They focus on interactive operations between hierarchical relations and intra-bag sentences, including relation-to-sentence attention (Han et al., 2018) as a hierarchical extension of selective attention, and sentence-to-relation attention (Li et al., 2020b) enriching sentences with multi-granular relations. As such, they achieve knowledge transfer by learning to distinguish coarse-grained relations for sentences with sufficient data, which provides a latent constraint for the long-tail relations. However, a coarse-grained relation usually denotes the only basic attribute of the distant oracle triple fact in KG, so a sentence scarcely contains its semantics and we can only imply the relation via background information. Again, true-labeled "*Jobs founded Apple*", does not explicitly contain any semantics of its coarse-grained relation "/BUSINESS/COMPANY", but we can directly reason it from the predicate *founded* and type of *Apple*. Thus, it is a challenge for a hierarchical DSRE model to correctly imply coarse-grained relations based solely on sentences, not to mention the existence of the wrong labeling problem.

A direct yet promising way to overcome this challenge is to incorporate extra information for entities (Vashishth et al., 2018; Hu et al., 2019; Chu et al., 2020). One popular source is the entity types, i.e., an entity's "IS A" attributes in KG, which characterizes the entity from multiple perspectives (Chen et al., 2020). As Figure 1 shows, although the 1st sentence's semantics is irrelevant to relation, the pairwise types *people.deceased_person* and *location.location* directly align with the fine grained relation. However, existing works (Vashishth et al., 2018; Chu et al., 2020) ignore this potential of explicit structured types information.

In this work, we aim to improve DSRE by exploiting structured information in the entity types from both pairwise and hierarchical perspectives to alleviate the wrong labeling and the long-tail problems respectively. To this end, we first propose a *context-free type-enriched embedding* module to generate word embeddings with pairwise types associated with the entity pair in a bag. As shown in Figure 1, even without the corresponding semantic support, pairwise types can provide direct attributes of entities to align with the relation. Besides, we develop a *context-related type-sentence alignment* module to generate robust sentence representation with pairwise types. Since entities have specific characteristic in certain semantics, we leverage semantics to select proper pairwise types and then enrich sentence representation, as the 2nd sentence in Figure 1 shows. Such an alignment is enhanced by a guidance from the relation to auto-seek for associations between pairwise types and sentences.

At the meantime, hierarchical information has been proven crucial in knowledge transfer for long-tail relations (Han et al., 2018; Zhang et al., 2019; Li et al., 2020b). Thereby, we naturally extend the base alignment module into a hierarchy by proposing a *hierarchical type-sentence alignment* module. An intuitive example in Figure 1 shows that different grained relations are pointed by various granular pairwise types. This indicates that these pairwise types contain hierarchical semantics, which makes it feasible to extend base alignment into hierarchy. Thus, the strong association between pairwise types and coarse-grained relations can improve knowledge transfer for long-tail relations.

We conduct extensive experiments on two popular benchmarks, NYT-520k and NYT-570k, showing that our model achieves new state-of-the-art overall and long-tail performance. Further analyses reveal insights into our model.

2 Approach

Task Definition. Given a bag of sentences $\mathcal{B} = \{s_1, \ldots, s_N\}$ containing a pair of subject $e^{(s)}$ and object $e^{(o)}$ entities, the distant supervision (Mintz et al., 2009) assigns the sentence bag with a relation label r according to KG triple fact. The goal of relation extraction is to predict the relation label $\hat{r}$ of an entity pair based on the corresponding sentences bag $\mathcal{B}$. Labels of coarse-grained relations, $[r^{(1)}, \ldots, r^{(M)}]$, can be derived from the mention of r. For instance, when $r =$ /BUSINESS/COMPANY/FOUNDERS, $r^{(1)} =$ /BUSINESS/COMPANY and $r^{(2)} =$ /BUSINESS. In the following, we will detail our approach, as illustrated in Figure 2.

2.1 Context-Free Type-Enriched Word Emb

Following most previous DSRE works, we first tokenize each sentence $s_j \in \mathcal{B}$ and employ a word2vec method (Mikolov et al., 2013) to derive a sequence of word embeddings by looking up a learnable matrix $\boldsymbol{W}^{(emb)} \in \mathbb{R}^{d_e \times |\mathbb{V}|}$, i.e., $\tilde{\boldsymbol{X}}^j = [\tilde{\boldsymbol{x}}^j_1, \ldots, \tilde{\boldsymbol{x}}^j_n] \in \mathbb{R}^{d_e}$, where $\mathbb{V}$ denotes word

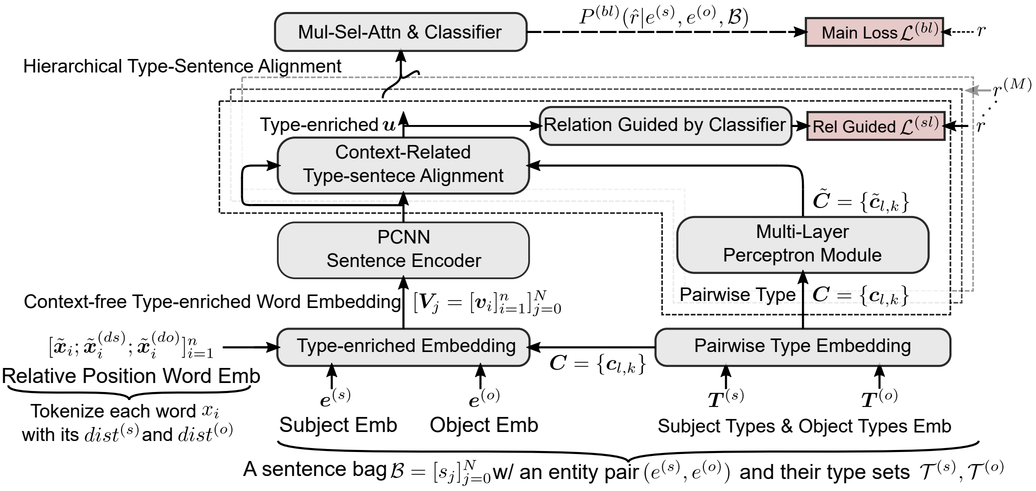

Figure 2: Our proposed model, called **Hi**erarchical **R**elation-guided Type-Sentence **A**lignment **M**odel (HiRAM), for DSRE.

vocabulary. j denotes the index of a sentence in the bag and n denotes the sentence length. In the sequel, we omit j if no confusion is caused. Then, as a common practice in DSRE (Zeng et al., 2014), a word's relative distances to both the subject and object entities (a.k.a relative positions) also play significant roles. The distances are first denoted as two integers ($dist^{(s)}$ and $dist^{(o)} \in \mathbb{Z}$) and then embedded into two learnable vectors ($\tilde{\boldsymbol{x}}_i^{(ds)}$ and $\tilde{\boldsymbol{x}}_i^{(do)} \in \mathbb{R}^{d_p}$). Therefore, the updated sequence of word embeddings is $\boldsymbol{X}^j = [\boldsymbol{x}_1, \dots, \boldsymbol{x}_n]$, where $\boldsymbol{x}_i = [\tilde{\boldsymbol{x}}_i; \tilde{\boldsymbol{x}}_i^{(ds)}; \tilde{\boldsymbol{x}}_i^{(do)}] \in \mathbb{R}^{d_w}$, $[;]$ denotes vector concatenation, and $d_w := d_e + 2d_p$.

Previous works (Li et al., 2020a,b) also found that explicitly enriching each word with both entity embeddings (i.e., $\boldsymbol{e}^{(s)}$ and $\boldsymbol{e}^{(o)}$) in a context-free manner is important to DSRE's success. However, many entities scarcely appear in the raw corpus and have multi-characteristics (e.g., *Apple* could be a fruit or a company). Thus, the model is hard to distinguish the relations only via sentence semantics.

Therefore, we leverage entity types to characterize entities' attributes. That is, given an entity e, its types are defined as a set of type mentions, i.e., $\mathcal{T} = \{t_1, t_2, \dots\}$. However, previous works (Chu et al., 2020) directly concatenate the entity types of both $e^{(s)}$ and $e^{(o)}$, completely regardless of potentials of explicit structured information of types. As demonstrated by Krompaß et al. (2015), a relation in KG is usually constrained by the entity types of $e^{(s)}$ and $e^{(o)}$ simultaneously (i.e., pairwise types), instead of their individuals. We thereby propose a pairwise type embedding module to enrich the word embedding $\boldsymbol{X}$ also in a context-free manner.

Type and Pairwise Type Embedding. First, given an entity type set $\mathcal{T} = \{t_1, t_2, \dots\}$ (either $\mathcal{T}^{(s)}$ for subject or $\mathcal{T}^{(o)}$ for object), we tokenize each type mention t_j into a sequence of words, then embed the words by looking up $\boldsymbol{W}^{(emb)}$, and lastly derive the type embedding $\boldsymbol{t}_j$ by applying a mean-pooling to the word embeddings of the mention. The embedding of the entire type is

$$\boldsymbol{T} = [\boldsymbol{t}_1, \boldsymbol{t}_2, \dots] \in \mathbb{R}^{|\mathcal{T}| \times d_e}. \tag{1}$$

As such, we subsequently define the embedding of the pairwise type by considering a combination of every subject $\forall t_l^{(s)} \in \mathcal{T}^{(s)}$ and object type $\forall t_k^{(o)} \in \mathcal{T}^{(o)}$. Instead of sole semantics via a vector concatenation, we take into account the prior structured information in each type pair by leveraging a translational scheme (Bordes et al., 2013). Hence, we represent each type pair $(t_l^{(s)}, t_k^{(o)})$ as

$$\begin{aligned} \boldsymbol{c}_{l,k} &= [\tilde{\boldsymbol{c}}_{l,k}^{(sem)}; \tilde{\boldsymbol{c}}_{l,k}^{(str)}] \in \mathbb{R}^{4d_e}, \\ \text{where, } \tilde{\boldsymbol{c}}_{l,k}^{(sem)} &= \boldsymbol{t}_l^{(s)} \odot \boldsymbol{W}^{(sem)} \boldsymbol{t}_k^{(o)}, \\ \text{and } \tilde{\boldsymbol{c}}_{l,k}^{(str)} &= \boldsymbol{t}_k^{(o)} - \boldsymbol{t}_l^{(s)}. \end{aligned} \tag{2}$$

Here, "$\odot$" denotes Hadamard product, and $\boldsymbol{W}^{(sem)}$ denotes a learnable projection. $\tilde{\boldsymbol{c}}_{l,k}^{(sem)}$ aims to capture the prior semantic relation in the pair (Nickel et al., 2011) since not all types combinations are valid in the whole dataset. $\tilde{\boldsymbol{c}}_{l,k}^{(str)}$ aims to measure its structured relation. Lastly, we denote all the embeddings of pairwise types as

$$\boldsymbol{C} = \{\boldsymbol{c}_{l,k}\}_{\forall l \in [1, |\mathcal{T}^{(s)}|], \forall k \in [1, |\mathcal{T}^{(o)}|]}, \tag{3}$$

where $\boldsymbol{C} \in \mathbb{R}^{4d_e \times m}$ and $m = |\mathcal{T}^{(s)}| \cdot |\mathcal{T}^{(o)}|$.

Type-Enriched Word Embedding. However, an open question still remains about how to operate on variable-length embeddings of pairwise types, $\boldsymbol{C}$, to enrich each word embedding, $\boldsymbol{x}_j \in \boldsymbol{X}$, in a context-free manner. Inspired by self-attentive sentence encoding (Lin et al., 2016), we present a bag-level type-attentive module, which compresses $\boldsymbol{C}$ into a single vector representation to facilitate type-enriching. Intuitively, such self-attentive module is focused on the prior knowledge of the type pair in the corpus. Formally, we first generate a global query (Lin et al., 2016) with structured information of both entities and types to retrieve possible prior pairwise types, i.e.,

$$\tilde{\boldsymbol{q}}^{(f)} = [\boldsymbol{e}^{(o)}; \text{Pool}(\boldsymbol{T}^{(o)})] - [\boldsymbol{e}^{(s)}; \text{Pool}(\boldsymbol{T}^{(s)})], \quad (4)$$

followed by a standard Bilinear-based attention,

$$\boldsymbol{q}^{(f)} = \boldsymbol{C} \cdot \text{softmax}(\boldsymbol{C}^T \boldsymbol{W}^{(sa)} \boldsymbol{q}^{(f)}) \in \mathbb{R}^{4d_e}, \quad (5)$$

where "$\cdot$" denotes matrix multiplication and $\boldsymbol{W}^{(sa)}$ is a learnable weight matrix. Lastly, we use a gate as in (Li et al., 2020b) to derive the context-free type-enriched word embedding, i.e.,

$$\begin{aligned} \boldsymbol{g}_i^{(gf)} &= \text{Sigmoid}(\text{MLP}([\boldsymbol{x}_i; \boldsymbol{q}^{(f)}]; \theta^{(gf1)})), && (6) \\ \boldsymbol{x}_i^{(gf)} &= \text{MLP}([\boldsymbol{x}_i; \boldsymbol{q}^{(f)}]; \theta^{(gf2)}), && (7) \\ \boldsymbol{v}_i &= \boldsymbol{g}_i^{(gf)} \odot \boldsymbol{x}_i + (\boldsymbol{1} - \boldsymbol{g}_i^{(gf)}) \odot \boldsymbol{x}_i^{(gf)}, && (8) \end{aligned}$$

where MLP denotes a multi-layer perceptron (MLP) module. Hence, word embeddings for s are updated to $\boldsymbol{V} = [\boldsymbol{v}_1, \ldots, \boldsymbol{v}_n] \in \mathbb{R}^{d_w \times n}$.

2.2 Context-Related Type-Sent Alignment

Sentence Encoding. In DSRE, piecewise convolutional neural network (PCNN) (Zeng et al., 2015) is used for sentence embedding. 1D-CNN (Kim, 2014) is first invoked over $\boldsymbol{V}$ for contextualized representations. Then a piecewise max-pooling performs over the output sequence to obtain sentence-level embedding with highlighted entity positions:

$$\begin{aligned} &\boldsymbol{H} = [\boldsymbol{h}_1, \ldots, \boldsymbol{h}_n] = \text{1D-CNN}(\boldsymbol{V}; \theta^{(cnn)}), \\ &\boldsymbol{s} = \tanh([\text{Pool}(\boldsymbol{H}^{(1)}); \text{Pool}(\boldsymbol{H}^{(2)}); \text{Pool}(\boldsymbol{H}^{(3)})]), \end{aligned}$$

where $\boldsymbol{H}^{(1)}$, $\boldsymbol{H}^{(2)}$ and $\boldsymbol{H}^{(3)}$ are three consecutive parts of $\boldsymbol{H}$ by dividing $\boldsymbol{H}$ w.r.t. the indices of subject $e^{(s)}$ and object $e^{(o)}$ entities. Consequently, $\boldsymbol{s} \in \mathbb{R}^{d_h}$ is the resulting sentence-level embedding.

Type-Sentence Alignment. Consider that types are not comprehensive enough to align with multi-granular relations, we leverage semantic context to select valid pairwise types for generating robust sentence representation. Hence, we first calculate alignment scores between a sentence $\boldsymbol{s} \in \mathbb{R}^{d_h}$ and the embeddings of pairwise types $\boldsymbol{C} \in \mathbb{R}^{4d_e \times m}$ by using a simple Bilinear layer, i.e.,

$$\begin{aligned} \tilde{\boldsymbol{C}} &= \text{MLP}(\boldsymbol{C}; \theta^{(p)}) \in \mathbb{R}^{d_h \times m}, && (9) \\ \boldsymbol{a} &= \text{softmax}(\tilde{\boldsymbol{C}}^T \boldsymbol{W}^{(al)} \boldsymbol{s}) \in \mathbb{R}^m. && (10) \end{aligned}$$

Then, we enrich the sentence embedding with the aligned type pairs via another gating mechanism:

$$\begin{aligned} \boldsymbol{z} &= \tilde{\boldsymbol{C}} \cdot \boldsymbol{a} && (11) \\ \boldsymbol{g} &= \text{Sigmoid}(\text{MLP}([\boldsymbol{s}; \boldsymbol{z}]; \theta^{(g)})), && (12) \\ \tilde{\boldsymbol{u}} &= \boldsymbol{g} \odot \boldsymbol{s} + (1 - \boldsymbol{g}) \odot \boldsymbol{z}. && (13) \end{aligned}$$

Lastly, following previous success (Li et al., 2020b; Devlin et al., 2019), we leverage a residual connection (He et al., 2016) with layer normalization (Ba et al., 2016) to derive the final context-related type-enriched sentence embedding, i.e.,

$$\boldsymbol{u} = \text{LayerNorm}(\boldsymbol{s} + \tilde{\boldsymbol{u}}; \theta^{(lm)}). \quad (14)$$

Relation-Guided Alignment at the Sentence Level. Due to the severe wrong labeling problem at the sentence level, previous DSRE works usually skip over sentence-level relation supervisions. Fortunately, empowered by the proposed context-free type enrichment and context-related type-sentence alignment, we can utilize the sentence-level relation label even if the relation label is wrong. The reason for this is that, a sentence has already been equipped with structured background to support sentence-level relation even if the sentence semantics cannot deliver the relation. We applied an MLP-based neural classifier to the type-enriched sentence embedding, $\boldsymbol{u}$, to determine the relation at the sentence level, i.e.,

$$P^{(sl)}(\hat{r}|\boldsymbol{u}) = \text{softmax}(\text{MLP}(\boldsymbol{u}; \theta^{(sl)})), \quad (15)$$

where, $P^{(sl)}(\hat{r}|\boldsymbol{u})$ is a categorical distribution over all possible relations. Hence, the training objective is to minimize the cross-entropy loss,

$$\mathcal{L}^{(sl)} = -\sum_{\mathcal{D}} \sum_{\mathcal{B}} \log P^{(sl)}(\hat{r} = r|\boldsymbol{u}), \quad (16)$$

where $\mathcal{D}$ denotes a DSRE dataset consisting of sentence bags $\mathcal{B}$. The guidance from the sentence-level relation leads to strong type-sentence alignment (as illustrated in §3.1 and §3.2). As a result, the sentence-level wrong labeling problem is alleviated. In contrast, previous works w/ sentence-level relation supervisions (Li and Roth, 2002) suffer from the confirmation bias problem (Chen et al., 2019) caused by the sentence-level wrong labeling.

2.3 Hierarchical Type-Sentence Alignment

Inspired by former works (Han et al., 2018; Zhang et al., 2019; Li et al., 2020b) for handling long-tail relations, we also extend our basic model into hierarchy. However, the basic attributes contained by coarse-grained relation are irrelevant to the semantics in sentences. Thus, instead of direct operating on the hierarchy of relations (i.e., from fine-grained r to coarse-grained $[r^{(1)} \dots r^{(M)}]$ relations), we leverage coarse-grained entity types describing the domain/type properties of the entities in the triple facts to enrich each sentence via the guidance from coarse-grained relation.

Formally, we adapt the relation-guided type-sentence alignment (§2.2) into hierarchy, which shares a high-level inspiration with multi-head attention (Vaswani et al., 2017). First, we reuse the architecture from Eq.(9-14) by defining

$$\begin{aligned} \boldsymbol{a}^{(l)}, \tilde{\boldsymbol{C}}^{(l)} &= \text{TS-Align}^{(l)}(\boldsymbol{s}, \boldsymbol{C}),\ \forall l \in [1, M], \\ \boldsymbol{u}^{(l)} &= \text{TS-Integrate}^{(l)}(\boldsymbol{a}^{(l)}, \tilde{\boldsymbol{C}}^{(l)}, \boldsymbol{s}), \end{aligned} \quad (17)$$

where $\text{TS-Align}()$ denotes Eq.(9-10) to obtain type-sentence alignment $\boldsymbol{a}^{(l)}$ and $\text{TS-Integrate}()$ denotes Eq.(11-14) to generate enriched sentence representation $\boldsymbol{u}^{(l)}$ at level l. Note that, these modules are parameter-untied from each other. Then, we update the sentence-level relation-guided loss in Eq.(16) to its hierarchical version, i.e.,

$$\mathcal{L}^{(sl)} = -\sum_{\mathcal{D},\mathcal{B},l\in[1,M]} \log P^{(sl)}(\hat{r}^{(l)}{=}r^{(l)}|\boldsymbol{u}^{(l)}) \quad (18)$$

Again, learnable parameters of the sentence-level classifiers across l are also untied. Lastly, we obtain the hierarchical type-enriched representation, i.e.,

$$\boldsymbol{u}^{(h)} = [\boldsymbol{u}; \boldsymbol{u}^{(1)}; \dots; \boldsymbol{u}^{(M)}] \in \mathbb{R}^{(1+M)d_h}. \quad (19)$$

Different to previous works (Han et al., 2018; Zhang et al., 2019; Li et al., 2020b) focusing on hierarchical relation embeddings, our work explores the constraints by pairwise types for relations to mitigate sentence-level wrong labeling and uses the hierarchy of entity types on par with that of the relation to improve long-tail performance.

2.4 Relation Classification and Objectives

Lastly, we put the sentences back into the bag and derive bag-level embedding for the final relation classification. Hence, for a bag $\mathcal{B} = [s_1, ...s_N]$, we can obtain sentence embeddings of all the sentences $\boldsymbol{U}^{(h)} = [\boldsymbol{u}_1^{(h)}, \dots, \boldsymbol{u}_N^{(h)}]$, where $\boldsymbol{u}_j^{(h)}$ is hierarchical type-enriched sentence encoding derived from Eq.(19). To preserve the hierarchical information learned in $\boldsymbol{u}_j^{(h)}$, we proposed to apply multiple selective modules to its different parts, i.e.,

$$\begin{aligned} &\boldsymbol{b} = \text{Mul-Sel-Attn}(\boldsymbol{U}^{(h)}) = [\boldsymbol{b}^{(0)}; \boldsymbol{b}^{(1)}; \dots; \boldsymbol{b}^{(M)}], \\ &\boldsymbol{b}^{(0)} = \text{Sel-Attn}([\boldsymbol{u}_1; \dots, \boldsymbol{u}_N]), \\ &\boldsymbol{b}^{(l)} = \text{Sel-Attn}([\boldsymbol{u}_1^{(l)}; \dots, \boldsymbol{u}_N^{(l)}]),\ \forall l \in [1,M]. \end{aligned}$$

where, $\text{Sel-Attn}()$ represents the selective attention among the sentences in each granular relation, and $\text{Mul-Sel-Attn}()$ represents the selective attention among the multi-granular bag representations. For bag representation, $\boldsymbol{b}^{(0)}$ denotes the finest grained and $\boldsymbol{b}^{(l)}$ denotes coarser grained. Lastly, we use an MLP-based classifier upon $\boldsymbol{b}$ to derive a bag-level categorical distribution, i.e.,

$$P^{(bl)}(\hat{r}|e^{(s)}, e^{(o)}, \mathcal{B}). \quad (20)$$

Meanwhile, the corresponding training loss is

$$\mathcal{L}^{(bl)} = -\sum_{\mathcal{D}} P^{(bl)}(\hat{r} = r|e^{(s)}, e^{(o)}, \mathcal{B}). \quad (21)$$

Therefore, the final training objective is to minimize a linear combination of both sentence-level in Eq.(16) and bag-level (in Eq.(21)) losses, i.e.,

$$\mathcal{L} = \mathcal{L}^{(bl)} + \beta \mathcal{L}^{(sl)}. \quad (22)$$

3 Experiments

Datasets. We evaluate our HiRAM on DSRE benchmarks, New York Times – NYT (Riedel et al., 2010), including NYT-520K and NYT-570K. NYT datasets have 53 distinct relations, including an *NA* class denoting the unavailable relation between entity pairs. Each relation includes two coarse-grained relations (i.e., $M = 2$), and the number of relations from fine to coarse are 53, 36 and 9. NYT-520K and NYT-570K have the same testing set containing 172,488 sentences, with 96,678 entity pairs. The only difference is that there is an overlap of 11,416 entity pairs between training and testing in NYT-570K. Thus, NYT-520K has severer wrong labeling and long-tail problems.

Table 2: Model Evaluation on NYT-570K, published by PCNN+HATT (Han et al., 2018)
.

Evaluation Metrics. Following previous works (Lin et al., 2016; Han et al., 2018; Zhang et al., 2019; Li et al., 2020b; Chu et al., 2020), we use area under precision-recall curve (AUC) and top-N precision (P@N) to measure models' performance with the disturbance of wrong labeling, and use Hits@K to measure the performance on long-tail relations. AUC measures the ability of relation classification, while P@N measures the precision of high-confidence predictions ranked by the model.

Settings. For both versions of NYT datasets, d_e, d_p, d_w, d_h and M are 50, 5, 60, 690, and 2 respectively. The types number of each entity is various but we set an upper limit and pad BLANK as a choice. We use AdaDelta (Zeiler, 2012) with 0.1 learning rate. Batch size is 160 with 15 epochs and 5-th is the best, dropout probability is 0.5, weight decay of L2-reg is 10^{-5}. We use random initialization or RoBERTa-base to initialize our models.

Comparative Approach. We compare our HiRAM with many strong competitors, including **(1) PCNN+ATT** (Lin et al., 2016) proposes a selective attention to alleviate wrong labeling. **(2) PCNN+HATT** (Han et al., 2018) extends selective attention with hierarchical relations. **(3) RESIDE** (Vashishth et al., 2018) leverages side KGs' information to improve DSRE. **(4) PCNN+BAG-ATT** (Ye and Ling, 2019) proposes intra-bag and inter-bag attentions to handle the wrongly labeled sentences. **(5) PCNN+KATT** (Zhang et al., 2019) integrates externally pre-trained graph embeddings with relation hierarchies for long-tail relations. **(6) SeG** (Li et al., 2020a) focuses on one-sentence bags and proposes entity-aware embedding. **(7) CoRA** (Li et al., 2020b) transfers multi-granular relations features into sentences in hierarchies for long-tail relations. **(8) InSRL** (Chu et al., 2020) integrates sentence, entity description and types together via intact space representation learning.

3.1 Overall Performance on Benchmarks

As shown in Tables 1 and 2, HiRAM outperforms former baselines on NYT-570K. Different from CoRA's poor performance on NYT-520K, HiRAM achieves a new state-of-the-art on both popular

# Training Instance	**<100**			**<200**		
Hits@K (Macro)	**10**	**15**	**20**	**10**	**15**	**20**

Table 3: Hits@K (Macro) tests only on the relations whose number of training instance $< 100/200$. “Hits@K” denotes whether a test sentence bag whose gold relation label $r^{(0)}$ falls into top-K relations ranked by their prediction confidences.“Macro” denotes macro average is applied regarding relation labels. “*” denotes the model is trained on NYT-570K.

Case Sentence 1: although the regime of president **bashar_al-assad** hails from an obscure offshoot of shiism – the alawites – syria is nearly three-quarters sunni, with alawites, members of other **muslim** sects and ...		
$r^{(2)}$: /people	$r^{(1)}$: /people/person	$r^{(0)}$: /people/person/religion
Case Sentence 2: having so many operating systems makes it expensive to make software **, said faraz_hoodbhoy**, the chief executive of camera phones save and share multimedia content.		
$r^{(2)}$: /business	$r^{(1)}$: /business/company	$r^{(0)}$: /business/company/founder

Table 4: Two cases with long-tail relations are mis-classified by previous works whereas HiRAM is competent. Analysis of the attention probability shown in Figure 3 proves the utility of context-related type-sentence alignment with relation guidance.

benchmarks in P@N and AUC. Compared with InSRL integrating both clean entity types' concatenation and accurate entity descriptions, HiRAM increases the AUC score by nearly 7%, verifying the capability of our specific model designer.

3.2 Ablation Study

We conduct an ablation study on NYT-520K, as shown at the bottom of Table 1. Compared to HiRAM, “HiRAM w/o Hierarchy” drops 6% in AUC. “HiRAM w/o Rel Guidance” performs well on P@N and AUC but has huge gap in P@One, which represents that the relation-Guided alignment in hierarchy can empower sentence representation with less data in Multi-instance Learning. Meanwhile, top-n precision of “HiRAM w/o CF” drops by nearly 10.5%. To prove the superiority of our specific design, we replace the pairwise type in §2.1 with simple type concatenation. The AUC score of “HiRAM w/ TC” decreases by 4.5% and nearly 5.6% of top-n precision. To further emphasize our word embedding §2.1 is module-agnostic, we combine RoBERTa (Liu et al., 2019) with our module respectively. As the bottom panel shows, “RoBERTa w/ CF” makes great progress, and “RoBERTa w/ HiRARM” achieves the best performance among three RoBERTa-related experiments. However, due to the strong ability of RoBERTa model, the wrong labeling problem hurt the performance severely, especially in P@N.

3.3 Performance on Long-Tail Relations

Since former baselines are mainly trained on NYT-570K, we reproduce CoRA on NYT-520K for fair comparison as shown in Table 3. HiRAM achieves a new state-of-the-art result in Hits@K with 20% superiority. Removing hierarchy module in §2.3, the performance of “HiRAM w/o Hierarchy” decreases by nearly 30% on Hits@10 but is better than baselines in other settings, verifying the importance of hierarchical model for long-tail relations. The huge decline of “HiRAM w/o Rel Guidance” verifies the necessity of relation guidance. Due to lacks of plenty reliable training data, RoBERTa is hard to handle the long-tail problem but our specific modules further increase its performance.

3.4 Case Study and Error Analysis

Firstly, we conduct a case study to qualitatively analyze the effect of our model in §2.3 The case study of two samples are shown in Table 4 and the type-sentence alignment distribution is shown in

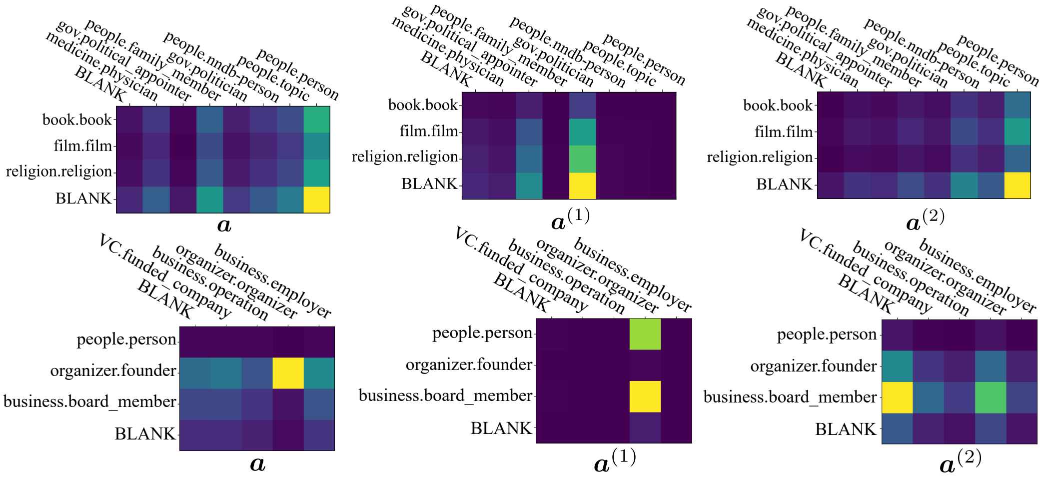

Figure 3: Each heatmap represents the distribution of type-sentence alignment $\boldsymbol{a}$ in Eq.(10) and $\boldsymbol{a}^l$ in Eq.(17). The horizontal axis represents the types of subject entity, and the vertical axis represents the types of object entity. The top row, from left to right, represents three alignment distributions of first case, and the bottom row represents three alignment distributions of second case, as Table 4 shows. Notice that "VC" is the abbreviation of venture captial.

Figure 3. Secondly, we investigate the possible reasons for the misclassifications of HiRAM.

Distribution of Type-Sentence Alignment. For the first case, despite the failure in expressing the long-tail relation "/PEOPLE/PERSON/RELIGION", the selected pairwise types are sufficient to predict this relation. As the top row of Figure 3 shows, *people.person* with *BLANK* helps to identify the character of subject entity, and *religion.religion* with high alignment score can provide direct attributes. For the second case, the semantics is implicitly related to its long-tail relation "/BUSINESS/COMPANY/FOUNDER". The proper pairwise types are selected by coarser relation guidance, like (*organizer.organizer*, *organizer.founder*).

Error Analysis. To analyse the implicit reasons for wrong predictions, we have manually checked several randomly-sampled error test examples. 1) Most of error cases are annotated as /PEOPLE/PERSON/PLACE_OF_BIRTH because the semantics and the relation may be completely irrelevant and the types are hard to maintain people's birth place. 2) Mean pooling in Eq.(4) might not be the most optimal way to replace entity itself when the entity has too many characters.

4 Related Work

Wrong Labeling Problem. Many works (Liu et al., 2016; Ji et al., 2017; Ye and Ling, 2019; Li et al., 2020a) propose various extensions of vanilla selective attention (Lin et al., 2016). Ye and Ling (2019) combine intra-/inter-bag level selective attention for DSRE. For one-sentence bags, Li et al. (2020a) design the entity-aware embedding in a context-free manner with a gate mechanism.

Long-tail Relations. Knowledge transfer via hierarchical relations is effective. Han et al. (2018) design relation-to-sentence attention in hierarchies, and Li et al. (2020b) modify it to sentence-to-relation attention. Many works (Vashishth et al., 2018; Hu et al., 2019; Chu et al., 2020) resort to extra knowledge, i.e., entity description and entity types. Entity description (Hu et al., 2019; Chu et al., 2020) mainly stems from the Wikipedia page, which contains factual statements of the relation with other entities. Such oracle knowledge can boost DSRE performance but is impractical.

5 Conclusion

In this work, we propose a new model, HiRAM, training on a single Titan XP, except for RoBERTa w/ RTX 6000, to alleviate wrong labeling and long-tail problems in DSRE. For the wrong labeling problem, we propose a context-free type-enriched word embedding to enrich each word with prior knowledge and a context-related type-sentence alignment module to complement sentences with semantics-fitted pairwise types. For the long-tail problem, we extend the base alignment into the hierarchy to utilize the multi-granular entity types. The experiments with extensive analyses show the superiority of HiRAM.

Abstract

BERT and other pre-trained language models (PLMs) are ubiquitous in modern NLP. Even though PLMs are the state-of-the-art (SOTA) models for almost every NLP task (Qiu et al., 2020), the significant latency during inference prohibits wider industrial usage. In this work, we propose Patient and Confident Early Exiting BERT (PCEE-BERT), an off-the-shelf sample-dependent early exiting method that can work with different PLMs and can also work along with popular model compression methods. With a multi-exit BERT as the backbone model, PCEE-BERT will make the early exiting decision if enough numbers (patience parameter) of consecutive intermediate layers are confident about their predictions. The entropy value measures the confidence level of an intermediate layer's prediction. Experiments on the GLUE benchmark demonstrate that our method outperforms previous SOTA early exiting methods. Ablation studies show that: (a) our method performs consistently well on other PLMs, such as ALBERT and TinyBERT; (b) PCEE-BERT can achieve different speed-up ratios by adjusting the patience parameter and the confidence threshold. The code for PCEE-BERT can be found at `https://github.com/michael-wzhu/PCEE-BERT`.

1 Introduction

Since BERT (Devlin et al., 2018), the pre-trained language models (PLMs) have become the default state-of-the-art (SOTA) models for natural language processing (NLP). The recent years have witnessed the rise of many PLMs, such as GPT (Radford et al., 2019), XLNet (Yang et al., 2019), ALBERT (Lan et al., 2020), and so forth. These BERT-style models achieved considerable improvements in many Natural Language Processing (NLP) tasks by pre-training on the unlabeled corpus and fine-tuning on labeled tasks, such as text classification, natural language inference (NLI) and sequence labeling. Despite their excellent performances, there are two issues for PLMs.

First, previous studies show that PLMs such as BERT suffer from the over-thinking problem. (Zhou et al., 2020; Zhu et al., 2021) shows that in the sentence classification task, BERT's last few layers may be too deep for some samples. For a sentence classification task, if we insert a classifier on a certain intermediate layer and drop the deeper layers, these intermediate layers may outperform the last layer.

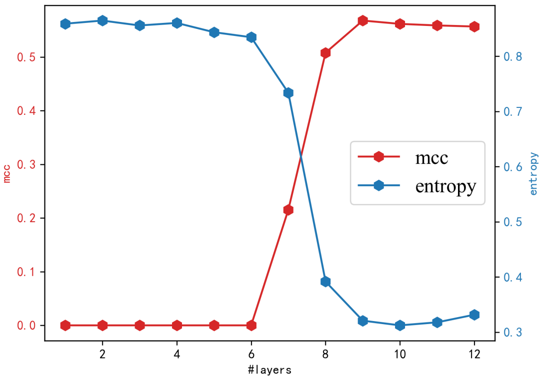

Figure 1: This figure demonstrates the overthinking problem in BERT when it is applied to the sentence classification task, such as CoLA from the GLUE benchmark.

The second drawback of PLMs is their high latency. Sentence classification (CLS) tasks play a central role in many application scenarios, such as dialogue systems, document analysis, content recommendation, etc. However, these applications are time-sensitive. For example, if a task-oriented dialogue (TOD) system takes a lot of time to respond, users will no doubt stop using this system. User experience studies show that a response has to be made in between 0-100 ms. Thus, a CLS mod-

(a) PABEE

(b) PCEE-BERT

Figure 2: Comparison between PABEE (Zhou et al., 2020) and our PCEE-BERT, a novel early exiting method that combines the score-based early exiting with the patience-based early exiting.

ule should be efficient and accurate. In addition, a special feature of consumer queries is that there are times when the number of queries is extremely high. For example, during the flu season, online medical consultation will be used much more often than usual. Thus, it is important for deployed models to adjust their latency dynamically. During peak hours, it switches to a low-latency mode to deal with more queries. And in other hours, it makes the best of itself to provide accurate answers. So how can we make model inference dynamically? The answer is adaptive inference.

There exists a branch of literature focusing on making PLMs' inference more efficient via network pruning (Zhu and Gupta, 2018; Xu et al., 2020; Fan et al., 2020; Michel et al., 2019), knowledge distillation (Sun et al., 2019; Sanh et al., 2019; Jiao et al., 2020a), weight quantization (Zhang et al., 2020; Bai et al., 2020; Kim et al., 2021) and adaptive inference (Zhou et al., 2020; Xin et al., 2020; Liu et al., 2020). Adaptive inference has drawn much attention. The idea of adaptive inference is to deal with simple examples with only shallow layers of BERT and process more difficult queries with deeper layers, thus significantly speeding up the inference time on average while maintaining high accuracy. The speed-up ratio can be easily controlled with certain hyper-parameters to handle significant changes in query traffic without re-deploying the model services or maintaining a group of models.

Early exiting is one of the most important adaptive inference methods (Bolukbasi et al., 2017). As depicted in Figure 2(b), it implements adaptive inference by installing an early exit, i.e., an intermediate prediction layer, at each layer of BERT and early exiting "easy" samples to speed up inference. At the training stage, all the exits are jointly optimized with BERT's parameters. At the inference stage, there are two different settings. First, in budgeted exiting mode, the model makes a prediction with a fixed exit for all queries. This mode deals with heavy traffic by assigning a shallower exit for prediction. The other one is dynamic exiting mode. That is, some strategies for early exiting are designed to decide whether to exit at each layer given the currently obtained predictions (from previous and current layers) (Teerapittayanon et al., 2016; Kaya et al., 2019; Xin et al., 2020; Zhou et al., 2020). In this mode, different samples can exit at different depths.

There are mainly three early exiting strategies for BERT dynamic exiting. The first one is score-based early exiting. BranchyNet (Teerapittayanon et al., 2016), FastBERT (Liu et al., 2020), and DeeBERT (Xin et al., 2020) calculated the entropy of the prediction probability distribution as an estimation for the confidence of exiting classifiers to enable dynamic early exiting. Shallow-Deep Nets (Kaya et al., 2019) and RightTool (Schwartz et al., 2020a) leveraged the maximum of the predicted distribution as the exiting signal. The second type is the learned exiting (Elbayad et al., 2020). In this type of work, an early exiting signal is generated by a learnable module in the neural network. For example, BERxiT (Xin et al., 2021) install a fully connected layer right after each transformer block of BERT to output a score that is used to decide whether the BERT should stop inference and exit early. The third type is patience-based early exiting, which relies on cross-layer comparison to formulate the exiting signal. PABEE (Zhou et al., 2020) propose a dynamic exiting strategy analogous to early stopping model training. That is, if the exits' predictions remain unchanged for a pre-defined number of times (patience), the model will stop inference and exit early. PABEE achieves SOTAs results for BERT early exiting.

Despite its state-of-the-art performances during early exiting, PABEE is inflexible in adjusting the speedup ratios. On a given task, once the multi-exit BERT is fine-tuned and the patience parameter is fixed, PABEE can only achieve a fixed average speedup ratio. Thus, PABEE can not achieve speedup ratios of certain values. This drawback makes PABEE inconvenient to use in real industrial scenarios. Thus, it is of great importance to come up with a method that can flexibly adjust its speedup ratios and performs comparable to or better than PABEE.

In this work, we propose Patiently Confidently Early Exiting BERT (PCEE-BERT), a novel early exiting method that combines the advantage of score-based methods and the patience based early exiting method. A multi-exit BERT is adopted as the backbone model, and an intermediate classifier (i.e., an exit) is installed right after each transformer block. PCEE-BERT will early exit if there are enough numbers (i.e., the patience parameter) of consecutive exits being confident for their predicted distributions. We mainly use entropy as the confidence measure. Intuitively, our method requires patience and confidence. It will not rush into an early exiting if we only see a couple of intermediate layers being confident. In addition, it allows the next layer to modify the predictions. In this way, our PCEE-BERT can exit with higher accuracy while maintaining flexibility.

Extensive experiments are conducted on the GLUE benchmark (Wang et al., 2018). The results show that our method outperforms the previous SOTA early exiting methods, especially in cases where the speedup ratio is large. In addition, one can adjust the patience and confidence threshold so that PCEE-BERT can arrive at different speedup ratios. A series of ablation studies are conducted, resulting in the following observations: (a) PCEE-BERT can work with different confidence measures; (b) our method performs consistently well on different PLMs, and can work alongside model compression methods to further speed up the BERT's inference; (c) our PCEE-BERT can also be applied to computer vision tasks.

The rest of the paper is organized as follows. First, we introduce the preliminaries for multi-exit BERT and early exiting. Second, we elaborate on our PCEE-BERT method. Third, we conduct experiments on the GLUE benchmark and conduct a series of ablation studies. Finally, we conclude with possible future works.

2 Preliminaries

In this section, we introduce the necessary background for BERT early exiting. Throughout this work, we consider the case of multi-class classification with samples $\{(x, y), x \in \mathcal{X}, y \in \mathcal{Y}, i = 1, 2, ..., N\}$, e.g., sentences, and the number of classes is K.

2.1 Backbone models

In this work, we adopt BERT as the backbone model. BERT is a multi-layer Transformer (Vaswani et al., 2017) network, which is pre-trained in a self-supervised manner on a large corpus. The number of transformer layers of our backbone is denoted as M, and the hidden dimension is d.

2.2 Early-exiting Architecture

As depicted in Figure 2, early exiting architectures are networks with exits at each transformer layer. With M exits, M classifiers $f^{(m)}(x; \theta^{(m)}) : \mathcal{X} \rightarrow \Delta^K$ $(m = 1, 2, ..., M)$ are designated at M layers of BERT, each of which maps its input to $p^{(m)}(x; \theta^{(m)})$, a probability distribution over the K classes. All the parameters of the transformer layers and exits are denoted as Θ.

2.2.1 Training

At the training stage, all the exits are jointly optimized with a summed loss function. Following Huang et al. (2017) and Zhou et al. (2020), the loss function is the weighted average of the cross-entropy (CE) losses given by

$$\mathcal{L} = \frac{\sum_{m=1}^{M} m * \mathcal{L}^{(m)}}{\sum_{m=1}^{M} m}, \quad (1)$$

where $\mathcal{L}^{(m)} = \mathcal{CE}(y, p^{(m)}(x; \theta^{(m)}))$ denotes the cross-entropy loss of the m-th exit. Note that the weight m corresponds to the relative inference cost of exit m.

2.2.2 Inference

During inference, the multi-exit BERT can exit early in two different modes, depending on whether the computational budget to classify an example is known or not.

Budgeted Exiting. If the computational budget is known, we can directly appoint a suitable exit m^* of BERT, $f^{(m^*)}(x;\theta^{(m^*)})$, to predict all queries.

Dynamic Exiting. Under this mode, after receiving a query input x, the model starts to predict on the classifiers $f^{(1)}(x;\theta^{(1)})$, $f^{(2)}(x;\theta^{(2)})$, ..., in turn in a forward pass, reusing computation where possible. It will continue to do so until it receives a signal to stop early at an exit $m^* < M$, or arrives at the last exit M. At this point, it will output the final predictions based on the current and previous predictions. Note that under this early exit setting, different samples might exit at different layers.

3 PCEE-BERT

3.1 Motivation

PABEE achieves the SOTA performances for BERT early exiting by applying an early exiting decision-making process that mimics the early stopping of model training. However, one drawback of PABEE is that it can not flexibly adjust the average inference layers (i.e., speed-ups) for a given dataset once its patience parameter is set. Table 1 shows PABEE can not achieve certain values for average inference layers, such as around 4.0, 6.0, or 9.0 on RTE. This drawback may limit the industrial usage of early exiting techniques. Thus, it is of great importance to develop a new method that performs comparably with PABEE and is more flexible than PABEE.

	RTE	QNLI	MRPC
patience=1	3.24	2.25	2.00
patience=2	4.96	3.87	3.00
patience=3	6.69	5.32	4.18
patience=4	7.77	6.50	5.60
patience=5	8.78	7.61	6.81
patience=6	9.75	8.64	7.91
patience=7	10.68	9.54	8.83
patience=8	11.47	10.36	9.72
patience=9	11.79	11.04	10.51
patience=10	11.92	11.57	11.26
patience=11	12.00	12.00	12.00

Table 1: Average inference layers of PABEE on the RTE, QNLI and MRPC tasks.

3.2 PCEE-BERT: a novel dynamic exiting method

The inference process of PCEE-BERT is illustrated in Figure 2(b). Assume the feed forward process for predicting sample x has gone through layers 1, ..., $m-1$, and we are now at layer m. After going through the transformer layer m, the intermediate classifier $f^{(m)}(x;\theta^{(m)})$ predicts a class label distribution $p^{(m)}(x;\theta^{(m)})$. The confidence level of layer m is measured by the entropy value of distribution $p^{(m)}(x;\theta^{(m)})$:

$$C^{(m)} = \frac{\sum_{k=1}^{K} p_k^{(m)} \log p_k^{(m)}}{\log(1/K)}, \qquad (2)$$

where $p_k^{(m)}$ is the probability mass for k-th class label. If $C^{(m)}$ is smaller than a pre-defined threshold τ, the predictions of layer m is considered confident. Otherwise, it is considered in-confident.

We use a patience counter pct to store the number of times that the predictions remain confident in consecutive layers. Formally, at layer m, $pct^{(m)}$ is calculated as

$$pct^{(m)} = \begin{cases} pct^{(m-1)} + 1, & \text{if } C^{(m)} < \tau, \\ 0, & \text{otherwise.} \end{cases} \qquad (3)$$

We stop inference early at layer m when $pct^{(m)}$ reaches a predefined integer number t (the patience parameter). If this condition is never fulfilled, we use the final classifier M for prediction. In this way, the model can make an early exit without passing through all layers to make a prediction.

Our method draws advantages from the previous score-based early exiting method (Teerapittayanon et al., 2016) and patience-based method (Zhou et al., 2020) and overcomes their shortcomings. First, the score-based early exiting method relies on the confidence score from only the current layer. However, as revealed by Szegedy et al. (2014); Jiang et al. (2018), prediction of probability distributions (i.e., softmax scores) suffers from being over-confident to one class, making it an unreliable metric to represent confidence. In our method, early exiting occurs when a group of consecutive layers is confident, thus making the early exiting decision more reliable. Second, with a patience-based early exiting method like PABEE, when a deeper layer tries to correct the predictions, the patience count resets to zero. As a result, PABEE is less efficient than our PCEE-BERT. Third, since our method is a combination of PABEE and the score-based method, one can conveniently adjust the threshold and patience parameters to control the speed-up ratios, which makes our method more flexible than PABEE.

4 Experiments

4.1 Datasets

We evaluate our proposed approach to the classification tasks on the GLUE benchmark. We only exclude the STS-B task since it is a regression task, and we exclude the WNLI task following previous work (Devlin et al., 2018; Xu et al., 2020).

4.2 Baselines

We compare our approaches with three groups of baselines.

Backbone models: We mainly choose the BERT-base model open-sourced by Devlin et al. (2019) as the backbone model. We also investigate whether our method is applicable across different backbones, so we also run ablation experiments with ALBERT base (Lan et al., 2020) and TinyBERT$_6$ (Jiao et al., 2020b).

Budgeted exiting: In the section 2.2 we have introduced how to train a multi-exit BERT. Once the multi-exit BERT, we can conduct budgeted early exiting, that is, asking a designated intermediate layer to encode and predict all the samples. Budgeted exiting is a direct way to speed up BERT's inference, but it is not instance adaptive. Some of the samples may not need to go through many of the BERT's layers, and the others may be more difficult and require deeper feature encoding from the deeper layers of BERT.

Dynamic exiting: In this part, we compare our methods with a series of strong baselines, including BranchyNet (Teerapittayanon et al., 2016), Shallow-Deep (Kaya et al., 2019), BERxiT (Xin et al., 2021), and PABEE (Zhou et al., 2020). Note that PABEE can not flexibly adjust the average inference layers on a task once the patience parameter is set. So we will adjust the thresholds in the other baselines and our PCEE-BERT so that all methods' number of average inference layers are close.

4.3 Evaluation of early exiting method

In this work, we strictly follow the GLUE benchmark to report the performances metrics on each task. Note that this work focuses on investigating the early exiting of PLMs. Thus we have to consider the trade-offs between performance and efficiency. Following PABEE (Zhou et al., 2020), we mainly report the speedup ratio as the efficiency metric. Assume the PLM backbone has N layers in total. For each test sample x_i ($i \in \{0, 1, ..., N\}$), the early exiting layer is m_i, then the average speedup ratio on the test set is calculated by

$$\textbf{Speedup} = 1 - \frac{\sum_1^N m_i}{\sum_1^N M}. \tag{4}$$

We choose this efficiency metric for the following reason: (1) it is linear w.r.t. the actual amount of computation; (2) according to our experiments, it is proportional to actual wall-clock runtime and is also more stable across different runs compared with actual runtime due to randomness by other processes on the same machine.

4.4 Experimental settings

Training We add a linear output layer after each intermediate layer of the pre-trained BERT or other backbone models as the internal classifiers. We perform grid search over batch sizes of 16, 32, 128, and learning rates of 1e-5, 2e-5, 3e-5, 5e-5 with an Adam optimizer. The hyper-parameters are selected via the 5-fold cross validation on the train set of GLUE tasks. We implement PCEE-BERT on the base of Hugging Face's Transformers (Wolf et al., 2020). Experiments are conducted on a single Nvidia V100 16GB GPU.

Inference Following prior work on input-adaptive inference (Teerapittayanon et al., 2016; Kaya et al., 2019), inference is on a per-instance basis, i.e., the batch size for inference is set to 1. This is a common scenario in the industry where individual requests from different users (Schwartz et al., 2020b) come at different time points. We report the median performance over five runs with different random seeds.

4.5 Main results

In Table 2, we report the performance comparisons of each method on the GLUE benchmark under three different speedup settings. The three speedup settings are: (1) 74% to 82% speedup; (2) 46% to 54% speedup; (3) 23% to 28% speedup. Since PABEE can not flexibly adjust the speedup ratios for a given patience parameter and a given task, we adjust the hyper-parameters (such as entropy threshold) of our PCEE-BERT and the other baselines to achieve similar speedups with PABEE. The results in table 2 clearly show that our PCEE-BERT

Table 2: Experimental results of different early exiting methods with the same fine-tuned BERT backbone on the GLUE benchmark. The results show that PCEE-BERT is effective in accelerating BERT's inference with less performance loss compared with the baseline methods.

method outperforms the baseline methods under different speedup ratios. Table 2 also shows that the PABEE method is the best performing baseline. Thus, in order to further analyze and better visualize the results, we draw the score-speedup curves (in Figure 3) for budgeted early exiting, PABEE and PCEE-BERT, on the QNLI and MRPC tasks. [1] With Table 2 and Figure 3, we can make the following observations:

- Although it is clear that PABEE performs better than the other baselines when the speedup ratio is around 50% or 25%, its advantages over the other baselines with the 75% speedup ratio is relatively small. With the 75% speedup ratio for seven GLUE tasks, it performs better than the score-based methods only on three tasks. This observation motivates us to improve PABEE by combining its patience-based early exiting mechanism with the score-based ones.

- Our PCEE-BERT consistently performs better than the baseline methods, especially when the speedup ratio is large. Note that our PCEE-BERT also consistently outperforms the budgeted exiting speedup ratios, which the other baselines do not achieve. Figure 3(b) and 3(a) show that score-speedup curve for PABEE is interleaving with that of the budgeted exiting. However, the score-speedup curve for PCEE-BERT distances itself from the others for most of the GLUE tasks.

- The overthinking problem is prevailing in the GLUE benchmark, and our PCEE-BERT early exiting can effectively take advantage of this phenomenon. For 6 of the GLUE tasks, PCEE-BERT can outperform BERT-base with a 25% (or more than) speedup ratio. And for 2 of the GLUE tasks, PCEE-BERT can outperform BERT-base with a 50% (or more than) speedup ratio.

Putting performance comparisons aside, one benefit of PCEE-BERT is that it is flexible since by adjusting the threshold and the patience parameter, it can easily control the average inference layers and cover (or achieve values close to) any speedup ratios.[2]

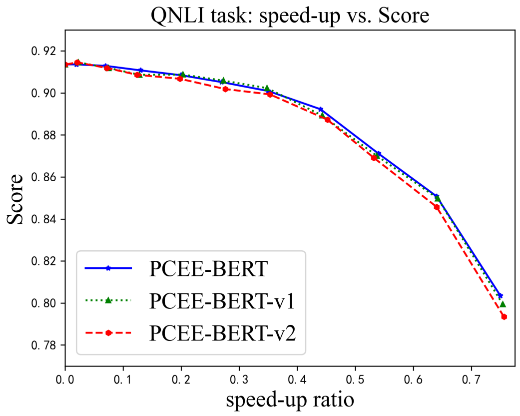

Figure 4: This figure demonstrates that PCEE-BERT can work with other confidence measures.

4.6 Ablation studies

4.6.1 Ablation on the confidence measures

Note that our PCEE-BERT is a novel combination of PABEE and BranchyNet. Thus PCEE-BERT mainly uses the entropy of predicted distributions as the confidence measure of an intermediate layer. However, can PCEE-BERT work with the other confidence measures, such as Shallow-Deep? We switch the entropy-based confidence level $C^{(M)}$ (Equation 2) with that from Shallow-Deep (Kaya et al., 2019):

$$C^{(M)} = \text{Argmax}_k p_k^{(m)}, \tag{5}$$

and we will call this version of PCEE-BERT as PCEE-BERT-v1. Note that PCEE-BERT-v1 does not require a newly fine-tuned model.

With BERxiT, we can come up with PCEE-BERT-v2. Following BERxiT, PCEE-BERT-v2 fine-tunes the multi-exit BERT with a fully connected layer right after each transformer block designated to evaluate the confidence score $C^{(M)}$ for early exiting at that layer. $C^{(M)}$ is learned along with the training of intermediate classifiers. Note that PCEE-BERT-v2 can not reuse the fine-tuned checkpoints used in PCEE-BERT and requires one to fine-tune the BERT backbones on the task at hand.

We conduct the experiments on the QNLI tasks, and the results are reported in Figure 4. We can see that PCEE-BERT-v1 and PCEE-BERT-v2 perform comparably to PCEE-BERT. The results show that the proposed PCEE-BERT early exiting mechanism is off-the-shelf, and the reason for the success of our PCEE-BERT is its early exiting mechanism,

---

[1] The score-speedup curves for the other five GLUE tasks can be found in the appendix.

(a) ALBERT base as backbone

(b) TinyBERT$_6$ as backbone

Figure 5: Ablation study on alternative PLMs.

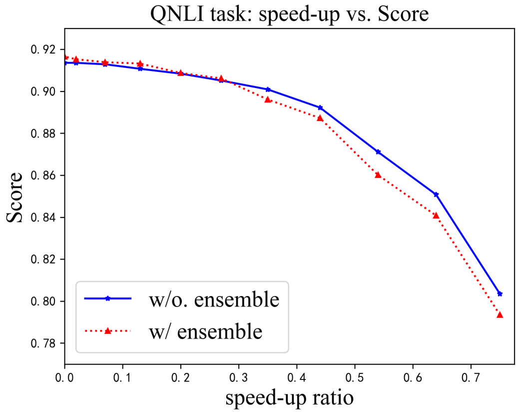

Figure 6: Results for ablation study of whether PCEE-BERT should apply the cross-layer ensemble.

that is, early exit if a group of consecutive exits is confident for their predictions.

4.6.2 Ablation of PLM backbones

In the main experiments, we use BERT as the pre-trained backbone model. However, PCEE-BERT can also work with the other types of pre-trained backbones, such as ALBERT base (Lan et al., 2020) and TinyBERT$_6$ (Jiao et al., 2020b). We conduct the experiments on the QNLI task with these two backbone models, and results are presented in Figure 5(a) and 5(b). We can see that when using the other pre-trained backbones, PCEE-BERT also performs better than the baseline methods.

The results for PCEE-BERT on the TinyBERT also convey an important message: as an inference speedup method, our PCEE method can work alongside the model compression methods to further reduce the latency of BERT.

4.6.3 Ablation of cross-layer ensemble

Since we have a prediction module at each layer of BERT, we can conduct model ensemble across layers that the forward pass has gone through already. In Figure 6, we conduct the ablation studies on the RTE and QNLI tasks. According to Figure 6, cross-layer ensemble leads to performance degradation when the speedup ratio is large, while when the average inference layers is close to the number of BERT's transformer blocks M, cross-layer ensemble results in slight improvements. In conclusion, the cross-layer ensemble does not result in consistent performance improvements.

A possible application of the above results is to apply the cross-layer ensemble when a low speedup ratio is applied. And when we ask the model to exit early in the shallow layers, the cross-layer ensemble is not used.

4.6.4 PCEE-BERT are effective for image classification

Our main experiments are conducted on BERT, a pre-trained language model, and the GLUE benchmark, a series of natural language understanding tasks. However, our PCEE-BERT method is a plug-and-play early exiting and can be applied to models and tasks of different modalities. To demonstrate the effectiveness of PCEE-BERT on the image classification task, we follow the experimental settings in PABEE (Zhou et al., 2020). We conduct experiments on two image classification datasets, CIFAR-10 and CIFAR-100 (Krizhevsky, 2009). The ResNet-56 model (He et al., 2016) serves as the backbone, and we compare PCEE-BERT with PABEE. We place an exiting classifier

Method	CIFAR-10		CIFAR-100	
	speed-up	Acc.	speed-up	Acc.
ResNet-56	0.0	91.8	0.0	68.6
PABEE	77%	78.3	76%	51.2
	52%	86.7	48%	62.5
	26%	91.9	24%	69.2
PCEE-BERT	76%	81.2	74%	55.6
	51%	87.3	49%	64.8
	25%	92.1	24%	69.4

Table 3: Experimental results of PCEE-BERT when applied in the image classification tasks.

at every two convolutional layers. We set the batch size to 128 and use an SGD optimizer with a learning rate of 0.1.

Table 3 reports the results. PCEE-BERT outperforms PABEE when early exiting at different speedup ratios. In addition, the performance advantages of PCEE-BERT are larger when the speedup ratio is large, which is also observed in the NLP tasks. And PCEE-BERT outperforms the original ResNet-56 on both tasks even when it provides around 25% speedup.

5 Conclusion

In this work, we propose PCEE-BERT, a novel efficient inference method that can yield a better performance-speed trade-off than the existing early exiting methods. PCEE-BERT adopts BERT as the backbone model and makes the exiting decision if there are enough intermediate layers to make confident predictions. The confidence level is measured by the entropy of the predicted distributions. Experiments on the GLUE benchmark demonstrate that our method outperforms the previous SOTA early exiting methods, especially when the speedup ratio is large. In addition, PCEE-BERT can achieve different speedup ratios by adjusting the patience parameter and the confidence threshold, which makes it more flexible in industrial usage. Ablation studies show that: (a) our PCEE-BERT can adopt different confidence measures, such as maximum probability mass; (b) our method performs consistently well on different PLMs and can work together with model compression methods to speed up the BERT's inference; (c) our PCEE-BERT also performs well on computer vision tasks.

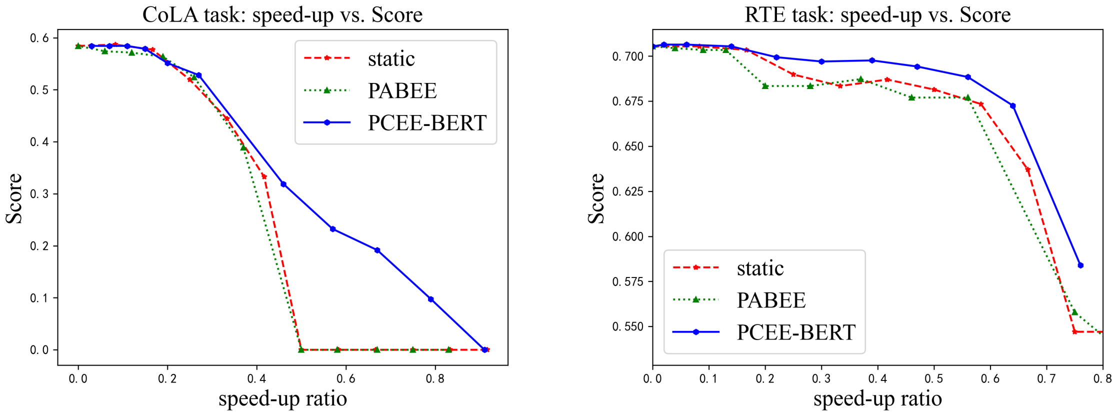
A Appendix

A.1 Quality–efficiency trade-offs on GLUE benchmark tasks.

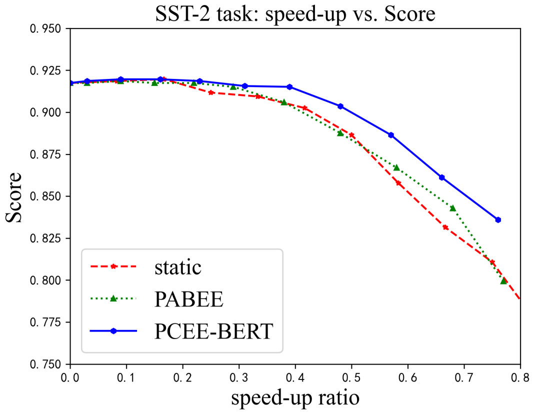
In the main content, we present the quality–efficiency trade-offs curves for four GLUE tasks. And here we put the results of the other three tasks in Figure 7.

A.2 Demonstrating PCEE-BERT can cover (or achieve values close to) any speedup ratios

PCEE-BERT's speedup ratio can be conveniently adjusted by setting different values for the patience parameter and the confidence threshold. To validate our claim, we alternate the threshold among 100 points between 0.0 to 1.0 when the patience parameter takes the value of 1, 2, 3, 6. The average numbers of inference layers are reported in the scatter plot (Figure 8). We can see that by adjusting the threshold and the patience parameter, one can easily control the average inference layers and cover (or achieve values close to) any speedup ratios.



(a) CoLA task (b) RTE task



(c) SST-2 task

Figure 7: Performance–efficiency trade-offs using different exiting strategies. We can see that our PCEE-BERT consistently outperforms the strong baseline, PABEE, especially when the speed-up ratio is large.

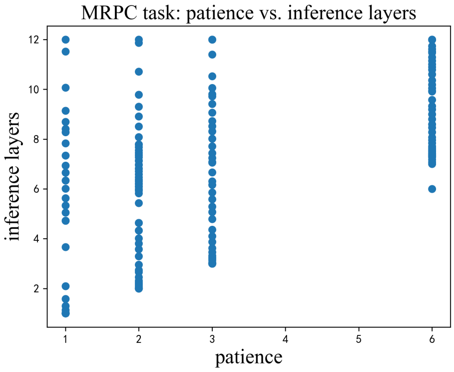


Figure 8: This figure demonstrates that PCEE-BERT can cover (or achieve values close to) any speedup ratios.

Learning to Repair: Repairing model output errors after deployment using a dynamic memory of feedback

Abstract

Large language models (LMs), while powerful, are not immune to mistakes, but can be difficult to retrain. Our goal is for an LM to continue to improve after deployment, without retraining, using feedback from the user. Our approach pairs an LM with (i) a growing memory of cases where the user identified an output error and provided general feedback on how to correct it (ii) a *corrector model*, trained to translate this general feedback into specific edits to repair the model output. Given a new, unseen input, our model can then use feedback from similar, past cases to repair output errors that may occur. We instantiate our approach using an existing, fixed model for *script generation*, that takes a goal (e.g., "bake a cake") and generates a partially ordered sequence of actions to achieve that goal, sometimes containing errors. Our memory-enhanced system, FBNET, learns to apply user feedback to repair such errors (up to 30 points improvement), while making a start at avoiding similar past mistakes on new, unseen examples (up to 7 points improvement in a controlled setting). This is a first step towards strengthening deployed models, potentially broadening their utility.[1]

1 Introduction

Language models (LMs) have achieved remarkable success on many tasks (Wang et al., 2019; Talmor et al., 2019), but they are still prone to mistakes (Bender and Koller, 2020). Correcting mistakes by retraining is not always easy due to the cost and/or unpredictability of how additional training data will change the model. Instead, our goal is to allow users to correct such errors directly through interaction, without retraining – by giving corrective feedback on the model's output. Our approach is to maintain a growing, dynamic memory of such feedback, and use a trained *corrector model* to apply such feedback to repair the model output. By doing so, the system can also potentially fix output errors for new unseen inputs using feedback from similar, past cases. The ability to leverage a fixed trained model without re-training could save costs and have a positive environmental impact.

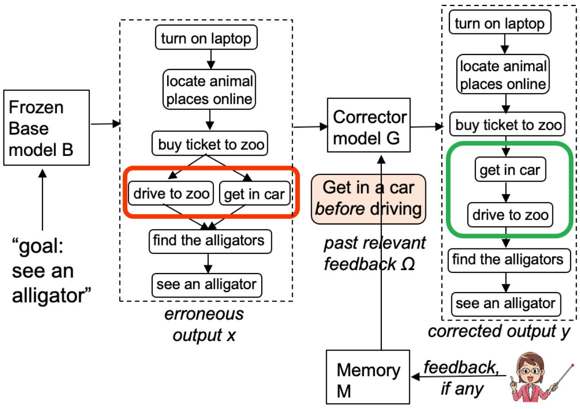

Figure 1: Given a frozen model $\mathbf{B}$, we train a *corrector model* $\mathbf{G}$ to apply feedback from a user about errors made by the original model. In the example, $\mathbf{B}$ has generated a script with an error in, stating that "driving" and "getting in a car" can occur in any order (red box). The user provides general feedback ("Get in a car before driving"), and $\mathbf{G}$ operationalizes this to generate a corrected graph (by predicting and applying a graph edit operation) in which "get in car" happens first (green box). The feedback is stored in a memory $\mathcal{M}$ so it can also be retrieved to repair similar, future errors.

We consider the class of problems where the model's output is *repairable*, namely a structured output that is (typically) nearly correct, and fixable through a small number of edit operations. Our system is general and admits a general graph based input, so in principle it applies to a large number of tasks. In this paper, we apply our approach to the task of *script generation* that provides a natural setting for users to critique, and has applications in smart assistants (Zhang et al., 2021). We use an existing, fixed model: proScript (Sakaguchi et al.,

---

[*] Equal Contribution

[1] Our code and data is available at `https://github.com/allenai/interscript`

Findings of the Association for Computational Linguistics: NAACL 2022, pages 339 - 352
July 10-15, 2022

2021) that satisfies the constraint of the model's output to be repairable. proScript takes as input a goal to achieve (expressed in natural language), and outputs a partially ordered sequence of steps - a *script* - required to achieve that goal. Our interest here is not in proScript itself, but in what to do when proScript's output contains an error.

This instantiation of our approach is illustrated in Figure 1. Here, proScript has generated a script $\mathbf{x}$ to achieve the goal "see an alligator", but the script contains an error: it states that the steps of "driving to the zoo" and "get in car" can be applied in any order. To repair this, the user provides the general feedback "Get in a car before driving". The corrector model $\mathbf{G}$ then takes that feedback and the erroneous script, translates it into appropriate edit operations on the script, and applies those edits to generate a corrected script ($\mathbf{y}$ in Figure 1). The feedback is stored in memory $\mathcal{M}$ so it can also be retrieved in the future. Our system, FBNET, comprises the corrector module $\mathbf{G}$, the memory $\mathcal{M}$, and searching and writing operations. To train our system, we collect examples of bad outputs, general feedback, and specific edits that the feedback should translate to (Section 4.2). This allows $\mathbf{G}$ to learn how to translate general feedback into specific edits to apply. Pairing $\mathbf{G}$ with the memory $\mathcal{M}$ allows FBNET to repair new, unseen scripts containing similar errors to the one the user corrected.

Our approach loosely follows some early AI systems that maintained a memory of the output problems and how to fix them (Sussman, 1973; Hammond, 1986; Riesbeck, 1981), but here, we use neural methods and interact with a user to provide corrective feedback. It also builds on the idea of allowing users to specify edits in natural language, e.g., NLEdit (Elgohary et al., 2021), except we use *general* user feedback (then translated to example-specific edits by $\mathbf{G}$) and add a memory so that feedback can also be automatically reused.

We evaluate FBNET along two dimensions: (a) How well does FBNET interpret NL feedback? (b) How well can FBNET learn from prior mistakes? We find that (a) it uses NL feedback effectively to repair script errors, with +30% (absolute) improvement over a baseline that does not use feedback, and that (b) it makes a start at avoiding past mistakes (+7% (absolute) improvement in a controlled setting). Although these results are only for a single deployment of our general approach, they suggest that memory-based architectures can help deployed models continue to improve with time, without retraining, potentially broadening their utility.

2 Related work

There have been numerous approaches to using user feedback to improve model performance, including:

(1) **Providing additional training examples:** Dasgupta et al. (2019) show how a user can correct bad model behavior by carefully selecting new training examples for the system to learn from, a style of interactive active learning (Settles, 2012).

(2) **Marking/scoring the system's answer(s):** In SHRDLURN, the user provides feedback by identifying which of the system's alternative interpretations of a user command is correct (Wang et al., 2016).

(3) **Providing hints:** (Mehta and Goldwasser, 2019) show how a system can learns to understand regional (e.g., "top left") and directional (e.g., "move down") hints from the user for a (simulated) robot.

(4) **Provide additional information:** In TeachYourAI (Talmor et al., 2020), given a wrong answer to a question, users can enter NL facts and rules to use as context when reasking the question, to (ideally) produce the correct answer.

(5) **Correcting bad answers:** In the semantic parsing task of NL-to-SQL, NLEdit learns to interpret and apply syntactic edit operations from the user expressed in NL, e.g., "replace course id with program id." (Elgohary et al., 2021).

These methods all augment/replace the standard use of automated answer feedback (if available), e.g., testing whether a semantic parse correctly executes to the correct answer, e.g., (Zettlemoyer and Collins, 2005), sometimes using unsupervised techniques to generate additional training data, e.g., BIFI (Yasunaga and Liang, 2021).

Our work expands on the above approaches in two important ways. First, users provide *general* feedback in NL, that can potentially be applied to *multiple* cases (rather than just correcting a specific instance). The corrector model $\mathbf{G}$ is trained to operationalize that advice in different ways for different examples appropriately, in contrast to (say) NLEdit where the user-provided specific corrective edits for a single example only.

Second, we use a feedback memory, allowing feedback to be reused. While adding external mem-

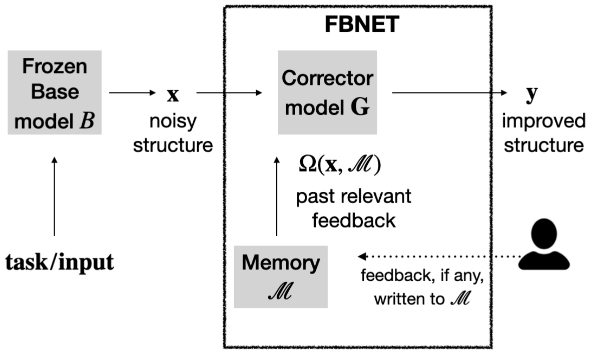

Figure 2: Proposed architecture: (left) $\mathbf{B}$ does not account for user feedback. (right) FBNET maintains a memory $\mathcal{M}$ of corrective feedback, and searches for feedback from prior queries with similar error intent as $\mathbf{x}$ using a retrieval function Ω. $\mathbf{x}$ is then concatenated to the retrieved feedback to form the input to the corrector model $\mathbf{G}$. Users can also give new feedback which is added to $\mathcal{M}$. In this work, we focus on script generation models that might generate an erroneous script which are correctable using an edit (feedback).

ory to neural systems is not new, e.g., RAG (Lewis et al., 2020), REALM (Guu et al., 2020), ours is the first to utilize a memory of prior user feedback to improve future neural model performance. This can be viewed as a modern approach to failure-driven reminding, an essential theme in earlier AI and Cognitive Science research (Riesbeck, 1981; Schank and Leake, 1989; Ross, 1984).

3 FBNET

3.1 Overview of the Architecture

Fig. 2 gives an overview of FBNET. The input is a potentially noisy graph $\mathbf{x}$ generated by a base model $\mathbf{B}$ and the output $\mathbf{y}$ is a corrected graph. At inference time, i.e., after deployment, a user can critique $\mathbf{y}$ by providing natural language feedback $\mathbf{fb}$ on an error $\mathbf{e}$. As output, the model generates the corrected graph $\mathbf{y}$ that accounts for $\mathbf{fb}$.

The corrector model $\mathbf{G}$ is responsible for improving the potentially noisy output from $\mathbf{B}$. $\mathbf{G}$ achieves it using user feedback stored in a continuously updated memory $\mathcal{M}$.

The Memory $\mathcal{M}$ is a growing lookup table of key-value pairs: key ($\mathbf{x}_i$) - value ($\mathbf{fb}_i$), where $\mathbf{x}_i$ is a particular incorrect graph, and $\mathbf{fb}_i$ is the corresponding feedback. This memory supports lookup (read) and write operations. Given a new query $\mathbf{x}$, FBNET uses feedback $\mathbf{fb}$ from similar, prior queries in the memory to enrich $\mathbf{x}$. This feedback $\mathbf{fb}$ is retrieved using the lookup function $\Omega(\mathbf{x}, \mathcal{M})$. The corrector then combines $\mathbf{fb}$ with $\mathbf{x}$, and generates $\mathbf{y}$. The write operation is used whenever a user gives new feedback.

3.2 Assumptions

We make two assumptions on the characteristics of the feedback and the input.

A1. Base model $\mathbf{B}$'s output is **repairable**: $\mathbf{B}$ typically produces syntactically correct output graph but can have semantic errors that the user can recognize and describe using natural feedback. For example, the script in Figure 1 is repairable.

A2. Feedback is **reusable**: If two examples i, j have similar errors e_i and e_j then the feedback fb for one should apply to the other, i.e., $(e_i \sim e_j \Leftrightarrow fb_i \sim fb_j)$

3.3 Memory $\mathcal{M}$ and Ω

As mentioned, the feedback is stored in a memory of key ($\mathbf{x}$), value ($\mathbf{fb}$) pairs. Ω is a retrieval function that matches a query key ($\mathbf{x}_j$) to a similar $\mathbf{x}_i$ in memory implicitly on the similarity of the errors e_i and e_j.

3.4 Corrector model G

The graph corrector model $\mathbf{G}$ generates an improved output $\mathbf{y}$ given a noisy graph $\mathbf{x}$ and $\mathbf{fb}$. This is done in a two-step process, (i) learning to predict a graph edit operation $\mathbf{y}^e$ given $\mathbf{x}$ and $\mathbf{fb}$ (ii) using simple graph operations to apply $\mathbf{y}^e$ to $\mathbf{x}$ to produce $\mathbf{y}$. Our approach of generating an edit instead of directly generating the corrected graph is beneficial for two reasons. First, generating edits is simpler for the model than generating entire graphs. Second, it simplifies evaluation metrics as it is much simpler to compare two smaller generated edits. Note that we can deterministically fix a script given an edit. Thus, the two-step process helps us achieve the same end goal (corrected scripts from noisy scripts and feedback).

3.5 Training and Inference

As mentioned, the graph corrector $\mathbf{G}$ first generates an edit $\mathbf{y}^e$, which is applied to the incorrect graph $\mathbf{x}$ to generate the correct graph $\mathbf{y}$. We need a corpus of $(\mathbf{x}, \mathbf{fb}, \mathbf{y})$ to train this system. Specifically, we extract an edit from each such tuple, where edit y^e is the difference between the output $\mathbf{y}$ and the input $\mathbf{x}$. $\mathbf{x}$ and $\mathbf{y}$ can be expressed in a string representation using a graph description language such as

DOT. We then train a language model to estimate $P_\theta(y^e \mid \mathbf{x}, \mathbf{fb})$, which allows us to generate an edit for a given $(\mathbf{x}, \mathbf{fb})$ using greedy sampling, where θ denotes the parameters of the language model.

4 Application: Script Generation

4.1 Task

We instantiate our framework for the task of *script generation*. Formally, the script generation task (Sakaguchi et al., 2021) takes as input a scenario and generates a script $G(V, E)$, where V is a set of essential events $\{v_1, ...v_i, ...v_{|V|}\}$ and E is a set of temporal ordering constraints between events $\{e_{ij}\}$ which means that the events v_i must precede the event v_j ($v_i \prec v_j$). Partial ordering of events is possible, e.g., you can wear a left sock and a right sock in any temporal order. To solve this task, script generation models are required to *generate* events (V) and predict the edges (E) jointly. See Figure 3 for an example.

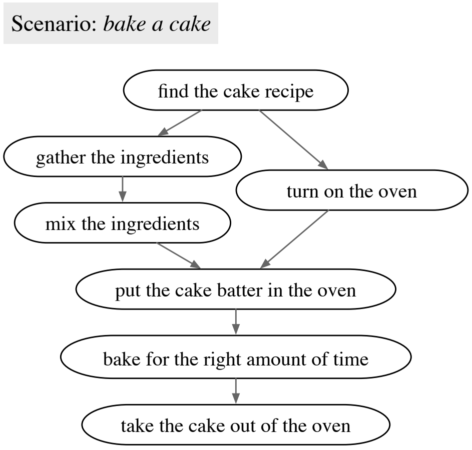

Figure 3: An example of a *script* in Sakaguchi et al. (2021). In a script generation task, models take the goal as the input and generate a (possibly) partial-order graph, which consists of essential steps and their ordering.

PROSCRIPT$_{gen}$ (Sakaguchi et al., 2021) is a recently released model that, given a goal, generates V and predicts the edge structure E jointly. It is based on the T5-XXL model (11B parameters) and generates the script as a graph in DOT format. The authors report that the DOT format is always valid at inference time and that V and the graph structure are generally of high quality. They characterize the graph edits required to correct a generated script (such as removing a node, adding a node, changing edge order, etc.). Mechanical Turk workers could repair most of the generated scripts within a few edits (typically an edit distance of 5) - we further validate this in Appendix §8.1. This makes for an attractive use-case for interactive learning because the generated content from the model is repairable through user feedback.

4.2 Feedback Data Collection

To train the corrector G, as well as evaluate our approach, we collected a set of (x, fb, y) tuples using crowdworkers, where x is a possibly erroneous script generated by PROSCRIPT$_{gen}$, fb is general feedback about the error (if any), and y is the corrected script. In practice, crowdworkers specified the edits to x to create y (using simple graph operations we can generate $\mathbf{y}$ from $\mathbf{y}^e$– see Table 7 for an example). We collected 1542 tuples of data, randomly splitting it into 843 train, 154 validation, and 545 test points. Examples of the resulting dataset are shown in Table 1.

4.3 Training the Corrector Model

We initialize θ with a checkpoint from the text-to-text pre-trained T5 transformer (Raffel et al., 2020) and fine-tune on our dataset. We use the default hyperparameters (including the Adafactor optimizer) in the T5 library.[2] We fine-tune a T5-XXL model for the main results, fine-tuned for 5,000 steps (batch size 8), selecting the checkpoint with the highest validation score (usually the final step). To implement the memory $\mathcal{M}$, we use a BERT-based Sentence Transformer to encode x (Reimers and Gurevych, 2019), and use cosine distance with a threshold of 0.9 to find a matching key $\mathbf{x}_m$. We leave the investigation of more complex retrieval functions (e.g., using attention mechanism to future work.)

5 Experiments

We empirically evaluate two questions:

RQ1. **How well does FBNET interpret NL feedback?** Specifically, we measure how well FBNET can translate general feedback **fb** from a user into the correct repair edit on an imperfect script x. The main focus of RQ1 is to test the performance of **G** in the pipeline (Fig. 2)

RQ2. **How well can FBNET learn from prior mistakes?** We make the same measurement, but using feedback **fb** recalled from similar,

Table 1: Some examples of the data points and model predictions. $\mathbf{y}^e$ takes the form: `<EDIT TYPE>` over `[<ARG>]` at `<LOCATION>` The dataset contains partial order points as well, but they are omitted here for simplicity.

previous examples. The main focus of RQ2 is to test the performance of $\mathcal{M}$ and Ω.

Metrics To compare the gold edit $\mathbf{y}^{e^*}$ and the generated edit $\mathbf{y}^{\hat{e}}$, we use standard metrics used to evaluate generated text. We report the following metrics:

- **Exact match**: EM gives a score of 1 if $\mathbf{y}^{e^*}$ is equal to $\mathbf{y}^{\hat{e}}$ and 0 otherwise.
- **Generation metrics**: We report standard generation metrics BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) to account for similar but not exact matches. We use the implementation released in the metrics package of the GEM-benchmark (Gehrmann et al., 2021).[3]

We report these metrics over the entire edit: EM, BLEU, ROUGE. The components of $\mathbf{y}^e$ broadly follow a template: `<EDIT TYPE> over [ARG] at <LOCATION>` (see Table 1). This allows comparison of the location or edit type in $\mathbf{y}^{e^*}$ and $\mathbf{y}^{\hat{e}}$: EM $_{loc}$, BLEU $_{loc}$, ROUGE $_{loc}$ and EM $_{type}$, BLEU $_{type}$, ROUGE $_{type}$

Baseline As baseline, we train a model that does not use any feedback (we call this, NO-FB) and is trained only with *input* = *erroneous script* and *output* = *edit*. The language model used in this baseline and FBNET is the same (T5-XXL), allowing a meaningful comparison.

---

[3] https://github.com/GEM-benchmark/GEM-metrics/

	EM	EM_{loc}	EM_{type}	BLEU	ROUGE
NO-FB	3.5	9.7	30.4	21.7	39.0
FBNET$_o$	**38.6**	**45.8**	**69.3**	**54.2**	**70.6**

Table 2: **Interpreting NL Feedback:** Correctness of Predicted Edits .... Given an erroneous script x, and general feedback fb from the user, FBNet perfectly predicts the specific repair edits 38% of the time (EM, exact match) - an order of magnitude better than a baseline NO-FB predicting the repair from x alone. EM_{loc} and EM_{type} compare just parts of the edit sequences (locations/types of the required edits, respectively), while BLEU and ROUGE are softer matching metrics.

5.1 RQ1: How well does FBNET interpret NL feedback?

To measure how well the graph corrector $\mathbf{G}$ learns to interpret NL feedback, we provide oracle feedback to FBNET, and we call this FBNET$_o$. Table 2 shows that FBNET$_o$ learns to react to the feedback, as indicated by a sharp increase in both the exact match scores and automated metrics. Further, we note that the model is good at identifying the error type that the feedback indicates. Still, it is difficult for the model to localize the error in the graph, probably because the location is not explicitly mentioned in the feedback, and the model must infer it.

How consistently does FBNET interpret similar feedback? In ~15% of the data points, multiple $\mathbf{fb}$ can lead to the same $(\mathbf{x}, \mathbf{y})$ pair. FBNET is expected to behave consistently for such re-phrasings of $\mathbf{fb}$. The model consistently produces exactly the same $\mathbf{y}$ for $\mathbf{fb}$ re-phrasings $\sim$ 60% of the time. Furthermore, we observe majority agreement as the number of $\mathbf{fb}$ re-phrasings for a $(\mathbf{x}, \mathbf{y})$ pair increases. In our analysis, a large proportion of the inconsistent edits occur because different $\mathbf{fb}$ phrasings prompt the model to generate slightly different, but semantically similar edits: see Table 3 for an example.

feedback	predicted edit
The feedback is if a person is going to open a book, they need to choose one first	insert node 'choose a book to read' before 'open the book'
The feedback is you can't open something you're not holding	insert node 'get the book out of the bag' before 'open the book'

Table 3: Multiple feedbacks for the same ($\mathbf{x}$, $\mathbf{y}$). Here, $\mathbf{x}$ is: You are given a plan to read to child. decide which books to read, open the book, read the book to the child, turn the pages ... . $\mathbf{y}^e$ is *insert node 'pick a book off the shelf' before 'open the book'*

How well can FBNET handle wrong feedback? While the ability to react to feedback is a desired trait for FBNET, we also want to ensure that the performance of FBNET is proportional to the quality of feedback. This will ensure that FBNET can act faithfully in settings where the feedback might be potentially misleading. We investigate this question by identifying lexically similar scripts but irrelevant feedback from the training set for each test example. Note that our setup easily allows us to test this hypothesis since the train/test/val splits were carefully designed to ensure no overlap between the examples. Thus the feedback from one example will typically not apply to another example. We find that with irrelevant feedback, the performance of FBNET drops to 3%. This shows that FBNET is sensitive to the quality of feedback, and no feedback is better than misleading and irrelevant feedback.

How well does FBNET perform across error types? FBNET$_o$ gets the highest performance (EM 63.0%) on wrong-step error type where $\mathbf{fb}$ typically contains negative words that signal the error type, and the model learns to localize the error node. One of the most challenging error types is partial order removal or addition (EM 10.5%). This can be attributed to the challenging localization involving multiple nodes that participate in a partial order. The lowest-performing is the missing step error type (EM 2.73). The reason for this low EM score is that the edit must *generate* the missing node, and EM undercounts the correctness of the generated text. Other metrics such as ROUGE are much higher validating that the model performs well on this error type. Section §9 Table 8 breaks down the performance of FBNET by error type.

5.1.1 Error analysis

We randomly sampled 50 instances from the test set where the model generates an incorrect edit (i.e., $EM = 0$). Our goal is to understand the typical errors made by the model and use the analysis to calibrate the findings in Table 2.

- **Lexical variation (36%)** Exact match underestimates the performance of our model (as the task involves generation). We find that more than 35% of the predicted edits are semantically similar (typically lexical variation) to the reference gold edit. Some examples include: insert node *picking a book...* vs, insert node *choosing a book to read.* Another kind of example is the model suggesting swapping the order of *edges A and B* while the reference edit swaps *edges B and A* - but both of these are equivalent.

- **Challenging feedback (24%)** This type of error occurs when the model fails to interpret a feedback because it is difficult to interpret e.g., the feedback is expressed abstractly. For example, for the goal "go to locker room," the generated script repeats the step "walk to the locker room.". However, the feedback is 'you can't go where you already are', and FBNET generates the edit "reorder edge between '⟨ walk towards the locker room , walk to the locker room ⟩' " , failing to interpret the feedback.
- **Error not localized (20%)** In about 20% of the failures, FBNET fails to localize the error given the feedback. For example, consider the erroneous input script about the goal *buy an xbox*: *1. go to the store 2. talk to the cashier 3. make the transaction 4. get the receipt 5. load the video game into the car 6. get into the car 7. take xbox home* The feedback is *after a person makes a transaction, they then head to their car*. The expected edit is: *insert node 'walk to the car' after 'get the receipt'*, but the predicted edit *insert node 'get into the car' after 'make the transaction'* does not correctly identify the erroneous node. The feedback points to making a transaction, but it also involves getting the receipt.
- **Alternative answers (16%)** We also encounter cases where there are multiple ways to correct a script. For example, an edit can be expressed as *insert node 'X' before 'step 4'* or *insert node 'X' after 'step 3'*. This comprises ∼ 16% of the errors.

In ∼32% cases, the model generates a correct edit that differs from the gold. Extrapolating this performance under-counting to the entire test set, the accuracy of FBNET in Table 2 would increase to ∼70% (+32%).

	EM	EM_{loc}	EM_{type}	BLEU	ROUGE
NO-FB	6.94	15.3	34.7	24.1	44.2
FBNET	16.72	20.9	56.9	32.5	48.5
FBNET$_o$	22.2	27.8	72.2	44.6	65.8

Table 4: **Learning from prior mistakes:** On the reuse dataset, given an erroneous script x, and feedback fb recalled from similar, prior examples, FBNet perfectly predicts the specific repair edits 16.7% of the time (or 20.9% the edit location and 56.9% the edit type), a promising start to learning from prior mistakes.

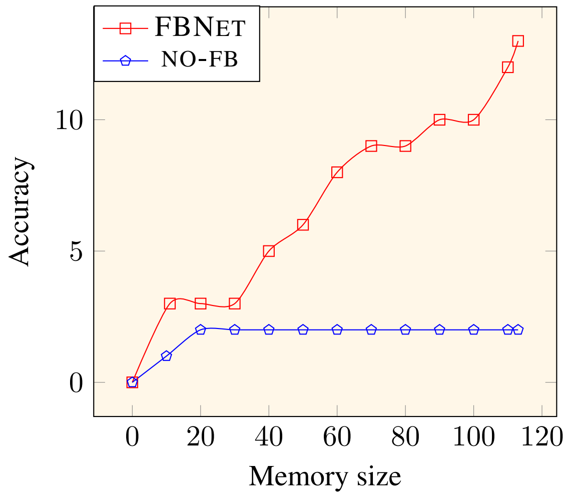

Figure 4: Performance on unseen examples (number of correct data points) improves as memory size grows. NO-FB baseline performance remains static. Note that accuracy is evaluated using exact match, and thus is a lower bound on the actual equivalence as exact match might miss rephrasings.

5.2 RQ2: How well can FBNET learn from prior mistakes?

Section §5.1 shows that the corrector $\mathbf{G}$ can utilize user-supplied feedback to fix an incorrect structure. FBNET combines $\mathbf{G}$ with a memory $\mathcal{M}$ of feedback, allowing us to leverage past feedback on new examples. This section presents a setup where feedback on previously seen inputs is used to fix new, unseen examples.

To investigate this setting, we create a new test set, called the *interaction-reuse set* or ISET. To create it, we randomly sample 72 test points (referred as *interaction-reuse set*-genesis or ISET-SOURCE) and perturb them linguistically to generate *interaction-reuse set*(also referred as ISET). The perturbations are performed on the salient entities in the script, including (i) linguistic perturbation on ∼20% samples (e.g., box → carton, package) and

Algorithm 1: FBNET inference on a stream of inputs with growing memory

```
Given: FBNet, $\mathcal{M}$, $\Omega$
Given: Set $\{\text{ISET} \cup \text{ISET-SOURCE}\}$ of $N$
       queries.
for $i \leftarrow 1, 2, \ldots, N$ do
    /* Check memory for feedback */
    $\bar{\mathbf{fb}}_i = \Omega(\mathbf{x}_i, \mathcal{M})$;
    /* Get corrected structure from
       FBNET. $\bar{\mathbf{fb}}_i$ can be empty. */
    $\mathbf{y}_i = \text{FBNET}\ (\mathbf{x}_i, \bar{\mathbf{fb}}_i)$;
    /* Get user feedback */
    $\mathbf{fb}_i$ = User feedback on $\mathbf{y}_i$;
    /* Grow memory with new
       feedback */
    Write $\mathbf{fb}_i$ to $\mathcal{M}$
end
```

(ii) the relatively harder analogical perturbation on the remaining $\sim$80% samples (e.g., bus → train, and how to lift blinds → how to open oven door because the event structure is analogical). The $\mathbf{y}^e$ to the original script also applies to the substituted script. We ensured that the perturbations did not introduce additional errors in the substituted script. This ensures that the *interaction-reuse set*now contains similar examples to the original test set, a condition that our original splits do not satisfy. There are a total of 72 data points in *interaction-reuse set*.

Continually learning using a memory of errors Examples in *interaction-reuse set* are randomly mixed with the original test set. This combined test set of queries Q is then evaluated using our setup as shown in Algorithm 1. Intuitively, *interaction-reuse set* allows us to simulate a setting where the system has been deployed in the wild, and end-users can query. Algorithm 1 runs the memory-based inference described in Section §3 (Figure 2). As the system is run through the stream of queries, we expect that i) the overall performance of the system will be better than no feedback, as some of the examples in the interaction set will provide meaningful feedback, and ii) the *running* performance of the system will improve with growing memory: the probability of relevant feedback being present for an unseen example increases with time, thus boosting the performance.

Our experiments show that FBNET meets both these expectations. First, Table 4 shows that retrieved feedback improves over no feedback by 10 points (exact match) and similarly in terms of BLEU and ROUGE scores, respectively. Further, Figure 4 shows a graph confirming that FBNET can improve continuously as memory grows.

6 Scope

In principle, we could apply FBNET to any task that satisfies the assumptions (§3.2). However, our approach has some limitations in practice, several of which merit further detailed follow-up work.

- **On Assumption A1:** We assume that the output of $\mathbf{B}$ is repairable. Such an assumption is only possible for models that generate mostly correct outputs and have errors that are easy to highlight for humans. In practice, this implies that our approach will most efficiently work in conjunction with modern language models (Bommasani et al., 2021) that are shown to be syntactically correct in form, but can produce output that lacks commonsense (Bender and Koller, 2020), making their output repairable.
- **On Assumption A2:** Having reusable, general feedback is costly and requires careful instructions to collect from general users and crowdworkers (e.g., we asked the crowdworkers how they would explain the model error to a five-year-old). As the domain of the task becomes more specialized, such as database query generation (Elgohary et al., 2021) or code correction (Yasunaga and Liang, 2020), collecting data to train $\mathbf{G}$ becomes difficult. Systems that produce structured explanations are better suited to our model (see Wiegreffe and Marasović (2021) for an overview), rather than specialized domains that require expert users to provide feedback (e.g., in database query generation).
- **Consistent memory:** We show in Section §5.1 that FBNET is sensitive to the appropriateness of the feedback. However, adversarial or incorrect feedback could pollute the memory and possibly make it inconsistent. There has been some recent work to ensure consistency of beliefs of a model (Kassner et al., 2021), and more effort is required in this direction to apply to more complex settings like ours.
- **Using multiple feedbacks:** Ω can be enhanced with more complex attention mechanisms that aggregate from multiple relevant memory entries and possibly generalize them. We conducted an initial experiment using attention and

found that we would need a larger dataset to train Ω effectively.

Advancements in these directions would further increase the applicability of FBNET. Still, there are several applications (Wiegreffe and Marasović, 2021) where our approach would currently apply in principle, or is easy to set up.

7 Summary

Our goal is to create a system that can continuously improve the structured output of a model. Our approach is to train an error correction model that uses natural language (NL) feedback to correct errors in that output. We have presented the first step towards this goal, showing that an error correction module can learn to interpret NL feedback successfully, resulting in 40% fewer errors in script generation. We have also described ongoing work on the next step, namely adding a memory layer where human feedback is stored and later retrieved efficiently. Together, these offer a possible path to systems that can continuously improve their output over time, with progressively less feedback and without retraining.

8 Appendix

8.1 Initial study on the errors of B (PROSCRIPT)

On PROSCRIPT's test set, we performed inference using the released checkpoint (both GPT-2 and T5-XXL based model). We then randomly sampled 30 generated graphs and manually wrote feedback for them. Similar to Sakaguchi et al. (2021), we found that the model makes repairable mistakes (leading to assumption A1 being satisfied). Further, we found there instances where a general principle feedback applies across more than one instances (e.g., you have to be near something to use it). (see Table 5).

What was the error	General principle feedback
Script was missing the step of not turning off the alarm after waking up	People don't leave their alarms ringing all day.
Script mentioned coming to the doorway and passing through it	One cannot walk through the doorway without opening the door first.
Script tells that getting in car and drive in zoo can be done in any order	People must get into a vehicle, before driving to any place.
Script is looking for a butterfly after placing it	You don't need to look for a butterfly if it's already in a container.

Table 5: Sample error and the corresponding general principle feedback that could, in principle, repair the model output.

On an average, there were about two mistakes present in the graphs. Often, the error was that the script was using an entity before having it (e.g., write on the paper comes before the node find the paper or reach for the paper). Thus, there seems to be a possibility of applying similar feedback to more than one example. We also found some cases where the script might have to be changed to adapt to special cases. For example, for a script *visit Disneyland*, an event *obtain a visa* might be required for some users. We believe the original ProScript dataset aims to generate widely applicable scripts and grounded in commonsense; rather than cover all possible outcomes.

On the surface, the generated scripts were of good quality. However, a closer look at the mistakes revealed that most of them could be attributed to the model lacking basic commonsense. For example, Figure 1 shows a typical mistake the model makes. This underscores the gap between the syntax and semantic correctness of machine-generated output in the context of automatic script generation. This observation is in-line with other NLP tasks (Bender and Koller, 2020) that distinguish the success of recent models on the correctness of form rather than the far-from-over goal of understanding of meaning.

8.2 Data collection

An average user could point out mistakes in the generated scripts, as a majority of the errors in generated scripts are caused by a lack of basic commonsense (§8.1). Consequently, we designed a Mechanical Turk task to provide feedback on mistakes. A broad overview of the annotation process is shown in Figure 5.

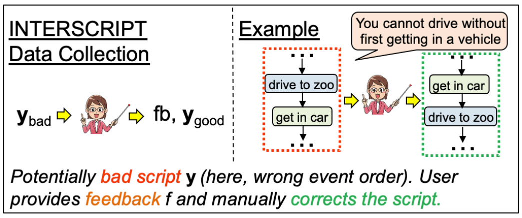

Figure 5: A broad overview of the annotation process. For actual annotation task (including the M-turk task template), see our code repository.

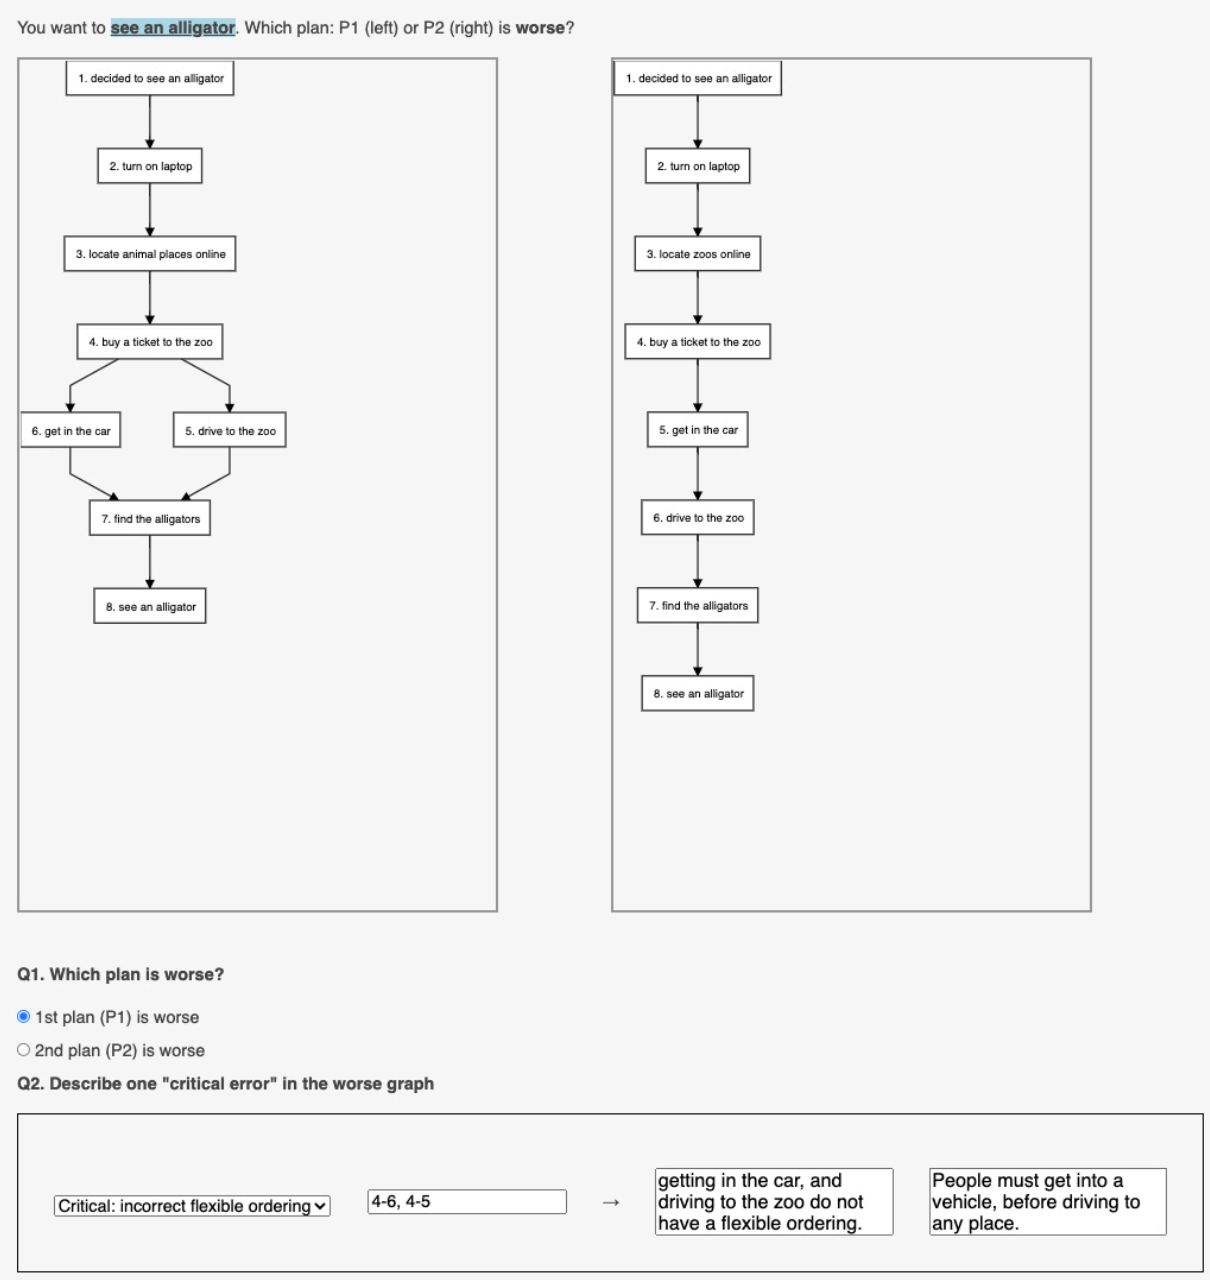
Annotation Now we discuss our crowdsourcing setup to collect the data. To maximize the opportunity to get more feedbacks for a predicted script, we filtered a subset of the test set in ProScript where the human evaluated graph edit distance was likely to be high (i.e., there were likely to be more errors). The ProScript authors released the graph edit value for the set of test set samples they evaluated. We performed inference using their released PROSCRIPT$_{gen}$ model on those data points with high graph edit distance value (≥ 8). With this we collected about 400 (predicted graph, expected gold graph) tuples. The ProScript paper describes that their expected gold graph is also imperfect and might contain about 20% noise. Nevertheless, having the gold reference graph guides and constrains an annotator about the common script for a scenario rather than the wide open space of solving the task using multiple potentially correct scripts. (e.g., one could go to a zoo without driving the car by hiring a taxi and then they won't need to drive or park the car). As mentioned in §8.1 our annotation process must focus on scripts that are widely applicable and grounded in commonsense.

The annotators are shown the model-generated



You want to see an alligator. Which plan: P1 (left) or P2 (right) is **worse**?

Q1. Which plan is worse?

● 1st plan (P1) is worse

○ 2nd plan (P2) is worse

Q2. Describe one "critical error" in the worse graph

Critical: incorrect flexible ordering

4-6, 4-5

→

getting in the car, and driving to the zoo do not have a flexible ordering.

People must get into a vehicle, before driving to any place.

Figure 6: The mechanical turk page for annotation. We show the generated and the expected ProScript gold reference. The annotator must answer which script is worse and why. They must point out an egregious mistake (and not any trivial errors that have minor grammatical errors), and annotate: the error type (missing step, wrong step, wrong order, wrong partial order), localize the error by providing the node or edge id, and give feedback why it is wrong, and finally to gather the general principle behind the feedback they are asked to explain the feedback to a five-year-old.

and expected gold (reference) scripts, and are required to answer which script is worse and why. It is possible that the gold script is marked as worse. However, we later post-process and remove such cases, as our focus is to get errors on the generated scripts and not the manually created scripts. The annotators must point out an obvious mistake (e.g., an event or an edge that does not follow commonsense). They were asked to ignore grammatical and fluency errors, and focus on critical errors of four types:

- **Wrong ordering:** the order in the sequence of steps is not correct (e.g., wearing shoes is described before wearing socks).
- **Flexible ordering:** some steps can be done in a flexible order (e.g., you can wear left sock or right sock first). A good script captures such flexibility.
- **Missing critical steps:** a bad script might have missed critical steps (e.g., the script can say: "wait for a plane" followed by "get off the plane" – here an obvious step "get on the plane" is missing) . There is no strict definition for a critical step, so the annotators were instructed to use their commonsense judgment.
- **Wrong step:** a bad script might have irrelevant and wrong steps (e.g., the script describing "go to a party" might describe an irrelevant step such as read a book, open a book, etc.).

For every data point, the annotators were asked to answer the following:

- Explicit feedback type-1: the error type (missing step, wrong step, wrong order, wrong partial order)
- Explicit feedback type-2: localize the error by providing the erroneous node or edge id
- Implicit feedback type-1: give feedback in a few words, explaining the error
- Implicit feedback type-2: An explanation of the error that would potentially make sense to a five-year-old. Such an explanation of the feedback helped gather the general principle that is violated, and is targeted in the feedback.

Fig. 6 shows a sample of our Mechanical Turk task. Annotators were required to list only one critical error that they believe was most important. Each data point is annotated by three annotators, adding some diversity in the errors. The annotators were paid $15 an hour. The annotators were English speaking crowdworkers on Mechanical Turk from USA. The average time for completion of one script was 2 minutes.

fb type	count	example
explicit **fb** type-1	1,553	Remove node 'put the shirt on'
explicit **fb** type-2	1,553	The following step is not right: put the shirt on
implicit **fb** type-1	1,553	It tells you to iron your shirt while it's still on your body.
implicit **fb** type-2	1,553	If you hold a hot iron against the clothes you're currently wearing, you'll get terrible burns.
total	6,212	`https://anonymous.4open.science/r/interscript/data.json`

Table 6: Dataset statistics. In this paper, we use the hardest feedback (implicit-feedback-type-2). This example is from the input script: input script for the following table (goal: press the wrinkles out) = 1. put the shirt on, 2. find place to press, 3. grab iron from drawer, 4. place iron on shirt, 5. wait for iron to heat up, 6. use iron to smooth out wrinkles, 7. press the wrinkles out

We measured the agreement on labels (which graph is worse), and on explicit feedback type-1 and type-2. It was difficult to measure agreement on implicit feedback because it is not easy to perform binary comparison on the generated text without accounting for linguistic variations. On the labels, the Fleiss Kappa agreement was 0.90 (almost perfect agreement) and on explicit feedback the agreement was 0.75 Fleiss Kappa (substantial agreement). This also shows that there is some diversity in what the users perceive as a serious mistake in y_{bad}.

Eventually, we compiled these annotations into a dataset of 1,553 4-tuples where each entry consists of (explicit feedback type-1, explicit feedback type-2, implicit feedback type-1, implicit feedback type-2).

8.3 Model Output Examples

Table 7 provides some sample model outputs.

9 Performance of FBNET by error type

Table 8 breaks down the performance of FBNET by error type.

x	**fb**	$\mathbf{y}^{e^*}$	**y**

Abstract

Complex Word Identification (CWI) aims to detect words within a text that a reader may find difficult to understand. It has been shown that CWI systems can improve text simplification, readability prediction and vocabulary acquisition modelling. However, the difficulty of a word is a highly idiosyncratic notion that depends on a reader's first language, proficiency and reading experience. In this paper, we show that personal models are best when predicting word complexity for individual readers. We use a novel active learning framework that allows models to be tailored to individuals and release a dataset of complexity annotations and models as a benchmark for further research.[1]

1 Introduction

Illiteracy affects at least 773 million people globally.[2] For these individuals, reading information from unfamiliar sources or on unfamiliar topics can be extremely difficult. Furthermore, there are a reported 1.5 billion English-language learners worldwide, spanning all proficiency levels. Statistics such as these illustrate that the comprehension of written text across the world varies substantially. Even those who are deemed functionally literate have differing degrees of text comprehension. There are many characteristics of a written text that impact how difficult it is to read. However, one of the main aspects contributing to overall text difficulty is lexical complexity, i.e. word complexity (Dubay, 2004). Lexical content has been shown to be more important than syntactic features when predicting readability (Vajjala and Meurers, 2012) and a study performed by Nation (2006) found that a reader needs to be familiar with at least 95% of the words contained within a text for them to understand the content.

(1) The *cantankerous* cat.
↓
The ***grumpy*** cat.

Complex word identification (CWI) focuses on identifying words in a text that may be difficult for a reader to understand and therefore may benefit from simplification (Shardlow, 2013a). For instance, in example (1) a CWI system may identify *cantankerous* as a complex word, then a lexical simplification system is able to substitute it with a simpler alternative, e.g. *grumpy* (Paetzold and Specia, 2016a; Gooding and Kochmar, 2019c).

Many downstream tasks benefit from the identification of complex words. For example, CWI has been shown to improve readability assessment systems (Maddela and Xu, 2018) as well as vocabulary acquisition modules in educational applications (Zaidi et al., 2020). Furthermore, CWI can significantly reduce errors in simplification systems (Shardlow, 2014) and result in higher quality simplifications (Lee and Yeung, 2018).

Previous work on modelling CWI, including two shared tasks, has relied on the collection of large corpora containing words that have been annotated for their complexity (Paetzold and Specia, 2016c; Yimam et al., 2018). However, annotating the difficulty of words is a subjective task, and previous data collection has yielded low levels of annotator agreement (Specia et al., 2012; Paetzold and Specia, 2016c). As a way of mitigating individual differences, such datasets typically present a homogeneous view on word complexity, by merging annotations across readers (Gooding et al., 2021). Further attempts to improve annotator agreement have included offering bonus incentives for annotators who select words matching other annotations (Yimam et al., 2017), as well as providing guidelines for annotators to mark words that they assume would be complex for audiences such as children and those with learning difficulties. Such incentives

---

Findings of the Association for Computational Linguistics: NAACL 2022, pages 353 - 365
July 10-15, 2022

and instructions change the motivation of annotators and undermine the validity of the resulting complexity labels (Gooding, 2022).

It is evident that lexical complexity is a highly subjective and idiosyncratic notion. In this paper, we argue that contrary to the one-size-fits-all paradigm currently dominating many natural language processing tasks, the modelling of individual differences in word complexity is critical. Many of the downstream tasks that benefit from CWI, such as text simplification, would be more effective if tailored to the individual reader. In order to facilitate personalised CWI, and therefore personalised text simplification and readability systems, audience specific complexity annotations are required (Bingel et al., 2018). Whilst it has been shown that the concept of word complexity, and thus the level of agreement, is aligned between individuals sharing a common background (Gooding and Kochmar, 2018a; Gooding et al., 2021), we argue that the best CWI model for each individual is trained with them 'in the loop'.

In our paper, we use active learning to produce per-individual models of word complexity. We collect complexity annotations from 1,225 English as a second language (ESL) readers. Using a novel active learning framework, we show that individual models of word complexity can be trained without extensive annotation. Our experiments demonstrate that bespoke models outperform baselines and a state-of-the-art system when predicting word complexity for individuals, thereby emphasising the importance of viewing the task at a personal level. We present the following contributions:

- We are the first to train personalised word complexity models and show that training can be achieved in real-time using active learning.
- We show that per-individual models outperform baseline and state-of-the-art approaches when predicting word complexity for individuals, most notably for lower proficiency levels.
- We demonstrate the benefits of bespoke CWI models in downstream tasks such as text simplification and proficiency prediction.
- We release a novel dataset containing 55,125 English word complexity annotations from 1,225 ESL participants, as well as all trained models, as a benchmark for further research.

2 Background

2.1 Complex Word Identification

The first dataset collected for the evaluation and benchmarking of CWI was the CW corpus (Shardlow, 2013b). The dataset contained 731 instances, collected using simplifications made by human editors when adapting content for Simple Wikipedia articles. This dataset was extended with further Wikipedia examples, including data collected by Horn et al. (2014), for the first CWI shared task. The resulting dataset contained a total of 9,200 sentences which were annotated by 400 non-native speakers for complex words. The shared task organised by Paetzold and Specia (2016b) required the prediction of binary word complexity for non-native speakers. However, as the dataset had low annotator agreement, the merged notion of complexity was difficult to model, and all systems resulted in low F-scores.

Following this, Yimam et al. (2017) collected a CWI dataset which was used in a second shared task (Yimam et al., 2018). The annotations for this data were collected using the Amazon Mechanical Turk platform. For each sentence, ten non-native and ten native English speakers were asked to mark words or phrases as complex. Words and phrases were annotated as complex (label `1`) if at least one of the 20 annotators annotated them as such, and simple (label `0`) otherwise. The winning system for the binary track was a feature based ensemble approach (Gooding and Kochmar, 2018b). The system used traditional features associated with word complexity such as the frequency, word length and psycholingustic attributes of words. The performance on this dataset was subsequently improved using a neural sequence labelling approach by Gooding and Kochmar (2019a).

The prior datasets and systems largely focused on binary approaches to modelling CWI. Recognising the limitation of viewing word complexity in this way, Shardlow et al. (2021) arranged a shared task on lexical complexity prediction based on the Shardlow et al. (2020) dataset. The dataset contains judgements on word complexity using a Likert scale of 1–5, allowing an indication of the annotators' familiarity with the term. The framing of word complexity in a continuous fashion allows for more subjective approaches of CWI to be introduced. However, overall judgements of difficulty in this dataset are still produced by averaging the labels across multiple annotators. Whilst the data gives an insight into complexity as a continuous measure, it does not provide insight into the individual differences across annotators.

Closest to our work, Gooding et al. (2021) make the case for audience specific CWI by showing that the best models for a given proficiency group are produced using annotations from the target audience. They use proficiency annotations from the Yimam et al. (2017) dataset and find that the features contributing to word complexity differ depending on the audience background. This work illustrates the importance of considering the target audience in CWI. However, the populations investigated still represent coarse groups, such as native vs non-native, or beginner, intermediate and advanced. Whilst this work is a step in the right direction for subjective complexity, there still remain many differences in complexity judgements even within such groups.

Finally, a similar task to CWI is that of vocabulary prediction, whereby the size and extent of a learner's vocabulary is estimated (Meara and Buxton, 1987; Laufer and Nation, 1999). Whilst word difficulty is subtly different to vocabulary size, as a learner may recognise a word but still find it difficult to understand, the areas are closely aligned. Empirical studies have found strong correlations between receptive vocabulary size tests and reading comprehension tests for ESL readers with learners from different proficiency levels (e.g. Laufer, 1992; Qian, 1999, 2002; Henriksen et al., 2004). In fact, vocabulary size has been found to predict as much as 72% of the variance in reading, leading many researchers to emphasise that receptive vocabulary size is the determinant factor for reading success in L2 (Staehr, 2008). Therefore, being able to predict a readers' vocabulary size, with a small number of samples, is very useful. The effectiveness of active learning for vocabulary prediction was investigated by Ehara et al. (2014), who showed that graph-based active learning improves vocabulary prediction for Japanese speakers. However, the active learning process is simulated and not performed in real-time with participants.

2.2 Active Learning

Annotated data can be time consuming and expensive to obtain, notably in specialised domains where only experts can provide reliable labels (Konyushkova et al., 2017). By enabling a classifier to interactively query data points, active learning allows machine learning classifiers to achieve higher accuracies with fewer training instances. It is well-motivated in many modern machine learning problems where data may be abundant, but labels are scarce or expensive to acquire (Settles, 2009). For instance, active learning has been used in text classification (Hoi et al., 2006), information extraction (Settles and Craven, 2008) and financial applications (Gooding and Briscoe, 2019).

The task of personalised CWI is a good candidate for active learning for two reasons:

Labelling time Previous CWI datasets contain thousands of annotated instances to train word complexity models. It is unfeasible to collect this amount of data, in a reasonable time frame, for an individual reader.

Learner lifetime In complex word identification we can expect the needs of a user to change over their 'learner lifetime'. Whilst a model may be effective for a reader at one point in time, as their proficiency improves, the model will require retraining.

2.2.1 Uncertainty Sampling

In uncertainty sampling an active learner queries the instances it is least certain about how to label. This is implemented using an uncertainty measure and is one of the most commonly used active learning frameworks (Lewis and Gale, 1994; Settles, 2009). For many real-world learning problems, large collections of unlabelled data can be gathered easily. For instance, in our setting the unlabelled data represents all possible words. This motivates an uncertainty sampling approached called pool-based sampling (Lewis and Gale, 1994) which assumes that there is a small set of labelled data $\mathcal{L}$ and a large pool of unlabelled instances $\mathcal{U}$. Instances are drawn from this unlabelled pool for labelling in a greedy fashion, according to an informativeness measure calculated by applying the classifier and measuring the uncertainty.

In our paper, we employ active learning for the task of complex word identification. We train classifiers to identify whether a word would be considered difficult for a reader based on 23 word familiarity questions.

3 Experiment Design

In our experiment, participants are presented with vocabulary and asked whether they could confidently define the meaning. There are two stages to the data collection; initially, word annotations are requested in tandem with a classifier as part of an active learning process. During this stage, participants are shown a total of 23 words to annotate.[3] These annotations are used to train a personal word complexity model. Following this, annotations are collected for a test set, per participant, which can be used to validate the trained classifier. The test set contains 22 words across CEFR levels and is presented in a randomised order. Annotators are not aware of the switch from training to test data collection. The study was hosted online and implemented using the Flask framework for Python (Grinberg, 2018).

3.1 Participants

We collected annotations via the Prolific platform from 1,255 ESL readers spanning 57 different first languages.[4] Participants were required to fill out a demographic questionnaire which is available to view in our data repository. The questionnaire was informed using guidelines on judging reading ability (Acheson et al., 2008) and included the self-reported English proficiency, native language, hours spent reading per week and highest level of formal education. Demographic statistics are available in Appendix A.

3.2 Materials

We created a test set containing 22 words spanning different levels of the Common European Framework of Reference for Languages (CEFR) (North and Piccardo, 2020) shown in Figure 1. The items were selected by sampling those with the fewest dictionary entries to minimise word ambiguity.

To bootstrap the active learning process, we train an initial logistic regression classifier with 150 instances from the CWI dataset of Yimam et al. (2017). The features used are those found to correlate most with non-native judgements of word complexity according to Gooding et al. (2021), namely the word length, word frequency and psycholinguistic properties of the words such as the familiarity, concreteness, and imagability, which have been shown as important when predicting word complexity (Carroll and White, 1973; Begg and Paivio, 1969; Zevin and Seidenberg, 2002). This classifier is then tuned to the individual during the active learning process.

3.2.1 Pre-clustering

A typical approach for collecting annotations, in an active learning setting, is to select samples close to the classification boundary. However, it has been shown that taking into account the prior data distribution can improve performance (Settles, 2009). One way to achieve this, is by modelling the input distribution using clustering, and propagating label information to instances in the same cluster (Nguyen and Smeulders, 2004). In our experiment, we use the Yimam et al. (2017) dataset as our unlabelled pool and perform clustering on the 7,476 uniquely labelled words prior to active learning.

We use agglomerative clustering, a hierarchical clustering approach which performs clustering in a bottom up fashion (Gowda and Krishna, 1978). Each word initially belongs to its own cluster and the algorithm successively merges these to form larger groups. This type of unsupervised clustering has been used across multiple natural language processing tasks including word clustering, co-reference resolution and word sense disambiguation (Chen and Ji, 2010). The features used for clustering are the same as employed for the task of the complexity prediction.

We set the number of clusters to 7 in an attempt to align with the CEFR categories chosen in our test set. One disadvantage of hierarchical clustering methods, is that they have large storage requirements, and so can be computationally intensive to compute (Gan et al., 2020). However, as we precalculate and cache clusters the time complexity is that of base informativeness measures, e.g. uncertainty sampling (Settles and Craven, 2008). The time complexity is a necessary consideration, as we are conducting active learning interactively with oracles in real-time.

An example of words from the resulting clusters is displayed in Figure 2a. Words of length 5 were sampled randomly and have been colour coded according to the corresponding CEFR level.[5]

3.2.2 Cluster Evaluation

We evaluate our clusters using two techniques; the first employs EFLLEX which is a graded lexical resource for learners of English as a foreign language. The dataset, collected by Dürlich and François (2018), contains 15,280 entries from 1,971 graded texts. The frequency of the lemma at each level of

---

[3] 23 annotations were found to be the minimum number required for model convergence during trial runs.

[4] `https://prolific.co`

[5] CEFR levels were obtained via `https://languageresearch.cambridge.org/wordlists/text-inspector`

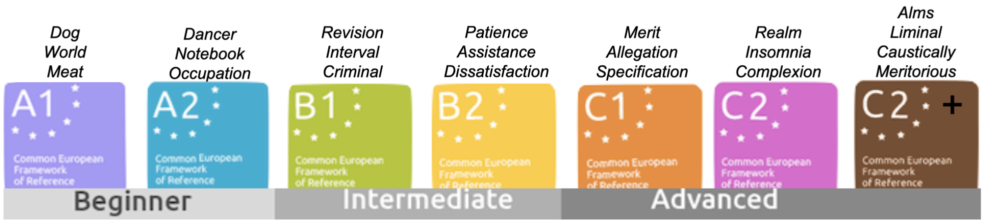

Figure 1: Test set

Figure 2: Clustering statistics

the CEFR (C2 excepted) is provided. A total of 5,983 entries were present in both EFLLEX and our clusters. We plot the average frequencies of words in each cluster across CEFR levels in Figure 2b. Generally, the plot shows that there are clear differences in the levels of vocabulary across clusters. When we consider A1 texts, the cluster with the highest average frequency of words is Cluster 1. There is a linear decrease in the frequency of words at this level as the cluster level increases. When we consider the proportion of higher level vocabulary (i.e. B1 to C2), a clear trend emerges where Clusters 5–7 contain words that appear much more frequently at this level. Cluster 7, contains words at the highest level of CEFR for instance *glyph*, and is shown to contain words that occur much more commonly at C1 and B2 level.

The second way we evaluate clusters is using the annotations of the Yimam et al. (2017) dataset. As we use this data for our unlabelled pool, we have the complexity annotations for each item from both native and non-native annotators. Our work focuses on complexity prediction for ESL readers and so we evaluate clusters using the non-native annotations. This results in a complexity score per word ranging from 1–10 which represents how many non-native annotators considered the word to be complex. A histogram showing the density of non-native complexity annotations present for words in each cluster is shown in Figure 2c. The average of these scores per cluster ($\bar{x}$) is shown in Figure 2c, as well as the number of words present in each cluster (n). Clusters are colour coded according to the same key in Figure 2c. Cluster 7 contains the highest average complexity labels (5.39) and Cluster 1 the lowest (0.01). As the cluster levels increase, we see a shift in the density of complexity annotations present, supporting the notion that these clusters contain vocabulary at differing levels.

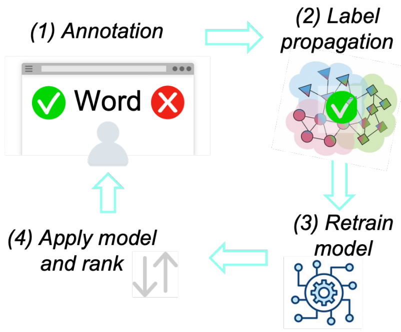

Figure 3: Figure showing the stages of our active learning framework

3.3 Active Learning Loop

Figure 3 shows the four stages that take place during the active learning process. Each of these steps is described below.

(1) Annotation In the initial step, the annotator is presented with a word form and asked whether they could confidently define the meaning. Whilst the context of a word impacts its meaning and complexity, we use word forms as this allows for a pool-based active learning approach. Furthermore, the use of word forms alone has been shown as an effective measure of proficiency and vocabulary prediction (Lemhöfer and Broersma, 2012; Ehara et al., 2014). The user interface showing the instructions for this experiment are provided in Appendix B. When the annotator selects an answer this provides a binary annotation for the word.

(2) Label propagation The chosen label is then propagated to the closest 150 instances from the clustered pool.

(3) Re-train model We train a log-linear model (i.e. logistic regression) per individual, for the following reasons: the model can provide a class ownership probability which is required for active learning, log-linear models are flexible and interpretable, finally the algorithm is efficient and able to train in $\mathcal{O}(nd)$ time, where n is the number of samples and d the feature dimensions (Gujarati and Porter, 2009; Bulso et al., 2019). As each model is retrained every time an annotation is provided, the speed of training was a critical consideration.

(4) Apply model and re-rank Once the model has been re-trained, it is applied to the unlabelled pool so that the samples can be ranked according to the model uncertainty. The uncertainty sampling technique we use is entropy (Shannon, 1948). In the following notation x^* denotes the most informative instance from an unlabelled vocabulary pool:

$$x^*_H = \underset{x}{\operatorname{argmax}} - \sum_i P_\theta(y_i|x) \log P_\theta(y_i|x)$$

where y_i ranges over the possible labellings. The instance from the pool that the model is least certain about is then presented to the annotator for the next annotation step.

4 Results

In our experiment, each participant produces a gold test set containing annotations for words across CEFR levels. This varies for each individual, as word complexity is subjective. For instance, consider the test set samples shown in Table 1; words marked with a 1 have been annotated as difficult by participants. Participant a, who is self-reported to be intermediate, has found three words in this sample difficult, whereas participant b, self-reported at a near native level, only reports one.

	World	*Realm*	*Merit*	*Alms*
P_a	0	1	1	1
P_b	0	0	0	1

Table 1: Test set samples from participants P_a and P_b

We calculate the F-score and Kappa agreement across all annotations to evaluate the performance of bespoke models. The F-score represents the harmonic mean between the precision and recall of the classifier, whereas the Kappa coefficient measures pairwise agreement, correcting for expected chance agreement (Cohen, 1960).

We additionally run an experiment to evaluate the effectiveness of active learning compared to randomly sampling vocabulary. In the experiment, we require annotators to label a sample of 22 random words, as well as 22 words sampled using active learning. As this doubles the annotation effort we perform this with a subset of 100 annotators. The results are shown in Table 3. We compare with models trained using random sampling as well as random sampling with cluster-based label propagation. The best results are achieved using the active learning framework.

We evaluate the performance of the active learning models and compare to the following baselines. (1) Group Average: we calculate the average of the test set complexity annotations across participants, if a word has been labelled as complex by more than 10% of the target group it is labelled as difficult. This is a competitive baseline as we use the direct annotations of the target audience on the test sets. (2) Seq-CWI: we compare to a state-of-the-art system for complex word identification (Gooding and Kochmar, 2019a). However, we note that this is an unfair comparison as the system is one-size-fits-all and not audience specific. (3) Frequency: relies on frequency thresholding, where all words below a given frequency are marked as complex. (4) All Simple: all words are marked as simple.

Table 2 shows the results of the active learning models compared to baselines. We group results according to the proficiency of participants. The beginner results are shown for completeness, but should be interpreted with caution due to the smaller test set size (176). Kappa values in the range of 0.40–0.60 represent moderate agreement (Cyr and Francis, 1992), although it has been argued that scores above 0.45 represent substantial agreement (Munoz and Bangdiwala, 1997).

Model	**Proficiency level**					
	All	Beginner	Intermediate	Advanced	Near Native	Native
			F-score			
Active Learning	**0.751**	**0.763**	**0.720**	**0.752**	**0.764**	**0.761**
Group Average	0.669	0.608	0.624	0.679	0.726	0.754
Seq-CWI	0.677	0.620	0.688	0.689	0.660	0.642
Frequency	0.534	0.461	0.529	0.541	0.530	0.514
All Simple	0.441	0.450	0.436	0.437	0.447	0.454
			Kappa			
Active Learning	**0.503**	**0.525**	**0.441**	**0.504**	**0.529**	**0.524**
Group Average	0.379	0.296	0.304	0.395	0.473	0.523
Seq-CWI	0.395	0.300	0.409	0.414	0.371	0.347
Frequency	0.189	0.083	0.173	0.194	0.196	0.182
Test size	26,136	176	4,180	12,122	7480	2,156

Table 2: Model results grouped by annotator proficiency

Model	*F-score*	*Kappa*
Random	0.605	0.218
Cluster	0.649	0.361
AL	0.740	0.482

Table 3: Results showing differing sampling techniques applied to 2,200 annotations from 100 participants

When we consider the active learning models, we see that the F-score calculated across all test annotations is 0.751, and the Kappa agreement is 0.503. The active learning models outperform the competitive group-average baseline which supports the hypothesis that individual models are preferable to aggregate group-level approaches. The best scores for all proficiency groups are achieved using the active learning framework. However, for the native annotations, the difference between the group-based approach and active learning models is small. When considering the group-average baseline we see that both the F-score and Kappa values increase in line with proficiency. This supports the notion that the concept of word complexity stabilises for higher proficiency levels (Krstić et al., 2018; Gooding et al., 2021). As such, aggregate models may work well for highly proficiency audiences and individual models best for lower levels where word knowledge is more variable.

4.1 Analysis

Each annotator produces a bespoke model based on their personal perception of word difficulty. We tested whether there was a significant difference in complexity predictions of models depending on the annotator's self-reported proficiency. To investigate this, we selected 100 models from near native, advanced and intermediate annotators. We control for the number of classifiers due to having an unequal number of annotators across levels.

These models are applied to the EFLLEX dataset, removing any vocabulary that may have been seen during train time. This results in complexity predictions for approximately 10,000 words per model. The average number of words found complex by these classifiers is shown in Table 5. The intermediate classifiers, on average, identify more complex words across all vocabulary levels, whereas the near native classifiers predict fewer words as difficult across all levels compared to both the intermediate and advanced classifiers. We calculate the significance using Satterthwaite's method (Kuznetsova et al., 2017), applied to a mixed-effects model that treats the first language of annotators and the trained model as random effects.[6] We find that the difference between model predictions depending on the proficiency of the annotator is highly significant ($p < 1{\times}10^{-10}$).

4.2 Downstream Tasks

Being able to distil the vocabulary experience of an individual, using a limited number of annotations, is extremely useful for many applications.

---

[6] Using R formula notation, the model is: model_predictions ∼ annotator_proficiency + (1 | annotator_L1) + (1 | model)

				Near Native:	0.34		0.32		
				Advanced:	0.51		0.47		
				Intermediate:	0.59		0.59		
(1) The	current	cuts	in	public	expenditure	will	exacerbate	this	situation.
					↓				
(2) The	current	cuts	in	public	*spending*	will	exacerbate	this	situation.
(3) The	current	cuts	in	public	*spending*	will	*worsen*	this	situation.

Table 4: Example of how simplification output changes depending on audience specific CWI models. The complexity probability for audiences is the result of aggregating output from all trained models across proficiencies. A word is considered complex if the probability is above 0.50.

	A1	A2	B1	B2	C1
Intermediate	333	881	1208	2109	2474
Advanced	277	754	1016	1773	2062
Near Native	232	643	866	1505	1735

Table 5: The average number of words identified as complex across CEFR levels. Results are averaged from a sample of 100 classifiers from each proficiency group.

For instance, when judging the proficiency of a reader. Using our trained classifiers, we run a preliminary experiment to see if it is possible to predict the proficiency of the annotator using their model predictions. We train a linear model to predict whether the annotator self-reported at an intermediate, advanced or near native level. We use the total number of C1 words identified as complex as a feature and test using 5-fold stratified cross-validation. By training a simple model with this feature alone, we can obtain a precision of 0.70. We release the trained models with our paper to encourage further work on the applications and evaluation of personal CWI models for proficiency prediction.

Finally, a further application that benefits from individualised models of word complexity is text simplification. To illustrate, we provide an example in Table 4 which was produced using an open source lexical simplification system by Gooding and Kochmar (2019c). The system is designed to accommodate differing models of word complexity so that simplification output can be personalised. In this example, we use the mean probability that a word is complex by averaging the output from our classifier groups. Sentence (1) shows the result of using near native CWI models, no words are considered complex and so no simplifications are performed. The advanced models produce a probability larger than 0.50 for the word *expenditure* and it is therefore simplified. Finally, the intermediate models result in two words being identified as complex which are subsequently simplified. This example provides further motivation for why considering word complexity in a subjective manner is beneficial.

5 Conclusions and Future Work

We show that with active learning it is feasible to build individual models of word complexity. Our models are able to be trained efficiently, in real-time, using only 23 word annotations per individual. Models trained in this fashion are able to accommodate the subjective nature of word complexity, thereby facilitating personalised readability and simplification systems. We release our dataset containing 55,125 word complexity annotations, participant metadata and models, providing a new benchmark for the task of human-centered word complexity prediction.

Our work is a first step towards the development of personal complexity models. In future work, we aim to more extensively investigate the relationship between a learner's perceived and actual knowledge of words, as it has been reported that there is a misalignment between what a learner thinks they know, and what they are actually able to define (Laufer, 1997). Additionally, the context of a word impacts its perceived difficulty (Gooding and Kochmar, 2019b; Strohmaier et al., 2020); considering token-level complexity as opposed to type-level complexity is another important avenue for future work.

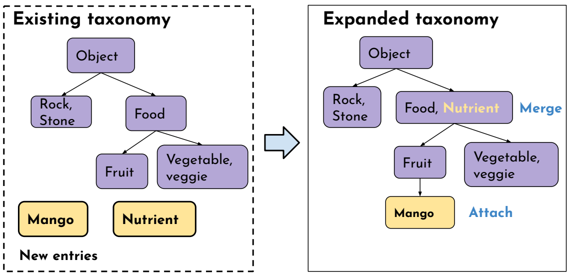
Abstract

Taxonomy expansion is a crucial task. Most of the taxonomy expansion approaches are of two types, *attach* and *merge*. In a taxonomy like WordNet, both merge and attach are integral parts of the expansion operations, but the majority of studies consider them separately. This paper proposes a novel multi-task learning-based deep learning method known as *Taxonomy Expansion with Attach and Merge (TEAM)* that performs both the merge and attach operations. This is the first study that integrates both the merge and attach operations in a single model to the best of our knowledge. The proposed models have been evaluated on three separate WordNet taxonomies, viz., Assamese, Bangla, and Hindi. From the various experimental setups, it is shown that TEAM outperforms its state-of-the-art counterparts for attach operation and also provides highly encouraging performance for the merge operation.



Concept- words Synset (s)	Concept definition (d)
Object	A tangible and visible entity.
Rock, Stone	A lump or mass of hard consolidated mineral matter.
Food	Any substance that can be metabolized by an organism to give energy and build tissue.
Vegetable,Veggie	Edible seeds or roots or stems or leaves or bulbs or tubers or non sweet fruits of any of numerous herbaceous plant
Fruit	The ripened reproductive body of a seed plant.
Nutrient	A substance used by an organism to survive, grow, and reproduce.
Mango	A mango is an edible stone fruit.

Figure 1: Example of WordNet taxonomy expansion with attach and merge operations to include new terms *"Mango"* and *“Nutrient”*.

“Mango” is a specific concept of *Fruit* not present in the existing WordNet. Hence, a new concept node is created in the taxonomy by attaching it to its generic concept *Fruit* . As *“Nutrient”* refers to the same concept as *"Food"*, no new concept is created. *“Nutrient”* is merged with the existing concept *“Food”*.

1 Introduction

Taxonomy, such as the WordNet, is a crucial resource for developing NLP related technologies, as it plays a vital role in various text processing tasks such as information retrieval, information extraction, text classification, summarization, etc. (Pang et al., 2008; Allan et al., 1998; Singhal et al., 2001) (Miller, 1998). As most of the WordNets are manually curated, it often suffers from the problem of limited coverage. Therefore, an automatic taxonomy expansion is a crucial problem to handle the above issue. For taxonomy expansion, WordNet in particular, may need two types of operations; (i) *merge*, where a new concept [1] is merged to an existing node, and (ii) *attach*, where a new concept is inserted as a new node. Figure 1 illustrates these two operations where the word *Mango* is inserted as a new concept with the attach operation, and the word *Nutrient* is inserted as a new synonymy in an existing concept with the merge operation.

Though both of these operations are integral parts of a WordNet taxonomy expansion, all of the existing studies on taxonomy expansion have considered expansion with either attach operation (Schlichtkrull and Alonso, 2016; Vedula et al., 2018; Shen et al., 2020; Yu et al., 2020b; Zhang et al., 2021; Takeoka et al., 2021; Liu et al., 2021) or merge operation (Nakashole et al., 2012; Nguyen et al., 2017; Nakashole et al., 2012; Qu et al., 2017; Boteanu et al., 2018; Wang et al., 2019; Fei et al., 2019), but not together. Realizing the need to apply both the operation, SemEval-2016:task 14 (Semantic taxonomy enrichment) Jurgens and Pilehvar (2016) includes a call for expansion with both attach and merge operations. However, none of the submissions incorporate both operations in a single model.

---

*Equal contributions.

[1] Concept is a basic building block of WordNet, which refers a definition with associated synonym words

Findings of the Association for Computational Linguistics: NAACL 2022, pages 366 - 378
July 10-15, 2022 ©2022 Association for Computational Linguistics

Motivated by the above observations, in this study, we propose an integrated deep learning-based method, namely, *Taxonomy Expansion with Attach and Merge* (TEAM), which performs both the attach and merge operations in a multitask-learning framework. Though most of the existing studies consider the expansion a regression problem (Shen et al., 2020; Yu et al., 2020b; Zhang et al., 2021), considering that our method performs both the attach and merge operation in a single model, it can also be considered a classification task. As a result, we propose two versions of TEAM, namely, TEAM-RG: *Regression*, and TEAM-CL: *Classification* to perform with explicit and implicit rankings. The proposed models have been evaluated on three different WordNet taxonomies, viz., Assamese, Bangla, and Hindi. From the various experimental setups, it is observed that the proposed TEAM-RG and TEAM-CL outperform their baselines counterparts for attach operation, and also obtained encouraging performance for merge operation as well. The major contributions of the paper are summarized as follows:

- A multi-task learning based taxonomy expansion framework *TEAM* is jointly trained to perform both the *Attach* and *Merge* operations. To the best of our knowledge, it is the first integrated model to perform both the *Attach* and *Merge* operations in a single model.
- Two variants of TEAM, namely *TEAM-Regression (RG)* and *TEAM-Classification (CL)* are proposed.

2 Taxonomy Expansion - Attach and Merge

In this study, we have considered WordNets as our target taxonomies. A WordNet may be defined by a collection of concepts connected by various semantic relationships such as *hypernymy, hyponymy, troponymy*, etc., where each concept is further defined by a set of attributes such as *definition, synonyms, examples*, etc (Bhattacharyya, 2010). In this study, we have considered only the hypernymy relation and the *definition* and *synonymy* attributes.

In order to be able to apply the proposed model, we first transform the original WordNet taxonomy into an experimental intermediate taxonomy (*directed unweighted acyclic graph*) $\mathcal{T} = (V, E)$ where V represents the set of concepts and E represents the set of hypernymy relations between the concepts. A concept $v \in V$ is further defined by a tuple $v = (d_v, s_v)$ where d_v represents the *definition* of the concept, and s_v represents the set of associated synonyms. An edge $e \in E$ represents a hypernymy relation from a parent concept v_p to its child concept v_{ch} and is denoted as $e : (v_p \xrightarrow{\text{hyper}} v_{ch})$. The taxonomy $\mathcal{T}$ is arranged in a hierarchical manner with directed edges in E, as shown in Figure 1. Given the taxonomy $\mathcal{T}$ and a query concept $q = (d_q, s_q)$, the *attach* and the *merge* expansion operations are defined below.

Attach (A) — An attach operation is performed when the concept q is not present in $\mathcal{T}$. The objective of the attach operation is to identify the best matching parent node in taxonomy network known as anchor concept $a = (d_a, s_a)$, and insert a new concept q with an edge $e : (a \xrightarrow{\text{hyper}} q)$. In a taxonomy network, a parent node represents a more generic concept of its children. After an attach operation i.e., insertion of q in $\mathcal{T}$ under the anchor a, the expanded taxonomy is updated as follows.

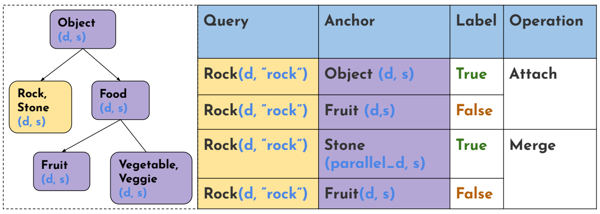
$$\mathcal{T} \quad = \quad (V \cup \{q\}, E \cup \{e\}) \qquad (1)$$

Merge (M) — A merge operation is performed when an equivalent concept $a = (d_a, s_a)$ of the query q (i.e., $d_a \equiv d_q$) is already present in $\mathcal{T}$, but the synset s_q is not present in a (i.e., $s_q \cap s_a = \emptyset$). The objective of the merge operation is to identify the best matching concept $a = (d_a, s_a)$, known as the anchor concept, in the taxonomy network $\mathcal{T}$ and add the synset s_q to s_a. It neither creates a new node nor adds a new edge. It only updates the synset of the anchor concept. After the merge operation, the updated anchor concept in the expanded taxonomy can be expressed as follows.

$$a \quad = \quad (d_a, s_a \cup s_q) : a \in V \qquad (2)$$

3 Proposed Methods

Our objective is to develop an integrated model that performs both attach and merge operations for taxonomy expansion. Since we have two tasks to unify in a single model, we resort to a multi-task learning framework known as **T**axonomy **E**xpansion Framework with ***A**ttach* and ***M**erge* (TEAM). This joint learning objective facilitates information flow so that the two tasks can aid each other. Also, we are interested in deciding which expansion operation is to perform given a triplet (expansion task classification) and retrieving the ranked list of candidates



Query	Anchor	Label	Operation
Rock(d, "rock")	Object (d, s)	True	Attach
Rock(d, "rock")	Fruit (d,s)	False	
Rock(d, "rock")	Stone (parallel_d, s)	True	Merge
Rock(d, "rock")	Fruit(d, s)	False	

Figure 2: Example of training dataset generation. The table shows positive and negative training instances corresponding to the query concept *"Rock"* for both operations *Attach* and *Merge*.

(ranking) as prospective anchors to associate the query with. For this *first-of-its-kind* novel taxonomy expansion task, we propose two versions of TEAM, namely *TEAM–Regression* (TEAM-RG) and *TEAM–Classification* (TEAM-CL) — where we show that using either regression or classification learning objectives, this task can be accomplished.

3.1 Training dataset generation

Given a transformed taxonomy $\mathcal{T}$ (as described in Section 2), we generate a training dataset for building the model as follows. The training samples are defined by a 3-tuple $< q, a, label >$, where q is the query, a is the potential anchor, and *label* is associated class, i.e., true/false (1/0). We randomly select a set of nodes in $\mathcal{T}$ as a set of queries [2], and generate the training samples for the attach and the merge operations separately as follows.

Attach (A) — We first remove the query nodes from the $\mathcal{T}$. For each query $q = (d_q, s_q)$, we consider its parent as anchor node $a = (d_a, s_a)$ and generate positive sample $< q, a, TRUE >$. We then randomly pick up $\mathcal{N}$ number other nodes $a' = (d_{a'}, s_{a'})$, and generate N negative samples $< q, a', FALSE >$. Thus, for a given query node q, we extract one positive and $\mathcal{N}$ negative samples.

Merge (M) — For each of the randomly selected query node $x = (d_x, s_x >)$ in $\mathcal{T}$, we generate the following positive training sample $< q, x, True >$ where $q = (d_x, s_q), s_q \subset s_x$ is the query and $x = (d_x, s_x - s_q)$ is the anchor.The s_q is a randomly selected synonym in s_x. Unlike attach, for generating the training sample for the query q, we only remove the query synset s_q from the anchor synset s_x i.e., $s_x = s_x - s_q$, and, not the node. Like attach, we randomly pick up $\mathcal{N}$ number other nodes a', and generate N negative samples $< q, a', FALSE >$.

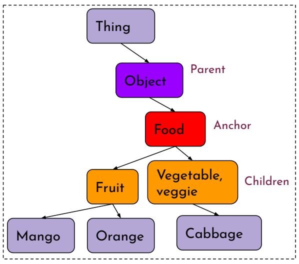


Figure 3: Ego tree of the anchor node *"Food"*. 1-hop ego-tree is extracted around the anchor *"Food"*. The color-codes distinguish various roles w.r.t the anchor node *"Food"*, eg., Deep Purple: Grand-parent, Red: Anchor/ Parent, Orange: Childrens

Figure 2 illustrates the generation of the training samples from a taxonomy.

3.2 TEAM-Regression (TEAM-RG)

The proposed *TEAM-RG* works in two tiers process. Given a training input sample $< q, a, c >$, it first generates encoding of the query q and the anchor a. It then merges to a shared layer to produce two different multi-tasking dense networks; one for merge and another for attach, as shown in figure 4.D.

For learning embedding of the anchor concept from the taxonomy network and the query concept from the associated attributes, we consider the publicly available Fasttext pre-trained embedding available at `https://fasttext.cc/docs/en/crawl-vectors.html`.

Processing of the query concept: As mentioned in Section 2, a query concept consists of its definition and the associated synset i.e., $q = (d_q, s_q)$. The definition is a piece of text describing the concept, and the synset is a synonym associated with the query concept. . The two embeddings are then concatenated to represent the query.

Processing of the anchor concept: For generating the encoding of the anchor concept, we exploit the proximity structure of the nodes in the taxonomy $\mathcal{T}$. For a given anchor node $a \in \mathcal{T}$, we first extract its ego-tree from the taxonomy. An ego tree $\mathcal{T}_a : (V_a, E_a)$ of a node a in the taxonomy $\mathcal{T}$ is a sub-tree that comprises the node a and its k-hop neighborhood nodes. In this study, we considered $k = 1$, i.e., the anchor node, its parent node, and all its children nodes. Figure 3 illustrates an example of an ego tree. A similar approach has also been used in (Wang et al., 2021; Yu et al., 2020b; Zhang et al., 2021; Shen et al., 2020) studies. To obtain the embedding of the anchor concept, we further apply graph embedding as described below.

---

[2] As we consider the same query set for both attach and merge experiments, nodes with at least two synonyms are considered.

3.2.1 Embedding Ego-tree

Ideally, we should be able to use any graph embedding method to obtain the embedding of the anchor node. As the objective is to incorporate the positional information of the parent and children node in the ego tree, we use the Graph Attention Network (GAT) proposed in Taxo-Expan (Shen et al., 2020). This GAT is a special type of graph neural network (GNN) (Kipf and Welling, 2016) with a neighborhood-based attention mechanism. The details of GAT and its difference from GNN are given in Section B of Appendix. Thus we used position enhanced GAT to obtain the node embeddings of an anchor's ego tree.

We summarize the tree by applying an activation function over the average of the embedding vectors of all nodes in the ego-tree as given in equation 3 to define the encoding of the anchor node.

$$\bar{\mathcal{T}}_a = \sigma\Big(\frac{1}{|V_a|}\sum_{x \in V_a} \bar{x}\Big) \tag{3}$$

where $\sigma(.)$ is an activation function. We have considered *Sigmoid* function in this study.

3.2.2 Multi-task Learning

Once we obtain the embeddings of the anchor and query concepts, the concatenated vector is subjected to a shared dense layer and then build two multi-task layers to perform the merge and attach operations as shown in Figure 4.D. Given a query concept and its true anchor concept with $\mathcal{N}$ false anchor concepts, the task is to design a regression-based ranking model such that the true concept is ranked higher than the $\mathcal{N}$ false concepts. This objective should be realized for all the queries in the training dataset.

Given the embedding vectors of anchor $\bar{a}$ and query $\bar{q}$ as learned above, we first estimate similarity between the two using a bi-linear model proposed in (Gutmann and Hyvärinen, 2010). It learns the discrimination between q and a through a learnable bi-linear scoring matrix $B \in \mathbb{R}^{|\bar{q}| \times |\bar{a}|}$ via a function $\mathcal{D} : \mathbb{R}^{|\bar{q}| \times |\bar{a}|} \mapsto \mathbb{R}$ as follows.

$$\mathcal{D}(q, a) = \sigma(\bar{q}^T B \bar{a}) \tag{4}$$

Here σ is sigmoid non-linearity. The output of this matching module is a probability estimate indicating the strength of association between the query and anchor. Now, considering the query concept q and its associated $\mathcal{N} + 1$ anchor concepts, we estimate the probability of being the correct anchor using InfoNCE loss proposed in (Oord et al., 2018). Let $\mathcal{X}$ be a set of query concepts and their respective $\mathcal{N} + 1$ anchor nodes (one positive and $\mathcal{N}$ negative). An element of $x_q \in \mathcal{X}$ for a given query q consists of $\{(q, a, 1), (q, a'_1, a'_2, ..., a'_{\mathcal{N}}, 0)\}$, where a is the positive anchor, and a' are the negative anchors of q. InfoNCE estimates loss function using an average probability of being true anchor node across the dataset $\mathcal{X}$ as follows.

$$\mathcal{L}_{A/M} = -\frac{1}{|\mathcal{X}|}\sum_{x_q \in \mathcal{X}} log \frac{\mathcal{D}(\bar{q}, \bar{a})}{\sum_{v \in \mathcal{M}(q)} \mathcal{D}(\bar{q}, \bar{v})} \tag{5}$$

where $\mathcal{M}(q)$ denotes the set of both positive and negative anchors of q. As mentioned earlier, the loss defined in Equation 5 is estimated separately for attach and merge operations. Therefore, we generate two different training datasets for attach and merge, and estimate $\mathcal{L}_A$ and $\mathcal{L}_M$ separately using respective datasets, The final model loss is defined as $\mathcal{L} = \mathcal{L}_A + \mathcal{L}_M$ — considering both the operations attach and merge.

3.3 TEAM-Classification (TEAM-CL)

Figure 4E shows the schematic diagram of the *TEAM-CL*. We use the identical representations for query q and candidate anchors a_A, a_M as described for TEAM-RG. We also adopt the same position-enhanced graph propagation and read-out modules as described in Section 3.2.1 for learning anchor $a = (d_a, s_a)$ concept representation. Once we obtain the query and anchor representations, we model the strength of association of an input query and the candidate anchors based on their features to predict the expansion task i.e., merge M or attach A. The matching module, a multi-layer perceptron (MLP) based classifier, takes the features of query $\bar{q} \in \mathbb{R}^{|\bar{q}|}$ and anchor $\bar{a} \in \mathbb{R}^{|\bar{a}|}$, and generates a contextualized pair representation $\bar{k} = [\bar{q} \oplus (\bar{q} - \bar{a}) \oplus (\bar{q} \times \bar{a}) \oplus \bar{a}]$ (assuming $|\bar{q}| = |\bar{a}|$). Here, $\oplus$ denotes concatenation. The anchor a can be any of the attach or merge candidates (a_A/a_M). A three-way classifier is learned to produce the categorical probability distribution over the training samples for *Merge (M)*, *Attach (A)* and *No-operation (N)* — three classes ($|\mathcal{Z}| = 3$) of operations. If $\theta \in \mathbb{R}^{|\bar{k}| \times |\bar{\mathcal{Z}}|}$ be a learnable projection matrix that projects the contextualized pair embedding $\bar{k}$ to the label space $\mathcal{Z} \in \mathbb{R}^3$. The predictions are obtained as below,

$$\hat{Y} = \text{softmax}(\text{MLP}(\bar{k}; \theta)) \tag{6}$$

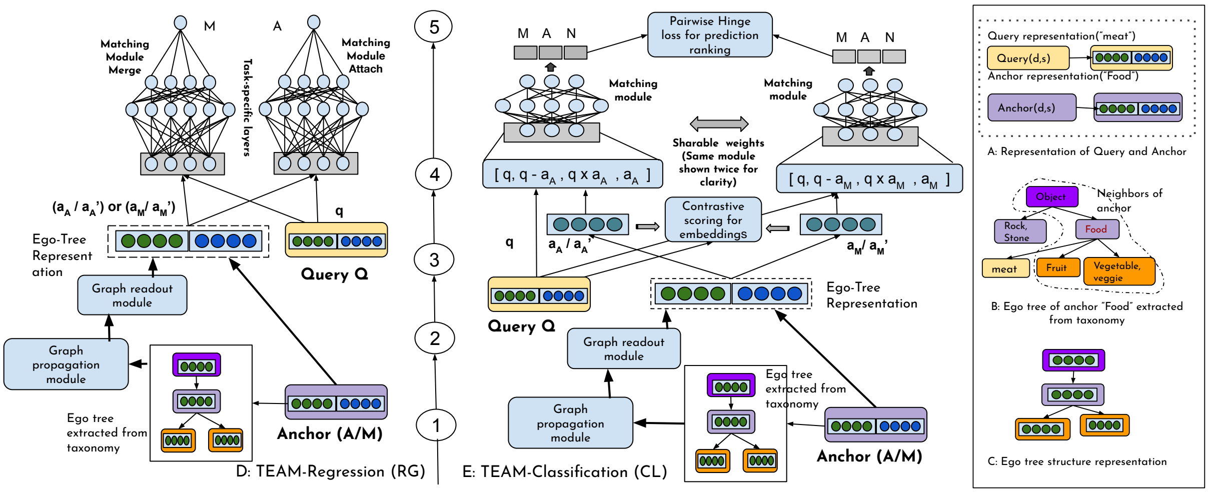

Figure 4: Taxonomy Expansion framework with Attach and Merge (TEAM) **D: TEAM-Regression-RG** — •1. (Query Q, Anchor, (N+1) Negative Anchors) are fed to the model, •2. Representation learning via shared graph propagation and readout modules, •3. Projection to shared hidden layers, •4. Task-specific matching modules with non-shareable weights, •5. Representation learning via shared graph propagation and readout modules, •3. Projection to shared hidden layers, •4. Simultaneous optimization of classification and ranking losses. •5.Three-way merge, attach, no-operation (M, A, N) prediction.
Explanation of used color-codes. Light-Purple: Anchor (A/M) nodes, Orange: Children of the anchor, Purple: Parent of the anchor. Green: Definition representation of anchors, Blue: Synset representation of anchors, Yellow: Query representation.

For two versions of TEAM, we chose two different kinds of matching models based on empirical performances to capture different kinds of embedding interaction in the latent space.

3.3.1 Multi-task Learning

Classification. Unlike in TEAM-RG, where we posit taxonomy expansion as a regression task with implicit ranking viz. discriminating true and false examples via InfoNCE loss, *in TEAM-CL, we simultaneously optimize for classification and explicit ranking objectives.* We obtain classification predictions from the matching module as described before. Given a training set $\mathcal{X}$, and a set of classes $\mathcal{Z}$ (M: Merge, A: Attach, N: No-operation), we optimize for the self-supervised cross-entropy loss over the task predictions $\hat{Y}$ given the ground-truth task-classes Y for an input query-anchor pair.

$$\mathcal{L}_C = -\frac{1}{|\mathcal{X}|}\sum_{i\in\mathcal{X}}\sum_{z\in\mathcal{Z}} Y_{iz} ln \hat{Y}_{iz} \tag{7}$$

Ranking. The classification objective can only learn and infer the confidence score of an operation (M/ A/ N) for a training sample. It fails to give us a reliable ranked list of prospective anchors-(A/ M) given a query — since it does not learn the relative ranks of positive and negative anchors for a query. As illustrated in Figure 4, for a query q, (i) the ego-tree of anchor-A comprises of that query's parent's hierarchical neighborhood, and (ii) the ego-tree of anchor-M comprises of that query's replica's (same/similar definition with a missing portion of synset) hierarchical neighborhood. *Since a query q is very similar to both of its anchor-A and anchor-M's ego-trees – these operations are hardly distinguishable.* Thus, a model must accommodate a provision for directly comparing the prediction scores of M and A operations and learning a margin of separation between the scores. Here, we introduce two ranking objectives in the framework — (i) a contrastive objective to compare and contrast among a positive anchor and $\mathcal{N}$ negative anchors, (ii) a pair-wise hinge loss to learn a maximum margin between the M and A prediction scores.

Let, $dist(.)$ be a function to measure the distance between a query $\bar{q}$ and its true/ false anchor-(A/ M) representations $(\bar{a_A}, \bar{a_A}'), (\bar{a_M}, \bar{a_M}')$. We use "slash" (/) to denote either. We intend to rank a positive query-anchor pair $(q, a_A/a_M)$ higher than $\mathcal{N}$ no of negative pairs $(q, a'_A/a'_M)$ by enforcing a group-wise contrastive loss using a margin λ as,

$$\begin{gathered}\mathcal{L}_{R1_A} = \\ \frac{1}{\mathcal{X}}\sum_{i\in\mathcal{X}}\frac{1}{|\mathcal{N}(\bar{q}_i)|}\sum_{\bar{a_A}'_i\in\mathcal{N}(\bar{q}_i)}\max(0, \lambda - m + m') \\ m = -\,\mathrm{dist}(\bar{q}_i - \bar{a_A}_i),\ m' = -\,\mathrm{dist}(\bar{q}_i - \bar{a_A}'_i)\end{gathered} \tag{8}$$

We can similarly compute the margin-based group-wise contrastive loss $\mathcal{L}_{R1_M}$ for the Merge (M).

Now, to distinguish between M and A operations, let, $f(\bar{k})$ be a function that projects the contextualized (q, a) embedding $\bar{k}$ in Equation 6, to a hidden space $\mathbb{R}^h$. Here we introduce a margin-based hinge-loss on sample anchor pairs attach-merge $\langle a_A, a_M \rangle$ for a given query q via their contextualized vectors $\langle \bar{k}_A, \bar{k}_M \rangle$. If class labels of merge and attach are $M = 2, A = 1$, we ensure the prediction scores $\hat{Y}_{A/M} = f(\bar{k}_{A/M})$ for M and A are separated by a margin of λ.

$$\mathcal{L}_{R2} = \sum_{Y(\bar{k}_A) > Y(\bar{k}_M)} \max(0, \lambda - f(\bar{k}_M) + f(\bar{k}_A))$$

Therefore, the final loss is, $\mathcal{L} = \mathcal{L}_C + \mathcal{L}_{R1_A} + \mathcal{L}_{R1_M} + \mathcal{L}_{R2}$ — considering both margin-based group-wise contrastive loss and pairwise hinge loss comprising the overall ranking loss.

3.4 Model Inference

We follow Taxo-Expan's (Shen et al., 2020) evaluation strategy for inferring the best candidate anchor a given a query q. We use our classification objective to decide which operation among merge, attach, or no-operation (M, A, N) to perform when q is given. *i)* For TEAM-RG, we augment a classification layer on top of the task-specific regression layers. Given a query q and a set of candidate anchors a, we obtain the merge and attach regression scores and choose the best value along with the corresponding operation as the apt operation to perform. *ii)* For TEAM-CL choosing which operation to perform is obtained based on the three-way prediction scores, given $< q, a, (0/1) >$ as input. Since both of our proposed frameworks optimize for ranking loss, i.e., discriminates true candidate pairs from the negative ones — we get a ranked list of candidate anchors a while matching each of them with q via respective matching modules.

4 Experiments and Results

Here we give you an overview of our experiment settings and provide the detailed reproducibility information in the Sections C, D, E of the Appendix.

Datasets. Table 1 shows the basic statistics of three WordNet taxonomies used in this study. The taxonomy networks are extracted from Assamese, Bengali, and Hindi WordNets, respectively.

	Nodes	Edges	Max-in degree	Max-out degree	leaf nodes
Assamese WordNet	8466	8363	1	525	7072
Bengali WordNet	26007	25815	1	924	22847
Hindi Wordnet	28242	28016	1	951	24737

Table 1: Dataset Statistics

Metrics. We use Mean Rank (MR), Hit@k, and Mean Reciprocal Rank (MRR) to evaluate the ranks of the retrieved results obtained from different models, for the test queries. Like Taxo-Expan (Shen et al., 2020) evaluation strategy, we scale the MRR score by a factor of 10 to highlight the discrepancy of the performances among different methods. Further, we use Accuracy, Micro/ Macro F1, Precision, Recall, and F-Scores to evaluate a method's prediction capability to decide which operation among merge (M), attach (A), and no-operation (N) needs to be performed.

Baselines. We choose two most recent benchmark SOTA taxonomy-expansion frameworks TaxoExpan (Shen et al., 2020) and Triplet Matching Network(TMN) (Zhang et al., 2021) as the competing methods. As Taxo-Expan and TMN outperform SemEval-2016 (Shen et al., 2020; Zhang et al., 2021), we have not included SemEval-2016 as baseline in this study. In terms of learning objective, Taxo-Expan is similar to ours. It uses ego-tree-based anchor features for matching query features in a regression-based setting. TMN captures fine-grained relationship dynamics of query and anchor concepts using channel-wise gating mechanism-based attention learning.

All datasets and our model implementations are available at: `https://github.com/barnal/TEAM`

5 Results

Here we report the classification and ranking results of the competing methods. We also compare and contrast among the variants of our TEAM framework. Apart from the two versions of the TEAM, namely, TEAM-RG and TEAM-CL, we have task-specific model variants specified as — attach–A, merge–M and merge+attach–MA. Here, (attach+merge) means simultaneously optimizing for both the tasks.

5.1 Ranking Results

In Table [2], we show the performance of the competing methods in terms of (best) ranking scores. We see similar trends for all taxonomies in the sub-tables. When considering only attach operation and the test ranking scores, we see TEAM-RG clearly beats Taxo-Expan by a large margin of $(196.87, 487.75, 470.87)$ in MR, by a margin of

Table 2: Ranking results for test queries

$(0.2, 0.14, 0.24)$ in Hit@1 and $(0.31, 0.32, 0.37)$ in Hit@3 for Assamese, Bengali and Hindi WordNet respectively. We see TEAM-CL though performing competitively but is outperformed by TEAM-RG by a margin of $(44.82, 86.01, 43.04)$ in MR, by a margin of $(0.11, 0.12, 0.28)$ in Hit@1 and $(0.14, 0.18, 0.43)$ in Hit@3 respectively for Assamese, Bengali and Hindi WordNet. In TEAM-RG(M), we obtain near-perfect MRR scores. This is because the definitions are already present in training set for the query concepts with known definitions (test sample drawn from the base taxonomy). The score of 1 indicates the ability of the proposed method TEAM-RG(M) to correctly identify the appropriate anchor nodes for the merge operation. TMN gives better performance than Taxo-Expan owing to its useful attention mechanism. But, Team-RG(A) outperforms TMN in all the metrics except Hits@1. We only compare Taxo-Expan results for the attach since it is originally proposed for the attach operation. In the (merge-M) and (merge+attach-MA) section of the tables also, we see that TEAM-RG outperforms TEAM-CL on all three WordNet taxonomies. We attribute this huge performance improvement of TEAM-RG to InfoNCE based training — as it simultaneously provides pseudo-supervision from the negative examples while optimizing for the task-specific regression layers.

5.2 Classification Results

In Table [3], We observe similar trends on all three WordNet taxonomies. Since Taxo-Expan is a regression-based algorithm proposed for only attach operation in taxonomy expansion task — we could not obtain its classification performance. Therefore, we only consider variants of our frameworks as competing methods. As described in the sub-section 3.4, using a classification layer on top of the regression layer in TEAM-RG, we obtain classification performances for the attach, merge operations along with both (attach+merge) operations. Whereas obtaining classification performance for TEAM-CL is straightforward since this is already a classification framework.

When comparing TEAM-RG (attach) and (merge) variants — we see, unlike ranking results where ranking results of merge operation were always better than the attach operation, here the classification results of merge operation are inferior to attach operation. It means that the RG variant learns better ranking as compared to CL variants, but they fail to distinguish M and A – the operation to perform. This is expected since we do not provide a scheme here to contrast M and A operations — which is the motivation for our CL variant framework.

When comparing TEAM-RG and TEAM-CL for (merge+attach), we see TEAM-CL gives better classification scores using test queries except for Macro-F1 scores. TEAM-RG gives the best performance for the Macro-F1 score for the test cases. This essentially means that class-wise prediction performances are inferior for TEAM-CL. This is expected behavior since, in each batch of the training sample, we include a substantially large number $(\mathcal{N})$ of negative examples with class-label (N–No operation). We design our training samples like this so that the contrastive loss is better approximated. Nevertheless, it leads to a class-imbalance issue in our three-way classification setup, i.e., a large number of samples with N class labels as compared to the other M/ A class labels. Thus, TEAM-CL biases its prediction towards the N class, leading to poorer Macro-F1 scores than TEAM-RG.

To summarize, we observe that TEAM-RG gives the best ranking performances, whereas TEAM-CL gives the best classification performances. TEAM-

	Assamese WordNet						**Bengali WordNet**						**Hindi WordNet**

Table 3: Classification results for test queries

CL performs poorly in Macro-F1 since it presumably suffers from class-imbalance issues owing to the style of training sample generation. Frameworks with multi-task learning strategy (TEAM-RG and TEAM-CL) outperform frameworks (Taxo-Expan) designed to perform a single task — which is motivated by the fact that simultaneously optimizing for multiple tasks provides self-supervision to each other, resulting in better performances.

5.3 Expansion of Assamese WordNet Taxonomy with Out-Of-Vocabulary (OOV) words

	Assamese WordNet-Noun			
Methods	Micro_MR	Hit@1	Hit@3	MRR
TEAM-RG(A)	**65.30**	**0.33**	**0.53**	**0.80**
TEAM-CL(A)	240.47	0.02	0.16	0.06
Taxo_Expan(A)	386.30	0.05	0.05	0.11
TEAM-RG(M)	**170.79**	**0.07**	**0.14**	**0.38**
TEAM-CL(M)	331.93	0.03	0.12	0.29

Table 4: Ranking result for out-of-vocabulary words

To investigate the effectiveness of the proposed models, we employ the models for expanding a WordNet with OOV words. For this, first, we find out-of-vocabulary words, i.e., words that are not present in Assamese WordNet. Second, we manually identify true anchors of respective out-of-vocabulary words with associated operations (Attach/Merge) in Assamese WordNet. We evaluate the predicted results of the proposed model against the manually identified true anchors. Since we can either perform an A or M operation with OOV words and not both, we do not predict expansion tasks for OOV words using any of the MA variants of our proposed frameworks. Table 4 shows the ranking performance of the model in predicting true anchors for attach and merge expansion operations. We see a similar trend of prediction ranking as seen with the test set in our earlier experiments. TEAM-RG gives the best performance in both expansion operations. The detailed analysis of results is in Section F of the Appendix.

6 Related Works

Existing methods for taxonomy expansion can be divided into two categories: relying on alignment between multiple taxonomies [Ruiz-Casado et al. (2005), Toral et al. (2008), Ponzetto and Navigli (2009), and Yamada et al. (2011)] or relying on machine learning-based rating sub-graphs. Further, the latter category can be divided into two sub-categories (1) by expanding synonymy relations/Merge (2) by expanding hypernymy relations/Attach. Synonymy-based taxonomy expansion leverages synonymy relations of the taxonomy. Given a seed taxonomy, the distributional approach discovers synonyms by representing strings with their distributional feature and learning a classifier to predict the relation between strings [(Nakashole et al., 2012), (Wang et al., 2019), (Fei et al., 2019)]. Most of the recent taxonomy expansion approaches are based on hypernymy expansion. These methods attempt to determine the attachment position by scoring between several nodes. Recently numerous methods have been proposed to solve this problem(Shen et al., 2018), (Shen et al., 2020), (Yu et al., 2020b), (Zhang et al., 2021), (Liu et al., 2021). (Shen et al., 2020). Hence, all the existing taxonomy expansion approaches expand a taxonomy either by merge operation(synonymy expansion) or by attach operation(hypernymy expansion). However, particular to WordNet expansion it is an integrated task of Merge and attach operation. We are the first to study the problem of taxonomy expansion using both the Attach and Merge taxonomy expansion operations in a single model. A detailed related study is in Section A of the Appendix.

7 Conclusion

In this paper, we proposed an integrated framework called *Taxonomy Expansion with Attach and Merge (TEAM)* for expanding taxonomy with attach and merge operations together. We built two multi-task learning-based variants of TEAM, namely, TEAM-Regression and TEAM-Classification, which solve the taxonomy expansion problem as regression and classification, respectively. Our proposed methods learned to predict the taxonomy expansion operation (merge, attach, or no-operation) to perform and provided a ranked list of candidates. We evaluated the effectiveness of TEAM on WordNet taxonomies of three distinct languages, viz., Assamese, Bangla, and Hindi. In various experimental setups, the proposed TEAM-RG and TEAM-CL outperformed its state of the art for attach operation and provided a highly encouraging performance on merge operation. We had also investigated the performance of the proposed model with out-of-vocabulary concepts.

In the future, we plan to investigate the response of the proposed model with different types of taxonomies and WordNet of different languages. Another future research possibility can be to explore the response of this model using advanced contextual encoders.

A Related Works

Expansion by resource alignment: In the first category of studies, Poprat et al. (2008) first attempted to automatically expand a WordNet with biomedical terminology; however, they were unable in developing the resource. Ruiz-Casado et al. (2005), Toral et al. (2008), Ponzetto and Navigli (2009), and Yamada et al. (2011) exploit structured information in Wikipedia to expand WordNet with new synsets. Snow et al. (2006) leverage distributional similarity techniques for WordNet expansion. Jurgens and Pilehvar (2015) enrich the existing WordNet taxonomy using an additional resource, Wiktionary, to extract sense data based on information in the term concepts.

Synonymy Expansion: Synonymy expansion in a taxonomy leverages synonymy relations to enrich a taxonomy with new concepts. Approaches for synonymy expansion can be divided in to two categories: (1) Distributional based approach (Wang et al., 2019), (Fei et al., 2019) (2) Pattern-based approach (Nguyen et al., 2017), (Nakashole et al., 2012). Given a seed taxonomy, the distributional approach discovers synonyms by representing strings with their distributional feature and learning a classifier to predict the relation between strings. However, in the pattern-based approach, consider the sentences mentioning a pair of synonymous strings and learn some textual patterns from these sentences, which are further used to discover more synonyms. Qu et al. (2017) proposed an approach that integrates both the categories. Boteanu et al. (2018) focus on the problem of expanding taxonomies with synonyms for applications in which entities are complex concepts arranged into taxonomies designed to facilitate browsing the product catalog on amazon.com. They first generate synonymy candidates for each node in the taxonomy and then filter synonymy candidates using a binary classifier. Yu et al. (2020a) study a task of synonym expansion using transitivity named SYNET, which leverages both the contexts of two synonymy pairs.

Hypernymy expansion : Jurgens and Pilehvar (2016) formulated a task of synonymy expansion, where it is proposed to enrich the WordNet taxonomy by performing two operations for each new concept. The first action is *Attach*, where a new concept is treated as a new synset and is attached as a hyponym of one existing synset in WordNet, and the second action is *Merge*, where a new concept is merged into an existing synset. The best solution proposed by Schlichtkrull and Alonso (2016) included only the attach operation. Later solutions for attaching, as in Shen et al. (2020), adopted self-supervision and tried to exploit the information of nodes in the seed taxonomy to perform node pair matching. On the other hand, Yu et al. (2020b) resorted to classification along mini paths in the taxonomy. In contrast, in our current approach, we have incorporated both the attach and merge operations.

B Graph Propagation Module (in details)

Graph Neural Network (GNN) allows us to transform and propagate node features as messages to learn structure-aware node representations. The EXTRACT() mechanism extracts the messages from a target node and its neighborhood, which is later on combined based on a chosen ATTENTION() mechanism by the AGGREGATE() operation. Next, the aggregated message is propagated to the rest of the graph. Studies apply various aggregation strategies to combine the propagated and extracted messages from the target node's neighborhood based on the importance of each node in the neighborhood towards that target node. GCN (Kipf and Welling, 2016) and GAT (Veličković et al., 2017) are popular GNN frameworks.

GCN uses $N(*)$ neighborhood-based normalization constant to calculate the importance ($att_{v\longrightarrow u}$) of node v towards the target node u without considering the participating nodes' features as follows.

$$H_u^l = \sigma\Big(\sum_{\forall v \in \tilde{N}(u)} att^{l-1}_{v\longrightarrow u} W^{l-1} H_v^{l-1}\Big) \tag{9}$$

$$\begin{array}{rcl}
\textsc{Attention}_{\mathrm{GCN}}(v \rightarrow u) & : & \\
att^{l-1}_{v\longrightarrow u} & = & \dfrac{1}{\sqrt{|\tilde{N}(u)||\tilde{N}(v)|}} \\
\textsc{Extract}_{\mathrm{GCN}}(v) & : & W^{l-1}H_v^{l-1} \\
\textsc{Aggregate}_{\mathrm{GCN}}(*) & : & \sigma(*)
\end{array}$$

where σ is non-linear activation function, W^l is a projection matrix for a GNN layer l and $\tilde{N}(*)$ is a node's extended neighborhood structure including the node itself (i.e., including self-loop edges).

GAT uses the same message extraction and aggregation strategies as above except for the fact that it uses attentive aggregation strategies that consider both the participating nodes' features as well as the neighborhood information, as follows.

$$\textsc{Attention}_{\text{GAT}}(v \rightarrow u) : att^{l-1}_{v \rightarrow u} = \underset{\forall v \in N(u)}{\textsc{Softmax}} \Big(c^{l-1} (W^{l-1} H^{l-1}_{u} \oplus W^{l-1} H^{l-1}_{v}) \Big)$$

where c^{l-1} is a learnable parameter to approximate the importance of node v towards u ($att^{l-1}_{v \rightarrow u}$) based on their interaction in the latent space in l layer-wise manner, W is the layer-wise projection matrix, and $\oplus$ denotes concatenation.

C Dataset Statistics

Table 1 shows the basic statistics of the datasets that we consider in this study. The taxonomy networks are extracted from Assamese, Bengali, and Hindi WordNets, respectively. The Assamese WordNet dataset consists of 8466 of noun concepts and 8463 edges. The network has the maximum in-degree path of 1, implying that each concept node has only one parent node or predecessor. The network consists of 7072 leaf nodes. Bengali WordNet dataset contains 26007 of noun concepts and 25815 edges and has the maximum in-degree path of 1. The network consists of 7072 leaf nodes. Hindi WordNet dataset consists of 28242 of noun concepts and 28016 edges. It contains 24737 leaf nodes.

D Ranking and Classification Metrics

We use an array of performance metrics from the domain of classification and ranking to evaluate the competing methods' performances. Among the ranking metrics, we use Mean Rank (MR), Hit@k (k=1, 3), and Mean Reciprocal Rank (MRR) to judge how well a competing method performs in producing a ranked list of candidate anchors given a test query and a taxonomy expansion operation to carry-out – merge or attach.

- **Mean Rank:** It calculates the average rank of true anchors among all the candidate anchors with respect to the matching scores, given a query.
- **Hit@k:** It calculates the number of times a true anchor appears in the top k positions when matched with a test query.
- **Mean Reciprocal Rank(MRR):** The Mean Reciprocal Rank is used to assess the ranking quality of the true anchor. The reciprocal rank can be computed by finding and inversing the rank of a true anchor in the predicted anchors' list of each query. MRR is averaged over all queries.

Further, we use Accuracy, Micro/ Macro F1, Precision, Recall, and F-Scores as classification metrics for deciding given a test query and an initial taxonomy tree, which operation among merge (M), attach (A), and no-operation (N) is to be performed.

- **Accuracy:** It summarizes the performance of the classification model as the fraction of the number of true tasks predicted over the total number of ground-truth tasks for a set of queries.
- **Precision:** It calculates the fraction of true-positive predicted expansion task classes among the total number of true-positive and false-negative task classes.
- **Recall:** It calculates the fraction of true-positive predicted expansion task classes among all the relevant ground-truth task classes.
- **F-Score:** The harmonic mean of precision and recall. It is also known as F1-Score.
- **Micro/ Macro F1 :** The Macro F1 computes F1-Score for each class (merge M/ attach A) independently but averages the final score by treating each expansion task-class as equally contributing. However, Micro F1 computes the F1-Score for each query sample in the training set and therefore aggregates the contributions of all expansion task classes to compute the final average metric.

E Evaluation Strategy

We obtain the initial feature vector for train and test concepts using pre-trained subword-aware Fast-text embeddings. For each concept, we generate its definition embedding by averaging the embedding of each word in its textual definition. We employ PyTorch and DGL framework [3] to load and train embeddings. In TEAM, we use a two-layer position-enhanced GAT where the first layer (of size 300) has four attention heads and the second layer (of size 600) has one attention head. We use 50-dimension position embeddings for both layers and apply dropout with the rate of 0.1 on the input

---

[3] https://github.com/dmlc/dgl

feature vectors. We use Adam optimizer with an initial learning rate of 0.001.

F Ranking result for out-of-vocabulary words

In the case of attach expansion, TEAM-RG beats state-of-the-art Taxo-expan by a large margin of $(321, 0.31, 0.48, 0.69)$ in MR, Hit@1, Hit@3, MRR, respectively. However, our proposed frameworks are seen not to perform so well in merge M operation as compared to the attach A operation. Intuitively, this is because, for OOV words, we use a set of manually collected paraphrase definitions of the OOV words to match them with the candidate anchor concepts in the existing taxonomy. Whereas for actually training our model, we have used the same definitions in the replica nodes. That is, we have used the same definition in the original anchor concept and in the input query-concept with mutually exclusive synset information. Thus, in this case-study, the paraphrase-based definition matching deems challenging for our learning model resulting in poorer results for M operation. We believe we can always eliminate this drawback by using a description generation tool (Wang et al., 2021) to generate different definitions of the same concept nodes and train our learning model in a more powerful way.

Extracting Temporal Event Relation with Syntax-guided Graph Transformer

Shuaicheng Zhang♣**, Qiang Ning**♠**, Lifu Huang**♣
♣Virginia Tech, ♠Amazon
♣`{zshuai8,lifuh}@vt.edu`, ♠`qning@amazon.com`

Abstract

Extracting temporal relations (e.g., before, after, and simultaneous) among events is crucial to natural language understanding. One of the key challenges of this problem is that when the events of interest are far away in text, the context in-between often becomes complicated, making it challenging to resolve the temporal relationship between them. This paper thus proposes a new Syntax-guided Graph Transformer network (SGT) to mitigate this issue, by (1) explicitly exploiting the connection between two events based on their dependency parsing trees, and (2) automatically locating temporal cues between two events via a novel syntax-guided attention mechanism. Experiments on two benchmark datasets, MATRES and TB-DENSE, show that our approach significantly outperforms previous state-of-the-art methods on both end-to-end temporal relation extraction and temporal relation classification; This improvement also proves to be robust on the contrast set of MATRES. The code is publicly available at https://github.com/VT-NLP/Syntax-Guided-Graph-Transformer.

1 Introduction

Temporal relationship, e.g., *Before*, *After*, and *Simultaneous*, is important for understanding the process of complex events and reasoning over them. Extracting temporal relationship automatically from text is thus an important component in many downstream applications, such as summarization (Jiang et al., 2011; Ng et al., 2014), dialog understanding and generation (Ritter et al., 2010; Sun et al., 2021), reading comprehension (Harabagiu and Bejan, 2005; Sun et al., 2018; Ning et al., 2020; Huang et al., 2019) and future event prediction (Li et al., 2021; Lin et al., 2022). While event mentions can often be detected reasonably well (Lin et al., 2020; Huang and Ji, 2020; Wang et al., 2021, 2022), extracting event-event relationships, especially temporal relationship, still remains challenging (Chen et al., 2021).

S1: Now, Lockheed Martin which (***e_1*: bought**) an early version of such a computer from the Canadian company D-Wave systems two years ago is confident enough in the technology to upgrade it to commercial scale, becoming the first company to (***e_2*: use**) quantum computing as part of its business.

Figure 1: Examples of temporal relation annotations. Event mentions are boldfaced, the temporal relations between these events are listed below each sentence, and the temporal cues deciding those temporal relations are highlighted in red.

Recent studies (Han et al., 2019b; Ning et al., 2017; Vashishtha et al., 2019; Wang et al., 2020a) have shown improved performance in temporal relation extraction by leveraging the contextual representations learned from pre-trained language models (Devlin et al., 2018; Liu et al., 2019). However, one remaining challenge of this task is that it requires accurate characterization of the connection between two event mentions and the cues indicating their temporal relationship, especially when the context is wide and complicated. For instance, by manually examining 200 examples of human annotated temporal relations from the MATRES (Ning et al., 2018) dataset, we find that about 52% of the temporal cues[1] come from the connection between two event mentions (e.g., S1 in Fig. 1), 39% from their surrounding contexts (S2 in Fig. 1) and the remaining 9% from others, e.g., event co-reference or subordinate clause structures (S3 in Fig. 1).

---

[1] Temporal cues refer to the words of which the semantic meaning or related syntactic relations can determine the temporal relation of two event mentions.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 379 - 390

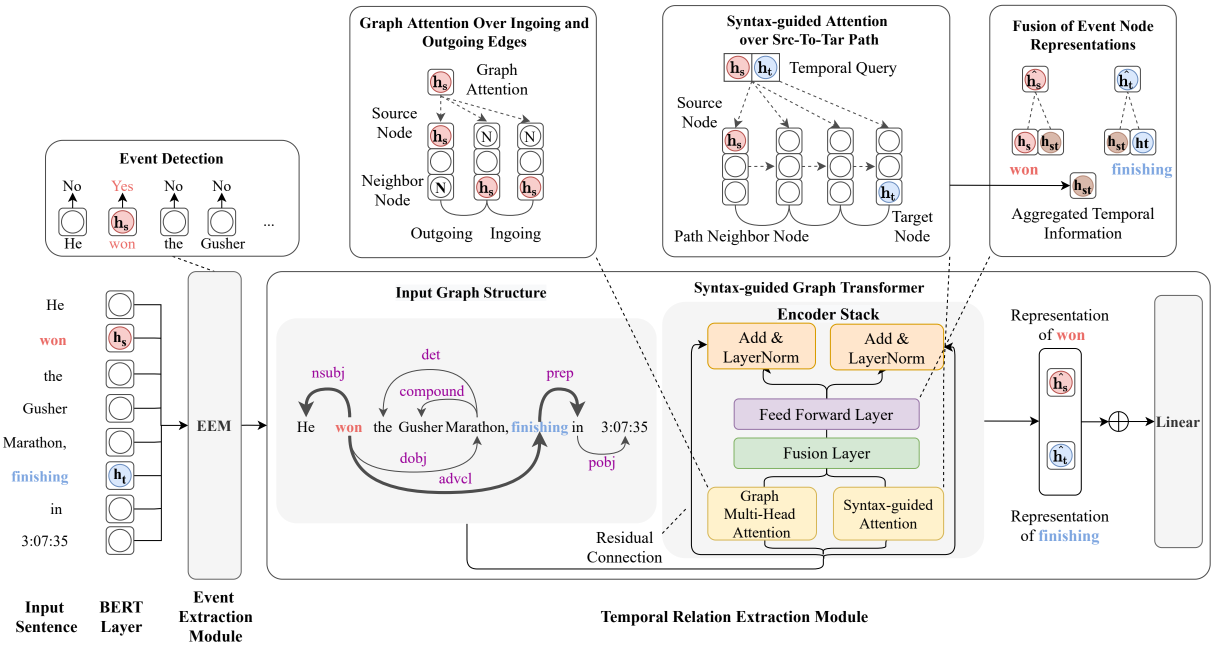

Figure 2: Architecture overview. The tokens highlighted with red and blue colors in the Input Sentence show the source and target events to be detected. The bold edges in the Input Graph Structure indicate the triples from the dependency path between the source and target event mentions as well as their surrounding context, and are considered by the syntax-guided attention.

Syntactic features, such as dependency parsing trees, have proved to be effective in characterizing the connection of two event mentions in pre-neural methods (Chambers, 2013; Chambers et al., 2014; Mirza and Tonelli, 2016). However, how to make use of these features has been under-explored since the adoption of neural methods in this field. This paper closes this gap with a novel Syntax-guided Graph Transformer (SGT) network – in addition to the attention heads in a typical Graph Transformer, we bring in a new attention mechanism that specifically looks at the path from a source node to a target node over dependency parsing trees. SGT thus not only learns event representations as in a typical Graph Transformer, but also provides a way to represent syntactic dependency information between a pair of events (for temporal relation extraction, this means attending to the aforementioned temporal cues). We conduct experiments on two benchmark datasets, MATRES (Ning et al., 2018) and TB-DENSE (Cassidy et al., 2014) on both end-to-end temporal relation extraction and classification, which demonstrate the effectiveness of SGT over previous state-of-the-art methods. Experiments on the contrast set (Gardner et al., 2020) of MATRES further proves the robustness of our approach.

2 Approach

Figure 2 shows the overview of our approach. Given an input sentence $\tilde{s} = [w_1, w_2, ..., w_n]$ with n tokens, we aim to detect a set of event mentions $\{e_1, e_2, ...\}$ where each event mention e_i may contain one or multiple tokens by leveraging the contextual representations learned from a pre-trained BERT (Devlin et al., 2018) encoder. Then, following previous studies (Ning et al., 2019, 2017; Han et al., 2019b; Wang et al., 2020a), we consider each pair of event mentions that are detected from one or two continuous sentences, and predict their temporal relationship.

To effectively capture the temporal cues between two event mentions, we build a dependency graph from one or two input sentences and design a new Syntax-guided Graph Transformer network to automatically learn a new contextual representation for each event mention by considering the triples that they are locally involved as well as the triples along the dependency path of the two event mentions within the dependency graph. Finally, the two event mention representations are concatenated to predict their temporal relationship.

2.1 Sequence Encoder

Given an input sentence $\tilde{s} = [w_1, w_2, ..., w_n]$, we apply the same tokenizer as BERT (Devlin et al., 2018) to get all the subtokens. Then, we feed the sequence of subtokens as input to a pre-trained BERT model to get a contextual representation for each token w_i. If a token w_i is split into multiple subtokens, we use the contextual representation of the first subtoken to represent w_i. To enrich the contextualized representations, for each token, we create a one-hot Part-of-Speech (POS) tag vector and concatenate it with BERT contextual embeddings. In this way, we obtain a final representation $\boldsymbol{c}_i$[2] for each w_i. These representations will be later used for event mention detection and also as the initial representations to our syntax-guided graph transformer network.

2.2 Event Detection

To detect event mentions from the sentence, we take the contextual representation of each word as input to a binary linear classifier to determine whether it is an event mention or not, which is optimized by minimizing the following binary cross-entropy loss:

$$\tilde{\boldsymbol{y}}_i = \text{softmax}(\boldsymbol{W}_{eve}\boldsymbol{c}_i + \boldsymbol{b}_{eve})$$

$$\mathcal{L}_{eve} = -\sum_{\tilde{s}\in\mathcal{S}}\sum_{i=1}^{|\tilde{s}|}\sum_{\pi\in\{0,1\}} \alpha_\pi y_{i,\pi}\log(\tilde{y}_{i,\pi})$$

where $\mathcal{L}_{eve}$ denotes the cross-entropy loss for event detection. $\mathcal{S}$ is the set of sentences in the training dataset. α_π is a weight coefficient for each class (0 or 1) to mitigate the data imbalance problem and $\alpha_0 + \alpha_1 = 1$. $y_{i,\pi}$ is a binary indicator to show whether π is the same as the groundtruth binary label ($y_{i,\pi} = 1$) or not ($y_{i,\pi} = 0$). $\tilde{y}_{i,\pi}$ denotes the probability of the i-th token in s being predicted with a binary class label π. $\boldsymbol{W}_{eve}$ and $\boldsymbol{b}_{eve}$ are learnable parameters.

2.3 Syntax-guided Graph Transformer

From the example sentences in Fig. 1, the temporal cues for characterizing the temporal relationship between two event mentions mainly come from their surrounding contexts as well as their connections from their syntactic dependency path. However, a sequence encoder usually fails to capture such information, especially when the context between two event mentions is complicated, thus we further design a new Syntax-guided Graph Transformer (SGT) network.

Given a source event e_s and a target event e_t detected from one or two continuous sentences, we apply a public dependency parser[3] to parse each sentence into a tree-graph and connect the graphs of two continuous sentences with an arbitrary *cross-sentence* edge (Peng et al., 2017; Cheng and Miyao, 2017) pointing from the root node of the preceding sentence to the root node of the following one, and obtain a graph $G = (V, E)$. For each node v_i, we use $\mathcal{N}_i^{in} = \{(v_k, r_{ki}, v_i) \in E | v_k, v_i \in V\}$ and $\mathcal{N}_i^{out} = \{(v_i, r_{ij}, v_j) \in E | v_i, v_j \in V\}$ to denote all the neighbor triples of v_i with in-going and out-going edges respectively, $r \in \Upsilon$ where Υ is the label set for syntactic dependency relation, and use $\mathcal{P}_{ij} = \{(v_i, r_{ig}, v_g), ..., (v_h, r_{hj}, v_j)\}$ as the triple set along the path from v_i to v_j.

Node Representation Initialization For each node v_i in graph G, we map it to a particular token $w_{i'}$ from the original sentence and obtain a contextual representation $\boldsymbol{c}_{i'}$ from the BERT encoder. Then, we learn an initial node representation for each node v_i as:

$$\boldsymbol{h}_i^0 = \boldsymbol{W}_e\boldsymbol{c}_{i'} + \boldsymbol{b}_e$$

where $\boldsymbol{W}_e$ and $\boldsymbol{b}_e$ are learnable parameters.

Graph Multi-head Self-attention Following transformer model (Vaswani et al., 2017; Wang et al., 2020b), we adapt the multi-head self-attention to learn a contextual representation for each node in the graph G. Each node v_i in graph G is associated with a set of neighbor triples $\mathcal{N}_i^{in} \cup \mathcal{N}_i^{out}$ and a node representation $\boldsymbol{h}_i^{l-1}$ where l is the index of a layer in our transformer architecture. To perform self-attention, we first apply a linear transformation to obtain a query vector based on each node v_i, and employ another two linear transformations to get the key and value vectors based on the node's neighbor triples:

$$\begin{aligned}
&\boldsymbol{Q}_i^l = \boldsymbol{W}_q^m\boldsymbol{h}_i^{l-1} \\
&\boldsymbol{K}_{ij}^l = \boldsymbol{W}_k^m\boldsymbol{R}_{ij}^{l-1} \\
&\boldsymbol{U}_{ij}^l = \boldsymbol{W}_u^m\boldsymbol{R}_{ij}^{l-1} \\
&\boldsymbol{R}_{ij}^{l-1} = \boldsymbol{W}_r^m(\boldsymbol{h}_i^{l-1}\big|\big|\boldsymbol{r}_{ij}\big|\big|\boldsymbol{h}_j^{l-1}) + \boldsymbol{b}_r^m
\end{aligned}$$

where m is the index of a particular head. $\boldsymbol{Q}_i^l$ denotes a query vector corresponding to node v_i,

---

[2] We use bold lower case symbols to denote vectors.

[3] https://spacy.io/api/dependencyparser

$\boldsymbol{K}_{ij}^{l}$ and $\boldsymbol{U}_{ij}^{l}$ is a key and value vector respectively, and both of them are learned from a triple $(v_i, r_{ij}, v_j) \in \mathcal{N}_i^{in} \cup \mathcal{N}_i^{out}$, which is represented as $\boldsymbol{R}_{ij}$. m is the index of a particular head. || denotes the concatenation operation. $\boldsymbol{r}_{ij}$ denotes the representation of a particular relation r_{ij} between v_i and v_j, which is randomly initialized and optimized by the model. $\boldsymbol{W}_q^m$, $\boldsymbol{W}_k^m$, $\boldsymbol{W}_u^m$, $\boldsymbol{W}_r^m$ and $\boldsymbol{b}_r^m$ are learnable parameters.

For each node v_i, we then perform self-attention over all the neighbor triples that it is involved, and compute a new context representation with multiple attention heads:

$$\boldsymbol{g}_i^l = (\overset{M}{\underset{m}{\Big|\Big|}} \text{Head}_i^m)\boldsymbol{W}_o$$

$$\text{Head}_i^m = \text{softmax}(\frac{\boldsymbol{Q}_i^l(\boldsymbol{K}^l)^\top}{\sqrt{d_k}})\boldsymbol{U}^l$$

where $\boldsymbol{g}_i^l$ is the aggregated representation computed over all neighbor triples of node v_i with M attention heads at l-th layer. $\boldsymbol{g}_i^l$ will be later used to learn the updated representation of node v_i. $\sqrt{d_k}$ is the scaling factor denoting the dimension size of each key vector. $\boldsymbol{W}_o$ is a learnable parameter.

Syntax-guided Attention To automatically find the indicative temporal cues for two event mentions from their connection as well as surrounding contexts, we design a new syntax-guided attention mechanism. For two event nodes v_s and v_t, we first extract the set of nodes from the dependency path between v_s and v_t (including v_s and v_t), which is denoted as Θ_{st}. We then get all the triples from the dependency path between v_s and v_t as well as the triples that any node from Θ_{st} is involved, which are denoted as $\Phi_{st} = \cup_{v_i \in \Theta_{st}} \{\mathcal{N}_i^{in} \cup \mathcal{N}_i^{out}\} \cup \mathcal{P}_{st}$. To compute the syntax-guided attention over all the triples from Φ_{st}, we apply three linear transformations to get the query, key and value vectors where the query vector is obtained from the representation of two event mentions, and key and value vectors are computed from the triples in Φ_{st}:

$$\begin{aligned}
\tilde{\boldsymbol{Q}}_{st}^l &= \tilde{\boldsymbol{W}}_q^m \cdot (\boldsymbol{h}_s^{l-1} \big|\big| \boldsymbol{h}_t^{l-1})^x \\
\tilde{\boldsymbol{K}}_{ij}^l &= \tilde{\boldsymbol{W}}_k^m \tilde{\boldsymbol{R}}_{ij}^{l-1} \\
\tilde{\boldsymbol{U}}_{ij}^l &= \tilde{\boldsymbol{W}}_u^m \tilde{\boldsymbol{R}}_{ij}^{l-1} \\
\tilde{\boldsymbol{R}}_{ij}^{l-1} &= \tilde{\boldsymbol{W}}_r^m (\boldsymbol{h}_i^{l-1} \big|\big| \boldsymbol{r}_{ij} \big|\big| \boldsymbol{h}_j^{l-1}) + \tilde{\boldsymbol{b}}_r
\end{aligned}$$

where m is the index of a particular head, $\tilde{\boldsymbol{Q}}_{st}^l, \tilde{\boldsymbol{K}}_{ij}^l, \tilde{\boldsymbol{U}}_{ij}^l$ denote the query, key and value vectors respectively. $\tilde{\boldsymbol{R}}_{ij}^{l-1}$ is the representation of a triple $(v_i, r_{ij}, v_j) \in \Phi_{st}$. $\tilde{\boldsymbol{W}}_q^m$, $\tilde{\boldsymbol{W}}_k^m$, $\tilde{\boldsymbol{W}}_v^m$ and $\tilde{\boldsymbol{W}}_r^m$ are learnable parameters.

Given the query vector, we then compute the attention distribution over all triples from Φ_{st} and get an aggregated representation to denote the meaningful temporal features captured from the connection between two event mentions and their surrounding contexts.

$$\tilde{\boldsymbol{g}}_{st}^l = (\overset{M}{\underset{m}{\Big|\Big|}} \tilde{\text{Head}}_{st}^m) \cdot \tilde{\boldsymbol{W}}_p$$

$$\tilde{\text{Head}}_{st}^m = \text{softmax}(\frac{\tilde{\boldsymbol{Q}}_{st}^l(\tilde{\boldsymbol{K}}^l)^\top}{\sqrt{d_k}}) \cdot \tilde{\boldsymbol{U}}^l$$

where $\tilde{\boldsymbol{g}}_{st}^l$ is the aggregated temporal related information from all the triples in Φ_{st} based on the syntax-guided attention at l-th layer. $\boldsymbol{W}_p$ is a learnable parameter.

Node Representation Fusion Each event node in graph G will receive two representations learned from the multi-head self-attention and syntax-guided attention, thus we further fuse the two representations for both the source node v_s and the target node v_t:

$$\hat{\boldsymbol{h}}_s^l = \tilde{\boldsymbol{W}}_f(\boldsymbol{g}_s^l \big|\big| \tilde{\boldsymbol{g}}_{st}^l) \ , \ \ \hat{\boldsymbol{h}}_t^l = \tilde{\boldsymbol{W}}_f(\tilde{\boldsymbol{g}}_{st}^l \big|\big| \boldsymbol{g}_t^l)$$

where $\boldsymbol{g}_s^l$ and $\boldsymbol{g}_t^l$ denote the context representations learned from the multi-head self-attention for v_s and v_t. $\tilde{\boldsymbol{g}}_{st}^l$ denotes the representation learned from the triples from Φ_{st} using syntax-guided attention. $\hat{\boldsymbol{h}}_s^l$ and $\hat{\boldsymbol{h}}_t^l$ are the fused representations of v_s and v_t, respectively. $\tilde{\boldsymbol{W}}_f$ is a learnable parameter.

For each non-event node v_i, which only receives a context representation $\boldsymbol{g}_i^l$ learned from the multi-head self-attention, we apply a linear projection and get a new node representation:

$$\hat{\boldsymbol{h}}_i^l = \boldsymbol{W}_t \boldsymbol{g}_i^l$$

Our Syntax-guided Graph Transformer encoder is composed of a stack of multiple layers, while each layer consists of the two attention mechanisms and the fusion sub-layer. We use residual connection followed by LayerNorm for each layer to get the final representations of all the nodes:

$$\boldsymbol{H}^l = \text{LayerNorm}(\hat{\boldsymbol{H}}^l + \boldsymbol{H}^{l-1})$$

2.4 Temporal Relation Prediction

To predict the temporal relation between two event mentions e_s and e_t, we concatenate the final hidden states of v_s and v_t obtained from the Syntax-guided Graph Transformer network, and apply a Feedforward Neural Network (FNN) to predict their relationship

$$\tilde{\boldsymbol{y}}_{st} = \text{softmax}(\boldsymbol{W}_z(\boldsymbol{h}_s^L \,||\, \boldsymbol{h}_t^L) + \boldsymbol{b}_t)$$

where $\tilde{\boldsymbol{y}}_{st}$ denotes the probabilities over all possible temporal relations between event mentions e_s and e_t.

The training objective is to minimize the following cross-entropy loss function:

$$\mathcal{L}_{rel} = -\sum_{st\in\Delta}\sum_{x\in X}\beta_x y_{st,x}\log(\tilde{y}_{st,x}))$$

where Δ denotes the total set of event pairs for temporal relation prediction and X denotes the whole set of relation labels. $y_{st,x}$ is a binary indicator (0 or 1) to show whether x is the same as the groundtruth label ($y_{st,x} = 1$) or not ($y_{st,x} = 0$). We also assign a weight β_x to each class to mitigate the label imbalance issue.

3 Experiment

3.1 Experimental Setup

We perform experiments on two public benchmark datasets for temporal relation extraction: (1) TB-DENSE (Cassidy et al., 2014), which is a densely annotated dataset with 6 types of relations: *Before*, *After*, *Simultaneous*, *Includes*, *Is_included* and *Vague*. (2) MATRES (Ning et al., 2018), which annotates verb event mentions along with 4 types of temporal relations: *Before*, *After*, *Simultaneous* and *Vague*. Additionally, we use POS tag information from MATRES provided by (Ning et al., 2019). For TB-DENSE, we use spacy annotation for predicting POS tag information which is based on Universal POS tag set[4]. For both benchmark datasets, we use the same train/dev/test splits as previous studies (Ning et al., 2019, 2017; Han et al., 2019a,b). Note that, for evaluation, similar as previous work, we disregard the *Vague* relation from both datasets (in the evaluation phase, we simply remove all ground truth *Vague* relation pairs). In addition, we will only consider event pairs from adjacent sentences due to the fact that it will require an exponential number of annotations if we also consider event pairs from non-adjacent sentences, which is beyond the scope of this study. Table 1 shows statistics of the two datasets and Table 2 shows the label distribution.

Corpora		Train	Dev	Test
TB-DENSE	# Documents	22	5	9
	# Relation Pairs	4,032	629	1,427
MATRES	# Documents	255	20	25
	# Relation Pairs	13K	2.6K	837

Table 1: Data statistics for TB-DENSE and MATRES

Labels	TB-DENSE		MATRES	
Before	384	26.9%	417	49.8%
After	274	19.2%	266	31.8%
Includes	56	3.9%	-	-
Is_Included	53	3.7%	-	-
Simultaneous	22	1.5%	31	3.7%
Vague	638	44.7%	133	15.9%

Table 2: Label distribution for TB-DENSE and MATRES. For each dataset, the first column shows the number of instances of each relation type while the second column shows the percentage.

Implementation Details For fair comparisons with previous baseline approaches, we use the pre-trained bert-large-cased model[5] for fine-tuning and optimize our model with BertAdam. We optimize the parameters with grid search: training epoch 10, learning rate $\in \{3e\text{-}6, 1e\text{-}5\}$, training batch size $\in \{16, 32\}$, encoder layer size $\in \{4, 12\}$, number of heads $\in \{1, 8\}$. During training, we first optimize the event extraction module for 5 epochs to warm up, and then jointly optimize both event extraction and temporal relation extraction modules using gold event pairs for another 5 epochs.

3.2 Results

We evaluate SGT against two public benchmark datasets under two settings: (1) joint event and temporal relation extraction (Table 3); (2) temporal relation classification, where the gold event mentions are known beforehand (Table 4). Note in the "joint" setting, we adopt the same strategy proposed in (Han et al., 2019b): we first train the event extraction module, and then jointly optimize both event extraction and temporal relation extraction

Table 4: Comparison of various approaches on temporal relation classification with gold event mentions as input.

(using gold event pairs as input to ensure training quality) modules. Overall, we observe that our approach significantly outperforms baseline systems in both settings, with up to 7.9% absolute F-score gain on MATRES and 2.4% on TB-DENSE.

From Table 3, we see that our approach achieves better performance on event detection than baseline methods though they are based on the same BERT encoder. This is possibly because, during joint training, our approach leverages the dependency parsing trees, which improves the contextual representations of the BERT encoder. In Table 4, unlike other models which are based on larger contextualized embeddings such as RoBERTa, our approach with BERT base achieves comparable performance, and further surpasses the state-of-the-art baseline methods using BERT-large embeddings, which demonstrate the effectiveness of our Syntax-guided Graph Transformer network.

Some studies (Ning et al., 2019; Han et al., 2019b; Wang et al., 2020a; Zhou et al., 2020) focus on resolving the inconsistency in terms of the symmetry and transitivity of the temporal relations. For example, if event A and event B are predicted as *Before*, event B and event C are predicted as *Before*, then if event A and event C are predicted as *Vague* or *After*, it will be considered as inconsistent. However, our approach shows consistent predictions with few inconsistent cases when *Simultaneous* relation is involved. This analysis also demonstrates that our approach can correctly capture the temporal cues between two event mentions.

Model	Original Test	Contrast	Consistency
CogCompTime2.0 (Ning et al., 2019)	73.2	63.3	40.6
Our Approach	**77.0**	**64.8**	**49.8**

Table 5: Evaluation on the contrast set of MATRES. Original Test indicates the accuracy on 100 examples sampled from the original MATRES test set following (Gardner et al., 2020). Contrast shows the accuracy score on 401 examples perturbed from the original 100 examples. Consistency is defined as the percentage of the original 100 examples for which the model's predictions of the perturbed examples are all correct in the contrast set.

We also examine the correctness and robustness of our approach on a contrast set of MATRES (Gardner et al., 2020), which is created with small manual perturbation based on the original test set of MATRES in a meaningful way, such as rephrasing the sentence or simply changing a word of the sentence to alter the relation type. The contrast set

Prediction	Example
✗ BERT: ***Before*** ✓ BERT-GT: ***After*** ✓ BERT-SGT: ***After***	**S1:** Before (***e_1*: retiring**) in 1984 , Mr. Lowe (***e_2*: worked**) as an inspector of schools with the department of education and sciences , and he leaves three sons from a previous marriage .
✗ BERT: ***Before*** ✗ BERT-GT: ***Before*** ✓ BERT-SGT: ***After***	**S2:** Mr. Erdogan has long (***e_1*: sought**) an apology for the raid in May 2010 on the Mavi Marmara , which was part of a Flotilla that (***e_2*: sought**) to break Israel's blockade of gaza.

Figure 3: Comparison of the predictions from BERT, BERT-GT and our approach.

provides a local view of a model's decision boundary, thus it can be used to more accurately evaluate a model's true linguistic capabilities. Table 5 shows that our approach significantly outperforms the baseline model on both the original test set and the corresponding contrast set. The contrast consistency in Table 5 also indicates how well a model's decision boundary aligns with the actual decision boundary of the test instances, based on which we can see that by explicitly capturing temporal cues, our approach is more accurate and robust than the baseline method.

Ablation Study We further conduct ablation studies to compare the performance of our approach with two ablated versions of our method: (1) BERT with Graph Transformer (BERT-GT), for which we remove the syntaxic-guided attention and only rely on the standard multi-head self-attention to obtain graph-based contextual representations of two event mentions and then predict their relation; (2) BERT, where we further remove the Graph Transformer, and only use the pre-trained BERT language model to encode the sentence and predict the temporal relationship of two event mentions based on their contextual representations.

Ablation	F-score (%)	Gain (%)
BERT-SGT	79.3	0
BERT-GT	77.5	-2.0
BERT	75.5	-3.8

Table 6: Ablation study on MATRES. We use BERT base as the comparison basis.

Table 6 also shows that by adding Graph Transformer, BERT-GT achieves 2.0% absolute F-score improvement over the BERT baseline model, demonstrating the benefit of dependency parsing trees to temporal relation prediction. By further adding the new syntax-guided attention into Graph Transformer, the absolute improvement on F-score (1.8%) shows the effectiveness of our new Syntax-guided Graph Transformer and the importance of capturing temporal cues from the connection of two event mentions as well as their surround contexts.

Figure 3 shows two examples as qualitative analysis. In S1, BERT mistakenly predicts the temporal relation as *Before* probably because it's confused by the context word *Before*. However, by incorporating the dependency graph, especially the triples {*worked*, *prep*, *Before*}, {*Before*, *pcomp*, *retiring*} and the path between the two event mentions, *worked→prep→Before→pcomp→retiring*, both BERT-GT and our approach correctly determine the relation as *After*. In S2, both BERT and BERT-GT mistakenly predict the temporal relation as *Before* as the context between the two event mentions is very wide and complicated, and these two event mentions are not close within the dependency graph. However, by explicitly considering and understanding the connection between the two event mentions, $sought_{e_1}$ *→on→Marmara→was→part→Flotilla →*$sought_{e_2}$, our approach correctly predicts the temporal relation between the two event mentions.

3.3 SGT on Temporal Cues

To analyze the source of temporal cues for relation prediction, we randomly sample 100 correct event relation predictions given gold event mentions from MATRES and select the triple that has the highest temporal attention weight from the last layer of the Syntax-guided Graph Transformer network as a temporal cue candidate. We manually evaluate the validity of each temporal cue candidate, and further analyze if the cue is from the dependency path between two event mentions, their surrounding context, or both. Our analysis shows that about 64% of the temporal cues are valid, 37% of them come from the dependency path, 17% are from local context, and the remaining 10% are from both. This verifies our initial observation that most of the temporal cues are from the dependency path between two event mentions as well as their surrounding context. It also demonstrates the effectiveness of our new syntax-guided attention mechanism.

3.4 Impact of Wide Context

We further illustrate the impact of context width to both baseline model and our approach. For fair comparison, we use three context width category, [context length < 10, $10 <$ context length < 20, context length > 20]. As we can see in Fig. 4, the first category has 267 pairs, the second category has 343 pairs and the third category has 817 pairs. From our results, we observe that the BERT baseline cannot predict the temporal relation of two event mentions with wide context but rather working well when the event mentions are close to each other. Our model overall performs slightly worse in the second category but in general is very good at predicting the temporal relationship for the event mentions with short and context width. This also proves the benefit of syntactic parsing trees to the prediction of temporal relationship. For the second category where the context length is within [10, 20], the performance of our approach slightly drops due to two reasons: (1) the training samples within this range are not as sufficient as the other two categories; (2) for most event pairs from this category, their dependency path is very long and there is no explicit temporal indicative features within their context or dependency path, making it more difficult for the model to predict their temporal relationship.

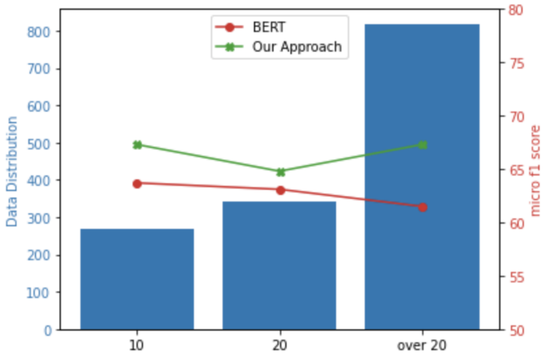

Figure 4: Context width analysis on TB-DENSE. The X axis shows the number of tokens between two events mentions. The left Y axis shows the data distribution of each width category indicating with blue bars. The right Y axis denotes the micro F-score for each width category.

3.5 Remaining Errors

We randomly sample 100 classification errors from the output of our approach and categorize them into four categories. As Figure 5 shows, the first category is due to the complex or ambiguous context (54% of the total errors). The second category is due to the complicated subordinate clause structure, especially the clauses that are related to quote or reported speech, e.g., S2 in Figure 5. The third error category is that our approach cannot correctly differentiate the actual events from the hypothetical and intentional events, while in most cases, the temporal relation among hypothetical and intentional events is annotated as *Vague*. The last category is due to the lack of sufficient annotation. We observe that none of the *Simultaneous* relation can be correctly predicted for MATRES dataset as the percentage of *Simultaneous* (3.7%) is much lower than other relation types. In TB-DENSE dataset, labels are even more imbalanced as the percentage of *Vague* relation is over 50% while the percentage of *Includes*, *Is_Included* and *Simultaneous* are all less than 4%.

4 Related Work

Early studies on temporal relation extraction mainly model it as a pairwise classification problem (Mani et al., 2006; Verhagen et al., 2007; Verhagen and Pustejovsky, 2008; Verhagen et al., 2010; Bethard et al., 2016; MacAvaney et al., 2017) and rely on hand-crafted features and rules (Verhagen and Pustejovsky, 2008; Bethard et al., 2007) to extract temporal event relations. Recently, deep neural networks (Dligach et al., 2017; Tourille et al., 2017) and large-scale pre-trained language models (Han et al., 2019a, 2021; Wang et al., 2020a; Zhou et al., 2020) are further employed and show state-of-the-art performance.

Similar to our approach, several studies (Ling and Weld, 2010; Nikfarjam et al., 2013; Mirza and Tonelli, 2016; Meng et al., 2017; Cheng and Miyao, 2017; Huang et al., 2017) also explored syntactic path between two events for temporal relation extraction. Different from previous work, our approach considers three important sources of temporal cues: *local context*, denoting the neighbors of each event node within the dependency graph; *connection of two event mentions*, which is based on the dependency path between two event mentions; and *rich semantics of concepts and dependency relations*, for example, the dependency

Error Category (Percent)	Example
Complex Context (54%)	**S1:** "This is not a Lehman , " he (**e_1: said**) to the disastrous chain reaction (**e_2: touched)** off by the collapse of Lehman brothers in 2008 . (*After*)
Subordinate Clause (22%)	**S2:** "We were pleased that England and New Zealand knew about it, and we (**e_1: thought**) that's where it would stop." He also (**e_2: talked**) about his " second job " as the group's cameraman. (*Vague*)
Hypothetical Events and Intentional Events (18%)	**S3:** The day before Raymond Roth was (**e_1: pulled**) over, his wife, Ivana, showed authorities emails she had discovered that (***e2*: appeared**) to detail a plan between him and his son to fake his death. (*Vague*)
Imbalanced Labels (6%)	**S4:** Microsoft (**e_1: said)** it has identified three companies for the china program to (***e2*: run)** through June . (*Simultaneous*)

Figure 5: Types of remaining errors

relation *nmod* between two event mentions usually indicates a *Before* relationship. All these indicative features are automatically selected and aggregated with the multi-head self-attention and our new syntax-guided attention mechanism.

Our work is also related to the variants of Graph Neural Networks (GNN) (Kipf and Welling, 2016; Veličković et al., 2018; Zhou et al., 2018), especially Graph Transformer (Yun et al., 2019; Chen et al., 2019; Hu et al., 2020; Wang et al., 2020b). Different from previous GNNs which aim to capture the context from neighbors of each node within the graph, in our task, we aim to select and capture the most meaningful temporal cues for two event mentions from their connections within the graph as well as their surrounding contexts.

5 Conclusion

Temporal relationship between events is important for understanding stories described in natural language text, and a main challenge is how to discover and make use of the connection between two event mentions, especially when the event pair is far apart in text. This paper proposes a novel Syntax-guided Graph Transformer (SGT) that represents the connection between an event pair via additional attention heads over dependency parsing trees. Experiments on benchmarking datasets, MATRES, TB-DENSE, and a contrast set of MATRES, show that our approach significantly outperforms previous state-of-the-art methods in a variety of settings, including event detection, temporal relation classification (where events are given), and temporal relation extraction (where events are predicted). In the future, we will investigate the potential of this approach to other relation extraction tasks.

From Cognitive to Computational Modeling: Text-based Risky Decision-Making Guided by Fuzzy Trace Theory

Abstract

Understanding, modelling and predicting human risky decision-making is challenging due to intrinsic individual differences and irrationality. Fuzzy trace theory (FTT) is a powerful paradigm that explains human decision-making by incorporating gists, i.e., fuzzy representations of information which capture only its quintessential meaning. Inspired by Broniatowski and Reyna's FTT cognitive model, we propose a computational framework which combines the effects of the underlying semantics and sentiments on text-based decision-making. In particular, we introduce Category-2-Vector to learn categorical gists and categorical sentiments, and demonstrate how our computational model can be optimised to predict risky decision-making in groups and individuals.

1 Introduction

Imagine that your town is preparing for a viral outbreak which is projected to kill 600 people. Two alternative programs to combat the virus have been proposed. Assume that the exact scientific estimates of the consequences of the programs are **Program A:** "*200 people will be saved*"; and **Program B:** "*1/3 probability that all 600 lives will be saved; 2/3 probability that no lives will be saved*". Given these choices, which program would you choose? Alternatively, if choices were presented as follows, which program would you choose? **Program C:** "*400 people will die*"; and **Program D:** "*1/3 probability that no one will die and a 2/3 probability that all 600 will die*". This problem is a modified version of the *Asian disease problem* (ADP) (Tversky and Kahneman, 1981), a well-studied *risky decision-making problem* (RDMP) in psychology where decisions are made under risk or include probabilistic outcomes (Edwards, 1954). In this RDMP, programs A and B form the *gain frame* where choices are worded in a positive and optimistic manner, whereas programs C and D form the *loss frame* where choices are written in a negative and pessimistic manner. Studies have validated that in the gain frame, humans overwhelmingly prefer the safe choice A (72%), whereas in the loss frame, they overwhelmingly prefer the risky choice D (78%) even though the choices and outcomes in both frames are equivalent (Tversky and Kahneman, 1981). This phenomenon, known as the *Allais paradox*, implies that observed human choices are inconsistent with predictions based on expected utility alone, thereby confirming the influence of language, wording of choices, and sentiments on human decision-making.

Being able to understand, model and predict human decision-making leads to many real-world applications, from predicting election results (Hillygus and Shields, 2005), to improving user experience in recommender systems (Chen et al., 2013). However, Allais paradox means that understanding the integral but complex cognitive process of decision-making, particularly in humans, is extremely challenging due to our diverse characteristics, beliefs and experiences. Furthermore, human decision-making is often fraught with irrationality even in the presence of overwhelming evidence against some choice or beliefs (Simon, 1993). This brings into question how human decision-making can be modelled with these complexities and nuances involved. This is an especially important task when considering current approaches to decision-making, such as utility theory which typically lacks any behavioural basis and ignore human sentiments during human decision-making (Lerner et al., 2015).

Our goal is to develop a model of automated human decision-making that bridges current decision-making techniques with *fuzzy trace theory* (FTT), an established cognitive theory to predict group and individual decision making outlined in sections 2.2. Originally proposed by Brainerd and Reyna in the 1990s, FTT aims to explain cognitive phenomena

Findings of the Association for Computational Linguistics: NAACL 2022, pages 391 - 409
July 10-15, 2022

in memory and reasoning (Brainerd and Reyna, 1990). In a nutshell, FTT posits that humans form two types of mental representations, known as *verbatim* which are detailed representations and *gist* which are fuzzy representations that only capture the most quintessential meanings, and people prefer to make decisions based on gist rather than verbatim representations.

In contrast with alternative cognitive and decision-making theories such as expected utility theory (Friedman and Savage, 1952) and prospect theory (Kahneman and Tversky, 1980), we adopt FTT for two reasons. Firstly, FTT is the most holistic cognitive model which encompasses theories of how information is stored in memory and how memory plays an important role in our decision-making rather than treating decision-making as an isolated process. Because of this, FTT provides us with an extensive set of tools to explain and evaluate decision-making. Secondly, is FTTs suitability for computational modelling as conceptual parallels can be drawn between representation learning, particularly in neural-based language modelling, and the process of creating gist representations by distilling the quintessential information. For example, popular embedding methods for words, sentences and documents in NLP aim to create fuzzy semantic representations through dimensionality reduction of language to semantic vectors which can be viewed as gist representations of the original language (Liu et al., 2020).

Contributions: We investigate two levels of text-based risky decision prediction tasks, group and individual-level prediction from a computational standpoint and incorporating state-of-the-art methods in NLP, we further investigate:

- *How do gist representations of choices give rise to decisions?* We present a framework of decision-making based on gist representation learning.

- *How can we computationally encode gist representations based on the language of choices?* We outline how gist representations can be computationally encoded using techniques in NLP and propose Category-to-Vector (Cat2Vec), to learn and predict categorical embeddings of choices.

- *How can we extract the underlying sentiments of gist representations?* By extending Cat2Vec, we show how sentiments can be learnt at a categorical level; this differs from traditional approaches of sentiment analysis in NLP that examine sentiments at a text level.

- *How can individual differences of individuals and groups be modelled, what impact do these differences have on decision-making?* We propose that individual differences are mechanisms that can encode errors at various points in the decision-making process and propose an optimisation method to infer these individual differences.

- Finally, we demonstrate in experiments that our proposed model achieves state-of-the-art performance in predicting group and individual-based risky decision-making compared to baselines.

2 Task Formulation and Related Work

Risky decision-making has been studied in many different contexts. Here we formulate *n-choice decision-making problem* (nDMP): Taking as input natural language descriptions of n possible choices/outcomes $\mathcal{O}$, choose the most preferred outcome from the set of choices $\mathcal{O}$. We focus on a sub-problem known as a *n-choice risky decision-making problem* (nRDMP) which is an nDMP where there is some risk or probabilistic outcomes associated with choices in $\mathcal{O}$, e.g., programs B and D in the ADP. Specifically, we investigate the *gain-loss framing problem* which is comprised of two nRDMPs, $\text{nRDMP}_{\text{gain}}$ where choices are written as *gain frames* which accentuate the positive features of the text, e.g., programs A and B form a $\text{2RDMP}_{\text{gain}}$ where 'saving people's lives' is the accentuated feature. Conversely, $\text{2RDMP}_{\text{loss}}$ where choices are written as *loss frames* which accentuate the negative features of the text, e.g., programs C and D form a $\text{2RDMP}_{\text{loss}}$ where 'people dying' is the accentuated feature. Additionally, choices have equivalent outcomes across both 2RDMPs.

2.1 Classical decision theory

Classical decision theory abstracts the outcomes using utilities, which are numerical values that reflect desirability. For example, *expected utility theory* (EUT) identifies the choice that maximises the expected utility assuming the axioms of rationality (Von Neumann and Morgenstern, 2007). However, in human decision-making these axioms are often violated, giving rise to, e.g., Allais (Allais, 1953) and Ellsberg (Segal, 1987) paradoxes. Generalised EUT such as *uncertain utility theory* (Gul et al., 2008), *cumulative prospect theory* (CPT) (Tversky and Kahneman, 1992), and *multiple-criteria decision-making* (MCDM) (Zeleny, 2012) were proposed to resolve these discrepancies. However, these classical approaches not only fail to take into account semantic information given by the working of choices which is important contextually for decision making, but they also ignore cognitive processes such as sentiments of decision-makers.

Recent breakthroughs in NLP have led to a revolution in the breadth and robustness of problems that can be solved involving natural language by successfully capturing the underlying semantics and relationships of language. For example, neural language models have found resounding success in representation learning (Mikolov et al., 2013; Devlin et al., 2018), the task of uncovering feature representations of language which are useful for downstream NLP tasks. One such downstream NLP task, sentiment analysis, has benefited largely from the application of language models such as XLNet (Yang et al., 2019) and ULMFiT (Howard and Ruder, 2018). Rapid advancements thus give hope for the development of sophisticated computational decision-making models.

2.2 Group/Individual-level Tasks

In this paper, we consider two specific 2RDMP, *group level risky decision making* (GL-RDM) which the majority of psychological studies focus on and the novel task of *individual level risky decision making* (IL-RDM), defined as follows.

GL-RDM: Given a set of observed outcomes from human RDM experiments, each of which is described by a 5-tuple (2RDMP$_{gain}$, 2RDMP$_{loss}$, P_{gain}, P_{loss}, category), where 2RDMP$_{gain}$ is the gain frame of a 2RDMP, P_{gain} is the proportion of individuals in the gain frame who chose the *risky* choice, and $category$ is a grouping of similar experiments based on design and participants described in Section 6.1. 2RDMP$_{loss}$ and P_{loss} can be defined similarly by replacing $gain$ with $loss$. GL-RDM's objective is to predict the distribution of choice between P_{gain} and P_{loss} and for unseen human experiments within the same category.

IL-RDM: Given a set of nRDMPs, RDP = $\{rdp_1, rdp_2, \ldots, rdp_n\}$ where gain/loss frames of the same problem can appear as separate RDPs rdp_i, a set of individuals $Ivd = ivd_1, ivd_2, \ldots, ivd_m$ and a function which maps individuals and RDPs to their preferred choice $PC(id_i, rdp_j) = pc_{i,j}$ where $pc_{i,j}$ is individual id_i's preferred choice for rdp_j. The objective for IL-RDM is to learn a model/mapping function for each individual which can predict an individual's preferred choice for unseen nRDMPs.

3 FTT-guided Risky Decision-making

The BR model. Broniatowski and Reyna laid out four main FTT principles in developing a cognitive model, i.e., the *BR model*, for the GL-RDM task (Broniatowski and Reyna, 2018, 2014). These principles are: (**C1**) Decision choices are encoded in different levels of gist representations, e.g., *categorical*- and *interval*-levels based on the psychological notion of levels of measurement (Stevens et al., 1946). (**C2**) Categorical gist representations of choices are distinguished based on binary (positive/negative) sentiments and decision-makers will prefer options with positive associations. In the BR model, sentiments of categories are drawn upon social and moral principles which are stored in long-term memory, e.g., saving lives is fundamentally good. (**C3**) When comparisons of categorical gist representations do not arrive at a conclusive result, the decision-maker will revert to more precise gist representations. In the BR model, gist representations compete and combine such that the simplest gist representation is chosen. (**C4**) Categorical gist is encoded based on the decision-maker's prior experiences and individual differences, i.e., *need for cognition* (NFC), *numeracy* (NUM), and *risk sensitivity* (RS).

Human experiments have provided evidence that the BR model is capable of explaining GL-RDM. However, being a box-arrow model, the BR model is comprised of hypothesized concepts or processes that lack precise definitions. Hence applying the model requires human interpretations and judgements on, e.g., notions such as gist lattices of each RDMP, the acquisition of sentiments, and individual differences. This informal nature, along with the inflexibility of the model being unable to be easily adapted to IL-RDM prevents the model from being used as an automated predictive tool.

Our model. Towards a fully automated tool for the RDMP tasks, we propose a computational model of risky decision-making that takes the input text descriptions of an RDMP and solves the GL-RDM and IL-RDM tasks automatically. The model is depicted in Figure 1. The key features of our model include: (1) All model components are automated, i.e., gist representations are extracted through NLP as categorical embeddings. (2) Categorical and interval representations are formally defined as hierarchical with the interval level encapsulating the properties and information of the categorical-level (Stevens et al., 1946). (3) Individualistic differences, NFC, NUM and RS (see below) directly affect decision-making at a representational level and errors in judgement can propagate through the model adding more expressive.

4 Computing Gist Representations

The first challenge we tackle is the computational encoding of gist representations and how individual differences encode *error*, a mechanism to model variations in human decision-making at a representation level to perform GL-RDM and IL-RDM.

4.1 Categorical Representations

Categorisation is the act of grouping documents into categories based on semantic or sentiment similarity. For example, the `entertainment` category in the news dataset (see Section 6.1) comprises of various articles spanning multiple topics such as games, movie reviews, and celebrity gossip. The ability to categorise and recall the underlying sentiments of categories is an important prerequisite for FTT decision making asserted by principle C2 where humans prefer choices associated with categories with positive connotations over negative connotations. For example, the sentiments of the `travel` category in the news dataset has a strong negative sentiment due to the news articles being collected during the outbreak of COVID-19. Given this negative sentiment, people would be dissuaded from travelling. Current sentiment analysis methods focus on granular extraction of sentiments from text rather than categories where words that are highly indicative of a category do not necessarily reveal any insights into their sentiment.

Vector representations of words (Mikolov et al., 2013), sentences (Devlin et al., 2018), and documents (Le and Mikolov, 2014) capture the semantic relationships between entities. At a higher level, a *categorical embedding* should capture semantic relations between categories of documents. To our knowledge, no such representation has been proposed. To fill this gap, we propose *Category-2-Vector* (Cat2Vec) and a sentiment based extension, *sentiment-Cat2Vec*. Cat2Vec aims to find model-agnostic categorical representations that facilitates the prediction of categories from text and sentiments from categories. More formally, given a set of M categories $C = \{k_1, k_2, \ldots, k_M\}$, a training set contains a number N of document-category pairs $\{(d_1, c_1), \ldots, (d_N, c_N)\}$, where each d_i is a document and $c_i \in C$ is the (ground truth) category of d_i. The objective is to maximise the average log probability $\frac{1}{N}\sum_{i=1}^{N} \log P\left(c_i|d_i\right)$ where $P(c_i|d_i)$ is the probability that document d_i belongs to category c_i. In sentiment-cat2vec, $P(c_i|d_i)$ is replaced by $P(s_i|c_i)$, the probability that category c_i belongs to a certain sentiment class. Here, we consider only binary positive and negative sentiments.

Cat2Vec extends a contrastive learning via negative sampling approach by simultaneously maximising the similarity between document encodings, v_{d_i}, with true category embeddings, v_{c_i}, by minimising the similarity between v_{d_i} and K negative category embeddings defined by the objective:

$$\log \sigma\left((v_{c_i} \odot v_{i_i}) \cdot v_{d_i}\right) + \sum_{j=1}^{K} \mathbb{E}_{k_j \sim P_{\text{noise}}(C)} [\log \sigma((-v_{k_j} \odot v_{i_j}) \cdot v_{d_i})] \tag{1}$$

where $\odot$ represents element-wise multiplication, $P_{\text{noise}}(C)$ is a noise distribution that dictates how categories are sampled, we select a uniform distribution, $\sigma(x) = 1/(1 + \exp(-x))$ and v_{i_i} is a category importance vector for category i which is learned simultaneously with the category embedding which provides an attention-like effect over category by accentuating or diminishing certain features in the category embedding when multiplied together. Furthermore, $v_{d_i} = Enc(d_i)$ where Enc is a document vector encoding function. In this paper we adopt a bi-directional LSTM with self-attention such that $v_{d_i} = (\overrightarrow{\alpha} \odot \overrightarrow{v}_{d_i} \| \overleftarrow{\alpha} \odot \overleftarrow{v}_{d_i})$ where $\overrightarrow{\alpha}, \overleftarrow{\alpha}$ are self-attention weights of the forwards and backwards LSTMs, resp., and $\overrightarrow{v}_{d_i}, \overleftarrow{v}_{d_i}$ are the hidden state output vectors for document d_i of the forward and backwards LSTMs, respectively. However, the encoder is interchangeable in Cat2Vec e.g. pretrained transformers like BERT (Devlin et al., 2018) can be used.

The novelty of our model lies in two main aspects, the introduction of a category importance vector to improve the ability of the model to learn relations between categories and the ability of our model to estimate $P(s_i|c_i)$ given labelled text doc-

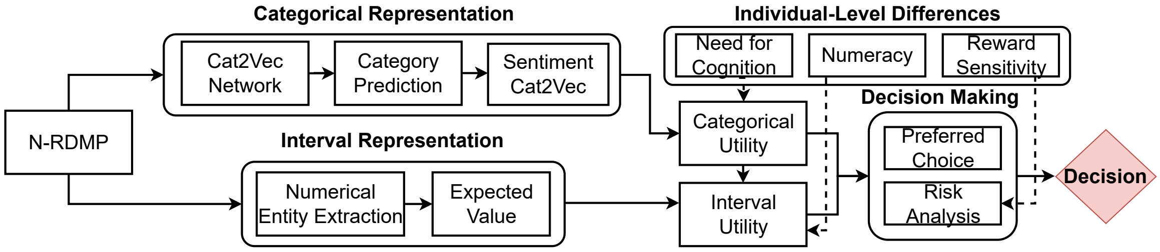

Figure 1: The main architecture of our computational model for decision making based on FTT

uments. To estimate $P(s_i|c_i)$ we introduce an extra dense output layer (D) in figure 2 which predicts $P(s|d_i)$, the probability that document i belongs to a certain sentiment class. In the case of binary sentiments, the joint loss becomes the binary cross-entropy loss of predicting the correct sentiment of a document plus the negative sampling loss in equation 1. After training the model we can estimate $P(s_i|c_i)$ by feeding the learned category embeddings, $(v_{c_i} \odot v_{i_i})$ into the output layers (D). Although these output layers are trained to learn $P(s|d_i)$, since the learned category embeddings are based on the document embeddings and are learned in the same semantic space, this approach gives us good estimates of $P(s_i|c_i)$.

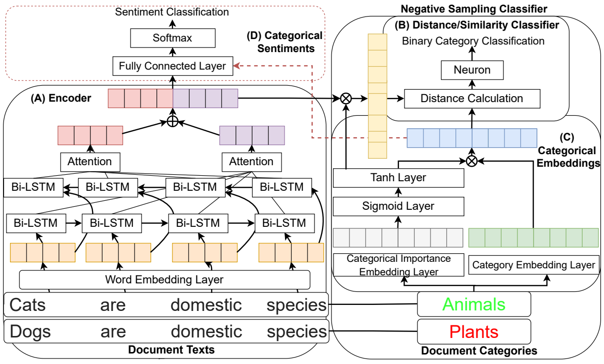

Figure 2: Cat2Vec Model

Equation 2 shows how error encoded categorical utility (CU) is calculated from categorical representations where Category(choice) is a function that takes RDM choices as inputs and outputs the underlying category related to the choice, Sentiment(category) is a function which takes a category as input and outputs the underlying sentiments related to that category as $\text{pos}_{\text{category}} - \text{neg}_{\text{category}}$. Categorical error is encoded based on NFC, an individual's tendency to engage in and enjoy cognitive activities (Cacioppo et al., 1996), can introduce error at a categorical level to account for individualism. To calculate an error encoded CU, we sample from a logistic distribution which is consistent with existing literature in qualitative discrete choice models (McFadden, 2001). Formally, NFC $\in (0,1)$ and $CU \sim \text{Logistic}(\mu, s)$ where $\mu = \mathbb{E}[X]$ is the expected or true utility value and $s(\text{NFC}) = |\text{NFC} - 1| \times \mathbb{E}[X]$.

$$\text{CU} = \text{Logistic}(\text{Sentiment}(\text{Category}(\text{choice})), \text{NFC}) \tag{2}$$

4.2 Interval Representations

Interval representations are a more precise representation than categorical representation. It encodes the calculation of the expected value (EV) and utility of choices. Numerical information from text can be extracted using simple text extraction or *named entity recognition* (NER) (Nadeau and Sekine, 2007) where probabilities and their associated quantities can be extracted as arrays, e.g., in program B of the RDMP in the introduction the probabilities would be $[1/3, 2/3]$ and their corresponding quantities would be $[600, 0]$.

Equation 3 outlines the process to generate error-encoded interval utilities where CU is the categorical utility defined in equation 2 and EV is an expected value function which takes an input RDM choices and outputs the corresponding expected value associated with probabilities and quantities in choices which can extracted using standard text identification techniques such named entity recognition. Error is encoded based on NUM (Kahneman, 2003), which measures a person's ability to interpret and work with numbers to account for individualism is calculated as $IU \sim \text{Logistic}(\mu, s)$ where NUM $\in (0,1)$, $\mu = \mathbb{E}[X]$ is the true expected value and $s(\text{NUM}) = Q|\text{NUM} - 1| \times \mathbb{E}[X]$ where Q is number of quantities in the choice to account for error involving multiple calculations.

$$\text{IU} = \text{Logisitic}(\text{EV}(\text{choice}), \text{NUM}) \cdot \text{CU} \tag{3}$$

4.3 Representations for Decision Making

Finally, combining these representations allows us to derive the most beneficial choice in an nRDMP. The *preferred categorical*, Pref_{Cat} and *preferred interval*, Pref_{Int} choices are calculated based on which choice maximises categorical and interval utilities, respectively. If $\text{Pref}_{\text{Cat}} = \text{Pref}_{\text{Int}}$, there is a consensus on the best choice. If $\text{Pref}_{\text{Cat}} \neq \text{Pref}_{\text{Int}}$, there is no clear best choice. In this case, RS, a person's preference towards pursuing riskier but more rewarding decisions (Kacelnik and Bateson, 1997), is adopted as in the BR model. Risk sensitivity influences the probability of choosing the *safest* or *riskiest* choice in an nRDMP as $P(\text{risky}) = 1/(1+e^{-RS})$ where $RS \in (-3, 3)$. The safest choice is one that involves the least probabilistic outcomes, whereas conversely, the riskiest choice involves the most probabilistic outcomes e.g., in the ADP in the introduction, program A is the safest as it involves one certain outcome while program B is the riskiest with two probabilistic outcomes.

4.4 Decision Making: A Worked Example

To demonstrate the fluidity of our model we apply our model to the ADP from the introduction. In the gain frame, the predicted category of programs A and B using the pretrained Cat2Vec from the experiments predicts the `life` category for both programs. The sentiments of the `life` category predicted by Sentiment-Cat2Vec is 0.9999 positive and 0.0001 negative giving categorical utility defined as $\text{pos}_{\text{category}} - \text{neg}_{\text{category}}$ for both programs equal to 0.9998. Taking into account numerical information, the expected value of programs A and B is 200 people being saved, the interval utility is thus the expected value times the categorical utility which is 199.6 for both programs. No consensus between categorical or interval choices can be made due to unclear preferred choices for both. Thus, the final choice is decided by risk sensitivity.

Individual differences encode error and preferences into choices allowing for consensus to arise, e.g., a person with low numeracy will sample interval utilities from a logistic distribution with a larger spread than someone with high numeracy who samples utility close to the true utility. Because the error encoded utilities are sampled, the preferred choice can change on different runs of the problem; however, individual differences influence the average choice. Figure 3 shows a snapshot when one parameter was altered while the others were fixed and how these parameters can alter utilities to prefer certain choices across frames in the ADP.

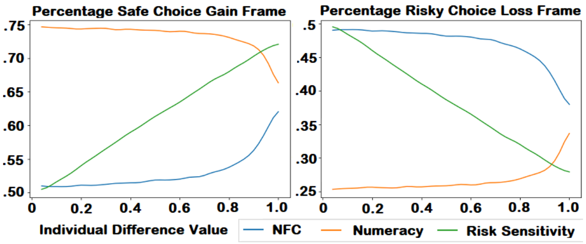

Figure 3: Effects of individual differences on the ADP.

5 Learning Individual Differences

The last challenge we explore is how optimal individual-level parameters, NFC, NUM and RS can be inferred in GL-RDM and IL-RDM by optimising the following objective functions.

$$\operatorname*{arg\,min}_{ivd} \sum_{P,P}^{\text{Exp}} |P_{\text{gain}} - \hat{P}_{\text{gain}}(ivd)| + |P_{\text{loss}} - \hat{P}_{\text{loss}}(ivd)| \quad (4)$$

$$\hat{P}_{\text{gain}}(ivd) = \sum_{exp \in \text{Exp}} \frac{\mathbb{E}[\text{CDM}(\text{RDMP}_{gain}, ivd) = \text{risky}]}{|\text{Exp}|} \quad (5)$$

GL-RDM Objective. Is given by equation 4 where $ivd = (\text{NUM}, \text{NFC}, \text{RS})$ are individual-level parameters which represent the characteristics of the entire group and $\text{Exp} = \{\text{e}_1, \text{e}_2, \ldots, \text{e}_i\}$ is the set of results based on human psychological experiments where each e is a 5-tuple described in the task formulation in section 2.2.

IL-RDM Objective. Is given by equation 6 where $ivd_i = (\text{NUM}, \text{NFC}, \text{RS})$ is the parameters which characterises individual i, RDP is a set of nRDMPs and PC is the mapping function of individuals to their preferred choices defined in the task formulation in section 2.2. Thus, the goal is to learn optimal individual parameters for each individual which maximises the expectation that CDM chooses their true preferred choice over all RDPs.

$$\operatorname*{arg\,max}_{ivd} \sum_{j}^{|\text{RDP}|} \mathbb{E}[\text{CDM}(\text{rdp}_j, ivd_i) = PC(ivd_i, \text{rdp}_j)] \quad (6)$$

6 Experiments

6.1 Datasets

Categorical News. A dataset used for training/fine-tuning Cat2Vec and benchmark algorithms. The dataset contains 22601 news articles with binary sentiments labelled from various news outlets dating from February to April 2020 using the Google News API spanning 46 news categories, e.g. `travel`, `entertainment` and `death`.

Group Risky Decision Making. A dataset of 88 psychological human experiments results grouped into categories used in the evaluation of the BR model. The categories represent differences in experiment controls and participants that undertook each experiment, e.g., 'ADP; within-subjects, low PISA'. The category outlines the risky decision-making problem; experimental design which can be grouped into *within*, where each participant is given both frames of a decision or *between* subject designs, where two independent groups answer each frame; and numeracy of participants, based on the performance of the country in which the experiment took place in the Program for International Student Assessment (PISA) (Stacey, 2015).

Individual 2-RDMP Prediction. A curated dataset of 38 unique 2-RDMPs selected from various psychological experiments regarding risky decision-making answered by 121 university students using a within-subject experimental design. Of the 38 2-RDMPs, most problems contain a corresponding gain and loss frame, e.g., the ADP in the introduction, each frame is considered a separate problem. Participants selected their preferred choice from the same pre-shuffled RDMP set[1] and no pre/post-processing of data was performed.

6.2 Evaluation Metrics

We apply different evaluation metrics suitable for each RDM task. For GL-RDM, we compare the true log-odds ratio (LOR) given by equation 7, between experimental results predicted by our model and the BR baseline model. Intuitively, the LOR measures the consistency of choices across the gain and loss frames.

$$\mathrm{LOR}(P_{\text{gain}}, P_{\text{loss}}) = \ln\left(\frac{P_{\text{gain}}(1-P_{\text{loss}})}{P_{\text{loss}}(1-P_{\text{gain}})}\right) \tag{7}$$

To determine the goodness-of-fit between the predicted LOR, we apply a hypothesis test, the Wald statistic (χ^2) given by equation 9. The standard error (SE) is given by equation (8) where $n_{\text{safe,gain}}$ represents the number of individuals choosing the safe choice in the gain frame, $n_{\text{safe,loss}}$, $n_{\text{risky,gain}}$, $n_{\text{risky,loss}}$ can be derived similarly. The standard error asymptotically approaches a normal distribution when n is sufficiently large; thus, the associated Wald statistic, equation (9), follows a chi-square distribution with one degree of freedom.

$$\mathrm{SE} = \sqrt{\frac{1}{n_{\text{safe,gain}}} + \frac{1}{n_{\text{safe,loss}}} + \frac{1}{n_{\text{risky,gain}}} + \frac{1}{n_{\text{risky,loss}}}} \tag{8}$$

$$\chi^2 = \left(\frac{\mathrm{LOR}(P_{\text{gain}}, P_{\text{loss}}) - \mathrm{LOR}(\hat{P}_{\text{gain}}, \hat{P}_{\text{loss}})}{\mathrm{SE}}\right)^2 \tag{9}$$

To compare the parsimony and implicitly the error between our the BR and null (Busemeyer et al., 2015) models, we use the Akaike information criterion (AIC) and Bayesian information criterion (BIC). For IL-RDM, we evaluate the accuracy of each model correctly predicting the true choices for each individual.

6.3 Benchmark Algorithms

In the paper, we use two different sets of baselines. For GL-RDM, we directly compare our model against the BR model. Due to the small number of experiments per grouping in the GL-RDM dataset, to maintain parity with the BR baseline, we apply the same jackknife-leave-one-out (JLOO) method used for parameter estimation in the BR baseline model to avoid post-hoc parameter estimation (Busemeyer and Wang, 2000). Formally, given m observed human risky decision making experiment results within a category of comparable RDPs, $\mathrm{Exp} = \{\mathrm{e}_1, \mathrm{e}_2, \ldots, \mathrm{e}_m\}$ as described in the task formulation in section 2.2. We wish to estimate m values of $G_i = (\mathrm{NUM}_i, \mathrm{NFC}_i, \mathrm{RS}_i)$ where G_i is group-level differences relating to observed experiments i where $i = 1 \ldots m$. To achieve this, we apply the G_i can be estimated by equation (10) where ER_{-i} is the set of experimental results excluding er_i as not to use the result in the estimation.

$$\arg\min_{G_i} \sum_{P_{\text{gain}}, P_{\text{loss}}}^{\mathrm{ER}_{-i}} |P_{\text{gain}} - \hat{P}_{\text{gain}}(G_i)| + |P_{\text{loss}} - \hat{P}_{\text{loss}}(G_i)| \tag{10}$$

For IL-RDM, due to a lack of existing benchmark algorithms we compare our model against two baselines (1) Naive binary model using pretrained transformer language models where all

---

[1] See appendix, section A.3 for questionnaire

RDM-choices are combined as a single input and outputs 0 or 1 corresponding to the safe or risky choice. (2) Sentiment analysis models as claim C2 asserts sentiments are highly influential in decision-making where decisions are based on choices with the highest positive sentiment. **Random:** Uniformly samples one of the available choices. **Vader:** A rule-based sentiment analysis for social media(Gilbert and Hutto, 2014). **XLNet:** SOTA pretrained autoregressive language model fine-tuned on the news dataset sentiments (Yang et al., 2019). **ULMFiT:** Pretrained language model fine-tuned on the news dataset sentiments using inductive transfer learning (Howard and Ruder, 2018).

6.4 Experiment Results

GL-RDM results. Table 1 (full table A.4 in Appendix) shows key discrepancies between our computational model, CDM, compared to both the actual LOR based on all 88 human experiments and those predicted by the BR model. Within each category, we find optimal group-level parameters which minimise (4) to calculate the predicted LOR of our model for each experiment using the jackknife-leave-one-out (JLOO) method to maintain comparability between the BR model.

Table 1: Group Level Experiment Results.

Critically, our results show that our computational model is capable of automating the prediction of human risky decision making on a wide range of RDMPs by predicting 82 of 88 (93.2%) experiments based on the Wald statistic. These results hold even when RDMPs were manipulated to capture a wider gamut of decision making through variations on framing and truncation of choices where options were removed (Reyna et al., 2014). These results are comparable to carefully crafted human conducted analysis using the BR model which also predicted 82 of 88 experiments.

To further demonstrate the parsimony of our model compared to the BR and null models by applying the AIC and BIC metrics under a null CDM model where parameters are set to 0, we get AIC=14941 and BIC=14950. Whereas under the null model of the BR model, AIC=14981 and BIC=14986. In the best cases, our model outperforms all variations of the BR baseline model, with our model attaining AIC=13374 and BIC=13383 compared to AIC=13409 and BIC=13510. Furthermore, taking into consideration the relative likelihood ratio (RLR) to compare models using the AIC scores, $\exp((13374 - 13409)/2) = 2.5 \times 10^{-8}$, yields a significant result where the BR baseline model is only 2.5×10^{-8} times as probable as our model to minimize the information loss. Thus, our model attains better goodness-of-fit compared to the BR model while using significantly fewer parameters, 3 compared to up to 172 in the BR model.

IL-RDM results. Table 2 displays the average 5-fold cross-validation result predicting all 121 individuals' decisions for all 38 questions. Our model with a modest 63.19% accuracy outperforms all benchmark algorithms which hover around 50% for sentiment and 60% for pretrained language model baselines. This reinforces that IL-RDM is a more challenging problem and although sentiment analysis is important for decision-making, current SOTA sentiment analysis is not suitable for IL-RDM and only performs comparably to random choice. It is worth noting that while pretrained language models can be naively applied to IL-RDM with competitive results, they can not be naively applied to GL-RDM which requires the simultaneous predictions of two distributions of choices across frames where often the same RDM and choices is used across all experiments within a category.

Also displayed in the table are results when using transformers as encoders within Cat2Vec and results from a minor ablation study. For IL-RDM, transformers do not significantly improve accuracy as the resulting predicted categories and sentiments of categories from RDM-choices are highly similar between encoders. In the ablation study where choices are derived based on preferred choices at different levels of representation, i.e., $\text{CDM}_{\text{Categorical}}$ and $\text{CDM}_{\text{Interval}}$, reinforces the full expressiveness of our model comes from the consensus between levels of representation and influence of individual differences.

Table 2: Individual-Level Experiment Results

6.5 Error Analysis and Discussion

To understand the shortfall of our model for both GL-RDM and IL-RDM, we analyse cases in which our model fails to predict human decision-making. In GL-RDM, of the 6 experiments that our model did not successfully predict, 3 of these ((4),(5) and (7) in table 1) were not predicted by the BR baseline model indicating problems with parameter estimation using JLOO as these experiments are outliers with relatively significant differences in LORs within their respective categories.

In IL-RDM, inconsistencies exist across 2-RDMPs due in part to the within-subject design as participants may notice the underlying problem causing them to compare between problems rather than independently (Kahneman and Frederick, 2002). For example, figure 4 shows loss frames where individuals overwhelming preferred the safe choice, e.g., Q2, Q4 and most gain-loss pairs do not show a clear distinction between safe and risky choices in opposing frames, e.g. (Q26, Q2). Both cases are inconsistent with psychological studies.

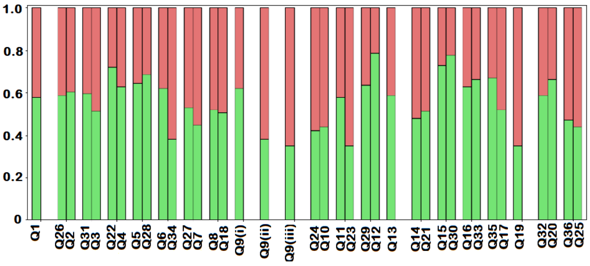

Figure 4: Ratio of choices for all questions with gain and loss frames grouped.

Quantity of data is also an issue. While the number of participants and questions answered were quite large for psychology experiments, this dataset is relatively small for machine learning tasks. Figure 5(A) shows the histogram of all 121 individuals' test accuracy on one fold. Overall, our model can predict most individual's choices accurately, but the average is lowered by some individuals our model cannot predict due to inconsistencies mentioned in (1). Also, since the size of each fold is relatively small, containing 7-8 test RDPs, any RDP not predicted correctly will cause a large decrease in accuracy. Figure 5(B) shows the percentage of correct choices our model predicts for all individuals from the combined 5-fold test questions. On average, our model predicts gain and loss RDMPs relatively equally with accuracy of 65.73% and 62.84% respectively. However, RDMPs with *"both frame"*, contains choices with combined gain and loss wording, cannot be predicted by our model due to this duality with an average of 42.73%.

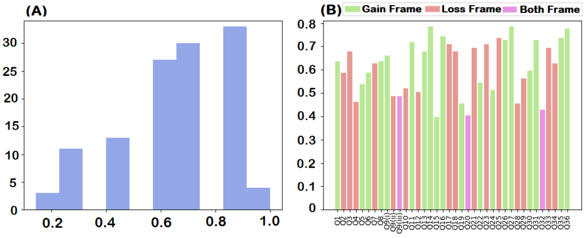

Figure 5: (A) Histogram of individual accuracy on one fold and (B) combined k-fold test accuracy per question

7 Conclusion and Future Work

This paper provides the first steps into a fully computational framework of risky decision-making, which adopts the cognitive and psychological basis of FTT with our model outperforming baselines in individual and group RDP prediction. Potential applications of our model are wide-ranging for scenarios in which predicting and understanding the characteristics of human risky decision-making is pivotal, e.g., the design of safety mechanisms based on how people make decisions in risky scenarios or in improving personalised recommendation systems based on understanding the users' personal traits and how they make decisions. Future work, therefore, involves adapting our model towards real-world applications, exploration of generalised decision-making and the design and evaluation of sophisticated end-to-end machine learning models for text-based decision-making.

A Appendix

A.1 Final Decision Algorithm

Algorithm 1 corresponds to the algorithm mentioned in section 6.1 of the main paper.

Algorithm 1 Computational Decision Making

```
Input: $n$RDMP, NUM, NFC, RS
Output: Decision/Preferred Choice
for choice in n-RDMP do
    if CU(Pref$_{\text{Cat}}$, NFC) $<$ CU(choice, NFC) then
        Pref$_{\text{Cat}}$ = choice
    if IU(Pref$_{\text{Int}}$, NUM) $<$ IU(choice, NUM) then
        Pref$_{\text{Int}}$ = choice
if Pref$_{\text{Cat}}$ $=$ Pref$_{\text{Int}}$ then
    return Pref$_{\text{Cat}}$
else if Uniform(0, 1) $\leq$ RiskSensitivity(RS) then
    return Riskiest Choice
else
    return Safest Choice
```

A.2 Evaluation Metric Calculations

The calculations for the second type of evaluation metric we use to compare the parsimony of our model against baseline algorithms are the Akaike information criterion (AIC) and Bayesian information criterion (BIC) are given by equations (13) and (14) using the log-likehood calculated by equations and (12). In these equations $n_{1,1}$ is the number of people who chose the first choice (safe choice) in the first problem (gain frame), $p_{1,1}$ is the predicted proportion of subjects who chose the first choice (safe choice) in the first problem (gain frame), etc. For the AIC, k is the total number of parameters of our model, 3 which correspond to each individual difference and in BIC, n is the total number of data points, 176 to represent the gain and loss frames in the 88 human experiments.

$$\ln[L(y_i)] = n_{1,1}\ln p_{1,1} + n_{1,2}\ln p_{1,12} + n_{2,1}\ln p_{2,1} + n_{2,2}\ln p_{2,2} \quad (11)$$

$$\ln[L(y)] = \sum_i \ln[L(y_i)] \quad (12)$$

$$\text{AIC} = 2k - 2\ln[L(y)] \quad (13)$$

$$\text{BIC} = k\ln(n) - 2\ln[L(y)] \quad (14)$$

To compare models using AIC, the relative likelihood ratio (RLR) given in equation 15 can be applied which compares the probability that the BR baseline model minimises the estimated information loss compared to our CDM model given that $\text{AIC}_{\text{CDM}} \leq \text{AIC}_{\text{BR}}$ where AIC_{BR} and AIC_{CDM} are corresponding AIC scores of each model.

$$\text{RLR} = \exp(\frac{\text{AIC}_{\text{CDM}} - \text{AIC}_{\text{BR}}}{2}) \quad (15)$$

A.3 Individual Level Questionnaire

Full inventory of all 36 questions used in the Individual 2-RDMP Prediction dataset:

Q1: Which of the following options do you prefer?

(a) A sure win of $30

(b) 80% chance to win $45

Q2: Imagine that 6000 pieces of precious paintings in a world-famous museum are accidentally exposed to a disastrous chemical pollution. Two alternative plans to rescue these art treasures have been proposed. Assume that the exact estimates of the consequences of the plans made by scientists are as follows:

(a) If plan A is adopted, 4000 pieces will be destroyed by the chemical pollution.

(b) If plan B is adopted, there is a one-third probability that none of these paintings will be destroyed, and two-thirds probability that all 6000 of these paintings will be destroyed.

Q3: A large car manufacturer has recently been hit with a number of economic difficulties and it appears as if three plants need to be closed and 6000 employees laid off. The vice-president of production has been exploring alternative ways to avoid this crisis and has developed two plans:

(a) Plan C: This plan will result in the loss of 2 plants and 4000 jobs.

(b) Plan D: This plan has a 2/3 probability of resulting in the loss of 3 plants and all 6000 jobs, but has a 1/3 probability of losing no plants and no jobs

Q4: Imagine you recieve a letter from the president of a subsidiary describing a dilemma concerning whether to fight an impending patent violation suit or settle out of court that reads: If we do not agree to this proposal, PMG will file their suit. Going to court would involve the possibility of losing $1,100,000 in damages and losing the Duraplast line. If we win in court, we will incur a small sum for legal expenses. Our corporate lawyer, Mr. Bell, and our outside law firm estimate that we have a 2 in 3 chance of losing the case.

(a) Agree to the proposal (no lawsuit)

(b) Disagree to the proposal: 2/3 chance of losing the lawsuit and incurring costs of $1100000

Q5: Imagine that you have lung cancer and you must choose between two therapies: surgery and radiation. Surgery for lung cancer involves an operation on the lungs. Most patients are in the hospital for two or three weeks and have some pain around their incisions; they spend a month or so recuperating at home. After that, they generally feel fine. Radiation therapy for lung cancer involves the use of radiation to kill the tumor and requires coming to the hospital about four times a week for six weeks. Each treatment takes a few minutes and during the treatment, patients lie on a table as if they were having an x-ray. During the course of the treatment, some patients develop nausea and vomiting, but by the end of the six weeks they also generally feel fine. Thus, after the initial six or so weeks, patients treated with either surgery or radiation therapy feel about the same.

(a) Surgery: Of 100 people having surgery, 90 live through the postoperative period, 68 are alive at the end of one year and 34 are alive at the end of five years.

(b) Radiation Therapy: Of 100 people having radiation therapy, all live through treatment, 77 are alive at the end of one year and 22 are alive at the end of five years.

Q6: Imagine that you brought $6000 worth of stock from a company that has just filed a claim for bankruptcy recently. The company now provides you with two alternatives to recover some of your money.

(a) You will save $2000 of your money

(b) You will take part in a random drawing procedure with exactly a one-third probability of saving all $6000 of your money, and two-thirds probability of saving none of your money.

Q7: Imagine that in one particular state it is projected that 1000 students will dropout of school during the year, two programs have been prosed to address this problem, but only one can be implemented. Based on other states experiences with programs, estimates of the outcomes that can be expected for each program can be made.

(a) Program 1: 600 of the 1000 students will drop out of school

(b) Program 2: 2/5 chance that none of the 1000 students will drop out of school and 3/5 chance that all 1000 students will drop out of school

Q8: Assume that you have just been given a gift of $1000.

(a) Taking an additional $500 for sure.

(b) Flipping a coin and winning another $1000 if heads comes up or getting no additional money if tails comes up.

Q9(i): Imagine that you face the following pair of concurrent decisions. First examine both decisions, then indicate the options you prefer.

(a) A sure gain of $240

(b) 25% chance to gain $1000, and 75% chance to gain nothing

Q9(ii): Imagine that you face the following pair of concurrent decisions. First examine both decisions, then indicate the options you prefer.

(a) A sure loss of $750

(b) 75% chance to lose $1000, and 25% chance to lose nothing

Q9(iii): Imagine that you face the following pair of concurrent decisions. First examine both decisions, then indicate the options you prefer.

(a) 25% chance to win $240, and 75% chance to lose $760

(b) 25% chance to win $250, and 75% chance to lose $750

Q10: You are staying in a hotel room on vacation. You paid $6.95 to see a movie on pay TV. After 5 minutes you are bored and the movie seems pretty bad. Would you continue to watch the movie or not?

(a) Continue to watch

(b) Turn it off and lose $6.95

Q11: Imagine that your country is preparing for the outbreak of an unusual disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimate of the consequences of the programs are as follows:

(a) If Program A is adopted, 200 people will be saved

(b) If Program B is adopted, there is 1/3 probability that 600 people will be saved, and 2/3 probability that no people will be saved

Q12: Imagine that you have decided to see a play where admission is $10 per ticket. As you enter the theatre you discover that you have lost a $10 bill.

(a) Still pay $10 for a ticket for the play

(b) Don't pay $10 for a ticket for the play

Q13: Consider the following two stage game. In the first stage, there is a 75% chance to end the game without winning anything, and a 25% chance to move into the second stage. If you reach the second stage, you have a choice between: A sure win of $30 and 80% chance to win $45

(a) A sure win of $30

(b) 80% chance to win $45

Q14: Imagine that six people in your family, including both of your parents, your brothers and your sisters, are infected by a fatal disease. Two alternative medical plans to treat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the plans are as follows:

(a) If plan A is adopted, two of them will be saved.

(b) If plan B is adopted, there is a one-third probability that all six of them will be saved, and two-thirds probability that none of them will be saved.

Q15: Your are presented with the following report from the head of a special team assigned to investigate the prospects of a project in Arizona: Our new analysis indicates that, if we choose to compete with ATC, we would face the possibility of capturing only a small market share. This would give us an after-tax return on investment of as little as 10%, while capturing a large market share would give us a return of 22%. We estimate our chance of getting a small market share to be 2 in 3. If we were to team up with ATC on the terms proposed, our return would be 14% after tax, with the same total investment.

(a) Compete with ATC: 1/3 chance of gaining a large market share of 22% and 2/3 chance of gaining a small market share of 10%

(b) Don't compete with ATC: 100% chance of capturing 14% market share

Q16: A committee found a fish disease in a nearby lake. About 12 fish species (among them the most popular dining fish) have the Proliferative Kidney Disease (PKD). This is a chronically developing infectious disease which can have deadly consequences for the fish. Young fish are especially susceptible, while others seem to be immune against an infection. Experts suggest that PKD is one cause of declining fish catches. The researchers assume human activities and water pollution foster the spread of the disease. They are considering releasing more fish into the lake to control the epidemic. Imagine that you are a government official of the adjacent village.

(a) Option A: If the release of fish is implemented, 4 fish species will survive.

(b) Option B: If the release of fish is implemented, there is 1/3 probability that all of the 12 fish species will survive, and 2/3 probability that none of them will survive.

Q17: Imagine a refinery that processes petroleum products. An investigation found that due to tank leaks, both soil and drinking water became contaminated. Due to this contamination 720 children from the adjacent village have a fatal disease. There is agreement among experts that children will not suffer health problems, provided they have a strong immune system. Otherwise, it is likely that children will have serious health problems. A vaccine against this disease has been developed and tested. However, the vaccine sometimes can cause side effects that can be fatal too. You are an environmental activist with much influence on the local hospital and you have to decide if you want to lobby for the vaccination or not.

(a) Option C: If the vaccination is adopted, the health of 480 children will be damaged for sure.

(b) Option D: If the vaccination is adopted, there is a one-third probability that the health of none of the 720 children will be damaged, and a two-thirds probability that the health of all 720 of them will be damaged.

Q18: Assume that you have just been given a gift of $2000. But you now are forced to choose between the following two alternatives:

(a) Losing $500 for sure

(b) Flipping a coin and losing $1000 if heads comes up or losing nothing if tails comes up

Q19: Which of the following options do you prefer?

(a) 25% chance to win $30

(b) 20% chance to win $45

Q20: Imagine that you are about to purchase a jacket for $125, and a calculator for $15. The calculator salesman informs you that the calculator you wish to buy is on sale for $10 at the other branch of the store, located 20 minutes drive away.

(a) Make the trip to the other store and save 5 dollars but lose 20 minutes

(b) Don't make the trip to the other store and save 20 minutes but lose 5 dollars

Q21: Imagine that six people in your family, including both of your parents, your brothers and your sisters, are infected by a fatal disease. Two alternative medical plans to treat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the plans are as follows:

(a) If plan A is adopted, four of them will die.

(b) If plan B is adopted, there is a one-third probability that none of them will die, and two-thirds probability that all six of them will die.

Q22: Imagine you recieve a letter from the president of a subsidiary describing a dilemma concerning whether to fight an impending patent violation suit or settle out of court that reads: If we do not agree to this proposal, PMG will file their suit. Going to court would involve the possibility of keeping the Duraplast line and incurring only a small sum for legal expenses. If we lose in court, we will incur $1,100,000 in damages. Our corporate lawyer, Mr. Bell, and our outside law firm agree that we have a 1 in 3 chance of winning the case.

(a) Agree to the proposal (no lawsuit)

(b) Disagree to the proposal: 1/3 chance of winning the case

Q23: Imagine that your country is preparing for the outbreak of an unusual disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimate of the consequences of the programs are as follows:

(a) If Program C is adopted 400 people will die.

(b) If Program D is adopted there is 1/3 probability that no one will die, and 2/3 probability that 600 people will die.

Q24: You are staying in a hotel room on vacation. You turn on the TV and there is a movie on. After 5 minutes you are bored and the movie seems pretty bad. Would you continue to watch the movie or not?

(a) Continue to watch
(b) Turn it off

Q25: Imagine that six people are infected by a fatal disease. Two alternative medical plans to treat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the plans are as follows:

(a) If plan A is adopted, four people will die.
(b) If plan B is adopted, there is a one-third probability that none of them will die, and two-thirds probability that all six people will die.

Q26: Imagine that 6000 pieces of precious paintings in a world-famous museum are accidentally exposed to a disastrous chemical pollution. Two alternative plans to rescue these art treasures have been proposed. Assume that the exact estimates of the consequences of the plans made by scientists are as follows:

(a) If plan A is adopted, 2000 pieces will be saved from the chemical pollution.
(b) If plan B is adopted, there is a one-third probability that all the 6000 paintings will be saved, and two-thirds probability that none of these paintings will be saved.

Q27: Imagine that in one particular state it is projected that 1000 students will dropout of school during the year, two programs have been prosed to address this problem, but only one can be implemented. Based on other states experiences with programs, estimates of the outcomes that can be expected for each program can be made.

(a) Program 1: 400 of the 1000 students will stay in school
(b) Program 2: 2/5 chance that all 1000 students will stay in school and 3/5 chance that none of the 1000 will stay in school

Q28: Imagine that you have lung cancer and you must choose between two therapies: surgery and radiation. Surgery for lung cancer involves an operation on the lungs. Most patients are in the hospital for two or three weeks and have some pain around their incisions; they spend a month or so recuperating at home. After that, they generally feel fine. Radiation therapy for lung cancer involves the use of radiation to kill the tumor and requires coming to the hospital about four times a week for six weeks. Each treatment takes a few minutes and during the treatment, patients lie on a table as if they were having an x-ray. During the course of the treatment, some patients develop nausea and vomiting, but by the end of the six weeks they also generally feel fine. Thus, after the initial six or so weeks, patients treated with either surgery or radiation therapy feel about the same.

(a) Surgery: Of 100 people having surgery, 10 die during surgery or the postoperative period, 32 die by the end of one year and 66 die by the end of five years.
(b) Radiation Therapy: Of 100 people having radiation therapy, none die during treatment, 23 die by the end of one year and 78 die by the end of five years.

Q29: Imagine that you have decided to see a play and paid the admission price of $10 per ticket. As you enter the theatre you discover that you have lost the ticket. The seat was not marked and the ticket cannot be recovered.

(a) Pay $10 for another ticket
(b) Don't pay $10 for another ticket

Q30: Your are presented with the following report from the head of a special team assigned to investigate the prospects of a project in Arizona: Our new analysis indicates that, if we choose to compete with ATC, we would have the possibility of capturing a large market share. This would give us an after-tax return on investment of as much as 22%, while capturing a small market share would give us a return of only 10%. We estimate a 1 in 3 chance of getting a large market share. If we were to team up with ATC on the terms proposed, our return would be 14% after tax, with the same total investment.

(a) Compete with ATC
(b) Don't compete with ATC

Q31: A large car manufacturer has recently been hit with a number of economic difficulties and it appears as if three plants need to be closed and 6000 employees laid off. The vice-president of production has been exploring alternative ways to avoid this crisis and has developed two plans:

(a) Plan A: This plan will save 1 plant and 2000 jobs

(b) Plan B: : This plan has a 1/3 probability of saving all 3 plants and all 6000 jobs, but has a 2/3 probability of saving no plants and no jobs

Q32: Imagine that you are about to purchase a jacket for \$15, and a calculator for \$125. The calculator salesman informs you that the calculator you wish to buy is on sale for \$120 at the other branch of the store, located 20 minutes drive away.

(a) Make the trip to the other store and save 5 dollars but lose 20 minutes

(b) Don't make the trip to the other store and save 20 minutes but lose 5 dollars

Q33: A committee found a fish disease in a nearby lake. About 12 fish species (among them the most popular dining fish) have the Proliferative Kidney Disease (PKD). This is a chronically developing infectious disease which can have deadly consequences for the fish. Young fish are especially susceptible, while others seem to be immune against an infection. Experts suggest that PKD is one cause of declining fish catches. The researchers assume human activities and water pollution foster the spread of the disease. They are considering releasing more fish into the lake to control the epidemic. Imagine that you are a government official of the adjacent village.

(a) Option C: If the release of fish is implemented, 8 fish species will die.

(b) Option D: If the release of fish is implemented, there is 2/3 probability that none of the 12 fish species will die, and 1/3 probability that all of the 12 fish species will die.

Q34: Imagine that you brought \$6000 worth of stock from a company that has just filed a claim for bankruptcy recently. The company now provides you with two alternatives to recover some of your money.

(a) You will lose \$4000 of your money

(b) You will take part in a random drawing procedure with exactly a two-thirds probability of losing \$6000 all of your money, and one-third probability of not losing any of your money

Q35: Imagine a refinery that processes petroleum products. An investigation found that due to tank leaks, both soil and drinking water became contaminated. Due to this contamination 720 children from the adjacent village have a fatal disease. There is agreement among experts that children will not suffer health problems, provided they have a strong immune system. Otherwise, it is likely that children will have serious health problems. A vaccine against this disease has been developed and tested. However, the vaccine sometimes can cause side effects that can be fatal too. You are an environmental activist with much influence on the local hospital and you have to decide if you want to lobby for the vaccination or not.

(a) Option A: If the vaccination is adopted, the health of 240 children will be saved for sure.

(b) Option B: If the vaccination is adopted, there is a one-third probability that the health of all of the 720 children will be saved, and a two-thirds probability that the health of none of them will be saved.

Q36: Imagine that six people are infected by a fatal disease. Two alternative medical plans to treat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the plans are as follows:

(a) If plan A is adopted, two people will be saved.

(b) If plan B is adopted, there is a one-third probability that all six people will be saved, and two-thirds probability that none of them will be saved.

A.4 Group Level Results

Table A.4 shows the full table corresponding to table 2 in the paper with extra information regarding the choices made in each human experiment. P represents the percentage of people that chose the risky choice given either the gain frame or loss frames, the true P_{gain} and P_{loss} values, and n represents the number of human subjects who answered each frame which corresponds to the number of decisions our model made to produce results in the table.

Few-Shot Self-Rationalization with Natural Language Prompts

Ana Marasović[*] **Iz Beltagy**[*] **Doug Downey** **Matthew E. Peters**

Abstract

Self-rationalization models that predict task labels and generate free-text elaborations for their predictions could enable more intuitive interaction with NLP systems. These models are, however, currently trained with a large amount of human-written free-text explanations for each task which hinders their broader usage. We propose to study a more realistic setting of self-rationalization using few training examples. We present FEB—a standardized collection of four existing English-language datasets and associated metrics. We identify the right prompting approach by extensively exploring natural language prompts on FEB. Then, by using this prompt and scaling the model size, we demonstrate that making progress on few-shot self-rationalization is possible. We show there is still ample room for improvement in this task: the average plausibility of generated explanations assessed by human annotators is at most 51% (with GPT-3), while plausibility of human explanations is 76%. We hope that FEB and our proposed approach will spur the community to take on the few-shot self-rationalization challenge.

1 Introduction

Models constrained to be more understandable to people are easier to troubleshoot and more useful in practice (Rudin et al., 2021). For instance, constraining a model that answers the question "Which linguist invented the lightbulb?" with "none" to also provide the reason—"Thomas Edison is the inventor of the lightbulb and he was not a linguist"—makes the model easier to control and interact with (Kim et al., 2021). Models that jointly predict task labels and generate *free-text explanations* for their predictions (as in the previous example) are known as *self-rationalization models* (Wiegreffe et al., 2021). Their explanations are arguably more faithful and stable than post-hoc explanations since they are intrinsic to the model (Melis and Jaakkola, 2018). The free-text format is essential for explaining tasks requiring reasoning about unstated knowledge such as commonsense (Marasović et al., 2020), and it makes explanations more intuitive to people compared to highlights of individual words (Camburu et al., 2018). Despite these benefits, self-rationalization models are not widely used, in part because their training currently requires an abundance of human-authored explanations for each task (Narang et al., 2020). A possible solution is few-shot learning, which has shown promising results in recent years. To help the research community begin tackling self-rationalization with only a few examples, we present (i) FEB—a standardized collection of four existing English-language datasets and associated metrics, and (ii) the first approach for the task established through an extensive evaluation of natural language prompts.[1]

One approach to few-shot learning is *prompt-based finetuning* with *natural language prompts*. Such prompts are produced by formatting finetuning instances using a format similar to that used in pretraining, based on the idea that finetuning examples that look similar to pretraining ones will be more informative in the fewshot setting. A few prompts are then used for finetuning. In this paper, we explore whether prompt-based finetuning can be extended to induce few-shot self-rationalization behavior in addition to few-shot prediction. To measure our progress, we first introduce FEB as a benchmark dataset consisting of human authored free-text explanations across four distinct end tasks including natural language inference and commonsense tasks (§2). Since finding appropriate prompts is often challenging (Gao et al., 2021), we then extensively explore natural language prompts for few-shot self-rationalization. In our experiments, we fine-tune the T5 and UNIFIEDQA pretrained encoder-decoder transformers (Raffel et al., 2020;

Findings of the Association for Computational Linguistics: NAACL 2022, pages 410 - 424
July 10-15, 2022 ©2022 Association for Computational Linguistics

Khashabi et al., 2020), and show that versatile question-answering prompts (defined in §3.1) outperform prompts based on span infilling by 8.7 accuracy points, as well as prompts designed by following the most similar T5's supervised pretraining task by 3.2.

We then study the impact of model size on few-shot self-rationalization to investigate whether the quality of generated explanations scales with the size as good as the accuracy of predicting task labels. To this end, we also evaluate GPT-3's (Brown et al., 2020) self-rationalization behavior. Our experiments show that explanation plausibility scored by human annotators (which range from 0–100) and end-task accuracy improve with increasing model size. Specifically, the difference in plausibility scores between the BASE and 3B model ranges from [6.2, 24.8] (on average 14.8). The average plausibility across datasets is 43.4 (UNIFIEDQA-3B) and 50.6 (GPT-3). While encouraging, our results show that there is still a large gap between model and human performance (25.7 for GPT-3), and we hope this work will help enable the research community to take on the few-shot self-rationalization challenge.

Our code for producing data splits, prompt construction, model training/evaluation, and human evaluation templates are publicly available.[2]

2 FEB Benchmark

There has been an explosion of interest in generating free-text explanations and in few-shot learning in the last 1–2 years. However, appropriate datasets and metrics for few-shot self-rationalization have not yet been established. We thus introduce the FEB benchmark—a suite of existing English-language datasets with human-authored free-text explanations and associated metrics for few-shot self-rationalization. We expect that FEB will simplify future model comparison and lower barriers to entry for those interested in working on this task.

Datasets in FEB To identify available datasets suitable for few-shot self-rationalization, we start with a recent overview of datasets with free-text explanations (Wiegreffe and Marasović, 2021) and filter them according to the following criteria: (i) the input is textual, (ii) the explanation consists of one sentence or 2–3 simple sentences, (iii) the task has a fixed set of possible labels, (iv) the explanation is human-authored, and (v) the dataset has at least 389 instances. We use the second and third criteria to narrow the scope to easier self-rationalization since we expect that few-shot self-rationalization is very challenging. The last requirement is introduced to have 48 training and 350 evaluation examples.

FEB Tasks		**# Shots**
E-SNLI	Classify the entailment relation between two sequences	16
ECQA	Select the correct answer to a given question from five answer choices	48
COMVE	Select one of two sequences as more nonsensical	24
SBIC	Classify a post as offensive or not	24

Table 1: Tasks that we have included in FEB. The number of shots is the number of training instances *per label*. Training sets for all classification tasks are balanced and contain 48 instances. Sources: E-SNLI (Camburu et al., 2018), ECQA (Aggarwal et al., 2021), COMVE (Wang et al., 2019), SBIC (Sap et al., 2020).

This gives us 5 datasets, 4 of which are included in FEB and overviewed in Table 1. These datasets span 4 different tasks: natural language inference, multiple-choice commonsense QA, nonsensical sentence selection, and offensiveness classification. We exclude COS-E (Rajani et al., 2019) as it is too noisy to be useful for modeling and evaluating self-rationalization (Narang et al., 2020), but we do not support using COS-E in the future, especially since ECQA is introduced.[3]

ECQA contains not only justifications of the correct answer, but also justifications that refute the incorrect answer choices. We use only the former since they answer "why is [input] assigned [label]?", just as explanations in other datasets that we have included in FEB. The SBIC dataset contains annotations of frames representing the social biases that are implied in language. We format these frames as a self-rationalization task as follows. We allow only two labels: "offensive" and "not offensive". If a post is not offensive, we assign it the explanation: "*This post does not imply anything offensive.*" A post can be offensive because it targets an individual or a demographic group. In the former cases, a post is assigned the explanation: "*This post is a personal attack.*" Otherwise, we define a set of rules to transform SBIC annota-

---

[2] `https://github.com/allenai/feb`

[3] Since COS-E is still actively used, we report COS-E results in Tables 8 and 9 in Appendix.

tions of which identity-based group is targeted and what stereotypes of this group are referenced or implied into a single, coherent sentence; e.g., `group`: *women*, `stereotype`: *can't drive* → "*This post is offensive because it implies that women can't drive*".

This is, to the best of our knowledge, the most comprehensive collection of self-rationalization tasks with textual inputs that could also be used even when working in a high-resource setting.

Automatic Evaluation Evaluating self-rationalization (predicting task labels and generating explanations for the predicted labels) requires end-task evaluation and assessing the explanation plausibility. We use accuracy as our end-task evaluation metric. Explanation plausibility may be described as a subjective satisfaction with how a given explanation justifies a label/answer (Yang et al., 2019). Kayser et al. (2021) present the largest currently available study on the correlation of 10 NLG metrics with human judgments of free-text explanation plausibility and report that BERTscore (Zhang et al., 2020) is most correlated (although the correlation is still weak). Thus, we use BERTscore to evaluate the similarity between gold and generated explanations. Following Kayser et al., we assign zero BERTscore to explanations of incorrectly predicted instances.[4]

We follow recent recommendations for reliable few-shot evaluation (Bragg et al., 2021). Specifically, we fix hyperparameters (HPs) and use 60 random train-dev splits with 350 examples in each dev set. For classification tasks, the number of shots (examples per label) is chosen such that we construct a balanced training set of size 48.[5] See Table 1 (col. 3) for exact values; for ECQA we sample 48 training examples. For each model, we report the mean and standard error of 60 mean accuracy/BERTscore values calculated on 60 dev sets of 350 examples.[6] Our HPs are reported in Table 7 in Appendix.

Human Evaluation For our final models (§4), we conduct a human evaluation of plausibility of generated explanations following prior work (Kayser et al., 2021; Marasović et al., 2020). For each model evaluation, Kayser et al. (2021) take the first 300 dev examples that are correctly predicted by the model. This means that the dev set subsets used for human evaluation differ across models that are evaluated. However, the overlap between the evaluation sets is maximized by fixing the order of dev instances and taking the first 300.

Prior work used a single train-dev split, while FEB has 60 train-dev splits. Multiple splits provides the opportunity to account for the variance caused by changing the random seed to produce a reliable estimate of plausibility of explanations produced with only a few examples. Therefore, we take the first 6 correctly predicted examples per train-dev split, i.e., 6*60=360 total instances. Moreover, for classification tasks, we propose to take the first 6/#labels correctly-predicted examples per label to have a balanced evaluation set.

Following Kayser et al. (2021), we conduct the human evaluation in two steps:

- **Step1**: Select the correct label/answer.
- **Step2**: Assess whether two explanations (gold and generated) justify the label/answer above.

The first step makes sure the annotators understood the task correctly and they are not able to submit their annotations if the answers are wrong.[7] Ground-truth explanations are evaluated to implicitly influence annotators with a gold reference point when they evaluate generated explanations, and to measure the quality of explanation datasets. To evaluate explanations, annotators are asked "Does the explanation justify the answer?" and given the options `{"yes","weak yes","weak no","no"}`. These options are mapped to plausibility scores of $\{1, \frac{2}{3}, \frac{1}{3}, 0\}$, respectively. For each of the 360 examples, we calculate the mean plausibility score of 3 annotators and report the mean and standard error of 360 mean scores. We also report the inter-annotator agreement calculated with Fleiss' kappa. Finally, models are evaluated independently to avoid penalizing worse models in the presence of explanations generated by a better model.

---

[4] Kayser et al. (2021): "An explanation is expected to be false when the answer is predicted incorrectly (as it is expected to justify a wrong answer)."

[5] In early studies, we found that 48 gives models that are at least slightly above the random baseline across all four tasks.

[6] To calculate the standard error for accuracy/BERTscore we use $n = 60$. The training (and likewise, dev) sets across splits can overlap, so this error reflects the variability expected in average scores when repeating our experiment with 60 new random splits of the same data sets.

[7] We skipped this step for ECQA because we could not teach crowdworkers sufficiently well to select the most likely answer out of multiple likely answer candidates in ECQA.

3 Prompting for Self-Rationalization

We approach few-shot self-rationalization with prompt-based finetuning using natural language (NL) prompts. The key idea behind NL prompts is that a pretrained language model (LM) is already well-positioned to solve the end-task if we format finetuning end-task examples as similar as possible to the format used in the LM's pretraining. Following that principle, in this section, we describe our prompting approach with T5 (Raffel et al., 2020) and comprehensively evaluate three distinct prompt types with FEB. Our results show that a unified question-answering (QA) prompt combined with a T5 variant that includes additional supervised multitask QA training (UNIFIEDQA; Khashabi et al., 2020) performs the best overall across tasks, when compared to three different alternative prompts as described below.

Self-rationalization models (Narang et al., 2020; Wiegreffe et al., 2021) are currently based on T5 for at least two reasons. First, T5 has been pretrained with many supervised tasks including classification and generation tasks, and self-rationalization involves both classification and generation. Second, T5 is one of the largest *open-sourced* and widely studied pretrained models, and higher LM performance is correlated with larger model size (Kaplan et al., 2020). Thus, all of our experiments are based on T5 (and the UNIFIEDQA variant when evaluating prompts based on a QA format). In this section, all results are obtained with the base version of these models and in §4 we scale model size.

When a LM is pretrained with masked language modeling (Devlin et al., 2019) only, an appropriate NL prompt is constructed by adding and infilling masked tokens (Jiang et al., 2020). T5, however, has been pretrained with span infilling and a suite of supervised tasks whose instances were formatted in various ways. One of these supervised tasks includes SQUAD 1.1 (Rajpurkar et al., 2016) which allows us to experiment with prompts based on QA templates. As a result, we were able to design several different types of NL prompts for T5 consistent with different aspects of its pretraining:

1. QA prompts (SQUAD$_{\text{T5}}$, QA$_{\text{SIMPLE}}$).
2. span-filling prompts (INFILLING),
3. prompts designed by following the formatting of the most similar T5's pretraining task (≈T5; see Table 6 in Appendix),

We illustrate these prompt types for COMVE in Table 11 in Appendix. The following sections describe these formats in detail and compare their performance using FEB.

3.1 QA Prompts

Formatting new instances as QA pairs has been shown to be useful for transfer learning from a QA model (Gardner et al., 2019). We first evaluate options for a versatile QA NL prompt for self-rationalization of tasks in FEB before comparing this approach with the other two prompt types (INFILLING and ≈T5) in §3.3. As alternative QA models, we investigate two models: T5 (which has been pretrained with QA supervision from SQUAD 1.1), and UNIFIEDQA (a T5 variant described in detail below). Since UNIFIEDQA was trained on a multitask mixture of many different QA datasets, these T5 variants allow us to examine the extent to which additional QA supervision can transfer to the few-shot self-rationalization setting.

Prior work (Bragg et al., 2021) introduced UNIFEW, a model based on UNIFIEDQA, that is finetuned on a few task-specific instances posed as QA. Despite its simplicity, UNIFEW achieves competitive few-shot learning performance with strong baselines for classification tasks. However, Bragg et al.'s prompts do not cover all task types in FEB, and the question structure in their prompts is highly task-specific (see Appendix A.1).

Alternatively, we propose to design QA prompts with a simple principle in mind: Given a non-QA task, construct an equivalent QA task in the form of short "Is...?" or "What is...?" questions. Here, "Is...?" questions have yes/no answers (sometimes "maybe"), and task labels verbatim are answers to "What is...?" questions (e.g., "offensive" and "not offensive"). Given such question-answer pairs, we develop prompts following the formats proposed in UNIFIEDQA (see Appendix A) and prompt UNIFIEDQA. We denote these prompts as QA$_{\text{SIMPLE}}$. For T5, we develop prompts following the SQUAD format for the T5's pretraining (SQUAD$_{\text{T5}}$; see Appendix A).

There is another factor to consider. We need to decide whether to add *tags*—a single description of each input element. Examples of tags are "`premise:`" and "`hypothesis:`" before the first and second sentence in the E-SNLI input. Without these tags the task seems impossible to understand, but UNIFIEDQA has not been trained with any tags.

The output always takes the form of "[*answer/label*] `because` [*explanation*]". See Table

11 (Appendix) for examples of our various QA prompts.

Results We present the results of UnifiedQA with QA$_{\text{SIMPLE}}$ in Table 2, and due to space limits, T5's results with SQuAD$_{\text{T5}}$ prompts in Table 10 in Appendix.

We observe that for E-SNLI and ComVE it is crucial to add tags (“`premise:`”/“`hypothesis:`”; “`choice1:`”/“`choice2:`”).[8] This result is intuitive—it should be difficult to pick one of the two sentences, or classify a relation between them, if sentences are not marked. On the other hand, adding label choices is not beneficial and in some cases can even decrease the performance. When tags are included, we see that across all the tasks the “What is...?” question performs the best. This also holds for T5 and SQuAD$_{\text{T5}}$ prompts (see Table 10). Finally, the prompt with the “What is...?” question and tags in the input outperforms UniFew for both tasks UniFew can be applied to. This result shows that this prompt is both versatile and effective.

Finally, we compare the best performing prompts we get with UnifiedQA with QA$_{\text{SIMPLE}}$ and T5 wtih SQuAD$_{\text{T5}}$. See prompts “SQuAD$_{\text{T5}}$ × What is...? + Tags” and “QA$_{\text{SIMPLE}}$ × What is...? + Tags” in Table 11. For ECQA and ComVE, we observe notable improvements from using UnifiedQA, and minor improvements for SBIC. For E-SNLI, T5 is better, presumably because UnifiedQA has lost some useful information from NLI after extensive continued pretraining for QA. These results suggest that UnifiedQA is a better model for prompting self-rationalization with QA prompts.

To recap, the analysis presented in this section suggests that QA prompting for inducing self-rationalization behavior is best done when UnifiedQA is combined with the NL prompt below. For true QA tasks, we use the original UnifiedQA formats.[9]

Input:
`explain what is this/more...? \\n tag`$_1$`:` [*sequence*$_1$] `tag`$_2$`:` [*sequence*$_2$] ...`</s>`

Output:
[*answer/label*] `because` [*explanation*]

	Prompt	Accuracy	BERTscore
E-SNLI	UniFew	$61.7_{0.6}$	$55.8_{0.5}$
	+ tags	$63.6_{0.4}$	$57.3_{0.4}$
	Is...?	$47.5_{0.5}$	$42.7_{0.5}$
	+ tags	$66.6_{0.5}$	$60.0_{0.5}$
	+ tags & choices	$64.4_{0.5}$	$58.2_{0.5}$
	What is...?	$40.7_{0.4}$	$36.5_{0.4}$
	+ tags	**75.0**$_{0.3}$	**67.5**$_{0.3}$
	+ tags & choices	$69.3_{0.7}$	$62.5_{0.6}$
	Random Baseline	33.3	-
ECQA	UnifiedQA	**41.4**$_{0.3}$	**36.7**$_{0.3}$
	Random Baseline	20.0	-
ComVE	Is...?	$52.7_{0.3}$	$47.7_{0.3}$
	+ tags	$52.5_{0.3}$	$47.5_{0.3}$
	+ tags & choices	$52.2_{0.3}$	$47.3_{0.3}$
	What is...?	$50.6_{0.2}$	$45.7_{0.2}$
	+ tags	**67.3**$_{0.7}$	**61.0**$_{0.6}$
	+ tags & choices	$62.6_{0.6}$	$56.7_{0.6}$
	Random Baseline	50.0	-
SBIC	UniFew	$66.1_{0.4}$	$63.8_{0.4}$
	Is...?	$63.5_{0.4}$	$61.2_{0.4}$
	+ tags	$62.6_{0.4}$	$60.4_{0.4}$
	+ tags & choices	$63.6_{0.4}$	$61.3_{0.4}$
	What is...?	$67.3_{0.4}$	$65.0_{0.4}$
	+ tags	**67.5**$_{0.4}$	**65.3**$_{0.4}$
	+ tags & choices	$65.4_{0.6}$	$63.1_{0.6}$
	Random Baseline	50.0	-

Table 2: Prompting UnifiedQA with QA$_{\text{SIMPLE}}$ with “Is...?” and “What is...?” questions, and UniFew. See §3.1 for descriptions of these prompts. For ECQA we use the original UnifiedQA format for multiple-choice QA. We also inspect the effects of adding label choices and *tags* (defined in §3.1) to the input.

3.2 Infilling Prompts

The simplest way to design an infilling prompt for self-rationalization with T5 is to add the span “`<extra_id_0> because <extra_id_1>`” to the input. A model should then replace `<extra_id_0>` with a label/answer and `<extra_id_1>` with an explanation. Besides being similar to T5's span infilling pretraining task, another benefit of this prompt is that it is very flexible—the span above can be added to any task input. This basic infilling prompt could be easily made more natural by prepending phrases such as: “`The answer is`” (ECQA), “`Less common is`” (ComVE), or “`This`

---

[8] Performance on ComVE with “Is...?” is close to random regardless of tags which suggests that this question form hinders the performance and tags cannot make a difference.

[9] Following Hendrycks et al. (2021), we add </s> to the end of our QA$_{\text{SIMPLE}}$ prompts.

	E-SNLI	ECQA	ComVE	SBIC
B	**75.2**$_{0.4}$	22.3$_{0.3}$	**50.4**$_{0.3}$	61.6$_{0.4}$
N	75.1$_{0.4}$	**27.6**$_{0.4}$	49.0$_{0.3}$	**64.7**$_{0.5}$

(a) Accuracy.

	E-SNLI	ECQA	ComVE	SBIC
B	**67.7**$_{0.3}$	19.8$_{0.3}$	**45.5**$_{0.3}$	59.2$_{0.5}$
N	67.5$_{0.4}$	**24.5**$_{0.3}$	44.3$_{0.3}$	**62.0**$_{0.5}$

(b) BERTscore.

Table 3: A comparison of the basic infilling prompt (B; "`<extra_id_0> because <extra_id_1>`") with its more natural sounding version (N; see §3.2).

`is`" (E-SNLI, SBIC). We hypothesize that these additional phrases could be beneficial because they suggest which subset of the vocabulary is the right word for filling in `<extra_id_0>`. We test whether it is beneficial to make the infilling prompt more natural-sounding.

Results T5 results are shown in Table 3. The outcome is mixed—while we observe notable benefits for ECQA/SBIC, for E-SNLI/ComVE there is a minor difference in favor of the basic prompt. A way to explain this is that T5 learned about NLI labels from MNLI during pretraining, so it does not an need additional phrase to nudge it in the right direction. ComVE results are comparable to the random performance, and the model could not learn the task from the infilling prompt, with or without the additional phrases. Thus, we recommend using the more natural version as it is not detrimental to E-SNLI/ComVE performance while it leads to big improvements for ECQA/SBIC.

3.3 Infilling vs. ≈T5 vs. QA

We have established appropriate QA and Infilling prompts in §3.1 and §3.2. We now turn to a comparison between all three prompt types: (i) Infilling (natural), (ii) ≈T5, and (iii) QA$_{\text{SIMPLE}}$ ("What is...?" with tags). The first two are used to prompt T5 and the last type UnifiedQA. To construct ≈T5 prompts, for each task in FEB, we identify the most similar T5's pretraining task (see Table 6, Appendix) and use that task's formatting (see, e.g., ≈T5 × COPA in Table 11).

Results A comparison of the three prompt types is presented in Table 4. The QA$_{\text{SIMPLE}}$ prompt outperforms other prompt types for all tasks except E-SNLI for which unsurprisingly ≈T5 is the best. Finally, this brings us to the end of our extensive exploration of natural language prompts for a prompt-based finetuning approach to few-shot self-rationalization. We identify the QA$_{\text{SIMPLE}}$ prompt as the most effective and we use it to study how few-shot self-rationalization performance scales with the size of the UnifiedQA model.

	Task	Accuracy	BERTscore
Infilling	E-SNLI	75.1$_{0.4}$	67.5$_{0.4}$
	ECQA	27.6$_{0.4}$	24.5$_{0.3}$
	ComVE	49.0$_{0.3}$	44.3$_{0.3}$
	SBIC	64.7$_{0.5}$	62.0$_{0.5}$
	Average	54.1	49.6
≈T5	E-SNLI	**79.2**$_{0.3}$	**71.3**$_{0.3}$
	ECQA	38.3$_{0.3}$	33.9$_{0.3}$
	ComVE	55.9$_{0.3}$	50.4$_{0.3}$
	SBIC	65.1$_{0.6}$	62.8$_{0.6}$
	Average	59.6	54.6
QA$_{\text{SIMPLE}}$	E-SNLI	75.0$_{0.3}$	67.5$_{0.3}$
	ECQA	**41.4**$_{0.3}$	**36.7**$_{0.3}$
	ComVE	**67.3**$_{0.7}$	**61.0**$_{0.6}$
	SBIC	**67.5**$_{0.4}$	**65.3**$_{0.4}$
	Average	**62.8**	**57.6**

Table 4: A comparison between three prompt types: Infilling, ≈T5, and QA$_{\text{SIMPLE}}$ prompts. See §3 for descriptions of these prompts.

4 Improving Self-Rationalization with Increasing Model Size

In §3, we discovered that a QA prompt combined with the base UnifiedQA model version is as an effective combination for few-shot self-rationalization through prompt-based finetuning. In this section, we provide two additional evaluations to establish the first approach to few-shot self-rationalization.

First, we assess how plausible the generated explanations are when evaluated by annotators on Amazon MTurk. Details of how we conduct human evaluation of plausibility are given in §2. One HIT contains 10 instances and we pay $1 per HIT.

Next, we investigate how self-rationalization performance changes with the model size since larger pretrained language models typically give better few-shot performance (Brown et al., 2020). We wonder whether the same trend will hold for a complex generation task of self-rationalization where

				Plausibility							
				All		*Label*$_1$		*Label*$_2$		*Label*$_3$	
	Model	**Accuracy**	**BERTscore**	**Score**	κ	**Score**	κ	**Score**	κ	**Score**	κ
E-SNLI	BASE	$79.2_{0.3}$	$71.3_{0.3}$	$16.7_{1.5}$	0.73	$15.6_{2.3}$	0.67	$17.5_{2.9}$	0.79	$17.1_{2.7}$	0.72

	RAND	50.0									

Table 5: The first results on the FEB benchmark using T5/UNIFIEDQA (BASE, LARGE, 3B) and GPT-3. T5 with ≈T5 prompt is used only for E-SNLI, and UNIFIEDQA +QA$_{\text{SIMPLE}}$ prompt is used for other datasets. The descriptions of these prompts are given in §3 and details of how evaluation metrics are calculated in §2. RAND stands for a random baseline and GOLD for human-authored explanations. *Label*$_1$/*Label*$_2$/*Label*$_3$ are entailment/neutral/contradiction in E-SNLI and offensive/not offensive in SBIC. The number of parameters is: 200M (BASE), 770M (LARGE), 2.8B (3B), and 175B (GPT-3).

it is conceivable that an enormous model could overfit on a few examples. To this end, we evaluate three versions of UNIFIEDQA (BASE, LARGE, 3B) and GPT-3 (Brown et al., 2020). We use `davinci-instruct-beta` which is a beta version of the INSTRUCTGPT model (Ouyang et al., 2022).

We evaluate GPT-3 using its API and "in-context demonstrations" (Brown et al., 2020). We pack as many training examples (demonstrations) as we can fit in the input, followed by the input of the test example, then run GPT-3 to generate its output. The number of demonstrations we are able to fit ranges from [28,45] which are randomly selected from the 48 used for UNIFIEDQA. Since evaluation using a single prompt costs us $1,050, we do not do prompt search for GPT-3. We use the prompts shown in Fig. 1 in Appendix.

A detailed description of evaluation metrics is given in §2. The dev set size (of each out of 60 dev sets) for GPT-3 is 18 instead of 350 (because of the API cost). Ground-truth explanations are evaluated together with explanations generated by 4 models. Therefore, for GOLD explanations, we report the average of 4 plausibility scores, std. errors, and κ values calculated with 4 Mturk batches (corresponding to 4 models).

4.1 Results

Results are shown in Table 5. Note that we use T5 with the ≈T5 prompt for E-SNLI, and UNIFIEDQA with $\text{QA}_{\text{SIMPLE}}$ (§3) for other datasets to establish the best possible performance for each dataset. The exact prompts for each task are given in Appendix A.2. We observe that all metrics—accuracy, BERTscore, and plausibility—monotonically increase with the model size for all datasets. That is, larger models learn to predict task labels and generate explanations from a few examples better. UNIFIEDQA-3B has a higher accuracy/BERTscore than GPT-3 for all datasets except SBIC, but GPT-3 generates explanations that are notably more plausible.

The following observations suggest that few-shot self-rationalization is a promising research direction. The difference in plausibility scores between the BASE and 3B model versions ranges from [6.2, 24.8] (on average 14.8). In other words, since it is possible to generate more plausible explanations by only increasing the model size, it is conceivable that further progress could be made with more creative approaches. Next, the plausibility score of the best model (GPT-3) ranges from [42.2, 72.7] ([42.2, 52.6] if we consider only SBIC "offensive" ($Label_1$) subset. This shows that a moderate plausibility can already be achieved with current models without any task-specific enhancements.

Despite that, the gap between our best models and human-authored explanations remains large. The average plausibility score across datasets is 43.4 (UNIFIEDQA-3B), 50.6 (GPT-3), and 76.3 (GOLD). In other words, the difference in plausibility scores between UNIFIEDQA-3B's and human explanations is 33.0, and between GPT-3's and human explanations is 25.7. We expect that the FEB benchmark, our UNIFIEDQA approach, and first results, present a good starting point to tackle this challenge.

Performance w.r.t. Labels For E-SNLI and SBIC, we can inspect the metrics with respect to labels. In E-SNLI part of the Table 5, $Label_1$ marks "entailment", $Label_2$ "neutral", and $Label_3$ "contradiction". There are notable differences between the plausibility scores for each label. The plausibility score for "entailment" does not scale with the model size and it is much lower than scores for other labels (the best score is 27.3 vs. 66.0/50.9). This issue stems from the difficulty of explaining the entailment label (Camburu et al., 2018). Even people struggle with explaining "entailment" as evident by the lower GOLD score for "entailment" compared to the other two labels. An interesting observation from the other two labels is that UNIFIEDQA-3B is explains "contradiction" instances best and GPT-3 "neutral" instances.

In SBIC part of the Table 5, $Label_1$ marks "offensive" and $Label_2$ "not offensive" instances. The latter achieve almost perfect plausibility since the models learn to generated "*This post does not imply anything offensive*". Thus, main plausibility scores for SBIC are those of offensive instances. We can observe that the relative differences between models for offensive instances are much larger than the relative differences when examples of both labels are accounted for (column "*All* / Score"). If we had only looked into a single plausibility score we would not notice these differences. This result is in line with Carton et al. (2020) who also recommend breaking down the evaluation of explanations w.r.t. labels whenever possible.

Annotator Agreement Finally, we observe challenges in collecting human judgments of plausibility. For all datasets except ECQA, Fleiss' κ is either moderate (between 0.41–0.6) or substantial (between 0.61–0.8). One exception is GPT-3 on SBIC ($Label_1$; offensive) where κ is only 0.34. We also observe that κ for GPT-3's explanations is lower than κ for UNIFIEDQA's or GOLD explanations, with the exception of COMVE. The most concerning is ECQA where κ is on average 0.35 for UNIFIEDQA's explanations, 0.34 for GOLD explanations, and only 0.12 for GPT-3's. Future work should investigate the reasons behind these differences more carefully.

5 Related Work

Few-Shot Self-Rationalization A standard approach to creating explanations in the form of *highlights* is the select-then-predict method (Lei et al., 2016) that does not use any human-author input highlights. On the other hand, a standard method for generating free-text explanations is to use human-written explanations (Liu et al., 2019; Wu and Mooney, 2019; Narang et al., 2020, among others). To the best of our knowledge, prior to submitting our work only two prior works have generated free-text explanations in a weakly-supervised way from the task prediction loss. Latcinnik and Berant (2020) approach commonsense QA in that fashion. Brahman et al. (2021) propose a distant supervision approach to explaining a defeasible inference task. In this paper, we introduce the FEB benchmark to unify the evaluation of few-shot self-rationalization and present the first approach and results on FEB.

Concurrent to our work, Yordanov et al. (2021) study self-rationalization transfer from a high-resource task to a task with only a few human-authored explanations. Wiegreffe et al. (2022) analyze explanations obtained by prompting GPT-3 multiple times to get multiple explanation candidates, and then filter these candidates using a model trained to predict acceptability of explanations. Their prompt consists of a few examples with high-quality explanations written by the authors and a new instance together with its gold label. Wei et al. (2022) demonstrate end-task performance improvements attained by prompting the PaLM model (Chowdhery et al., 2022) to first generate an explanation behind its reasoning ("chain of thought") and then the task label. Zelikman et al. (2022) extend this approach by using explanations generated in a few-shot manner to refine the same GPT-J (Wang and Komatsuzaki, 2021) model.

Few-Shot Learning We study natural language prompts (Brown et al., 2020; Schick and Schütze, 2021) to establish the first approach to few-shot self-rationalization. Alternatively, few-shot learning researchers are studying prompts in the form of continuous/soft vectors that do not correspond to real tokens (e.g., Qin and Eisner, 2021). Such methods present a promising research direction for few-shot self-rationalization. Namely, we show that larger models generate notably more plausible explanations, and "prefix tuning" (Li and Liang, 2021) has been show to learn two condition generation tasks using only 0.1% of the parameters, while maintaining comparable performance. In practice, such approaches still require a notable amount of GPU memory. Thus, any efforts to reduce required memory such as compression (Ganesh et al., 2021) may be valuable for few-shot self-rationalization.

6 Conclusions

We draw attention to the task of few-shot self-rationalization: predicting task labels and generating *free-text* explanations for the prediction using only a few human-written explanations. We present (i) the FEB benchmark, (ii) the first prompting approach for FEB established through a comprehensive search of natural language prompts, and (iii) results using models with a number of parameters ranging from 220M to 175B. Our human evaluation results show that progress is possible on this task given that just scaling the model size increases both the plausibility of generated explanations and task accuracy by a very large margin. Despite that, few-shot self-rationalization remains very challenging, with the plausibility of explanations generated by the best model being 27.7 points behind that of human-authored explanations. We hope that work presented in this paper spurs the community to work on this challenging problem to enable more intuitive interaction with NLP systems.

Abstract

In this paper, we introduce **DOCmT5**, a multilingual sequence-to-sequence language model pretrained with large scale parallel documents. While previous approaches have focused on leveraging sentence-level parallel data, we try to build a general-purpose pretrained model that can understand and generate long documents. We propose a simple and effective pretraining objective - **D**ocument **r**eordering **M**achine **T**ranslation (**DrMT**), in which the input documents that are shuffled and masked need to be translated. DrMT brings consistent improvements over strong baselines on a variety of document-level generation tasks, including over 12 BLEU points for seen-language-pair document-level MT, over 7 BLEU points for unseen-language-pair document-level MT and over 3 ROUGE-1 points for seen-language-pair cross-lingual summarization. We achieve state-of-the-art (SOTA) on WMT20 De-En and IWSLT15 Zh-En document translation tasks. We also conduct extensive analysis on various factors for document pretraining, including (1) the effects of pretraining data quality and (2) the effects of combining mono-lingual and cross-lingual pretraining. We plan to make our model checkpoints publicly available.

1 Introduction

Multilingual pretrained language models have been useful for a wide variety of NLP tasks. pretraining on large-scale multilingual corpora facilitates transfer across languages and benefits low-resource languages.

Previously, sentence-level or word-level cross-lingual objectives have been considered for pretraining large language models (LLM), but not much effort has been put in document-level objectives for pretraining. In this work, we propose a multilingual sequence-to-sequence language model pretrained with cross-lingual structure-aware document-level objectives. DOCmT5 is built on top of mT5 (Xue et al., 2021) and is further trained with parallel documents across multiple language pairs. To encourage the model to gain a deep understanding of the document structure and cross-lingual relationships, we consider a challenging translation scenario as a second-stage pretraining task: the input sentences are shuffled in a random order and random spans are masked. To effectively translate the input document, the model needs to reconstruct the document in the original order, making the model learn sentence relationships, and also recover the masked spans. This objective is effective on document-level generation tasks such as machine translation and cross-lingual summarization, outperforming previous best systems.

To enable cross-lingual pretraining at a large scale, we created a synthetic parallel document corpus. To avoid expensive human annotation, we use off-the-shelf neural machine translation (NMT) models to translate the documents in the mC4 corpus (Xue et al., 2021) into English. In our experimental results, this corpus is more effective for pretraining than existing large-scale automatically aligned corpora (e.g., CCAligned (El-Kishky et al., 2020)).

We also conduct extensive ablation studies and provide insights on document-level pretraining. We show that simple document-level pretraining is more useful than sentence-level pretraining for generative tasks. We also show that data quality matters when performing multilingual document pretraining. Finally, we don't observe improvements from combining mono-lingual and cross-lingual objectives when evaluating on two document-level translation tasks.

In summary, this paper makes the following contributions:

- We build a state-of-the-art multilingual document-level sequence-to-sequence language model pretrained with a structure-aware cross-lingual objective.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 425 - 437
July 10-15, 2022 ©2022 Association for Computational Linguistics

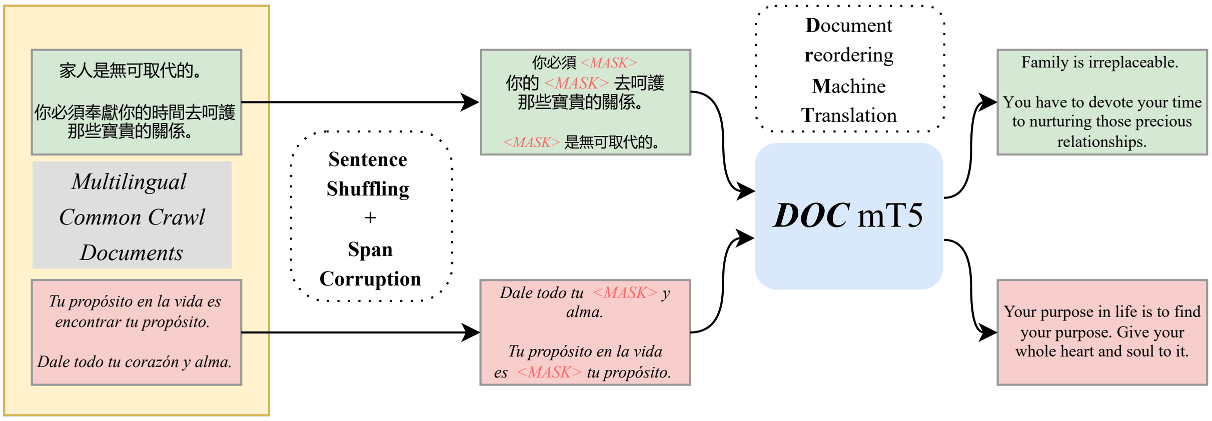

Figure 1: Overview of our proposed **D**ocument-**R**eordering **M**achine **T**ranslation (**DrMT**) pretraining. For each input document, the sentences are shuffled in random order and then randomly selected spans will be masked. The prediction target of DOCmT5 is to generate the translation of the input document.

- Our proposed model achieves strong results on cross-lingual summarization and document-level machine translation for seen and unseen language paris, including SOTA on WMT20 De-En and IWSLT2015 Zh-En tasks.
- We also conduct extensive experiments to study what works and what doesn't work in document-level multilingual pretraining.

2 Related Work

2.1 Multilingual Pretraining

Multilingual pretrained models provide a set of parameters that can be quickly finetuned for different downstream tasks (Ruder et al., 2021). Some popular models are: mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) which pretrain with masked language modeling objective using only monolingual data, mT5 (Xue et al., 2021) and mBART (Liu et al., 2020) which use a sequence-to-sequence language model and pretrain on large-scale mono-lingual corpora across many languages. Our proposed model uses mT5 as a backbone and further utilizes pseudo-parallel documents to learn better cross-lingual representations.

To capture cross-lingual information, translation language modeling (Conneau and Lample, 2019) and its variants (VECO (Luo et al., 2021), ERNIE-M (Ouyang et al., 2021)) was proposed to leverage sentence-level parallel data. AMBER (Hu et al., 2021) use two explicit alignment objectives that align representations at the word and sentence level. HICTL (Wei et al., 2020) pretrains on parallel sentences with word and sentence-level contrastive losses. mBART50 (Tang et al., 2021), mT6 (Chi et al., 2021) and nmT5 (Kale et al., 2021) focus on second-stage of pretraining using large-scale sentence-level translation data. Our model goes beyond the sentence and focuses on document-level understanding.

While sentence-level pretraining has received a lot of attention, document-level pretraining has been under-studied. Unicoder (Huang et al., 2019) replaces alternating sentences in a document with translations and pretrains with masked language modeling. MARGE (Lewis et al., 2020) adopts the retriever-generator paradigm and pretrains with an unsupervised translation objective on automatically retrieved documents. M2M100 (Fan et al., 2021) pretrains sequence-to-sequence language models on automatically mined parallel sentences and documents. Our model considers a challenging supervised translation objective on parallel documents.

2.2 Multilingual Parallel Data Sources

OPUS-100 (Aharoni et al., 2019; Zhang et al., 2020a) is collected from a variety of domains and is human labeled but it is at the sentence level. ML50 (Tang et al., 2021) is collected from different machine translation challenges and other publicly available corpora such as OPUS, but most of the data is at the sentence level. CCMatrix (Schwenk et al., 2021b) and Wikimatrix (Schwenk et al., 2021a) use multilingual sentence embedding to automatically mine parallel sentences. Perhaps the most closest to our proposed corpus is CCAligned (El-Kishky et al., 2020), which is also automatically mined but its quality is in question (Kreutzer et al., 2021). Our

2.3 Document-level Machine Translation

There are different ways to incorporate document context into translation model. Just to name a few, previous works have explored concatenation-based methods (Tiedemann and Scherrer, 2017; Junczys-Dowmunt, 2019; Sun et al., 2020; Lopes et al., 2020), multi-source context encoder (Zhang et al., 2018; Jean et al., 2017), and hierarchical networks (Zheng et al., 2020; Zhang et al., 2020b; Chen et al., 2020). This line of research focuses on architectural modifications of neural translation models. We focus on how to design a generalized pretraining objective and furthermore, our model can be finetuned for various downstream tasks (e.g. summarization) without task-specific changes.

3 Multilingual Pretraining

3.1 Datasets

3.1.1 mC4

For pretraining, we use mC4 (Xue et al., 2021), a large scale corpus extracted from Common Crawl that covers over 100 languages.

3.1.2 MTmC4: Creating Parallel Documents with mC4

To create large-scale parallel documents, we take mC4 as a starting point and use in-house NMT models to translate documents from 25 languages into English. Each sentence in each document is translated independently. For each language, we sample 1 million documents, if there are more than that to start with, in mC4. Detailed data statistics for all the languages can be found in Table 2.

3.2 Document Reordering Machine Translation (DrMT)

We start by introducing two related pretraining objectives:

- *NMT Pretraining*: Tang et al. (2021) and Kale et al. (2021) proposed to perform a second-stage of pretraining using sentence-level MT data. The objective here is to perform sentence-level translation without any other changes to the input.
- *Monolingual Document Reordering (Dr) Pretraining*: This objective, proposed by mBART (Liu et al., 2020), changes the order of the sentences in each document. This is then followed by the original span corruption objective in T5. The decoder is required to generate the original document in order.

We combine these two objectives and propose **DrMT**. In DrMT, we introduce two types of noise on the input: **(i)** sentences in the document are randomly shuffled and **(ii)** randomly sampled spans are masked. In order to correctly translate the content, the model needs to decipher the corrupted document in order first. This enforces the models to gain deep understanding of the document structure. More formally, suppose we have N language pairs and each language has a set of parallel documents, the whole collection of document pairs are $D = \{D_1, D_2, ..., D_N\}$. And a pair of (x, y) is an instance in one of the language documents D_i. The overall learning objective is maximizing the likelihood of y given a corrupted $C(x)$, that is

$$\sum_{D_i \in D} \sum_{(x,y) \in D_i} \log P(y|C(x)). \tag{1}$$

3.3 DOCmT5

We use mT5 as the backbone model. mT5 is a sequence-to-sequence language model pretrained with the span corruption objective in which random spans in the input are masked and the decoder is required to reconstruct the masked spans (see Raffel et al. (2020) and Xue et al. (2021) for further details). Our system, DOCmT5, incorporates a second-stage pretraining with a structure-aware cross-lingual objective(3.2) on pseudo parallel documents. Detailed comparisons with previous multilingual language models can be found in Table 1. We provide two variants of DOCmT5 with both Base and Large model settings:

- **DOCmT5-5** This model is pretrained with 5 languages: {De, Ru, Tr, Vi and Es}. For all of the pretraining objective baselines in this paper, we pretrain with this set of languages, unless specified otherwise.
- **DOCmT5-25** This model is pretrained with 25 languages. We show the full list of languages and their sizes in Table 2.

3.4 Implementation Details

We use mT5-Base[1] and mT5-Large[2] checkpoints at 1M steps as our pretrained models. We perform a second-stage of pretraining for an additional 0.5M steps using batches of 256 examples each of max length 1024. The learning rate is determined by a inverse square root scheduler as defined in T5, with the learning rate set to $1/\sqrt{n}$ where n is the number of training step. We use the same span corruption objective as T5, with 15% of random tokens masked and an average noise span length of 3. For finetuning, we use a constant learning rate of 0.001 and dropout rate of 0.1 for all tasks until convergence. We adopt greedy decoding during inference.

4 Experiments

4.1 Baselines

- **Second-Stage Pretraining on 5 Languages** Language models pretrained with huge numbers of languages suffer from curse of multilinguality. In order to make a fair comparison, we create a strong mT5 model by continuing to pretrain on the same 5 languages of mC4 as in DOCmT5-5 with the same number of steps using the original span corruption objective in mT5. Models pretrained with this objective is denoted as **cont-5langs**.

- **Monolingual Document Reordering (Dr)** We briefly mention this objective in Section3.2. We use the mC4 corpus for this pretraining objective. Models pretrained with this objective is denoted as **Dr** (**D**ocument **R**eordering).

- **Document TLM (DocTLM)** In Conneau and Lample (2019), the authors propose the translation language modeling(TLM) objective, which concatenates parallel sentences and applies masked language modeling to learn cross-lingual knowledge. Here we extend it to the document level by concatenating parallel documents. Instead of masking single tokens, we follow the span corruption objective in T5 and mask consecutive spans. The models are pretrained with this objective on MTmC4.

- **Document NMT (DocNMT)** We consider a standard document-level machine translation for pretraining. The source document is the input and the target translation is the output. We use MTmC4 for this pretraining objective.

Table 4: Results of three unseen langauges paris {Fr, Id, Hi} on Wikilingua.

4.2 Cross-Lingual Summarization

We evaluate *DOCmT5* on cross-lingual summarization as it is challenging for the model to summarize a long document and translate the salient information at the same time. We use Wikilingua, a cross-lingual summarization dataset, in which a document from an arbitrary language must be summarized in English. We adopt the GEM (Gehrmann et al., 2021) version where the data is re-split to avoid train-test overlap between languages. We use a special prefix for cross-lingual summarization: *"Summarize X to Y"*, where X and Y are the source and target language names respectively.

4.2.1 Results on Seen Language Pairs

We show the finetuning results of language pairs that are in the second stage of pretraining in Table 3. We use the same four languages that are in Wikilingua's original release {Es, Ru, Tr, Vi}. The *Dr* objective brings substantial improvements over *cont-5langs* in all four languages, justifying the importance of structure-aware objectives. As for cross-lingual objectives, *DocTLM* is better than *DocNMT* in almost all languages except for Russian. DOCmT5-5 substantially outperforms *DocNMT* and *DocTLM*, showing that our proposed pretraining objective leads to improved cross-lingual learning. The results of *DOCmT5-25* are inferior to *DOCmT5-5* and this is possibly due to capacity dilution (Arivazhagan et al., 2019). As we increase the capacity, we see that *DOCmT5-25-Large* outperforms *DOCmT5-5-Large*. *DOCmT5-25-Large* is the best overall model outperforming the strong prior system: mBART.

4.2.2 Results on Unseen Language Pairs

We show the finetuning results of language pairs that are not in the second-stage of pretraining stage in Table 4. We use three languages {Fr, Id, Hi}[3]. Once again, we see that the *Dr* objective brings substantial improvements over *cont-5langs*. Surprisingly, without directly pretraining on the same language pairs, *DOCmT5-5* leads to substantial improvements over strong baselines. This shows that our pretraining objectives are able to generalize to other languages. *DOCmT5-25* pretrains on French and Hindi but not Indonesian and hence we observe improvements of average results over *DOCmT5-5*. The improvements of *DOCmT5* are not so substantial and sometimes even hurt performance in high-resource languages: French and Indonesian, which have 44556 and 33237 training examples respectively and there are only 6942 examples in Hindi. *DOCmT5-25-Large* obtains the best results in almost all 3 languages except for French.

DOCmT5-25-Large	43.49

Table 5: Finetuning results on WMT20 De-En.

4.3 Document-Level Machine Translation

We evaluate DOCmT5 on document translation. We split each document into chunks with a max length of 512 tokens. During inference, the decoded chunks are concatenated together to form the final document. We use prefix *"Translate X to Y"* for translation, where X and Y are the source and target language names respectively.

4.3.1 Seen Language Pair: WMT20 De-En

WMT20 De-En is a document-level machine translation task. We use parallel training data from WMT20 without using additional monolingual data. From the results in Table 5[4], we see that *Dr* provides large gains. *DocNMT* outperforms *DocTLM*. This is probably due to the fact that *DocNMT* is more close to the document-level translation task. *DOCmT5-5* once again outperforms Dr and other strong cross-lingual baselines. *DOCmT5-5* is better than *DOCmT5-25* again because of capacity dilution as noted in Aharoni et al. (2019). As expected, *DOCmT5-5-Large* outperforms *DOCmT5-5* and to the best of our knowledge, achieves the SOTA. Note that previous systems use one or more of the following techniques: additional monolingual data, back-translation, ensembling or re-ranking tailored to a single translation pair.

Table 6: Unseen language pair results on IWSLT 2015 Zh-En. Chinese is in the second-stage pretraining language set of DOCmT5-25 but not in those of DOCmT5-5. DOCmT5-25-Large achieves SOTA.

4.3.2 Unseen Language Pair: IWSLT 2015 Zh-En

We use IWSLT 2015 Zh-En, another document-level machine translation task, to examine the multilingual transferability of *DOCmT5* when the target transfer language (Chinese in this case) is of a very different script. Chinese is only in the first-stage pretraining of mT5 but not in our second-stage pretraining. We use parallel training data from IWSLT15 without using additional monolingual data. Following HAN (Werlen et al., 2018), we use 2010-2013 TED as the test set. The results are in

---

[3] We choose French to study the transfer ability of the cross-lingual models on high-resource and same-script (latin) languages. Indonesian is for studying high-resource and different-script language. Hindi is for studying low-resource and different-script language.

[4] For all the document translation experiments in this paper, the numbers are calculated using sacreBLEU `https://github.com/mjpost/sacrebleu` in document level.

Table 6. *DOCmT5-5* outperforms the strong cross-lingual and mono-lingual baselines, demonstrating impressive transfer capability . *DOCmT5-25* includes Chinese as one of the second-stage pretraining languages therefore obtains better numbers than *DOCmT5-5*. Unsurprisingly, large models are better than their corresponding base models. To the best of our knowledge, *DOCmT5-25-Large* achieves the SOTA on this task. We qualitatively analyze the translations of different systems in Appendix A.

Pretrained Model	**De-En**	**Ru-En**	**Pl-En**	**Ja-En**
mT5				
w. DocNMT	44.09	40.48	3.13	0.92
w. DocTLM	0.31	0.11	0.23	0.22
DOCmT5-5	21.74	15.84	2.81	0.47
DOCmT5-5-Large	35.63	29.50	14.15	1.16
DOCmT5-25	22.00	14.62	17.40	16.93
DOCmT5-25-Large	28.24	24.34	23.18	19.17

Table 7: Document translation without finetuning on WMT20 De-En, Ru-En, Pl-En and Ja-En.

4.3.3 Document Translation Without Finetuning

We further show that *DOCmT5* is able to perform document translation without finetuning, i.e., evaluate the model right after second-stage pretraining without any finetuning on task-specific data. We show the results in Table 7. While the mono-lingual pretrained models completely fail to produce meaningful translations, *DOCmT5-5* is able to achieve over 20 BLEU points in De-En and 15 in Ru-En. Not surprisingly, *DOCmT5-5-Large* further improves to over 35 and 29 respectively. *DOCmT5-25* includes Pl-En and Ja-En in the second-stage pretraining and therefore obtains competitive results on these two language pairs with either base or large model. Although *DOCmT5-5* is not pretrained on Pl-En, the large model gets over 14 BLEU on this task. One hypothesis is that Polish uses the Latin script and shares common subwords with German and Spanish, allowing our model to transfer knowledge across languages. On the other hand, the *DOCmT5-5-Base* model fails to produce meaningful translations for Pl-En. This shows the importance of size when performing multilingual pretraining. The best model is *DocNMT* which obtains over 40 BLUE points in both De-En and Ru-En, outperforming *DOCmT5-5* and *DOCmT5-25*. This is reasonable because *DOCmT5* shuffles documents in pretraining and this is misaligned with the document translation task inputs. The impressive performance of both *DocNMT* and *DOCmT5* shows that our MTmC4 corpus is of very high-quality and is likely better than the parallel data provided by the specific tasks in question. Further analysis of the quality of this data will be an interesting avenue for future work.

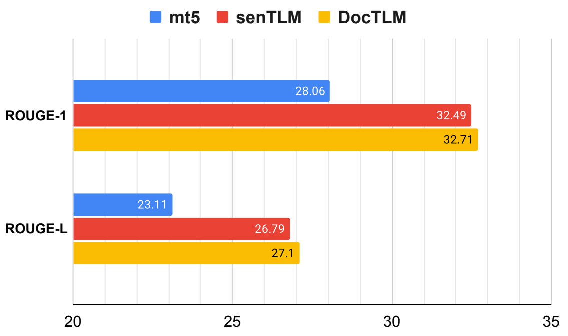

Figure 2: SenTLM and DocTLM finetuning results on Wikilingua. The numbers are average of four languages: {Es, Tr, Ru, Vi}.

5 Analysis

5.1 Are Document-level Models Better Than Sentence-level Models?

To demonstrate the benefits of pretraining with longer context, we pretrain mT5 using translation language modeling (TLM) on five languages: {De, Es, Tr, Vi, Ru} with two different inputs. In *DocTLM*, we concatenate the parallel documents into a single training sequence. As for *SenTLM*, we break down the document into individual sentences and find the alignments in the parallel document pair. Then we concatenate the single aligned sentence pair as a training sequence. We finetune these second-stage pretrained models on Wikilingua and WMT20 De-En. The results are shown in Figure 2 and Table 8. We see that document-level models offer small improvements on summarization and very significant improvements on document-level translation, showing that the longer context is indeed useful.

Pretrained-Model	**BLEU**
mT5	29.08
w. SenTLM	34.68
w. **DocTLM**	**37.74**

Table 8: SenTLM and DocTLM finetuning results on WMT20 De-En.

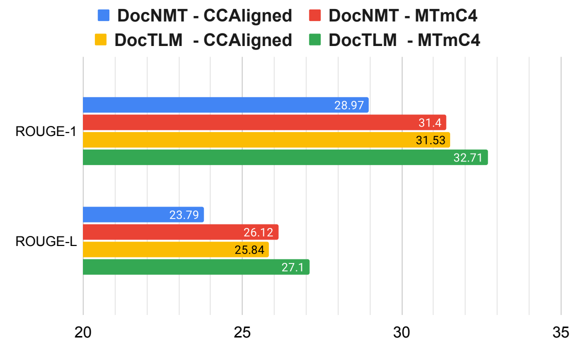

Figure 3: MTmC4 and CCAlgined finetuning results on Wikilingua. The numbers are average of four languages: {Es, Tr, Ru, Vi}.

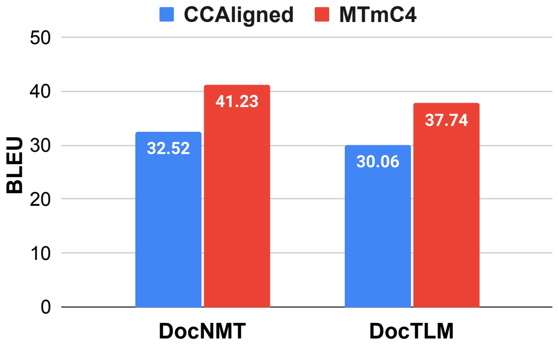

Figure 4: MTmC4 and CCAlgined finetuning results on WMT20 De-En.

5.2 Effect of Data Quality in Second-stage Pretraining

In our experiments, we observe big differences between different parallel corpora. We compare against the CCAligned corpus – a large automatically mined corpus from Common Crawl which is found to be very noisy (Kreutzer et al., 2021). In contrast, MTmC4 is produced by using high-quality translation systems. We pretrain mT5-Base on five languages: {De, Es, Tr, Vi, Ru} with these two corpora using *DocNMT* and *DocTLM*. We demonstrate the Wikilingua results in Figure 3 and WMT20 De-En results in Figure 4. Using our curated MTmC4 is consistently better regardless of pretraining objectives or tasks.

5.3 Does Combining Mono-Lingual and Cross-Lingual Pretraining Help?

Here we try to see if combining both monolingual and cross-lingual objectives helps. We try two different continual pretraining strategies for combining Dr and DrMT. We use five languages: {De, Ru, Tr, Vi, Es}. **(i)** Dr → DrMT: We first pretrain mT5 with Dr on mC4 for 0.5M steps and then pretrain with DrMT on MTmC4 for 0.5M steps. **(ii)** Dr + DrMT: We mix these two objectives with a 50-to-50% ratio and pretrain for 0.5M steps. In Table 9, we show that **(i)** slightly improves over only DrMT in both tasks and **(ii)** slightly improves on WMT20 De-En but seems to hurt performance on ISWLT15 Zh-En.

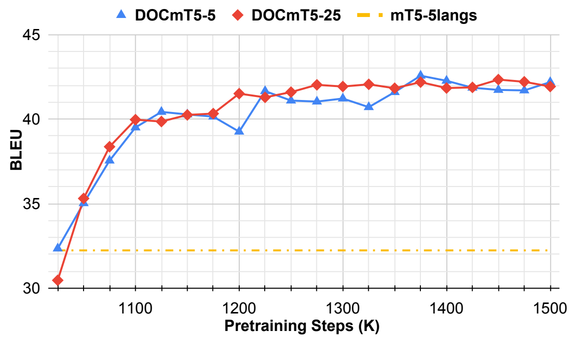

Figure 5: finetuning results of WMT20 De-En along with pretraining steps. We use DOCmT5-5-base.

Pretrained-Model	WMT20 De-En	IWSLT15 Zh-En
mT5		
w. Dr	36.63	23.75
w. DrMT	42.05	28.00
***w.* Dr → DrMT**	**42.75**	**28.18**
w. Dr + DrMT	42.37	27.35

Table 9: Methods of combining mono-lingual and cross-lingual and their finetuning results on WMT20 De-En and IWSLT15 Zh-En.

5.4 How Many Pretraining Steps is Required for DrMT?

To answer this question, we take different pretraining checkpoints of *DOCmT5-5* and *DOCmT5-25* and finetune with WMT20 De-En. The results are shown in Figure 5. After 50k steps of pretraining with *DrMT*, both systems outperform the *cont-5langs*. After 300k steps, both systems roughly converge and perform similarly.

6 Conclusion

In this paper, we present DOCmT5, a novel document-level multilingual pre-trained model. Our proposed objective, DrMT, is simple and effective and leads to large gains over strong baselines (e.g. mBART and MARGE) on cross-lingual summarization and document-level translation. DOCmT5 achieved SOTA on two competitive document-level translation tasks: WMT20 De-En and IWSLT15 Zh-En. We further analyze various factors that contribute to successful document-level pre-training. We plan to release the pre-trained model to facilitate future work on document-level language understanding.

Appendices

A Analysis of Document Translation

We take a deeper look at the translations produced by various systems to understand what makes *DOCmT5* better. We demonstrate an example in Table 6. We take the best system (*DOCmT5-25-Large*) and the *cont-5langs* baseline. We observe that *DOCmT5* uses time tenses better than the baseline, producing more coherent sentences (red-colored texts). Additionally, *DOCmT5* handles a compositional sentence more elegantly, instead of just using "and" (blue-colored texts). Finally, we observe that *cont-5langs* often makes minor translation mistakes while our *DOCmT5* makes much fewer of them.

Literature-Augmented Clinical Outcome Prediction

Abstract

We present BEEP (Biomedical Evidence-Enhanced Predictions), a novel approach for clinical outcome prediction that retrieves patient-specific medical literature and incorporates it into predictive models.[1] Based on each individual patient's clinical notes, we train language models (LMs) to find relevant papers and fuse them with information from notes to predict outcomes such as in-hospital mortality. We develop methods to retrieve literature based on noisy, information-dense patient notes, and to augment existing outcome prediction models with retrieved papers in a manner that maximizes predictive accuracy. Our approach boosts predictive performance on three important clinical tasks in comparison to strong recent LM baselines, increasing F1 by up to 5 points and precision@Top-K by a large margin of over 25%.

1 Introduction

Predicting the medical outcomes of hospitalized patients holds the promise of enhancing clinical decision making. With the advent of electronic health records (EHRs), more clinical data has become available to train AI models for outcome prediction (Rajkomar et al., 2018; Hashir and Sawhney, 2020). In particular, language models pretrained on biomedical and/or clinical text are demonstrating increasing proficiency when fine-tuned for the task of predicting outcomes such as in-hospital mortality or length of stay (van Aken et al., 2021).

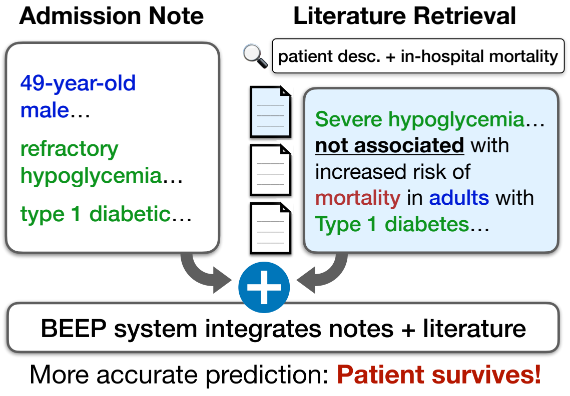

Figure 1: Overview of BEEP. We retrieve literature relevant to the patient description and an outcome of interest, in-hospital mortality in this example. We combine both sources of information to train a model to predict the outcome with better accuracy.

In this work, we explore a novel approach for improving clinical outcome prediction by dynamically retrieving relevant medical literature for each patient, and incorporating this literature into language models (LMs) trained for outcome prediction from clinical notes. This is in contrast to existing outcome prediction work that uses *only* clinical notes (Boag et al., 2018; Hashir and Sawhney, 2020). Recent LM-based approaches van Aken et al. (2021) have designed pretraining schemes over corpora of clinical notes and *general* biomedical literature. This is in contrast to our work, where we directly incorporate a literature retrieval mechanism into our outcome prediction model, by finding papers relevant to *specific* patient cases. Our approach, named BEEP (Biomedical Evidence-Enhanced Predictions), is broadly inspired by Evidence Based Medicine (EBM)—a leading paradigm in modern medical practice which calls for finding the "current best evidence" to support optimal clinical decisions for each *individual* patient (Sackett et al., 1996).

Our setting presents unique challenges. First, our approach requires retrieving literature based on noisy EHR notes containing multitudes of information (e.g., medical history, ongoing treatments), unlike orthogonal efforts on extracting and summarizing scholarly information related to well-formed questions (e.g., the efficacy of ACE inhibitors in adult patients with type-2 diabetes) (Wallace, 2019; Lehman et al., 2019; DeYoung et al., 2020, 2021).

---

Findings of the Association for Computational Linguistics: NAACL 2022, pages 438 - 453
July 10-15, 2022 ©2022 Association for Computational Linguistics

In addition, as our end task is predicting patient outcomes, another challenge lies in aggregating the retrieved literature in a way that maximizes prediction accuracy. Toward these challenges, we make the following key contributions:

- **Literature-Augmented Model.** As illustrated in Figure 1, for each ICU patient and each target outcome to be predicted (e.g., mortality), our model retrieves papers from PubMed, encoded and fused together with the ICU admission note for making a final prediction. We present several architectures for retrieving papers and for aggregating and combining them with clinical notes. We make our code, cohort selection, paper identifiers and models publicly available.
- **Adding Literature Boosts Results.** For evaluation, we measure both overall performance and precision/recall@Top-K, to account for the real-world scenario where "alarms" are only raised for high-confidence predictions to avoid alarm fatigue (Sendelbach and Funk, 2013). BEEP provides substantial improvements over baselines, with strong gains in overall classification performance and precision@Top-K. For example, we improve F1 by up to 5 points and precision@Top-K by a large margin of over 25%.
- **Exploring Patient-Specific Retrieval.** We explore a range of sparse and dense retrieval approaches, including language models, for the complex and underexplored task of retrieving relevant literature based on a patient's noisy, information-dense clinical note. Our final retrieval module employs a retrieve-rerank approach that effectively retrieves helpful literature, as shown in our analysis (section 5).

We hope our work opens new research directions for automatically scanning literature for patient-specific evidence, and combining it with EHR information to boost accuracy of medical predictive models. Finally, our work raises the more general prospect of building predictive models that can dynamically *learn to retrieve literature* for optimizing task accuracy, in medicine and other related areas.

2 Related Work

Patient-Specific Literature Retrieval. Since 2014, the Text REtrieval Conference (TREC) has organized a series of challenges to advance research in this area. The TREC Clinical Decision Support (CDS) tracks focused on evaluating systems on the task of retrieving biomedical articles relevant for answering generic clinical questions about patient medical records (e.g., identifying potential diagnoses, treatments, and tests) (Simpson et al., 2014; Roberts et al., 2015, 2016). TREC CDS 2014 and 2015 used short case reports as idealized representations of medical records due to the lack of available de-identified records. TREC 2016 shifted to using real-world medical records from the Medical Information Mart for Intensive Care (MIMIC) database (Johnson et al., 2016).[2] In our work, our focus is on *predicting clinical outcomes* using ICU admission notes and patient-specific retrieved literature.

Ueda et al. (2021) use contextualized representations on more structured retrieval tasks not involving clinical notes (Voorhees et al., 2021), leaving open the question of how large pretrained language models (LMs) would fare on long, noisy EHR text. We explore this by experimenting with LMs for retrieval based on EHR text.

Clinical Outcome Prediction. The idea of using automated outcome prediction for assisting clinical triage, workflow optimization, and hospital resource management has received much interest recently, especially given the conditions of the COVID-19 pandemic (Li et al., 2020). Predictive models based on structured (e.g., lab results) and unstructured (e.g., nursing notes) information have been built for key clinical outcomes including mortality (Jain et al., 2019; Feng et al., 2020), length of hospital stay (van Aken et al., 2021), readmission (Jain et al., 2019), sepsis (Feng et al., 2020), prolonged mechanical ventilation (Huang et al., 2020), and diagnostic coding (Jain et al., 2019; van Aken et al., 2021). Increasingly, models have leveraged unstructured text from notes since they can contain key information for outcome prediction (Boag et al., 2018; Jin et al., 2018). Most recently, van Aken et al. (2021) attempted this using large pretrained LMs. Our work compares the performance of a broader range of state-of-the-art pretrained language models on outcome prediction tasks.

3 BEEP: Literature-Enhanced Clinical Predictive System

Task & Approach Overview. Our goal is to improve models for clinical outcome prediction

---

[2] Since 2017, the focus has switched to TREC-PM (precision medicine) tracks where articles are retrieved based on short structured queries with attributes such as patient condition and demographics, a less realistic scenario.

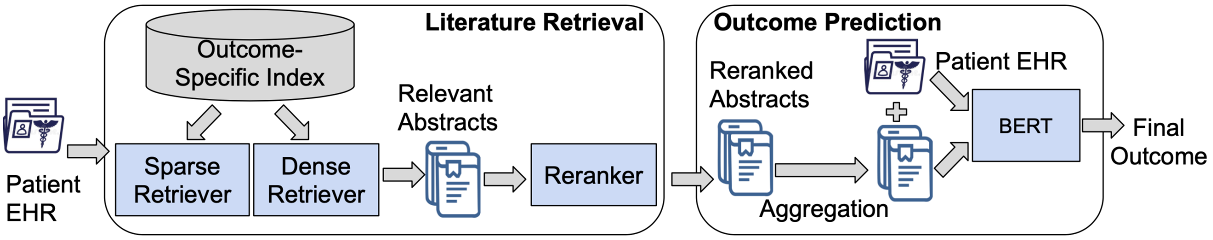

Figure 2: Complete system pipeline, unpacking the high-level overview seen in Figure 1. For a given patient ICU admission note, the literature retrieval module first retrieves relevant biomedical abstracts from a clinical outcome-specific index, then reranks a top-ranked subset of abstracts. The outcome prediction module aggregates information from these reranked abstracts and fuses it with the admission note to make the final prediction

from EHR notes by augmenting them with relevant biomedical literature. BEEP consists of two main stages: (i) literature retrieval, and (ii) outcome prediction. We also briefly experiment with a formulation that trains both jointly (details in section 4). Given a patient EHR note Q and a clinical outcome of interest y, the first stage is to identify a set of biomedical abstracts $Docs(Q) = \{D_1, ..., D_n\}$ from PubMed[3] that may be helpful in assessing the likelihood of the patient having that outcome. The next stage is to augment the input to an EHR-based outcome prediction model with these retrieved abstracts ($Q \cup Docs(Q)$) and predict the final outcome. Figure 1 provides a high-level illustration of BEEP, and Figure 2 unpacks it with more detail. Next, we describe our system's main components.

3.1 Literature Retrieval Module

Our literature retrieval module consists of three components: (i) an index of biomedical abstracts pertaining to the outcome of interest, (ii) a *retriever* that retrieves a ranked list of abstracts relevant to the patient note from the index, and (iii) a *reranker* that reranks retrieved abstracts using a stronger document similarity computation model. For the retriever, we experiment with both sparse and dense models. We follow the standard retrieve-rerank approach, which has been shown to achieve good balance between efficiency and retrieval performance (Dang et al., 2013), and has recently also proved useful for large-scale biomedical literature search (Wang et al., 2021). In the retrieval step, we prioritize efficiency, using models that scale well to large document collections but are not as accurate, to return a set of top documents. In the reranker step, we prioritize retrieval performance by running a computationally expensive but more accurate model on the smaller set of retrieved documents.

3.1.1 Outcome-Specific Index Construction

Since we are interested in identifying information related to a *specific outcome* for a patient, we begin by constructing an index of all abstracts from PubMed relevant to that outcome to limit search scope. To gather all abstracts relevant to a clinical outcome, we first identify MeSH (Medical Subject Heading) terms associated with the outcome by performing MeSH linking on the outcome descriptions using scispaCy (Neumann et al., 2019). These associated MeSH terms are then used as queries to retrieve abstracts.[4] For some MeSH terms that are too broad (e.g., "mortality"), we include additional qualifiers (e.g., "human") to make sure we do not gather articles that are not relevant to our overall patient cohort. Appendix A lists the final set of queries used for all clinical outcomes considered in this work. Abstracts retrieved via this process are used to construct the outcome-specific index.

3.1.2 Sparse Retrieval Model

The sparse retrieval model returns top-ranked abstracts based on cosine similarity between TF-IDF vectors of MeSH terms for the query (clinical note) and the documents (outcome-specific abstracts). MeSH terms from abstracts are extracted by running scispaCy MeSH linking over the abstract text. PubMed MeSH tagging is done only at the abstract level, and does not reflect actual term frequency in the text, requiring our extraction step. However, extracting MeSH terms from clinical notes requires a more elaborate pipeline, due to two major issues:

- **Entity type and boundary issues:** Off-the-shelf entity extractors like scispaCy and cTAKES (Savova et al., 2010) extract some entity types that are uninformative for relevant literature retrieval, e.g., hospital names, references

---

[3] https://pubmed.ncbi.nlm.nih.gov

[4] https://www.ncbi.nlm.nih.gov/books/NBK25499/

to family members, etc. They also have a tendency to ignore important qualifiers. For example, given a sentence containing the entity "right lower extremity pain", both extractors returned "extremity" and "pain" as separate entities.

- **Negated entities:** Clinical notes have a high density of negated entities (up to 50% of (Chapman et al., 2001)). These entities must be identified and discarded prior to literature retrieval to avoid retrieving articles about symptoms and conditions that are *not* exhibited by the patient.

To handle these issues, we train an entity extraction model that focuses on problems, tests, and treatments with empirically good coverage of important qualifiers (Uzuner et al., 2011). We then filter negated entities with negation detection (Harkema et al., 2009) and perform entity linking to MeSH terms. For more information and implementation details see Appendix B.

3.1.3 Dense Retrieval Model

We add a dense retrieval model to complement the sparse retriever, an approach that has shown promise in recent work (Gao et al., 2021). Our dense retrieval model maps clinical notes (queries) and biomedical abstracts (documents) to a shared dense low-dimensional embedding space. Computing similarity between these encoded vectors allows for softer matching beyond surface form. For dense retrieval, we use a BERT-based bi-encoder model. We use a bi-encoder to support scaling to large document collections, as opposed to cross-encoder models which are much slower (e.g., (Gu et al., 2021)). We use PubmedBERT (Gu et al., 2021) as the encoder and train our bi-encoder using the dataset from the TREC 2016 clinical decision support task (Roberts et al., 2016). For more details, see Appendix B. Our bi-encoder achieves mean precision@10 score of 45.67 on TREC 2016 data in 5-fold cross-validation, comparable to state-of-the-art results (Das et al., 2020).

3.1.4 Reranker Model

The reranker model takes a subset of top-ranked documents from both the sparse and dense retrieval models and rescores them. We use a BERT-based cross-encoder model for reranking, prioritizing ranking performance over efficiency on this smaller subset. Given a query clinical note Q and an abstract document D_i, we run a PubmedBERT-based encoder over the concatenation of both (`[CLS]` Q `[SEP]` D_i `[SEP]`) to compute an embedding E_{QD_i}. This embedding is run through a linear layer to produce a relevance score, trained using cross-entropy loss with respect to document relevance labels from the TREC 2016 dataset. Our cross-encoder achieves a mean precision@10 score of 48.33 on TREC 2016 in 5-fold cross-validation, which is also comparable to state-of-the-art performance on TREC CDS 2016 (Das et al., 2020).

From the top-ranked documents returned by the reranker, the top k are selected[5] to be passed alongside the patient clinical note to the outcome prediction module, which we describe next.

3.2 Outcome Prediction Module

The goal of this module is to compute an aggregate representation from the set of top k abstracts relevant to the clinical note, and then predict the outcome of interest using this aggregate representation and the note representation.

3.2.1 Aggregation Strategies

Let $Docs(Q) = D_1, ..., D_k$ be the set of relevant abstracts retrieved for clinical note Q and $\text{BERT}(X)$ be the encoder function that returns an embedding E_X given a document X. We experiment with four different strategies to compute an aggregate literature representation for $Docs(Q)$, which we denote by $LR(Q)$.

Averaging. Averaging encoder representations:

$$LR(Q) = \frac{1}{k}\sum_{i=1}^{k}\text{BERT}(D_i) \tag{1}$$

Weighted Averaging. Weighted average of encoder representations:

$$LR(Q) = \frac{1}{\sum_{i=1}^{k} w_i}\sum_{i=1}^{k} w_i \cdot \text{BERT}(D_i) \tag{2}$$

where weights w_i are the relevance scores computed by the reranker. The final outcome is computed by concatenating note representation $\text{BERT}(Q)$ with $LR(Q)$ and running this through a linear layer.

We also concatenate the note embedding with each abstract ($E_{QD_i} = [\text{BERT}(Q); \text{BERT}(D_i)]$), run outcome prediction and aggregate output probabilities as follows.

Soft Voting. Averaging per-class probabilities from k outcome prediction runs:

$$p(y=c) = \frac{1}{k}\sum_{i=1}^{k} p(y=c|E_{QD_i}) \tag{3}$$

---

[5] We treat k as a hyperparameter, see appendix C.

Outcome	0	1	2	3
PMV	3,776	3,335	-	-
MOR	43,609	5,136	-	-
LOS	5,596	16,134	13,391	8,488

(a) Class distribution for all outcomes. For PMV, classes 0 and 1 refer to cases that don't/do require prolonged ventilation. For MOR, classes 0 and 1 refer to patients that don't/do die in admission. For LOS, classes 0-3 refer to stay lengths of <3 days, 3-7 days, 1-2 weeks, and >2 weeks respectively.

Outcome	Train	Dev	Test	#Articles
PMV	5,691	712	708	81,311
MOR	33,997	4,918	9,830	90,125
LOS	30,421	4,391	8,797	93,594

(b) Training, development and test splits, and total number of PubMed articles in our outcome-specific index for each clinical outcome.

Table 1: Data statistics per outcome

Weighted Voting. Weighted average of per-class probabilities from k outcome predictions runs:

$$p(y=c) = \frac{1}{\sum_{i=1}^{k} w_i} \sum_{i=1}^{k} w_i \cdot p(y=c|E_{QD_i}) \tag{4}$$

4 Experiments & Results

We test our system on the task of predicting clinical outcomes from patient admission notes. Predicting outcomes from admission notes can help with early identification of at-risk patients and assist hospitals in resource planning by indicating how long patients may require hospital/ICU beds, ventilators etc. (van Aken et al., 2021).

4.1 Clinical Outcomes

We evaluate our system on three clinical outcomes:

- **PMV:** Prolonged mechanical ventilation prediction, identifying whether a patient will require ventilation for >7 days (Huang et al., 2020).
- **MOR:** In-hospital mortality prediction, identifying whether a patient will survive their current admission (van Aken et al., 2021).
- **LOS:** Length of stay prediction is the task of identifying how long a patient will need to stay in the hospital. We follow van Aken et al. (2021) and group patients into four major categories based on clinician recommendations: <3 days, 3-7 days, 1-2 weeks, and >2 weeks.

PMV and MOR are binary classification tasks, while LOS is a multi-class classification task. We predict these outcomes from patient admission notes extracted from the MIMIC III v1.4 database (Johnson et al., 2016), which contains de-identified EHR data including clinical notes in English from the Intensive Care Unit (ICU) of the Beth Israel Deaconess Medical Center in Massachusetts between 2001 and 2012. Admission notes are constructed by filtering discharge summary documents from MIMIC to only retain the following sections typically known at admission: Chief complaint, (History of) Present illness, Medical history, Admission medications, Allergies, Physical exam, Family history and Social history. Notes that do not contain any of these sections are excluded. For PMV, we follow the cohort selection process from Huang et al. (2020), and include all patients who were above 18 years of age and were on mechanical ventilation for at least 2 days with more than 6 hours each day. Patients transferred from other hospitals, organ donors, and patients with neuromuscular disease, head and neck cancer, and extensive burns, which always lead to PMV and may act as confounds, were excluded. For MOR and LOS, we follow the same cohort selection process as van Aken et al. (2021), and include all patients except newborns and remove duplicate admissions. Following these cohort selection processes results in the data splits shown in Table 1b. Table 1b also shows the numbers of relevant PubMed articles for all three clinical outcomes.

4.2 Selecting the Encoder Language Model

Since the encoder used for outcome prediction needs to produce representations for both clinical notes and relevant abstracts, we choose language models that have been pretrained on *both* biomedical and clinical text. We evaluate the following models on outcome prediction (without literature augmentation) to choose a suitable encoder:

- **ClinicalBERT** (Alsentzer et al., 2019): ClinicalBERT further pretrains BioBERT (Lee et al., 2020), a biomedical language model, on EHR notes from MIMIC III. We evaluate both versions: one trained on discharge summary notes only, and one trained on both discharge summaries and nursing notes.
- **CORe** (van Aken et al., 2021): CORe further pretrains BioBERT with a next sentence prediction objective on sentences describing admissions and outcomes. CORe jointly trains on EHR notes and biomedical articles.

	PMV			MOR			LOS		
Model	**AUROC**	**Micro F1**	**Macro F1**	**AUROC**	**Micro F1**	**Macro F1**	**AUROC**	**Micro F1**	**Macro F1**

+WAvg	59.30	**56.50**	53.70	83.59	90.35	59.61	71.02	44.58	39.95

Table 2: Performance of baseline and literature-augmented outcome prediction models on all clinical outcomes. We note that LOS is a multiclass target; we observe substantial gains in 2/4 of the classes (Table 10 in the Appendix).

- **BLUEBERT** (Peng et al., 2019): BLUEBERT further pretrains BERT (Devlin et al., 2019) jointly on EHR notes and PubMed abstracts.
- **UMLSBERT** (Michalopoulos et al., 2021): UMLSBERT further pretrains ClinicalBERT on EHR notes from MIMIC, with tweaks to the architecture and pretraining objective to incorporate conceptual knowledge from the Unified Medical Language System (UMLS) Metathesaurus (Schuyler et al., 1993).

Note that in this experiment, we predict clinical outcomes from patient admission notes only, without incorporating literature. We also use weighted cross-entropy loss to manage class imbalance (see Appendix B). Table 5 in the Appendix shows the performance of the above language models on the validation sets for all clinical outcomes. We select the top-performing language models BLUEBERT and UMLSBERT for our remaining experiments.[6]

4.3 Literature Augmentation Results

We provide two sets of results: for overall performance, and for high-confidence predictions.

	No PMV		PMV

(b) For MOR

Table 3: Precision and recall scores for top 10% high-confidence predictions per class.

Overall Performance. Table 2 shows the overall performance of our literature-augmented outcome prediction system on all three clinical outcomes. We test our system using both UMLSBERT and BLUEBERT as encoders, as well as all four literature aggregation strategies. We report three metrics for each setting: (i) area under the receiver operating characteristic (AUROC), (ii) micro-averaged F1 score, and (iii) macro-averaged F1 score. From Table 2, we observe that incorporating literature leads to performance improvements on two of three clinical outcomes, PMV and mortality. On LOS prediction, results are more mixed, with minor improvements on micro F1 but no improvements on other metrics. Comparing BLUEBERT and UMLSBERT, variants that use UMLSBERT do slightly better on PMV and mortality, while results on LOS are more mixed. Comparing across literature aggregation strategies, there is no clear winner, though voting-based strategies seem to have a slight advantage, especially on UMLSBERT.

Evaluating High-Confidence Predictions. In addition to standard evaluation, we evaluate the

---

[6] We also experiment with CORe but observe consistently lower scores (Table 8 in Appendix F).

top 10% high-confidence predictions per class for all models (precision/recall@TOP-K), informative for two key reasons. First, when using automated outcome prediction systems in a clinical setting, it is reasonable to only consider raising alarms for high-confidence positive predictions to avoid alarm fatigue (Sendelbach and Funk, 2013). Second, high-confidence predictions for both positive and negative classes can be used to reliably assist with hospital resource management (e.g., predicting future ventilation and hospital bed needs).

Tables 3a and 10 show the precision/recall@TOP-K scores for all models on prolonged mechanical ventilation, mortality, and length of stay prediction. In Table 3a, we see that our literature-augmented models achieve much higher precision scores than the baseline (∼9-12 points higher in most cases) for the PMV negative class. We also see higher precision scores than the baseline for the positive class (∼5-9 points higher in most cases). This is a strong indicator that our literature-augmented pipeline might offer more utility for PMV detection in a clinical setting than using EHR notes only. Table 3b shows similarly encouraging trends for mortality prediction. The mortality prediction dataset is the most skewed of the three datasets, and therefore we do not see much performance difference across models on the negative class. However, on the positive class, our literature-augmented models show dramatic increase in precision. In particular, BLUEBERT-based literature models show an increase in precision of ∼22-27 points, at the expense of only ∼6-7 point drop in recall relatively to non-literature models.[7] This also indicates that literature-augmented mortality prediction might be more precise and reliable in a clinical setting than using clinical notes alone. From Table 10 (Appendix H), we can see that for LOS prediction, our models show clear gains (∼2-5 points) on classes 1 and 2 (i.e., 3-7 days and 1-2 weeks), and minor gains for some variants on class 3 (>2 weeks). We also perform an alternate evaluation in which we only score predictions from our literature-augmented models that show a relative confidence increase of at least 10% over the baseline prediction, presented in Appendix H.

Learning To Retrieve Using Outcomes. BEEP trains separate models for literature retrieval and outcome prediction. Inspired by Lee et al. (2019), we develop a learning-to-retrieve (L2R) formulation that trains both jointly to ensure that the retriever can learn from outcome feedback. However, our L2R model does not improve performance over BEEP (results in Table 7 in Appendix E). We provide discussion for potential reasons in Appendix E. This is an interesting direction for future work.

5 Analysis and Discussion

Given BEEP's improved performance, we further assess the utility of retrieved literature and cases where adding literature is particularly helpful.

Diversity of retrieved literature. As a preliminary analysis, we evaluate the diversity of the abstracts retrieved for admission notes in our datasets, as a proxy for the degree to which literature is personalized to specific patient cases. For the 100 most frequently retrieved abstracts for each clinical outcome, Figures 4a, 4b, and 4c in Appendix H show proportions of patient notes for which these abstracts are judged as relevant by our retrieve-rerank pipeline. From these histograms, we see a stark difference for LOS which is much less diverse than both PMV and MOR, indicating that the literature retrieved for length of stay prediction may be less personalized to patient cases than the literature retrieved for other outcomes. We leave to future work exploration of diversifying retrieved papers across patients and examining the effect on outcome prediction performance.[8]

Qualitative examination of retrieved literature. We qualitatively examine literature retrieved for cases in which our model shows large confidence increases over the baseline to determine its utility in making the right prediction. We study increases in both directions, i.e. cases in which adding literature resulted in a confidence increase in either the *correct* outcome label (good) or *incorrect* outcome label (bad). For each clinical outcome, a bio-NLP expert looked at the top 5 cases from each category based on the magnitude of confidence increase (total 10 cases per outcome). For each case, the expert looks at the top 5 abstracts retrieved for the case (total 50 abstracts per outcome) and assigns each abstract to one of 8 categories we define for categorizing degree of relevance and type of evidence provided, including retrievals considered *helpful*

---

[7] Note that since the MOR class is rare, a larger recall drop could still translate to a small number of incorrect cases only

[8] We perform an ablation in which we use only the retrieved literature for prediction, showing quantitative evidence for the utility of retrieved literature (see Appendix G).

Patient EHR	Retrieved Abstract	Evidence Type	Outcome
CHIEF COMPLAINT: liver tranplant **PRESENT ILLNESS:** ...s/p liver transplant...Dx: ESLD secondary to alcoholic **cirrhosis**. **MEDICAL HISTORY**: EtOH Cirrhosis	Retrospective review of data of 73 consecutive patients with **cirrhosis requiring MV**...majority of patients, 51/64 **(79.7%), dying in the first 48 hours of intubation**...	Patient condition and outcome directly related	No PMV
CHIEF COMPLAINT: Aortic dissection **PRESENT ILLNESS:** ...72-year-old woman...chest pain...had **type A aortic dissection**...an intramural hematoma...proceed with **surgery**... **MEDICAL HISTORY:** HTN Renal failure	Acute **type A aortic dissection** presents a formidable challenge...the most important variables associated with **in-hospital mortality** in patients undergoing **surgery** for this condition...suggests that **CPB time, diabetes mellitus and postoperative bleeding** are the main determinants of in-hospital death.	Known outcome indicators **not** present in patient	No MOR
CHIEF COMPLAINT: Dyspnea, fever **PRESENT ILLNESS:** 58F w/ HCV **cirrhosis**...requiring BiPAP, ultimately urgent **intubation**... extubated ... short of breath... **MEDICAL HISTORY:** HCV cirrhosis	...study identifies specific predictors of increased mortality and resource utilization in **cirrhotic** patients...**Increased LOS** in the MICU was **associated with mechanical ventilation**...	Ongoing treatment and outcome related	LOS >2 weeks

Table 4: Qualitative examples of retrieved literature that is helpful for increasing prediction confidence of the correct outcome. Case 1 shows an example of retrieved literature that strongly matches patient condition and provides direct evidence linking it to the outcome of interest. Case 2 shows an example with indirect evidence, in which retrieved literature lists outcome indicators not present in the patient. Case 3 shows an example of retrieved literature describing a link between patient's ongoing treatment and outcome of interest. **green**: patient characteristics; **blue**: outcome of interest; **red**: known indicators of the outcome measure not present in the patient.

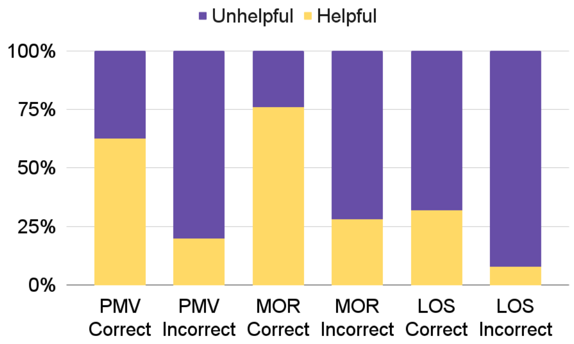

Figure 3: Literature categorization for both correct and incorrect outcome cases. For PMV and MOR, retrieved literature for correct cases is more often categorized as helpful, and unhelpful literature dominates for incorrect cases. For LOS, literature for both categories is more often categorized as unhelpful.

and *unhelpful*. For example, see Table 4 (evidence type column; more in Appendix).

As seen in Table 4, for *helpful* categories, retrieved literature matches patient characteristics (especially current condition) and includes evidential links between outcome of interest and patient conditions/treatment. In the first case, the retrieved abstract provides evidence that patients with cirrhosis have high mortality in the first 48 hours of intubation, entails the patient might not undergo prolonged ventilation. In the second case, the abstract lists comorbidities associated with in-hospital mortality (outcome of interest), but none are present in the patient under consideration, which can be taken as weak indication that the patient may survive. Similarly, for the third case, the retrieved abstract mentions that cirrhotic patients may have longer hospital stays if they are on mechanical ventilation. This matches our patient's treatment history since she has cirrhosis and was briefly intubated and extubated, before experiencing shortness of breath again. Given this, the patient might have a longer length of stay. Conversely, *unhelpful* retrieved literature often does not match patient characteristics or may not contain evidence relevant to the outcome. See more example explanations in Appendix I.

Figure 3 presents the distribution of helpful and unhelpful categories for both kinds of cases for all outcomes. We can see that for correct outcome cases from both PMV and mortality, retrieved literature is more frequently assigned to one of the helpful categories, while for incorrect outcome cases, retrieved literature is more frequently assigned to one of the unhelpful categories. For LOS, unhelpful categories dominate both types of cases, especially prevalent in incorrect outcomes.

6 Conclusion

In this paper, we introduced BEEP, a system that automatically retrieves *patient-specific literature* based on intensive care (ICU) EHR notes and uses the literature to enhance clinical outcome prediction. On three challenging tasks, we obtain substantial improvements over strong recent baselines, seeing dramatic gains in top-10% precision for mortality prediction with a boost of over 25%.

Our hope is that this work will open new research directions into bridging the gap between AI-based clinical models and the Evidence Based Medicine (EBM) paradigm in which medical decisions are based on explicit evidence from the literature. An interesting direction is to incorporate evidence identification and inference (Wallace, 2019; DeYoung et al., 2020) directly into our retrieval and predictive models. Another important question to explore relates to the implications our approach has on increasing the interpretability of clinical AI models.

Ethical Concerns

Incorporating outcome prediction models into a medical decision-making pipeline effectively will require these technologies to adhere to standards set by the core principles of medical ethics: beneficence, non-maleficence, autonomy, and justice (Beauchamp et al., 2001). These requirements may raise the following concerns when deploying outcome prediction models in clinical settings:

- **Out-of-Cohort Generalization:** The extent to which outcome prediction models generalize to patient cohorts that may not have been present in their training data is unclear. If model accuracy is significantly lower on "out-of-cohort" patients, using inaccurate/uncertain predictions during decision making may violate the requirement that any application of technology must be *beneficent* and *non-maleficent* to individual patients. Our proposed technique can partly mitigate the generalization issue by identifying additional supporting evidence from literature, which may be better tailored to individual patient characteristics, instead of using only cohort-level evidence. However, biomedical literature can also have blind spots, with certain cohorts and disease combinations being under-studied, and even literature-augmented prediction may not be sufficiently accurate.
- **Algorithmic Biases:** Since outcome prediction models are trained on historical health data, existing inequities in healthcare access may translate into models continuing to perpetuate unintentional discrimination against patients from under-served demographics. For example, models might predict poorer outcomes (e.g., high mortality, poor response to treatment, etc.) for specific demographics that have historically had worse outcomes due to poor access to care. Such issues are a clear violation of the *justice* requirement, and must be tackled before deployment.
- **Informed Consent:** Lastly, if outcome prediction models are used in clinical settings, patients and their caregivers must be made aware of their use, since the principle of *autonomy* emphasizes that patients must be provided all relevant medical information to support autonomous decision making. The black-box nature of these models raises another issue: how can we help patients/caregivers understand and interpret outcome predictions to further support their autonomy in decision making? We hope that literature-augmented prediction techniques can partly ease this by using evidence snippets from literature that contributed to the model's prediction as explanations.

A PubMed Queries Per Outcome

Following are the MeSH terms that we use to retrieve literature from PubMed to construct the outcome-specific index for each clinical outcome under consideration:

- **Prolonged Mechanical Ventilation (PMV):** "Respiration, Artificial". We also query using the terms "Ventilation, Mechanical" and "Ventilator Weaning" but do not find any new results.
- **In-Hospital Mortality (MOR):** "Hospital Mortality", "Mortality+Humans+Risk Factors". Note that the "+" operator is interpreted as AND by PubMed search.
- **Length of Stay (LOS):** "Length of Stay". All other MeSH terms from the tagger are aliases of this term.

B Implementation Details

Entity Extraction. First, we extract entities from clinical notes using a model trained on the i2b2 2010 concept extraction dataset (Uzuner et al., 2011). This dataset consists of clinical notes annotated with three types of entities: problems, tests, and treatments. These entity types cover the pertinent medical information that can be used to retrieve abstracts relevant to a clinical note. Moreover, the i2b2 guidelines require annotators to include all qualifiers within an entity span, so training a model on these annotations should bias it towards including pertinent entity qualifiers. Our entity extraction model uses a BERT-based language model to compute token representations, followed by a linear layer to predict entity labels.

We use ClinicalBERT (Alsentzer et al., 2019) as the the language model to train our i2b2 entity extractor. Table 6 shows the performance of our model on the i2b2 2010 test set. These numbers are close to the exact F1 scores reported by Alsentzer et al. (2019) on i2b2 2010 (87.8).

Entity Filtering. After extracting entities, we filter out all negated entities. Negated entities are detected using the ConText algorithm for negation detection from clinical text (Harkema et al., 2009). We use the implementation of ConText negated entity detection algorithm provided by medspaCy (Eyre et al., 2021).

MeSH Linking. Finally, the set of filtered entities is linked to MeSH terms using scispaCy. Entities not linked to MeSH terms are discarded. MeSH terms linked in clinical notes and abstracts are used to compute TF-IDF vectors for the sparse retrieval model.

Bi-Encoder Given a query clinical note Q and an abstract document D_i, a BERT-based encoder is used to compute dense embedding representations E_Q and E_{D_i}. A scoring function S is defined as the Euclidean distance between query and document embeddings:

$$S(Q, D_i) = \|E_Q - E_{D_i}\|_2 \tag{5}$$

Documents closest to the query vector in the embedding space are returned as top-ranked results. The bi-encoder is trained using a triplet loss function defined as follows:

$$\begin{aligned} L(Q, D_i^+, D_i^-) &= \\ &\max(S(Q, D_i^+) - S(Q, D_i^-) + m, 0) \end{aligned} \tag{6}$$

Here D_i^+ is an abstract more relevant to the clinical note Q than D_i^- and m is a margin value. We use PubmedBERT (Gu et al., 2021) as the encoder and train our bi-encoder using the dataset from the TREC 2016 clinical decision support task (Roberts et al., 2016).[9] This dataset consists of 30 de-identified EHR notes, along with ∼1000 PubMed abstracts per note marked for relevance. We select relevant abstracts per note as positive candidates (D_i^+), and irrelevant abstracts for the same note as negative candidates (D_i^-).

Outcome prediction module training. We use a weighted cross-entropy loss function to handle class imbalance. Given a dataset with N total examples, c classes and n_i examples in class i, class weights are computed as follows:

$$w_i = \frac{N}{c \cdot n_i} \tag{7}$$

We use Adam optimizer, treating initial learning rate as a hyperparameter. All models are implemented in PyTorch, and we use Huggingface implementations for all pretrained language models.

C Hyperparameter Tuning

We do a grid search over the following hyperparameter values for each aggregation:

Learning Rate (LR): [5e-4, 1e-5, 5e-5, 1e-6,5e-6]

Number of top abstracts (k): [1, 5, 10]

---

[9] We do not use data from TREC 2014 and 2015 since they use idealized case reports instead of actual EHR notes. Combining all three datasets degraded performance, likely due to differences in language between case reports and EHRs.

Gradient accumulation steps (GA): [10, 20] This hyperparameter grid stays consistent across all outcome prediction experiments. For all experiments, we currently report the outcome of a single run.

D Computing Infrastructure

Our experiments were carried out on 2 AWS p3.16xlarge instances, which are 8-GPU machines with 16 GB RAM per GPU. All our experiments can be run on a single 16 GB GPU.

E Results from Learning To Retrieve Model

Given a note Q, we first obtain a set of top 100 relevant abstracts ($Docs(Q) = \{D_1, ..., D_{100}\}$) from the BEEP retrieve-rerank pipeline. The retriever component is then defined as follows:

$$E_Q = BERT_Q(Q) \tag{8}$$

$$E_{D_i} = BERT_D(D_i) \tag{9}$$

$$S_{retr}(Q, D_i) = cosine(E_Q, E_{D_i}) \tag{10}$$

$BERT_Q(X)$ and $BERT_D(X)$ are the query and document encoder functions. Based on retriever scores S_{retr}, we select the top k abstracts and perform outcome prediction using the same structure as the BEEP outcome prediction module. We also add the following early update loss term to the outcome loss for the retriever component:

$$P_{early}(D_i|Q) = \frac{exp(S_{retr}(Q, D_i))}{\sum_{D_j \in Docs(Q)} exp(S_{retr}(Q, D_j))} \tag{11}$$

$$L_{early} = -\log \sum_{D_j \in Docs(Q)} y_j P_{early}(D_j|Q) \tag{12}$$

where y_j is set to 1 if using document D_j alongside Q results in a confidence increase in the correct outcome (as per BEEP) and 0 otherwise. Our L2R model does not improve performance over BEEP (results in Table 7). We speculate that this may partly be due to the fact that the heuristic we use to assign y_j values in early update loss is not as accurate as the one used by Lee et al. (2019) (directly checking for presence of the answer in a document, for the reading comprehension task).

Table 7 presents results for the learning-to-retrieve model on all clinical outcomes using UMLSBERT as the encoder. From the table, we can see that while L2R improves performance over a notes-only baseline, its performance is comparable to BEEP. As mentioned earlier, we speculate that this may partly be attributed to the fact that the heuristic we use to assign y_j values in early update loss is not as accurate as the one used by Lee et al. (2019) (directly checking for presence of answer in document, for the reading comprehension task). We believe that experimenting with other sources of supervision to generate y_j values and weighting mechanisms to better combine outcome and early update losses might lead to larger improvements, but we leave those to future work.

F Literature-Augmented Outcome Prediction with CORe

Table 8 shows the overall performance of our literature-augmented outcome prediction system

on all three clinical outcomes when the CORe language model is used as an encoder. From this table, we can see that adding literature improves performance in this setting as well (with the exception of macro F1 on length of stay). However the overall scores are lower than the settings in which UMLSBERT and BLUEBERT are used as encoders (Table 2).

G Literature-Only Outcome Prediction

To quantitatively test the quality of the retrieved literature, we run an ablation study in which we predict the clinical outcome using only the literature retrieved for a specific patient case, without incorporating any information from the patient clinical note. Table 9 shows the results for this ablation study, using both BLUEBERT and UMLSBERT encoders. From this table, we can see that while removing the clinical note leads to performance drops, especially on mortality and length of stay, the retrieved literature does have some predictive ability. We take this as indication that the retrieved literature contains some clinical indicators associated with the outcome, that are also present in the patient's clinical note.

H Analyzing High Confidence Increases Over Baseline

Finally, we also examine an alternate way of using high-confidence predictions made by our models. We run both baseline and literature-augmented systems, and only consider predictions from the literature-augmented system that show a high increase in confidence, such as $> 10\%$ increase relative to the baseline predictions for the same cases. Tables 11a and 11b show the precision scores of all models on prolonged mechanical ventilation and mortality in this setting. We can see that precision scores in this setting are fairly high, especially for the negative class in mortality prediction. Most averaging variants also do well on the positive class in mortality prediction.

I Examples of Literature For Incorrect Outcome Cases

We categorize examples into the following:

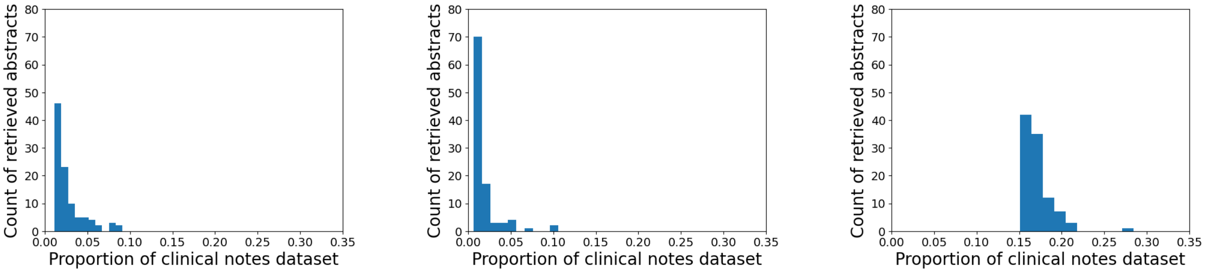
1. Patient condition and outcome directly related
2. Patient history and outcome related
3. Known outcome indicators not present in patient
4. Ongoing treatment and outcome related
5. No cohort match
6. No/weak condition match
7. Condition-outcome pair not studied
8. No evidence for outcome/Weak evidence for direct relationship between patient condition and outcome

From table 12, we can see that retrieved literature from *unhelpful* categories often does not match patient characteristics. The first case discusses a patient who has had an ICD firing incident, but the retrieved literature discusses ICD implantation therapy. While related, there is no discussion of the impact of ICD firing on various clinical outcomes.

For the second case, we see that the retrieved article discusses strokes in general, without matching any of the patient's indications or demographic characteristics. Moreover, the outcome of interest (mortality) is mentioned briefly, but links between the outcome and patient conditions are not studied. Finally, the third case provides an example of a common phenomenon we observe. There are a fair number of review articles retrieved that do not have strong evidential statements in the abstract. For the third case, the retrieved abstract discusses the need for early triage/transfer (which could lead to low length of stay), but then do not provide any conclusive evidence.

Patient EHR	Retrieved Abstract	Evidence Type	Outcome
CHIEF COMPLAINT: ICD firing **PRESENT ILLNESS:** 57 yo M presenting s/p ICD discharges...shocks preceded by prodrome of dizziness,...and was shocked once...Has not had ICD firing prior to these events since implant **MEDICAL HISTORY:** Heart failure...	...assess if selected clinical markers of organ dysfunction were associated with increased 1-year mortality despite ICD therapy...Clinical markers of liver dysfunction, recent mechanical ventilation, and renal impairment were independently associated with increased 1 year mortality...	Weak condition match, condition-outcome pair not studied	PMV
CHIEF COMPLAINT: acute onset right hemiplegia and aphasia **PRESENT ILLNESS:** 84yo M...acute onset of inability to speak and right hemiplegia...head CT showed dense L MCA and hypodensities in left inferior frontal lobe and left corona radiata. **MEDICAL HISTORY:** HTN Afib, off coumadin...	Stroke is indicated by an abrupt manifestation of neurologic deficits secondary to an ischemic or hemorrhagic insult to a region of the brain...ranked as the third leading cause of death in the United States...report shows that despite the use of antithrombotic and/or antiplatelet aggregating drugs, the key to stroke management is primary prevention.	No cohort match, condition-outcome pair not studied	MOR
CHIEF COMPLAINT: Substernal chest pain **PRESENT ILLNESS:** ...62 yo M... no prior cardiac history... substernal CP... mild SOB, nausea, diaphoresis and numbness in left arm... **MEDICAL HISTORY:** foot surgery 2 weeks ago ?COPD ?gastritis?	..rising health care costs have created pressures to increase efficiency of coronary care units. Possible strategies seek to decrease resource use by identifying low-risk patients for initial triage or early transfer to lower levels of care...	No cohort match, no evidence for outcome	LOS <3 days

Table 12: Qualitative examples of retrieved literature that is categorized as unhelpful for cases where adding literature increases confidence in incorrect outcome. Case 1 shows an example of retrieved literature that has a weak match with patient condition, but no evidence linking condition to outcome. Case 2 shows an example in which retrieved literature does not match patient case or contain evidence for outcome. Case 3 shows an example of a review article that again does not match patient case or provide outcome evidence.



(a) PMV (b) MOR (c) LOS

Figure 4: Proportion of admission notes associated with the 100 most highly retrieved abstracts for each clinical outcome. From these graphs, we can see that frequently-retrieved abstracts for LOS are associated with a larger proportion of cases from the dataset, than frequently retrieved abstracts for PMV and MOR (indicative of lower literature diversity in LOS).

Improving Few-Shot Relation Classification by Prototypical Representation Learning with Definition Text

Abstract

Few-shot relation classification is difficult because the few instances available may not represent well the relation patterns. Some existing approaches explored extra information such as relation definition, in addition to the instances, to learn a better relation representation. However, the encoding of the extra information has been performed independently from the labeled instances. In this paper, we propose to learn a prototype encoder from relation definition text in a way that is useful for relation instance classification. To this end, we use a joint training approach to train both a prototype encoder from definition and an instance encoder. Extensive experiments on several datasets demonstrate the effectiveness and usefulness of our prototype encoder from definition text, enabling us to outperform state-of-the-art approaches.

1 Introduction

Relation classification (RC) aims to determine the relation expressed between two entities in a sentence. Typical approaches to RC train a classification model or a prototype from labeled sentences, which are intended to represent the typical relation patterns including various syntactic, semantic and contextual features. In practical situations, we may have only a few labeled examples, which are insufficient for training a good classification model. In some cases, the labeled examples may also be atypical. For example, if a relation is exemplified by sentences describing Obama's presidency in the US, the resulting prototype would be largely tuned toward a political context, which would be difficult to apply outside the political context. Even for a human annotator, with only a relation ID and some examples, it would be difficult to learn to classify a relation correctly. This is exactly the same problem faced by a few-shot RC system: the best guess based on the limited labeled examples may fail.

If, however, the human annotator is told that the relation is named "position held", then he/she would have a better understanding of the relation to better generalize the examples to other instances. In this case, the human annotator indeed exploits the prior knowledge about the relation (from its name). If more information such as a description of the relation is available, then the annotator would do an even better job. The definition of a relation, being it the name or the description, is important to help the human annotator understand the relation. It is the same for an automatic RC model.

Several previous studies have explored using such extra knowledge about the relation (Qu et al., 2020; Dong et al., 2020; Zhang et al., 2021). For example, relation names have been used for better initializing the relation prototype before being trained with labeled instances (Dong et al., 2020). However, Dong et al. only considered a limited number of relations in the training data, making the few-shot RC model prone to over-fitting. Inspired by these studies and human behaviors, in this paper, we leverage relation definitions to build high-level prototype representations of the relations.

A second problem we consider in this paper is the ability to construct prototypes for new relations, i.e. zero-shot learning. In this case, if the new relation has a description, then one would be able to apply the same prototype encoder learned on the other relations to the new relation. In other words, the mechanism of building relation prototypes from their definitions could be generalized and transferred to a new relation. Some previous work (Qu et al., 2020) has considered prototype transfer based on a knowledge graph which provides relationships between relations. It is assumed that a relation's prototype can be partly transferred to a related relation in the graph. While this could be a possible way to generate a more reasonable prototype for a relation, we believe that relation definitions provide a better basis for constructing a

Table 1: Example of relation definitions (relation name and description) and weakly labeled data for relation P407 and P39 in Wikidata, both of which are used for prototypical representation learning.

relation prototype.

We propose to learn a general mapping function from relation definitions to their prototypes. The advantages of the approach come from the fact that the definition text expresses the intrinsic semantics of relation, which is not explicitly covered by labeled instances. For example, as shown in Table 1, the name of the relation "language of work" provides a general idea of the relation. The description further specifies that it is the language used for "creative work". Such information is not explicitly expressed, but only hinted, in the corresponding labeled examples. The definition and labeled instances provide different but complementary information about the relation, therefore can be combined to improve RC.

Mapping a relation definition to a prototype vector could be done naively using a pre-trained language model such as BERT (Devlin et al., 2019), but the resulting prototype may not be the most useful for relation instance classification. We believe that a good prototype encoded from a definition should be the one that helps RC. Therefore, we propose to train a prototype encoder together with RC of some examples. To tackle the problem of limited labeled examples, inspired by the RC-oriented pre-training work (Baldini Soares et al., 2019), we use abundant distantly labeled data to help train a prototype representation. The pre-training will generate the relation prototype vector that can best classify the weakly labeled data.

To integrate the prototype representation learned from relation definitions with the given limited hand-labeled instances, we adapt the Bayesian meta-learning approach (Qu et al., 2020) to learn a posterior distribution of the prototype vectors of relations based on both the initial prototype representations and the labeled instances. This process helps adapt the prototype to the labeled instances.

We test our approach on two few-shot RC datasets. It outperforms previous competitive models that apply pre-trained instance encoder or relation definition text. We also show that the encoder can be easily generalized to new relations in zero-shot RC setting. Experimental results demonstrate the effectiveness and generalization ability of our pre-trained prototype encoder.

Our main contribution in this paper is twofold: 1. We propose a new relation prototype construction method from relation definition; 2. We experimentally show that the approach is effective in few-shot RC and can be generalized to new relations in zero-shot RC.

2 Problem Definition

RC aims to predict whether a sentence (instance) $\mathbf{x}$ expresses a pre-defined relation between two given entities (e_1, e_2). Neural RC models usually contain an instance encoder that encodes the relation expressed by an instance into a dense vector and a classification layer to classify the dense vector to the relation which has the most similar prototype vector. In this work, we leverage the definition text denoted as $\mathbf{y}$ to help learn the relation prototype.

The prototype encoder is trained to help the classification of relation instances. Some training instances are required. Inspired by the RC-oriented pre-training work (Baldini Soares et al., 2019; Peng et al., 2020), we leverage a large set of distantly labeled data. The distant labeling (Mintz et al., 2009) is done as follows: given a known relation containing a pair of entities, any sentence mentioning the same entity pair is labeled by the relation.

Let us denote the set of distantly labeled instances as $\mathbb{D} : \{(\mathbf{x}_i, e_{1i}, e_{2i}, r_i)\}_{i=1}^{z}$ and a set of definition texts for all relations in $\mathbb{D}$ denote as $\mathbb{T} : \{(\mathbf{y}_t, r_t)\}_{t=1}^{n}$. The instance encoder (instance relation encoder) RelEnc_ϕ, parameterized by ϕ, produces an instance embedding $\mathbf{s} \in \mathbb{R}^d$ by $\mathbf{s} = \mathrm{RelEnc}_\phi(\mathbf{x}, e_1, e_2)$, where d is the vector dimension of prototype representation. The prototype encoder $\mathrm{ProtoEnc}_\theta$, parameterized by θ, produces a set of definition representations $\{\mathbf{v}_t\}_{t=1}^{n}$, where $\mathbf{v}_t \in \mathbb{R}^d$ is produced by $\mathbf{v}_t = \mathrm{ProtoEnc}_\theta(\mathbf{y}_t)$. The

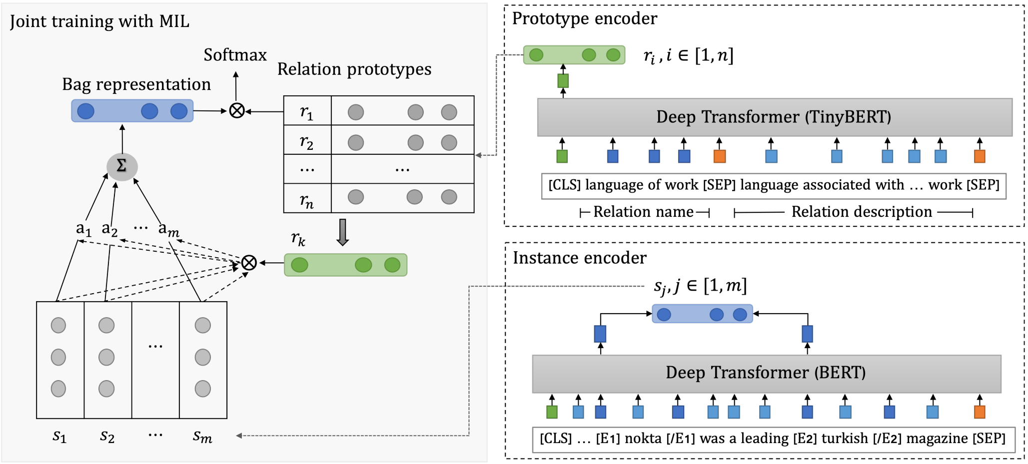

Figure 1: Overview of the prototype encoder pretraining framework. On the right side, two modules encode different text separately: the prototype encoder encodes the definition text as prototypes; the instance encoder encodes the possible relation expressed by an instance as the instance embedding. On the left side, a multi-instance learning method takes the representations from the two encoders for relation classification.

training goal is to map definition representations to relation prototypes useful for classifying instances.

3 Methodology

In this section, we first explain how a relation prototype is learned with the help of a set of distantly labeled instances. Then we describe how the learned prototype is further enhanced by the limited labeled instances in a Bayesian meta-learning framework.

3.1 Pre-training Framework

Pre-training a general prototype encoder involves two processes: generalizing contextual features of distantly labeled data to prototypes and mapping the relation definitions to their prototypes. As instances and the definition text describe relations in different forms, we adopt two pre-trained language models based on BERT (Devlin et al., 2019), as the backbones to encode them separately. The utilization of two distinct encoders is motivated by the different natures of the inputs: Relation definition provides a high-level, conceptual description of the relation, while a relation instance provides a concrete example about relation expression. From the former, the encoder would be asked to capture the general concepts, while from the latter, features relating to the syntactic/semantic pattern or the context can emerge. [1]. To cope with the large quantity of relations and the noisy labeling problem of distantly labeled data, we propose a simple yet effective design of instance encoder, prototype encoder and their joint training process, as illustrated in Figure 1. The joint training process learns the mapping function of prototype encoder by directly regarding definition representations as relation prototypes for classification. We elaborate the three components of the pre-training framework in the following parts.

3.1.1 Instance Encoder

We use the entity marker strategy to extract the instance relation following previous investigation about architectures of instance encoder (Baldini Soares et al., 2019). An example is shown in Figure 1. Four special entity markers - `[E1]`,`[/E1]`, `[E2]`, `[/E2]` are used to delimit entity1 and entity2. Then the hidden vectors of `[E1]` and `[E2]` at the last layer are concatenated to represent the relation expressed by the instance. Thus the hidden representation of an instance $\mathbf{x}_i$ is obtained as $H_i = \text{RelEnc}_\phi(\mathbf{x}_i, e_{1i}, e_{2i}) =< \mathbf{h}_{e_1}|\mathbf{h}_{e_2} >$, where $H_i \in \mathbb{R}^{2d}$ and d is the the size of the hidden representation space of the pre-trained language model. The final instance embedding is transformed into a d-dimensional representation by a linear layer as $\mathbf{s}_i = H_i^T W_t$, where parameters $W_t \in \mathbb{R}^{2d \times d}$.

3.1.2 Prototype Encoder

Each relation from KBs typically has a name and a description text. We use `[SEP]` to separate the relation name and description, and add the special token `[CLS]` at the beginning, another `[SEP]` at

---

[1] We also tested with the same encoder, but obtained poor results.

the end. Figure 1 shows an example. After tokenizing the input text, we feed the input tokens into TinyBERT and use the hidden vector of `[CLS]` (of dimension d) of the last layer as the definition representation. We adopt TinyBERT (Jiao et al., 2020) as the prototype encoder for its high efficiency. We also experimented the alternative with $\text{BERT}_{\text{BASE}}$ to update relation prototypes within a mini batch. However, this alternative converges much more slowly and at a higher final training loss than using TinyBERT.

3.1.3 Joint Training with MIL

Multi-instance learning (MIL) has been widely used to alleviate the noisy labeling problem (Ji et al., 2017; Alt et al., 2019) in distantly labeled data. It regards a set of instances containing the same entity pair as a bag and assign the bag with one relation label. Then relation classification is relaxed from sentence level to bag level. By selecting the most reliable instance or assigning different attention weights among the instances of the bag (Lin et al., 2016), the impact of wrong labels is reduced.

In this work, we use the relation definition to guide the instance attention learning among the bag. We assume that *instances that are semantically closer to the relation definition are more likely to express such a relation*. Let us denote a bag sample from the noisy dataset $\mathbb{D}$ as $(B_k, r_k, e_{1,k}, e_{2,k})$, where $B_k = \{\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_m\}$ is a set of instances containing the entity pair $(e_{1,k}, e_{2,k})$, which are encoded as $\{\mathbf{s}_i\}_{i=1}^m$ (also called 'instance embeddings') using RelEnc_ϕ. The bag representation $\mathbf{b}_k$ is computed by aggregating all instances according to the selective attention weights as follows:

$$\mathbf{b}_k = \sum_{i=1}^{m} a_i \mathbf{s}_i, \;\; a_i = \frac{\exp(\mathbf{s}_i^T \mathbf{v}_k)}{\sum_{j=1}^{m} \exp(\mathbf{s}_j^T \mathbf{v}_k)} \tag{1}$$

where the attention weight a_i represents the confidence score of instance $\mathbf{x}_i$ expressing relation r_k. a_i is calculated according to the similarity of instance embedding $\mathbf{s}_i$ and the definition representation $\mathbf{v}_k$.

We use dot product to compute the similarity of $\mathbf{b}_k$ and candidate relation prototypes $\{\mathbf{v}_i\}_{i=1}^n$. Then the bag-level prediction probability for relation r_k is computed as follows:

$$p(r_k | B_k, W_t, \phi, \theta) = \frac{\exp(\mathbf{b}_k^T \mathbf{v}_k)}{\sum_{j=1}^{n} \exp(\mathbf{b}_k^T \mathbf{v}_j)}. \tag{2}$$

Standard cross entropy is used to compute RC loss. We also add an auxiliary loss about language modeling over training instances to avoid catastrophic forgetting. We follow the same setting as previous work (Devlin et al., 2019; Baldini Soares et al., 2019) to compute the masked language modeling loss ($\mathcal{L}_{\text{MLM}}$). The final loss is defined as Eq. 3,

$$\mathcal{L} = \alpha * \mathcal{L}_{\text{MLM}} + \mathcal{L}_{\text{RC}}, \tag{3}$$

where α controls the importance of the language modeling loss, set as 0.5 by default. We update the parameters of $\{\phi, \theta, W_t\}$ for both encoders at each training iteration to minimize the final loss.

3.2 Application to Downstream RC

After the pre-training phase, we use the limited labeled instances to further enhance the prototype representation.

We adopt the Bayesian meta-learning approach proposed in (Qu et al., 2020), which models the uncertainty of prototype vectors by regarding them as random variables and learning the probability distribution for each relation. It could effectively learn the posterior distribution of the relation prototypes by combining the prior knowledge and a few labeled instances (i.e. the support set). In the model of (Qu et al., 2020), the prior of prototype vectors is derived from the structural relationship of different relations in a knowledge graph. The assumption is that a relation (a node in the graph) can gain some information from its neighbors. Relation representations are derived by applying graph neural network. In our case, prior relation prototypes are obtained from relation definition texts. A big advantage is that we do not require a relation be included in the knowledge graph to be able to handle it. A new relation can be handled if we have a definition of it, which is often the case (or the definition can be easily created) in practice. We will show later that our prototype representation performs better than that of (Qu et al., 2020).

The Bayesian meta-learning framework works as follows. For each sample in few-shot learning, given the candidate relations C, we denote their labels and textual definitions as $\mathbf{r}_C$ and $\mathbf{y}_C$; given a few supporting instances S, we denote their sentences and relation labels as $\mathbf{X}_S$ and $\mathbf{r}_S$, where each relation $r_s \in \mathbf{r}_C$. In Bayesian statistics, we infer the posterior distribution of relation prototypes as follows. Considering context variables $\{\mathbf{X}_S, \theta, \mathbf{y}_C\}$, we formulate a Bayesian formula for $p(\mathbf{v}_C | \mathbf{r}_S)$ in Eq. 5. Eq. 6 could be obtained when we assume that $\mathbf{r}_S$ is uniformly distributed. Since

$\theta, \mathbf{y}_C$ are independent to $\mathbf{r}_S$ and $\mathbf{X}_S$ is independent to $\mathbf{v}_C$, we could finally get Eq. 7.

$$\begin{aligned} & p(\mathbf{v}_C|\mathbf{r}_S; \mathbf{X}_S, \theta, \mathbf{y}_C) && (4)\\ &= \frac{p(\mathbf{r}_S|\mathbf{v}_C; \mathbf{X}_S, \theta, \mathbf{y}_C)p(\mathbf{v}_C|; \mathbf{X}_S, \theta, \mathbf{y}_C)}{p(\mathbf{r}_S|; \mathbf{X}_S, \theta, \mathbf{y}_C)} && (5)\\ &\propto p(\mathbf{r}_S|\mathbf{v}_C; \mathbf{X}_S, \theta, \mathbf{y}_C)p(\mathbf{v}_C|; \mathbf{X}_S, \theta, \mathbf{y}_C) && (6)\\ &\propto p(\mathbf{r}_S|\mathbf{v}_C, \mathbf{X}_S)p(\mathbf{v}_C|\theta, \mathbf{y}_C) && (7) \end{aligned}$$

Therefore, the posterior distribution of relation prototypes could be factorized as the likelihood of supporting instances and the prior knowledge of relation prototypes, which is derived from the definition text and pre-trained prototype encoder. $p(\mathbf{v}_C|\theta, \mathbf{y}_C)$ is the prior distribution for relation prototypes and each relation is assumed to follow a Gaussian distribution independently (i.e., $\mathcal{N}(\mathbf{v}_c|\text{ProtoEnc}_\theta(\mathbf{y}_c), I)$). $p(\mathbf{r}_S|\mathbf{X}_S, \mathbf{v}_C)$ is the likelihood of supporting instances computed by the softmax function, where dot product is used to compute the similarity of instance embeddings and the final relation prototypes.

Following the implementation of (Qu et al., 2020), we sample multiple prototypes for estimating the posterior distribution and each sampling is obtained via multiple stochastic updates. The optimization process is end-to-end and further details can be found in the paper (Qu et al., 2020).

Given a query instance $\mathbf{X}_q$ and a list of candidate relations C whose prototype vectors are denoted as $\mathbf{v}_C$, the relation distribution of the query instance over candidate relations can be computed by a softmax function as follows:

$$p(r_q|\mathbf{X}_q, \mathbf{v}_C) = \frac{\exp(\mathcal{E}(\mathbf{X}_q) \cdot \mathbf{v}_q)}{\sum_{c\in C} \exp(\mathcal{E}(\mathbf{X}_q) \cdot \mathbf{v}_c)}, \quad (8)$$

where $\mathcal{E}$ is the instance encoder (like BERT or RelEnc_ϕ).

4 Experiments

Pre-training details To run experiments with limited computation resources, we use $\text{BERT}_{\text{BASE}}$ [2] as the backbone of instance encoder and a four-layer TinyBERT [3] for the prototype encoder. We obtain a large-scale distantly-labeled dataset by processing the largest available alignments - T-REx (Elsahar et al., 2018), which align the documents from Wikipedia and triplets from Wikidata. We removed the relations that do not have the textual definition, i.e., all the relations in the distantly labeled data have the textual definition. After removing the repetitive instances, the final dataset contains 636 relations and ∼ 8M instances. We get the relation name and descriptions from Wikidata.

The hyper-parameters we used during the pre-training process are: batch size is 96; the number of training epochs is 3; optimizer is Adam with a learning rate of 1e-4, which decays by 0.8 per epoch. Our pre-training takes about 68 hours on four V100 GPUs.

4.1 Few-Shot Relation Learning

Dataset and evaluation metrics We adopt two few-shot RC datasets: FewRel 1.0 (Han et al., 2018) and FewRel 2.0 (Gao et al., 2019b). FewRel 1.0 contains 100 relations split into training, validation and test sets with respectively 64, 16 and 20 relations without overlapping. Each relation has 700 instance sentences from Wikipedia. FewRel 2.0 is constructed to evaluate models for domain adaption challenge and its validation data and test data are from biomedical domain.

The typical N-way K-shot setting means each evaluation episode will sample N relations, each of which has K labeled instances, and some query instances. The models are asked to classify query instances into the sampled N relations given the N×K labeled data. Accuracy is used to evaluate the classification performance. Note that we exclude entity pairs in test set of FewRel 1.0 that appear in the pre-training dataset to avoid data leakage.

Baselines We choose the following representative and strong baselines for comparison. (1) few-shot learning methods relying only on given training instances: **ProtoNet** (Snell et al., 2017), **Pair** (Han et al., 2018) ; (2) methods that integrate extra information: **REGRAB** (Qu et al., 2020) uses structural relationship between different relations in KBs, **MIML** (Dong et al., 2020) uses class semantic information from relation names; (3) RC-oriented pre-training methods that provide new instance encoders: **MTB** (Baldini Soares et al., 2019) constructs sentence pairs as training samples based on entity linking techniques, **COL** (Ding et al., 2021) uses relation prototypes for regularization assuming they are uniformly dispersed in a unit ball. **CP** (Peng et al., 2020) conducts contrastive pre-training over distantly labeled data. CP achieves state-of-the-art performance. For fair com-

parison, we re-run CP model with our pre-training dataset and denote the model as **CP-RI**. We also implement a baseline **BERT-EM** that is optimized by the cross-entropy loss on every instance during pre-training and uses exemplar comparison for few-shot classification (Baldini Soares et al., 2019).

Our model and variants Based on the Bayesian meta-learning approach (Qu et al., 2020), we present two kinds of implementations:

(1) Models denoted as REGRAB+* construct a global relation graph with relation embeddings. Detailed ablation analysis is conducted on those variations. **REGRAB+Proto** only replaces the original relation embeddings with definition representations by our ProtoEnc. Based on this, **REGRAB+Rel+Proto** further replaces original instance encoder with our pre-trained RelEnc.

(2) Other models that discard the global graph construction as introduced in section 3.2. Those models are denoted as "instance encoder" +Proto, e.g., **Rel+Proto** uses both of our pre-trained encoders, **CP+Proto** applies the public instance encoder CP (Peng et al., 2020) to our approach.

Results and analysis Table 2 shows the performance of different models. Our model Rel+Proto achieves state-of-the-art performance over strong baselines. This demonstrates the advantages of leveraging both extra knowledge from the definition text and pre-trained instance encoder.

Table 3 shows that our approach can further improve other strong pre-trained instance encoder CP by a large margin on both FewRel 1.0 and FewRel 2.0, verifying the wide applicability of our approach. We empirically found that REGRAB cannot be easily applied to FewRel 2.0 and MIML often produced unstable results.

Ablation analysis of the pre-trained prototype encoder and instance encoder is conducted with REGRAB. Compared with REGRAB, REGRAB+Proto consistently improves the performance on four settings, indicating the semantic relationship by our prototype encoder is more effective than the structural relationship from KBs. Compared with REGRAB+Proto, REGRAB+Rel+Proto achieves obvious improvements over four settings, showing the importance of pre-trained instance encoder. Besides, removing the operation of explicitly constructing a global relation graph, Rel+Proto further improves REGRAB+Rel+Proto, verifying our assumption that relation definitions could imply semantic similarities of different relations, and they provide a better way to construct representations for relations than through the relationships between them.

From Table 2, we observe CP-RI, whose instance encoder is pre-trained with the open-sourced code on our pre-training dataset, performs worse than the published results of CP, indicating our pre-training dataset may be noisier. Compared with CP-RI, BERT-EM performs more poorly, implying that the model using the label of each instance may suffer from noisy labels. Thus our design to leverage MIL algorithm is necessary.

4.2 Generalizability in Zero-Shot Relation Learning

To test how generalizable the prototype encoder is, we apply it to unseen relations in zero-shot RC to construct the prototype representation from their definitions. We test how effective such a relation prototype representation is.

# relations	2	5	10	15	25
BERT-Def	48.98	19.83	9.34	7.98	3.98
ZS-BERT	**87.60**	57.84	38.54	30.73	24.05
BERT-Proto	84.01	**65.60**	**52.46**	**44.80**	**34.72**

Table 4: Zero-shot classification accuracies (%) on NYT-25 with increasing candidate relations.

Dataset and evaluation setting We use two datasets, NYT-25 and PubMed-10, whose relations are nonoverlapping with FewRel training data and are obtained from the FewRel website[4]. NYT-25 contains 25 relations from Wikidata and its sentences are from New York Times; PubMed-10 contains 10 relations and both its relations and instances are from the biomedical domain. Each relation in the two datasets has 100 manually labeled instances. Relations from Wikidata have names and descriptions as the definition text, while the relations in PubMed-10 have only relation names as the definition text.

For N-way zero-shot RC setting, the classification difficulty is increased with the increase of candidate relation number N. We vary N from 2 to the max number. In each setting, a candidate set is made of N-1 negative relations and a positive relation.

Compared models We denote our combined RC model by the pre-trained prototype encoder and instance encoder as **BERT-Proto**, whose pre-training data exclude relations in NYT-25. To verify if the pre-trained language models understand the definition text for RC, we present a baseline **BERT-Def** that has the same model structure as BERT-Proto but does not perform the joint training with the instance encoder and prototype encoder.

We also present a competitive baseline **ZS-BERT** (Chen and Li, 2021) that classifies sentences based on embedding similarity. Similar to BERT-Proto, ZS-BERT learns two functions to project instances and relation definitions into an embedding space. The difference is that it uses a fixed pre-trained model, sentenceBERT (Reimers and Gurevych, 2019), to encode the definition text into an attribute vector. The attribute vectors are used to regularize the instance encoder during training and to compare with instance embeddings for classification during testing. We train ZS-BERT with FewRel training data for adapting to RC tasks.

# relations	2	5	8	10
BERT-Def	45.68	21.92	11.80	12.10
ZS-BERT	50.00	23.32	13.60	13.00
BERT-Proto	**63.78**	**32.82**	**21.40**	**18.00**

Table 5: Zero-shot classification accuracies (%) on PubMed-10 with increasing candidate relations.

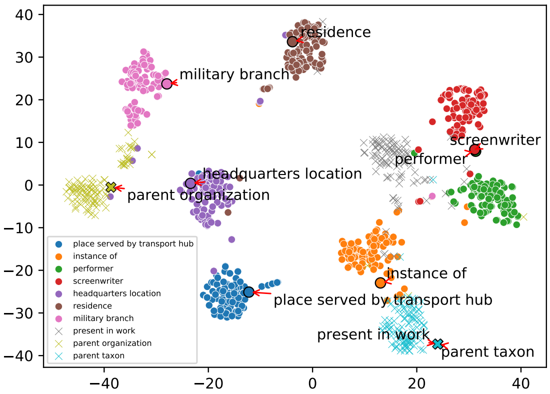

Figure 2: The t-SNE visualization of instance embeddings and definition representations (indicated by arrows) by our pre-trained BERT-Proto on selected relations. Each relation are represented by one color and the relations seen in pre-training are in circles and the unseen are crosses.

Zero-shot results and discussion From Table 4 and Table 5, we see BERT-Proto outperforms ZS-BERT, showing that our model is competitive for zero-shot RC even applied to a new domain and under the most difficult setting, while ZS-BERT performs slightly better than random on PubMed-10. We believe the advantages are mainly generated by the pre-training technique that helps learn a general mapping function, i.e. the prototype encoder. Note that BERT-Def presents almost random results, implying the ineffective encoding of relation definitions when no joint training is performed.

4.3 Visualization

To figure out how relation representations are distributed in the semantic space, we visualize the representations by our pre-trained instance encoder and prototype encoder with TSNE (Van der Maaten and Hinton, 2008) method. We also present relations of seen and unseen in the same space. The seen relations are selected from the FewRel training data and the unseen are from NYT-25.

From Figure 2, we observe that: (1) The definition representations of seen relations are close to instance embeddings of the same relation, show-

---

[4] https://github.com/thunlp/FewRel

ing that the prototype encoder could effectively map the definition text to its prototype vector. For some unseen relations, their own definition representations could also be the closest to their instance embeddings, providing effective prior knowledge for RC. (2) The distance between different relations reflects their similarities, which are mainly determined by contextual features, such as entity types, sentence structures and context semantics. For example, the relations of "performer", "screenwriter" and "present in work" all express the relationship between a person and an artwork. Their instance embeddings are much closer to each other than with the relations about locations such as "headquarters location", even though "present in work" is the unseen relation. This shows that pre-trained instance encoder could extract effective contextual features for relation representations and build a meaningful semantic space to guide our prototype encoder learning. (3) For new-emerging relations, their prototype vectors are determined by both the definition text and labeled instances, so as to benefit from the possible connections with seen relations through pre-trained prototype encoder and instance encoder.

5 Related Work

Relation classification (RC) is pivotal for natural language understanding and has been studied for a long time (Chieu and Ng, 2002). Supervised machine learning approaches achieve remarkable progress on RC (Kambhatla, 2004; Hendrickx et al., 2009), but rely on high-quality labeled data. To relieve the heavy burden of manual annotation, researchers study RC under distant supervision (Mintz et al., 2009) or few-shot RC (Han et al., 2018; Gao et al., 2019b). The former focuses on robust classifier training with automatically labeled noisy data (Lin et al., 2016; Li et al., 2020). Our work belongs to the latter, which aims to learn general knowledge transferable to new relations.

Few-shot learning methods have been well studied for image classification (Ravi and Larochelle, 2017) and some classical approaches such as prototype network (Snell et al., 2017), model-agnostic meta-learning (Finn et al., 2017) have been applied for RC (Han et al., 2018). Two types of efforts have been devoted to improving few-shot RC. Firstly, some approaches (Ye and Ling, 2019; Gao et al., 2019a; Wang et al., 2020; Han et al., 2021; Ren et al., 2020; Ohashi et al., 2021) design specific model architectures such as using attention mechanism to model complex interactions between labeled instances. However, these approaches are still limited when the few labeled instances are atypical and does not reflect the general patterns of the relation. Secondly, researchers leverage extra information to complement the insufficient labeled data (Qu et al., 2020; Dong et al., 2020). Our method belongs to this line.

Some methods (Qu et al., 2020; Zhang et al., 2021) leverage extra knowledge from KBs but they cannot deal with relations not covered by the KBs, showing limited applicability. Similar to our work, some studies (Dong et al., 2020; Yang et al., 2020) use relation names or descriptions as extra information. They design specific modules to integrate the extra information, but the whole few-shot RC model suffers from over-fitting and unstable performance due to the limited number of training relations. In contrast, our method adopts pre-training techniques to learn a general mapping function, which is more applicable and proven effective for domain adaptation.

Some recent studies (Baldini Soares et al., 2019; Ding et al., 2021; Peng et al., 2020) conduct RC-oriented pre-training to learn a general-purpose instance encoder. Such instance encoders improve RC on both supervised and few-shot learning settings. We adopt the same idea of pre-training but focus on learning the general function of mapping relation definitions to the prototype space for relation classification.

6 Conclusion

This paper studies prototypical representation learning for few-shot relation classification, and the key idea is to encode the definition text as prior knowledge to help classify new relations. We proposed to train a general-purpose prototype encoder that could encode the definition text of any relation into the prototype space. An instance encoder and the prototype encoder are trained jointly with a multi-instance learning method on distantly labeled data. Applying our prior prototypes with a Bayesian meta-learning approach, our method outperforms previous state-of-the-art models by using pre-trained instance encoder on two datasets, verifying its wide applicability. Our prototype model also presents competitive performance on the zero-shot learning setting.

Abstract

Large language models have achieved high performance on various question answering (QA) benchmarks, but the explainability of their output remains elusive. Structured explanations, called *entailment trees*, were recently suggested as a way to explain and inspect a QA system's answer. In order to better generate such entailment trees, we propose an architecture called *Iterative Retrieval-Generation Reasoner* (IRGR). Our model is able to explain a given hypothesis by systematically generating a step-by-step explanation from textual premises. The IRGR model iteratively searches for suitable premises, constructing a single entailment step at a time. Contrary to previous approaches, our method combines generation steps and retrieval of premises, allowing the model to leverage intermediate conclusions, and mitigating the input size limit of baseline encoder-decoder models. We conduct experiments using the ENTAILMENTBANK dataset, where we outperform existing benchmarks on premise retrieval and entailment tree generation, with around 300% gain in overall correctness.

1 Introduction

Large neural network models have successfully been applied to different natural language tasks, achieving state-of-the-art results in many natural language benchmarks. Despite this success, these results came with the expense of AI systems becoming less interpretable (Jain and Wallace, 2019; Rajani et al., 2019a).

With the desire to make the output of such models less opaque, we propose a question answering (QA) system that is able to explain their decisions not only by retrieving supporting textual evidence (rationales), but by showing how the answer to a question can be systematically proven from simpler textual premises (natural language reasoning).

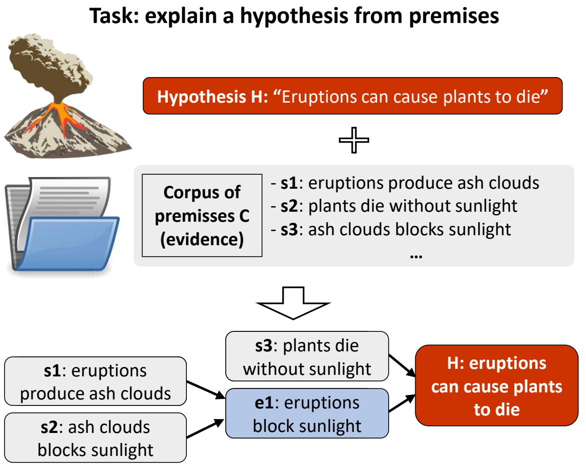

Figure 1: Task has as input a hypothesis H (e.g. an answer to a question) and a corpus of premises C (simple textual evidences), the goal is to generate an *entailment tree* that explains the hypothesis H by using premises from C.

These explanations are represented using *entailment trees*, as depicted in Figure 1. First introduced by Dalvi et al. (2021), entailment trees represents a chain of reasoning that shows *how* a hypothesis (or an answer to a question) can be explained from simpler textual evidence. In comparison, other explanation approaches such as retrieval of passages (rationales) (DeYoung et al., 2020) or multi-hop reasoning (chaining) (Jhamtani and Clark, 2020) are less expressive than entailment trees, which are comprised of multi-premise textual entailment steps.

In order to generate such entailment trees, previous works (Tafjord et al., 2021; Dalvi et al., 2021; Bostrom et al., 2021) have used encoder-decoder models that takes as input a small set of retrieved premises and output a linearized representation of the entailment tree. Such models are limited by (1) the language model's fixed input size, and they may construct incorrect proofs when the retrieval module cannot fetch all relevant premises at once

---

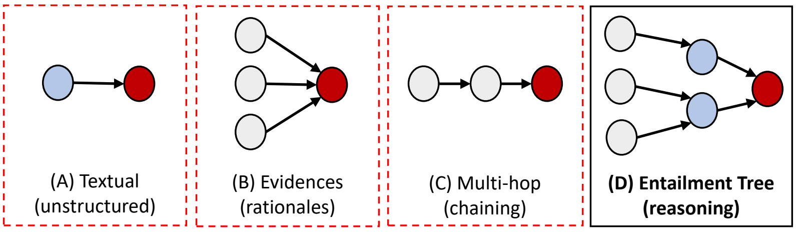

Figure 2: Comparison among different natural language explanation approaches. The images show (A) plain textual explanations (B) retrieval of evidence passages (C) multi-hop explanations (D) entailment trees. The approach in (D) allows for more detailed inspection of the reasoning behind an explanation. Nodes in gray are retrieved from a corpus, nodes in blue are generated, and the red node is the hypothesis or answer that is being explained.

(2) such approaches do not leverage the partially generated entailment trees. In contrast, we propose *I**terative* ***R****etrieval-****G****eneration* ***R****easoner* (IRGR), a novel architecture that iteratively searches for suitable premises, constructing a single entailment step at a time. At every generation step, the model searches for a distinct set of premises that will support the generation of a single step, therefore mitigating the language model's input size limit and improving generation correctness.

Our contributions are two-fold. First, we design a retrieval method that is able to better identify premises needed to generate a chain of reasoning, which explains a given hypothesis. Our retrieval method outperforms previous baselines by 48.3%, while allowing for a dynamic set of premises to be retrieved. Secondly, we propose an iterative retrieval-generation architecture that constructs partial proofs and augments the retrieval probes using intermediate generation results. We show that integrating the retrieval module with iterative generation can significantly improve explanations. Our proposed approach achieves new state-of-the-art result on entailment tree generation with over 306% better results on the All-Correct metric (strict comparison with golden data), while using a model with one order of magnitude fewer parameters.

2 Related Work

Traditionally, natural language processing (NLP) frameworks were based on white-box methods such as rule-based systems (Allen, 1988; Ribeiro et al., 2019; Ribeiro and Forbus, 2021) and decision trees (Boros et al., 2017), which were inherently inspectable (Danilevsky et al., 2020). More recently, large deep learning language models (black-box methods) have gained popularity (Song et al., 2020; Raffel et al., 2020), but their improvements in result quality came with a cost: the system's outputs lack explainability and inspectability.

There have been many attempts to mitigate this issue, including input perturbation (Ribeiro et al., 2018) and premises selection (DeYoung et al., 2020). One promising explanation approach is to combine the model's output with a human-interpretable explanation. For instance, Camburu et al. (2018) introduced the concept of natural language explanation in their e-SNLI dataset while Rajani et al. (2019b) expanded this idea to commonsense explanations. Jhamtani and Clark (2020) further explored the notion of explanation in multi-hop QA, where explanations contain a *chain of reasoning*, instead of simple textual explanations. Different from these explanation approaches, our work generates explanations in the form of *entailment trees*, introduced by Dalvi et al. (2021), which are composed of multi-premise textual entailment steps. Entailment trees are more detailed explanations, making it easier to inspect the reasoning behind the model's answer. Figure 2 shows a diagram compering different natural language explanation methods according to their structure and use of textual evidence.

The first approach used to generate entailment trees was based on the *EntailmentWriter* model by Tafjord et al. (2021). However, their approach is limited by the input size of the encoder-decoder language models, where a fixed set of supporting facts is used to generate an explanation. Instead, our model iteratively fetches a set of premises using dense retrieval conditioned on previous entailment steps, allowing for more precise explanations.

Our work is also related to some recent approaches that combine retrieval and neural networks for QA tasks (Karpukhin et al., 2020; Guu et al., 2020). The work of Lewis et al. (2020) combined dense retrieval with encoder-decoder models, where a different set of passages were retrieved

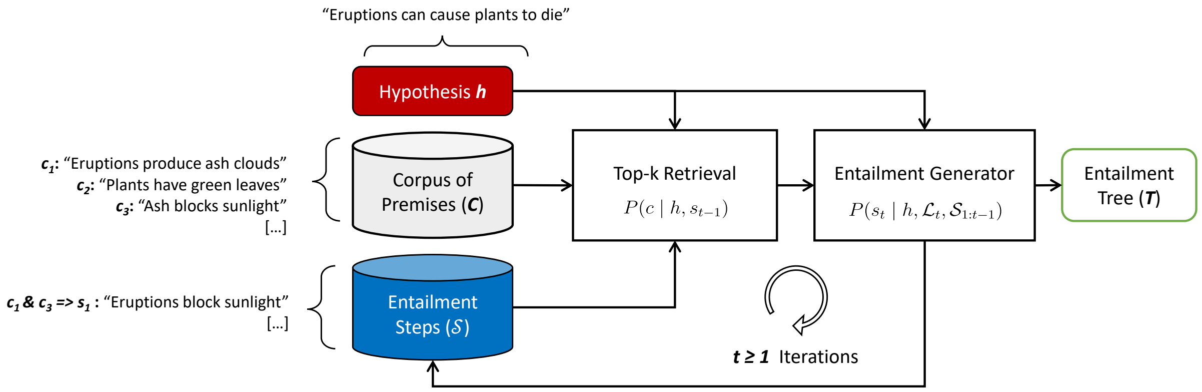

Figure 3: IRGR is composed of two modules, IRGR-retriever and IRGR-generator. The IRGR-retriever iteratively fetches a set of premises from a corpus C in order to generate an entailment tree (structured explanation for a given hypothesis). The IRGR-generator computes a single entailment step at a time, and the intermediate generated steps are stored and used for subsequent retrieval and generation.

for each generated character. Conditioning the retrieval of a passage on previously retrieved passages has been explored in the context of multi-hop QA (Zhao et al., 2021; Xiong et al., 2021), and multi-hop explanations (Valentino et al., 2021; Cartuyvels et al., 2020). However, these approaches either are not used to generate explanations or do not use inferred intermediate reasoning steps to retrieve premises.

3 Approach

3.1 Problem Definition

The problem input consists of a **corpus of premises** C (simple textual statements) and a **hypothesis** h. The objective is to generate an **entailment tree** T that explains the hypothesis h by using a subset of the premises in C as building blocks. Entailment trees are represented as a tuple $T = (h, \mathcal{L}, \mathcal{E}, \mathcal{S})$, where **leaf nodes** $l_i \in \mathcal{L}$ are retrieved from the corpus (i.e. $\mathcal{L} \subseteq C$), **internal tree nodes** $e_i \in \mathcal{E}$ are intermediate conclusions (new sentences not present in corpus C, note that intermediate conclusions are generated by the model), and $s_i \in \mathcal{S}$ is a list of **entailment steps** that can explain the hypothesis h, which is always the tree root and the final conclusion. An illustration of the problem and expected entailment tree can be found in Figure 1.

Each entailment step s_i represents one inference step from a conjunction of premises to a conclusion. For instance, "$l_1 \wedge l_2 \Rightarrow e_1$" or "$l_1 \wedge l_2 \wedge e_1 \Rightarrow h$" could be valid entailment steps in $\mathcal{S}$. Note that the root of T is always the node representing h.

3.2 Architecture

Our approach, which we call ***I**terative **R**etrieval-**G**eneration **R**easoner* (IRGR), consists of two modules, the IRGR-retriever and the IRGR-generator. The initial input to the model is the hypothesis h and the corpus of premises C. The generation process is performed through multiple iterations. At each iteration step $t \geq 1$ the IRGR-retriever selects a subset of premises from the corpus $\mathcal{L}_t \subseteq C$. The IRGR-generator outputs one entailment step s_t per iteration until the entailment tree T is fully generated. Given $\mathcal{S}_{1:t-1} = (s_1, \ldots, s_{t-1})$ as the list of the entailment steps generated up to the previous iterations $t-1$, the generator takes as input $\mathcal{L}_t$ and $\mathcal{S}_{1:t-1}$ and produces the next entailment step s_t. The generation stops when the entailment step's conclusion is the hypothesis h, i.e., the proof is finished. Formally, the t-th iteration of the generation process is defined as:

$$\mathcal{L}_t = \text{IRGR-retriever}(h, s_{t-1}) \quad (1)$$

$$s_t = \text{IRGR-generator}(h, \mathcal{L}_t, \mathcal{S}_{1:t-1}) \quad (2)$$

The IRGR-retriever searches over the premises in corpus C using *dense passage retrieval* (Karpukhin et al., 2020). Meanwhile, the IRGR-generator was implemented using T5, the Text-to-Text Transformer (Raffel et al., 2020), while any other sequence-to-sequence language model could also be used. An overview of the model can be seen in Figure 3.

3.2.1 IRGR-retriever

The IRGR-retriever module proposed in this work aims to retrieve premises from the corpus C. In existing baseline models the retrieval is done in one single step, fetching a fixed set of premises before generation (Tafjord et al., 2021). However, the generation of entailment trees requires a different set of leaves for each entailment step. To address this issue, our IRGR-retriever fetches k_t premises from C to produce $\mathcal{L}_t$ at iteration step t. Note that the size of C can be very large ($k_t << |C|$). The value k_t is chosen such that the size of $\mathcal{L}_t$ is small enough to fit in the context of a language model while still being large enough to fetch as many premises as possible (in our experiments, the value k_t is always below 25). We define the retrieval probability of a premise $c \in C$ at a certain iteration step t as:

$$P(c \mid h, s_{t-1}) = \frac{exp(\langle \mathbf{c}, \mathbf{q_t} \rangle)}{\sum_{c' \in C} exp(\langle \mathbf{c'}, \mathbf{q_t} \rangle)} \tag{3}$$

Where ϕ is the sentence encoder function used to encode both premises and hypothesis, transforming the input text into a dense vector representation in $\mathbb{R}^M$. The values $\mathbf{c} = \phi(c)$, $\mathbf{c'} = \phi(c')$ and $\mathbf{q_t} = \phi(h, s_{t-1})$ are dense M-dimensional vectors. The operator $\langle . \rangle$ represents the inner product between two vectors.

The encoder follows the Siamese Network architecture from Reimers and Gurevych (2019). We select a set of N positive and negative examples in the form of query-value pairs $\{(q_j, c_j)\}_{j=1}^{N}$ for training. Queries q_j encode both the hypothesis h and previous entailment step s_{t-1} by concatenating their textual values. The positive examples are taken from the golden entailment trees, where $c_j \in \mathcal{L}$. For negative examples, we pair a query q_j with either random premises from C or premises retrieved using the not fine-tuned version of the encoder (hard negatives).

We define $\hat{y}_j$ as the label given to the training example (q_j, c_j). For positive examples, the label $\hat{y}_j$ depends on how close the leaf node $l_i \in \mathcal{L}$ is to the intermediate step s_{t-1} in the golden tree:

$$\hat{y}_j = \begin{cases} 0, & \text{if negative} \\ \lambda, & \text{if positive and } l_i \notin \texttt{ant}(s_{t-1}) \\ 1, & \text{if positive and } l_i \in \texttt{ant}(s_{t-1}) \end{cases} \tag{4}$$

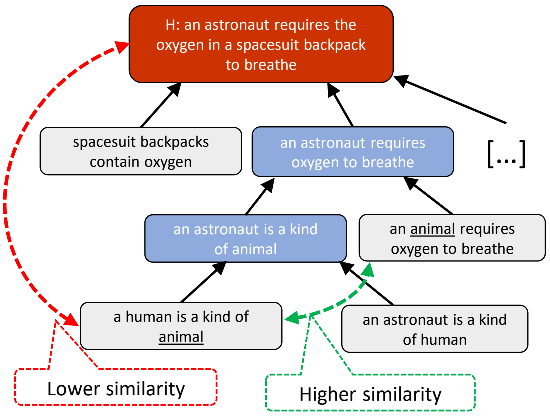

Figure 4: Entailment tree example showing how some retrieval examples are challenging. Leaf sentences are not always directly related to hypothesis.

Algorithm 1: Conditional Retrieval

```
Data: hypothesis $h$, corpus $C$, number of
      retrieved premises $k_0$
Result: retrieved premises $\mathcal{L}_0$
Parameter : conditioning factor $\omega$
$Q \leftarrow \{h\}$ ;  /* set of queries */
$\mathcal{L}_0 \leftarrow \{\}$;
for $i \leftarrow 0$ to $k_0$ do
    $C' \leftarrow \{c \in C : c \notin \mathcal{L}_0\}$;
    if $i \geq \omega$ then
        $l_i \leftarrow \arg\max_{(c \in C')} P(c \mid Q)$;
        $Q \leftarrow Q \cup \{l_i\}$;
    else
        $l_i \leftarrow \arg\max_{(c \in C')} P(c \mid h)$;
    end
    $\mathcal{L}_0 \leftarrow \mathcal{L}_0 \cup \{l_i\}$;
end
```

Where $\texttt{ant}(s_{t-1})$ denotes the set of antecedents in some entailment step s_{t-1}, and $l_i \in \texttt{ant}(s_{t-1})$ means that the leaf node l_i is used in the entailment step s_{t-1}. The value $\lambda \in [0:1]$ is used to give lower priority to leaf nodes not relevant to the current entailment step (λ = 0.75 gave the best results in our experiments). Finally, we fine-tune the encoder ϕ by minimizing the following loss function L_ϕ, where N is the number of training examples:

$$L_\phi = \frac{1}{N} \sum_{j=1}^{N} \left(\hat{y}_j - \frac{\langle \phi(q_j), \phi(c_j) \rangle}{\|\phi(q_j)\| \|\phi(c_j)\|} \right) \tag{5}$$

One significant challenge is that for the first generation step, when $t = 1$, the list of previously generated entailment steps $\mathcal{S}_0$ is empty. The retrieval only depends on h, meaning $\mathcal{L}_1 =$ IRGR-retriever(h). It is more difficult to retrieve premises for leaf nodes when the entailment tree's depth is large since the leaf nodes have low syntactic and semantic similarity with the hypothesis h. For instance, the example in Figure 4 shows how leaf node "*a human is a kind of animal*" (depth 3) is needed to build the entailment tree, but is syntactically distinct to hypothesis "*an astronaut requires the oxygen in a space suit backpack to breath*".

To mitigate this problem, we perform a conditional retrieval on the first step, where the retrieval module uses partial results as part of the query, as depicted in Algorithm 1. This algorithm assumes that leaf nodes (premises) further from the root node (hypothesis) are more similar to each other than to the root node itself. The parameter ω (value $\omega = 15$ yields the best results on development set) is used to split the search, such that part of the retrieved premises only depend on the hypothesis h. In contrast, the other parts of the retrieved premises depend on the hypothesis and previously retrieved premises stored in the set Q.

3.2.2 IRGR-generator

The IRGR-generator consists of a sequence-to-sequence model that outputs one single entailment step given a context. One key aspect of this module is encoding the input and output as plain text.

Encoding Entailment Trees: Entailment trees are linearized from leaves to root. Each leaf node $l_i \in \mathcal{L}$, intermediate node $e_i \in \mathcal{E}$ and root node h are encoded with the symbols "`sent`", "`int`" and "`hypothesis`", respectively. The entailment steps represent conjunctions with "`&`" and entailment with the symbol "`->`". For instance, the entailment tree depicted in Figure 1 can be represented as:

```
"sent1 & sent2 -> int1:
Eruptions block sunlight;
sent3 & int1 -> hypothesis;"
```

Note that the text of intermediate nodes have to be explicitly represented, since they are not part of the corpus C. Ultimately, they have to be generated by the model. The input to the model encodes the hypothesis h and retrieved premises $l_i^t \in \mathcal{L}_t$, which are straightforwardly encoded as follows:

```
"hypothesis: Eruptions can
cause plants to die;
sent1: eruptions emit lava
sent2: eruptions produce ash
clouds
sent3: [...];"
```

Method	R@25	All-Correct
Okapi BM25	45.01	22.35
EntailmentWriter	59.76	34.70
IRGR-retriever (sing.)	64.41	40.29
IRGR-retriever (cond.)	**68.28**	44.70
IRGR-retriever*	-	**51.47**

Table 1: Retrieval results. The methods with * retrieves more than 25 premises from corpus.

When a leaf sentence l_t^i is used in the entailment step, it is removed from the context for the following step, and the premise `sent` identifier is not used to encode new retrieved premises. A detailed example of input and output for the IRGR-generator module is shown in Appendix A.3.

4 Experiments

4.1 Datasets

We evaluate our architecture on the ENTAILMENTBANK dataset (Dalvi et al., 2021), which is comprised of 1,840 questions (each associated with a hypothesis h_i and entailment tree T_i) with 5,881 total entailment steps. On average, each entailment tree has 7.6 nodes (including leaf, intermediate, and root) and around 3.2 entailment steps. The corpus of premises C has around 11K entries and is derived from the WorldTree V2 (Xie et al., 2020) in addition to a few premises created by the EntailmentBank annotators.

4.2 Evaluation Metrics

4.2.1 Retrieval

We evaluate our IRGR-retriever module using two different sets of metrics. The first one is "Recall at k" (R@k), a standard evaluation metric for information retrieval. The second metric "All-Correct" is more strict, and the results are only considered correct if all the premises from the golden tree are retrieved. Formally, given the retrieved premises $\mathcal{L}$ and the set of gold premises $\mathcal{L}^*$, the metrics R@k is given by $|\mathcal{L} \cap \mathcal{L}^*| \;/\; |\mathcal{L}^*|$, and the metric All-Correct is 1 if $|\{x \in \mathcal{L}^* : x \notin \mathcal{L}\}| = 0$, or 0 otherwise. For our experiments, we consider k = 25 since that's roughly the maximum number of sentences that can fit in the T5 language model's 512 tokens context.

Method	Leaves		Steps		Intermediates		Overall
	F1	All-Cor.	F1	All-Cor.	F1	All-Cor.	All-Cor.
EntailmentWriter	39.7	3.8	7.8	2.9	36.4	13.2	2.9
IRGR	45.6	**12.1**	**16.3**	**11.8**	**38.8**	**36.5**	**11.8**
- w/o iter.	**46.6**	10.0	11.3	8.2	36.3	35.6	8.2
- w/o iter. & cond.	36.1	3.8	6.0	3.2	27.6	14.7	3.2

Table 2: Entailment tree scores for baseline methods and IRGR, along four different dimensions (test set). F1 scores measure predicted/gold overlap, while All-Correct scores are 1 when all the predictions for a tree are correct, 0 otherwise.

4.2.2 Entailment Tree Generation

We adopt the evaluation metrics defined by Dalvi et al. (2021), which compares the generated entailment tree $T = (h, \mathcal{L}, \mathcal{E}, \mathcal{S})$ with the golden entailment tree $T^* = (h, \mathcal{L}^*, \mathcal{E}^*, \mathcal{S}^*)$. The metrics evaluate the correctness along four dimensions: (1) leaf nodes, (2) entailment steps, (3) generated intermediate nodes, (4) and overall correctness. The first step is to align the nodes from T with the nodes from T^* by Jaccard similarity (alignment algorithm and further details of metrics described in Appendix A.2). This method tries to ignore variations between predicted and gold trees that do not change the semantics of the output. The four metric dimensions are described below as follows. For each metric with F1 value, there is also a strict "All-Correct" metric that is equal to 1 when F1 = 1 and 0 otherwise.

Leaf (F1, All-Correct): Tests if the predicted and golden leaf nodes match. This metric compares the sets $\mathcal{L}$ and $\mathcal{L}^*$ using F1 score.

Steps (F1, All-Correct): Tests if the predicted entailment steps follow the correct structure. Given that $s_i \in \mathcal{S}$ matches $s_j \in \mathcal{S}^*$ according to the alignment algorithm, tests if the premises of s_i are equal to those of s_j, and computes the F1 score according to the set of all matched steps.

Intermediates (F1, All-Correct): Tests if the sentences of the generated intermediate nodes are correct. Given that intermediate nodes $e_i \in \mathcal{E}$ and $e_j \in \mathcal{E}^*$ were matched by the alignment algorithm, the F1 score is computed by comparing the textual similarity between the set of the aligned and correct pairs e_i and e_j.

Overall (All-Correct): Tests all previous metrics together. The All-Correct value is only 1 if the All-Correct values for leaves, steps, and intermediates are 1. Note that this is a strict metric, and any semantic difference between T and T^* will cause the score to be zero.

4.3 Implementation Details

All experiments were conducted using a machine with 4 Tesla V100 GPUs with 16GB of memory. Our code is based on HuggingFace's Transformers (Wolf et al., 2020) implementation of the `t5-large` model (Raffel et al., 2020). The retrieval module uses the Sentence Transformers (Reimers and Gurevych, 2019) sentence embeddings by fine-tuning the `all-mpnet-base-v2` encoder. Please refer to Appendix A.1 for further details on hyper-parameters and training settings.

4.4 Results

4.4.1 Retrieval Results

We compare our retrieval module against two baselines: **Okapi BM25** and the retrieval module of **EntailmentWriter**, which constitutes of a classifier that retrieves relevant sentences using RoBERTA (Liu et al., 2020) and performs re-ranking with Tensorflow-Ranking-BERT (Han et al., 2020).

For comparison, we break down the results of our approach (the IRGR-retriever module) into three variations. The **IRGR-retriever (sing.)** method retrieves premises from the corpus using a single query element, namely the hypothesis h. The **IRGR-retriever (cond.)** method performs conditioned retrieval as described by Algorithm 1. This retrieval method is not iterative and fetches a fixed set of premises per example. Finally, **IRGR-retriever** tries to emulate the retrieval when combined with the generation module. It not only performs conditional retrieval, but also fetches a different set of premises for each iteration depending on the generated intermediate nodes. In this retrieval experiment, the IRGR-retriever uses the intermediate nodes from the golden entailment trees.

Task	Method	Leaves		Steps		Intermediates		Overall
		F1	All-Cor.	F1	All-Cor.	F1	All-Cor.	All-Cor.
Gold	EntailmentWriter	98.7	86.2	50.5	37.7	67.6	50.3	34.4
	IRGR	97.9	89.4	50.2	36.8	62.1	45.6	32.3
Gold+Dist.	EntailmentWriter	84.3	38.5	35.7	23.5	62.6	50.9	22.4
	IRGR	69.9	23.8	30.5	22.3	47.7	56.5	22.0

Table 3: Entailment tree scores for baseline methods and IRGR, along four different dimensions (test set). The "Gold" and "Gold+Dist." tasks do not require retrieval and evaluates solely on the model's entailment tree generation capabilities.

Therefore, IRGR-retriever results should be considered an upper bound since the generator might not produce the desirable intermediate steps used for queries.

Table 1 shows the R@25 and All-Correct metrics results for different methods. Our premise retrieval module performs consistently better than baselines. For instance, the "IRGR-retriever (cond.)" outperforms the retriever from EntailmentWriter by 14.2% on R@25 and 28.8% on All-Correct metric. Note that "IRGR-retriever" may retrieve a variable number of premises (greater than 25), so we are not reporting R@25 for this method.

4.4.2 Entailment Tree Generation Results

We compare our method against EntailmentWriter baseline model on entailment tree generation. As shown in Table 2, our method outperforms the EntailmentWriter in all metrics. The overall tree structure better matches the golden tree, where the score for Overall All-Correct metric has an impressive increase of over 300.0%. Note that EntailmentWriter uses the T5-11B model, which has around 10 times more parameters than our model.

We also show the ablation results of combining different retrieval modules with our proposed generation module on Table 2. The "**w/o iter.**" method does not iteratively retrieve premises, relying on one-shot retrieval at the beginning of the generation. As for the "**w/o iter. & cond.**" method, the model does not use the conditioned retrieval, only relying on the trained dense retrieval with the hypothesis h as the query instead.

The work of Dalvi et al. (2021) defines two other simplified entailment tree generation tasks for further ablation studies. We report the results for what they define as "Task-1" and "Task-2", which are generation tasks where the golden premises are given as input, disregarding the retrieval component. Results in Table 2 report what they define as "Task-3". For clarity, we rename "Task-1" and "Task-2" to "Gold" and "Gold+Dist.", respectively, and show the results in Table 3. In the "Gold" task, each context uses the golden leaves as input, while the "Gold+Dist." task uses the golden leaves plus some distractors (up to 25 distractors). When comparing models with the same number of parameters (we use their reported T5-large results), the generation results without retrieval are roughly the same as the EntailmentWriter method. This experiment shows that the iterative generation can create accurate explanations compared to a single pass generation when using golden retrieved premises.

4.5 Results Breakdown

We investigate how well the system performs relative to the number of steps in the gold tree. Figure 5 contains two graphs with results breakdown. The graph on the top shows the all-correct metric values for all three tasks (golden, golden + distractors, and retrieval). The bottom graph shows all F1 metrics (leaves, steps, and intermediates), but only for the "retrieval" task.

The results demonstrate that generating entailment trees becomes increasingly difficult as the size of the tree increases. The IRGR model cannot perfectly predict trees with more than four steps for any of the three different tasks. For the "retrieval" task (without the golden leaf sentences provided as input), the IRGR model cannot successfully generate trees with three or more steps. This could be explained by the fact that the all-correct metric is very strict, and missing or misplacing a single leaf sentence can result in an incorrect tree.

This downwards trend is also present in the "Break Down by Metrics" graph. Most noticeably, the "Intermediates (F1)" metric is especially challenging, having values close to zero for entailment trees with more than five steps. This metric is one

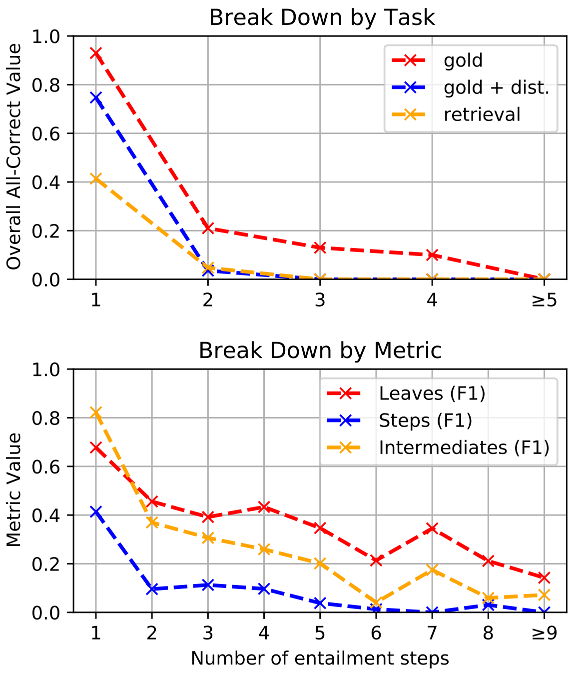

Figure 5: Result breakdown for number of steps in explanation (entailment steps).

of the main bottlenecks that lowers the value of the "Overall All-Correct" metric.

4.6 Analysis

To understand the strengths and weaknesses of our model, we conduct further analysis of the output of the IRGR. When analyzing errors in the generation of entailment trees, we use the results on the development set for the task with distractors. We manually annotate 50 predicted trees that contain some error compared to the golden tree. We categorize the different types of errors, identifying both individual generated steps errors and entailment tree errors.

4.6.1 Retrieval Error Analysis

We use ENTAILMENTBANK's development set to automatically compute metrics that will give us some insights into the type of errors made by the IRGR-retriever module. We use "IRGR-retriever (cond.)" to fetch a set of 25 premises for each data point, where we identify the set of **true positives** (correctly retrieved premises) and the set of **false negatives** (missing premises).

To understand if the false negatives are more challenging to retrieve than the true positives, we compute the number of overlapping uni-grams and bi-grams between premises and hypotheses in these two sets. We notice that true positives contain 28.5% more uni-gram overlap and 68.6% more bi-gram overlap to the hypothesis compared to the false negatives. These results suggest that premises lexically *dissimilar* to the hypothesis are, in theory, more challenging to retrieve.

We also investigate how the depth (number of edges in a path from the tree root) of a leaf node in the gold tree correlates to the errors of the IRGR-retriever module. We compute the average depth of true positive nodes as 2.3, while for false-negative nodes, the average depth is 3.0. These results strengthen the idea that leaf nodes deeper in the tree tend to be harder to retrieve, as depicted in Figure 4.

4.6.2 Entailment Step Error Analysis

The first error case is called **invalid entailment steps** (56% of errors), meaning that the conclusion of a step did not follow from the premises. For instance, in "*kilogram is used to measure heavy objects*" ∧ "*an automobile is usually a heavy object*" ⇒ "*kilogram can be used to measure the mass of an automobile*", the model assumes that "measure" is the same as "measure of mass", even though that is not explicitly stated.

The second error case accounts for **misevaluation and irrelevance** (27% of errors). It happens when the step is correct but does not match the golden tree, or when the step is correct but is not relevant or well placed in the final entailment tree. In the third error case, labeled **repetition** (17% of errors), the conclusion directly copied the premises, not creating a new sentence for the intermediate step.

4.6.3 Entailment Tree Error Analysis

When analyzing errors between the entire generated and golden trees, we noticed that **incorrect or missing leaves** (52% of errors) is the most common type of problem. For instance, when explaining the hypothesis "*light year can be used to measure the distance between the stars in milky way*" the premises "*the milky way is a kind of galaxy*" and "*a galaxy is made of stars*" are missing from the generated tree, making it impossible to explain the second part of the hypothesis.

The remaining errors are categorized as **invalid or skipped steps** (32% of errors), where the model commonly concludes an invalid conclusion from premises. This error often overlaps with **missing leaves** due to the fact that the model uses fewer premises when it skips important intermediate steps; **Imperfect evaluation** (12% of errors), where the tree produced is valid, but does not match the golden tree; **Disconnected or degenerate trees** (4% of errors), where the generated output does not form a tree, or follows the desired output format.

5 Conclusion

As deep learning models become more ubiquitous in the natural language field, it is desirable that users can understand the model's answer by inspecting the reasoning chain from simple premises to the answer hypothesis. To generate rich, systematic explanations, we proposed a method that can iteratively generate and retrieve premises to produce entailment trees. We show how our approach has advantages over previous baselines, where the retrieved premises and generated explanations are more accurate.

In future work, we plan to improve the generation module by leveraging the structure of the entailment tree instead of relying purely on the encoder-decoder models. This idea could potentially fix the issues with "invalid entailment steps" and "repetition", which account for 73% of entailment step errors. We also plan to understand how explanations can be generated in the case of a false hypothesis, where we would expect the model to build a conclusion explaining why a statement is incorrect. It could help users verify false claims and understand the meaning behind their incorrectness.

A Appendix

A.1 Experiment Details

The IRGR-generator used the `T5-large`[1] model from HuggingFace library. The best models were chosen according to the best "Overrall All-Correct" metric on the validation set. During training, we used the following hyper parameters: learning rate: $3 \cdot 10^{-5}$, epochs: 15, training batch size: 4, validation batch size: 4, max number of input tokens: 512, max number of output tokens: 256, warm-up steps: 0, weight decay: 0.

The IRGR-retriever module uses the version `all-mpnet-base-v2`[2] from the Sentence-Transformers library. During training, we used the following hyper parameters: learning rate: $5 \cdot 10^{-5}$, epochs: 10, training batch size: 32, validation batch size: 32, loss function: *cosine similarity loss*, warm-up steps: 0, weight decay: 0.

A.2 Entailment Tree Evaluation Metrics Details

The alignment algorithm between the nodes from gold and predicted entailment trees can be roughly described as follows:

1. For each intermediate node $e_i \in \mathcal{E}$ and $e_j \in \mathcal{E}^*$, compute the set of leaf sentences in which the nodes are ancestors.
2. Align each intermediate node e_i to the first golden node e_j for which the Jaccard similarity of their respective set of associated leaf sentences is maximum. If any node e_i is associated with no gold nodes e_j (Jaccard similarity is zero), then e_i is aligned to a blank node (no conclusion).

Given the list of aligned nodes, the metrics "Intermediates (F1, All-Correct)" compute the similarity between two generated intermediate steps using $BLEURT$ (Sellam et al., 2020), a learned evaluation metric based on BERT. We use the BLEURT-Large-512 model to compute textual similarity scores. The prediction between intermediate nodes is considered correct if $BLEURT(e_i, e_j) > 0.28$ (this threshold was originally picked by Dalvi et al. (2021) using a subset of 300 manually labeled pairs).

A.3 Generator Input and Output Examples

The generation is done in multiple steps. Below are the input and output examples for a tree with two entailment steps (T=1 and T=2). In the following example, only the golden premises are used, which is how the generator is trained. At test time this format is extended to use the retrieved premises instead.

INPUT T=1: "`hypothesis: notebook paper can be recycled many times; sent1: recyclable means a material can be recycled / reused many times sent2: paper is recyclable sent3: notebook paper is a kind of paper;`"

OUTPUT T=1: "`sent2 & sent3 -> int1: notebook paper is recyclable;`"

INPUT T=2: "`hypothesis: notebook paper can be recycled many times; sent1: recyclable means a material can be recycled / reused many times; sent2 & sent3 -> int1: notebook paper is recyclable;`"

OUTPUT T=2: "`int1 & sent1 -> hypothesis;`"

Note that the input for **T=2** removed the premises used in the previous entailment step, i.e. "`sent2`" and "`sent3`", and added the generated entailment step from **T=1** to the end of the input.

Abstract

Individuals, educational institutions, and businesses are prolific at generating instructional video content such as "how-to" and tutorial guides. While significant progress has been made in basic video understanding tasks, identifying procedural intent within these instructional videos is a challenging and important task that remains unexplored but essential to video summarization, search, and recommendations. This paper introduces the problem of instructional intent identification and extraction from software instructional livestreams. We construct and present a new multimodal dataset consisting of software instructional livestreams and containing manual annotations for both detailed and abstract procedural intent that enable training and evaluation of joint video and text understanding models. We then introduce a multimodal cascaded cross-attention model to efficiently combine the weaker and noisier video signal with the more discriminative text signal. Our experiments show that our proposed model brings significant gains compared to strong baselines, including large-scale pretrained multimodal models. Our analysis further identifies that the task benefits from spatial as well as motion features extracted from videos, and provides insight on how the video signal is preferentially used for intent discovery. We also show that current models struggle to comprehend the nature of abstract intents, revealing important gaps in multimodal understanding and paving the way for future work.[1]

1 Introduction

Instructional videos have become increasingly ubiquitous as users generate diverse "how-to", DIY, and tutorial videos. A Pew Research Center 2018 survey of U.S. adult YouTube users (Smith et al., 2018) found that over half of surveyed users use video content to learn how to do things they had not done before. These instructional videos convey both abstract and specific intent for physical tasks such as cooking where e.g., an abstract culinary intent is "let's bring out the flavor" and a detailed intent is "add a pinch of nutmeg". Thus, a key task in instructional video understanding is to discover both abstract and detailed intents. By discovering these intents, we can enable or improve important tasks such as semantic indexing of videos (Kofler et al., 2016), knowledge graph creation for video search and recommendations (Pei et al., 2011; Kofler et al., 2014), intent highlighting, and video summarization (Nalla et al., 2020).

An important domain with rich and complex examples of both abstract and detailed intent types are software training videos for creative tasks such as making photo or video effects. These types of software training videos have been shown to be effective for enhanced learning (Van der Meij, 2017) and are also considered a valuable resource in the era of online learning (Meyer, 2015). Existing video and phrase datasets such as HowTo100M (Miech et al., 2019) cover a wide variety of tutorials for visual tasks demonstrated by humans; however, software-based instructional videos are not a part of such corpora. Hence, in this paper, we present a new corpus of software-instructional videos containing instructional intents, which are derived from Behance Livestreams demonstrating the use of Adobe Photoshop software.[2]

Intent detection has been well-studied in dialogue systems (Wu et al., 2020), but is less explored for instructional video content, especially emerging livestream content (Fraser et al., 2019). While rich in complex procedural instruction and intent, the interactive and social nature of livestreams poses unique challenges. Analyzing language features alone will provide only limited information about

the actual instructional intent and the tools and commands used. For instance, the phrase “flipping the canvas” in “Are you flipping the canvas?” indicates a tool intent, but a closer look at the video clip reveals that it is in fact part of livestream chit-chat and does not take place on-screen. Incorporating both language and video modalities can enhance intent extraction of such ambiguous intents. Hence, in this paper, we present a new joint language-video intent discovery task and a multimodal dataset consisting of: Behance Intent Discovery, and the Behance Livestream video and transcript corpus that intents are found in. We frame intent discovery as a sequence labelling task; each sample in the intent discovery dataset contains a transcribed phrase annotated with token-level tags for abstract and detailed intents, and an associated video timestamp. Our goal is to predict the instructional intents from the transcript in each video.

To perform intent discovery within instructional videos, we propose a multimodal cascaded cross-attention model to predict both the abstract and detailed procedural intents that are present. Additionally, we use late fusion of multimodal embeddings to prevent the visual modality from overwhelming the textual signal, and show significant improvements on the video-based intent detection task using unimodal and multimodal pretrained models like HERO (Li et al., 2020). Further, we compare the performance of various video feature extractors as well as different video lengths, and present benchmark results on the proposed dataset. We find that discovery of tool intents benefit from sparsely-sampled spatial features while creative intents benefit from densely-sampled motion features. In the absence of motion features, most models struggle to utilize the video signal for identification of creative intents. Further, visualization of cross-attention and visual gate modules in the late fusion model suggests strong and meaningful interaction between the two modalities. Our contributions are:

- We introduce and explore the novel task of video-based multimodal intent discovery, and present an annotated dataset consisting of nearly 20K sentences from 66 livestreams for extraction of procedural intents from instructional videos.
- We release a large corpus of software-based instructional videos (2,049 sessions, 3,128 hours total), accompanied by timestamped transcripts, that can be used for pretraining multimodal models.
- We propose the multimodal cascaded cross-attention model and demonstrate the effectiveness of late fusion of multimodal embeddings in this task.
- We present empirical results for the proposed dataset using unimodal and multimodal approaches, and provide insights from analysis of modelling choices for future research.

2 Related Work

Intent discovery has been widely studied in the context of dialog modelling and generation wherein it has been framed as a binary or multi-class classification problem. The SNIPS (Coucke et al., 2018) and ATIS (Dahl et al., 1994) datasets consist of concise single-sentence texts containing intents with constrained vocabulary and attributes. Several works have explored intent classification of internet posts in the context of racial/radicalized intent (Agarwal and Sureka, 2016), purchase intents (Gupta et al., 2014; Wang et al., 2015), discussion forums (Chen et al., 2013) and health queries (Cai et al., 2017). Vedula et al. (2019) propose open intent discovery with unconstrained vocabulary as a sequence tagging task. Using this framework, we present our dataset on instructional intents.

In the wake of exploding visual social-media content, several image-based multi-modal intent datasets have been previously proposed. Kiela et al. (2020); Aprosio et al. (2020) study abusive language and hateful intent in memes and photo posts. Jia et al. (2021) explore intent categories derived from social psychology and use object localization to integrate visual context in task models. Instagram posts are another interesting source for multimodal content (Chen and Hsieh, 2020; Kruk et al., 2019). We introduce the task of video-based multimodal intent discovery, which has been unexplored.

Several tasks have been proposed in the recent years to probe joint video and text understanding. Lei et al. (2018); Kim et al. (2017); Maharaj et al. (2017); Jang et al. (2017); Tapaswi et al. (2016) and Yi et al. (2020) introduce video-based question answering datasets created from various sources of creative visual content, i.e. movies, TV shows, GIFs etc. Lei et al. (2020b) and Lei et al. (2020a) propose the task of video-moment retrieval and next frame prediction respectively, based on query subtitles, while Liu et al. (2020) present the multimodal version of natural language inference. Early

models for performing these tasks involve combining pretrained image representations from sparsely sampled videos, and text encodings from pretrained encoders (Devlin et al., 2019; Liu et al., 2019) in architectures for modelling global-local interactions (Zhu and Yang, 2020; Yang et al., 2020), temporal localization (Kim et al., 2019; Zhang et al., 2020), graph-based reasoning (Huang et al., 2020) etc. More recent attempts involve pretraining models on large video+text corpora (Miech et al., 2019) and finetuning on downstream tasks (Sun et al., 2019; Cho et al., 2021; Tang et al., 2021; Lei et al., 2021; Luo et al., 2020). We explore late-fusion of video and text embeddings (Yu et al., 2020) for intent detection in pretrained and non-pretrained multimodal settings.

3 Problem Setting: Intent Discovery from Livestreams

In our setting, each video captures a Behance livestream in which an instructor demonstrates the steps needed to accomplish various image editing or compositing tasks. We specifically focus on rich creative instructional or tutorial livestreams that teach photo editing and compositing methods using an image application such as Photoshop, which consists of over 1,300 basic menu commands and subcommands, tool icons, panels, and galleries.

The livestream itself consists of a screencast of the instructor's application software, a smaller video window showing the instructor, a time-coded transcript of the dialog within the session, and a tool timeline which is a time-coded log of the specific application tools used during the livestream. Given the transcript of an instructional video, the video itself, and optional Tool Usage (TU) information from the tool timeline, Fig. 1 shows examples of the Creative Intents (CI, shown at 01:36.16 and 01:37:09) and Tool Intents (TI, shown at 01:36:21, 01:36:29 and 01:36:46) we seek to discover. Further, we wish to combine joint language and video knowledge to gain improvements in detecting candidate intents that are false positives such as the text at 01:37:09, which is only a parenthetical comment by the instructor.

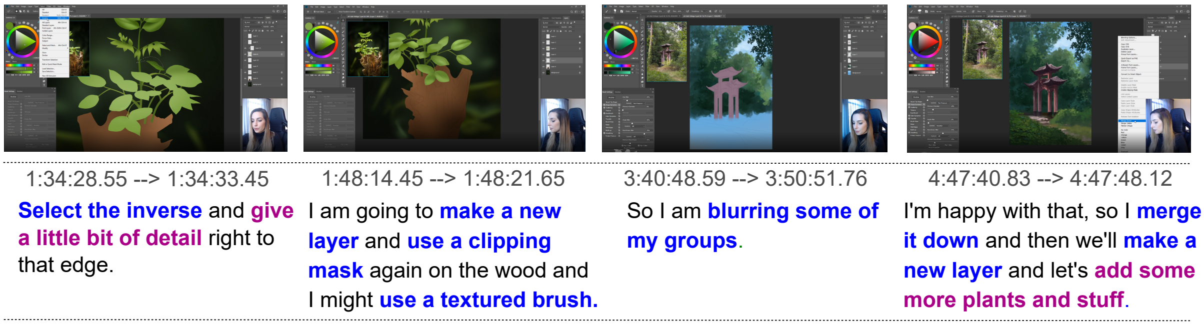
#Distinct tools in corpus	282

Table 1: Statistics of the Behance Livestreams corpus for sessions and transcribed phrases.

4 Behance Datasets

Dataset Collection. We first obtain 2,049 videos along with their transcripts and tool timelines from the Behance platform. The tool timeline contains a time-stamped record of the tools used in the software during the tutorial. The average session length is 80 minutes with an average of 587 transcribed phrases per session (see Table 1). The tool timelines contain 282 distinct tools with varying frequencies; `Color`, `Select Brush`, `Select Layer` are some of the most frequent ones. The instructional software-based domain of this dataset is significantly different from existing large corpora drawn from YouTube instructional videos (Miech et al., 2019) and TV content (Lei et al., 2018, 2020b), but it is an important learning resource. Hence, we include the unlabelled **Behance Livestreams** corpus as an addition to the pool of video+text corpora that can be leveraged for continued pretraining of multimodal models and finetuning on downstream tasks relevant to software-based livestream videos.

In order to prepare the intent discovery dataset,



1:34:28.55 --> 1:34:33.45
Select the inverse and give a little bit of detail right to that edge.

1:48:14.45 --> 1:48:21.65
I am going to make a new layer and use a clipping mask again on the wood and I might use a textured brush.

3:40:48.59 --> 3:50:51.76
So I am blurring some of my groups.

4:47:40.83 --> 4:47:48.12
I'm happy with that, so I merge it down and then we'll make a new layer and let's add some more plants and stuff.

Figure 3: Examples of tool intent (blue) and creative intents (magenta) from the Behance Intent Discovery dataset.

Attribute	Training/Validation/Test

#Tool intents	3,478/414/825
#Creative intents	674/106/189
#Livestream videos	54/6/6

Table 2: Statistics of the various splits in the Behance Intent Discovery dataset.

we extract candidate intent phrases from the transcripts of the Behance Livestream corpus. Following Vedula et al. (2019), we define an intent as a text phrase consisting of: (i) an *action* word or phrase, which constitutes a definite task, goal or activity and (ii) an *object*, which represents those words or phrases that the action is going to act or operate upon. We generate the dependency graph of sentences, and extract the VERB node as *action* and the direct object of the VERB as the *object*, along with all other children nodes (see example in Fig. 2).[3] Through manual analysis, we identified two major categories of meaningful intent: tool and creative. *Tool intents* are low-level intents that can be typically mapped to a single tool in the software. *Creative intents* are abstract intents used to describe a high-level creative goal that consist of a complex set of actions or tool intents. For instance, in Fig. 3, "make a new layer" is a tool intent that can be mapped to the tool `Create Layer`, while "add more plants and stuff" is a creative intent. All other intents in the corpus, predominantly from chit-chat statements, are irrelevant to our task. We frame the task of intent discovery as a sequence-tagging problem and tag the intent phrases within each sentence with IOB (inside, outside, beginning) span annotations for the two classes: tool and creative intents. Each sample consists of a timestamped sentence with span annotations and the video session it is extracted from.

Top Unique Verbs in Action	
Tool Intents	merge, select, add, use, paint, duplicate, make, delete, painting, do, flip, decrease, using, lower, figure, erase
Creative Intents	add, make, give, change, paint, create, convey, fill, animate, use, have
Top Unique Nouns in Object	
Tool Intents	layer, color, mask, things, brush, shapes, selection, tool, shift, opacity, canvas, adjustment, stuff, thing
Creative Intents	colors, details, light, shadow, texture, contrast, highlights, vibe, depth, sense, bounce, feeling, elements

Table 3: Unique words in the intent discovery dataset.

Based on the above defined framework, we collect manual annotations of tool and creative intents. We employed two annotators using the UpWork crowdsourcing platform and trained them for identifying intents from Behance videos and transcripts.[4] They were instructed to annotate spans for tool and creative intents within each sentence. The annotations were created using the open-source Doccano annotation tool.[5] In total, we collected annotations for 20,011 sentences from 66 Behance videos. The resulting **Behance Intent Discovery** dataset contains 13,989/2,105/3,917 samples in training, development and test splits respectively (see statistics in Table 2). We do not specify the duration of video clips for each sentence in the annotation. In our experiments, we explore varying clip duration and empirically choose a window of 10 seconds (±5s) around the sentence's timestamp (see Sec. 8.2). The full video sessions are released for further research.

Dataset Analysis. We analyzed tool and creative intents to find the most frequent, unique verbs and nouns mentioned in the phrases. While there are action verbs which are distinctly tool-specific, such as merge, select, and duplicate, there are many verbs

---

[3] https://spacy.io/api/dependencyparser

[4] https://www.upwork.com/. Annotators were compensated per the $20/hr rate.

[5] https://github.com/doccano/doccano

which are common to both tool and creative intents such as add, make, and paint. Hence, the task model needs to learn the difference between tool and creative intents to be able to classify intents with similar action verbs into the correct categories. Further, we examined the unique nouns occurring in the intents and found lesser overlap between the two intent classes. Creative intents contain abstract and subjective visual concepts which pose a unique and interesting challenge to multimodal models. See Appendix for probing experiments.

5 Methods for Intent Discovery

Intuitively, as in a lot of instructional sources like text books, the text or audio serves as the primary mode of high-level information transfer, while the video/image signal provides detailed context or demonstration. Thus, we start our exploration using text models, which are built on two pretrained models: RoBERTa (Liu et al., 2019) and GPT2 (Radford et al., 2019). There are several previous works focusing on a limited set of intents (Xia et al., 2018), and thus, treat the problem of intent discovery as a classification problem. In our case, given the vast possibilities of potential intents in our sources, we cast the problem as a span detection problem, and design our models accordingly.

5.1 Unimodal Sequence Labelling

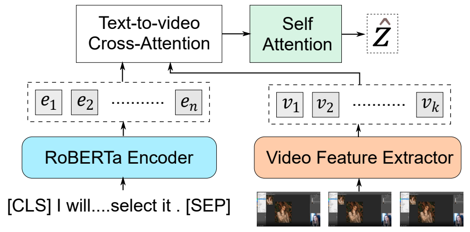
Our text models are designed similar to Named-Entity-Recognition models with a pretrained embedding layer and a sequence classification layer on top. Each phrase in the transcript is annotated separately in the intent dataset, leading to efficient processing. Although it is possible to process longer spans of text, in our annotations, we found out that each sentence usually gives enough information to extract the intent inside it, and extra context (neighboring sentences) does not significantly help the decision. We denote an input sentence as $X = [x_0, ..., x_N]$ with N as the length of the input sentence, $Z = [z_0, ..., z_N]$ denotes the common IOB tags of two classes: creative intent and tool intent. Using text encoder f_{enc}, we extract text encodings E i.e. $E = f_{enc}(X)$. The encodings are then passed to the classifier layer for computing tag probabilities i.e. $\hat{Z} = softmax(W_c * E + b_c)$ where W_c, b_c are parameters of the classifier layer. The model is trained end-to-end using cross-entropy loss i.e. $\mathcal{L}_\theta = -\frac{1}{N}\sum_{i=1}^{N} z_i log(\hat{z}_i)$, where θ represents parameters of the entire model.

5.2 Multimodal Sequence Labelling: Naïve Fusion

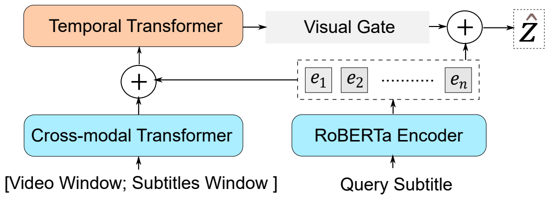
Seeking to leverage the video information, in our first attempt, we tried a simple feature fusion between the text signal and the video signal in the sequence labelling framework. We add a cross-attention layer on top of the pretrained text encoder in this naïve joint video-text model and use the output of the cross-attention layer for sequence label classification. Let's denote the video features as V. Our model (see Fig. 4 (a)) is described as follows:

$$\hat{Z} = softmax(W_c * f_{self}(f_{cross}(E, V)) + b_c)$$

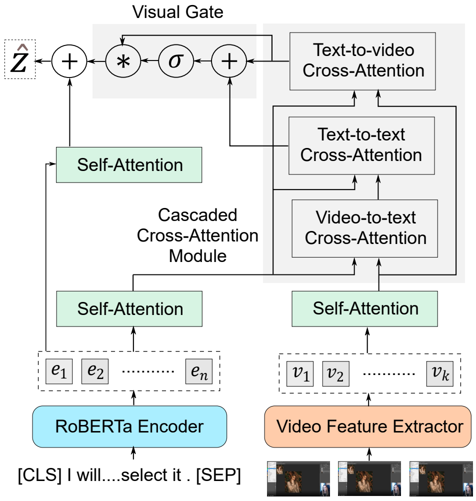
where E, f_{self} and f_{cross} are text encodings, self-attention and cross-attention layers respectively. This naïve fusion model, however, does not provide any significant improvements compared to text-only baselines (see Sec. 7). Analysis of the results revealed that the textual features dominate the final decision, especially in the creative intent classes. To understand this behaviour, we performed a pilot task in which a human annotator looks through the video segments and tries to guess the intent without any transcript or audio. Our annotator found the task very difficult, and only possible after watching a very long context window, which partially explains the low performance of this model. The video signal is much more ambiguous than the text signal, and when presented with two sources where one is vastly less informative than the other, the model learns to rely only on the text, leading to no improvement compared to the text-only baseline. Joining two sources of features with different predictive utility is difficult. Given the fact that the video feature extractor is not trained on similar data, the video feature might not contain enough information for a direct intent detection task. Fortunately, our pilot task also reveals an important insight, i.e., the video signal *is good at identifying whether an intent is present or not.* Many intent candidates identified by the text models are not creative or tool intents, but are chitchat utterances from the instructor interacting with the audience. In these cases, we posit that the inactivity presented in the video signal is a strong indication that a creative/tool intent does not occur at the current time window. Using this idea, we propose a cascaded model with deeper interaction between video and text signal.



(a) Multimodal RoBERTa: Naive Fusion



(b) HERO for Sequence Labelling



(c) Multimodal RoBERTa: Late Fusion with Cascaded Cross-Attention

Figure 4: Demonstration of multimodal models: (a) Multimodal RoBERTa with naïve fusion of video and text encodings; (b) Adaptation of HERO for sequence labelling with late fusion, see (c) for visual gate; (c) Multimodal RoBERTa with cascaded cross-attention and late fusion; σ, $+$, $*$ represent sigmoid function, concatenation and matrix multiplication respectively.

5.3 Cascaded Cross-Attention & Late Fusion

Using the intuition that the text signal would provide candidates for the vision model, which is subsequently used for filtering out the cases without intent, we design the cascade cross-attention model as follows: First, we extract the set of contextualized embeddings E from the text encoder f_{enc} and transform it through two self-attention layers to create a two-stream architecture (see Fig. 4). In the first stream, the text encodings are processed through a single-layer of self-attention to produce E_1. In the second stream, the output from self-attention i.e. E_2, is combined with video embeddings through a cascaded cross-attention module. Let $V = [v_1, v_2, ..., v_k]$ be the input sequence of video embeddings. The cascaded module contains three cross-attention layers: video-to-text $f_{v2t}(\cdot)$, text-to-video $f_{t2v}(\cdot)$ and text-to-text cross-attention $f_{t2t}(\cdot)$, with outputs computed as:

$$
\begin{aligned}
S_1 &= f_{v2t}(W_m V + b_m, E_2) \\
S_2 &= f_{t2t}(E_2, S_1) \\
S_3 &= f_{t2i}(E_{s2}, W_m V + b_m)
\end{aligned}
$$

where W_m, b_m are the parameters of a linear layer for transforming video embeddings. Next, the outputs from cross-attention layers are concatenated, linearly mapped and transformed into 0-1 values using a sigmoid, to generate the visual gate (see Fig. 4 (c)). Finally, the output from cross-attention layer is multiplied with this gate, i.e.

$$
\begin{aligned}
S_{gate} &= sigmoid(W_g[S_2; S_3] + b_g) \\
S_{clf} &= [S_{gate} * S_3; E_{s1}]
\end{aligned}
$$

The visual gate is dynamically computed using the contextualized video representations and is used to trim the video signal to the relevant bits. This helps in regulating the contribution of the two modalities for the final prediction as per the input. The concatenation represents the late-fusion of text-only embeddings and video-contextualized text embeddings. This merged representation is then sent to the classifier layer for classification i.e. $\hat{Z} = softmax(W_c * S_{clf} + b_c)$.

5.4 Sequence Labelling with Joint Video-Text Pretraining

In order to leverage joint modelling of video and text modalities through large-scale pretraining, we adapt the pretrained HERO (Li et al., 2020) and ClipBERT (Lei et al., 2021) for sequence tagging.

HERO. For each sample in video-based intent detection, we send the video clip and the corresponding subtitle for context as well as query, as input to HERO. V_{cross} represents the cross-contextualized frame embeddings from the Cross-modal Transformer module, which is then concatenated with query embeddings W^q_{emb} before being sent to the Temporal Transformer f_{temp} in HERO

Type	Model	Video Embeddings	Tool Intents			Creative Intents

for global contextualization. Thus, the output is:

$$S_{temp} = f_{temp}([V^{cross}; W^{q}_{emb}])$$
$$S_{out} = S_{temp}[N_v : (N_v + N_t), :]$$

where N_v and N_t are the number of frames and tokens in video and query respectively. The output of f_{temp} is masked to select the representations pertaining to the query only. In the naïve fusion setting, S_{out} is then sent to the classifier layer.

ClipBERT. Similarly, the output S_{out} from the Cross-modal Transformer f_{cross} in ClipBERT is masked and sent to the classifier layer for prediction i.e. $S_{out} = f_{cross}([V; W^{q}_{emb}])[: N_t, :]$.

Late Fusion. We integrate the late fusion approach into HERO and ClipBERT as follows:

$$S_{gate} = sigmoid(W_g * S_{out} + b_g)$$
$$S_{clf} = [S_{gate} * S_{out}; W^{q}_{emb}]$$

where the visual gate is computed as in Sec. 5.3 (see Fig. 4) and S_{clf} is sent to the classifier layer.

6 Experiments

Evaluation. Since the transcribed phrases in Behance Livestreams are the result of an automatic speech recognition (ASR) system, the exact span match metrics might be distorted by ASR errors. Hence, we use a more lenient 75% partial match-based Precision/Recall/F-score metric i.e., if there is more than 75% overlap between the ground truth and predicted span, we consider it as a match.

Video Representations. We experiment with 3D ResNext-101 (Xie et al., 2017) (fps=6), SlowFast (Feichtenhofer et al., 2019) (clip length=2s) and 2D ResNet-152 (He et al., 2016) (clip length=2s) following preprocessing steps in Li et al. (2020).

Models. We use the RoBERTa$_{LARGE}$ (Liu et al., 2019) models for the unimodal experiments, as well as the multimodal experiments that are based on unimodal pretrained models. We use the pretrained HERO (Li et al., 2020) and ClipBERT (Lei et al., 2021) in the remaining experiments; their language encoders are initialized from pretrained RoBERTa$_{BASE}$ and BERT$_{BASE}$ (Devlin et al., 2019) models. Each model is trained end-to-end using fully-supervised training and is subjected to grid-search based hyper-parameter optimization. The best checkpoints are selected based on overall F-Score. See Appendix for bounds.

7 Results

In this section, we discuss results from various models on the Behance Intent Discovery dataset (see Table 4).

The text baselines. Starting with the text-only baselines, we see the best performance from the RoBERTa models, i.e., 58% and 27% partial match F-scores on the tool and creative intents, respectively (rows 2 and 3 in Table 4). Notably, the tool intent predictor is biased with high recall but low precision performance i.e. it retains too many candidates, many of which do not correspond to any intents. These results also demonstrate that large pretrained language models like RoBERTa and GPT2 struggle to comprehend the abstract ideas represented in creative intents.

The Naïve Fusion models. The Naïve Fusion approach with pretrained RoBERTa yields upto 2% improvement over the text-only baselines. In some cases, such as the 3D ResNext representations, this approach degrades the performance, especially in the harder creative intent set. We attribute this to the difference in informativeness between the text and the video signal, as discussed in Sec. 5.2.

The Late Fusion models. With the Late Fusion approach, we see significant improvements in almost all cases. Compared to the corresponding Naïve Fusion models, Late Fusion models mainly improve precision for tool intents. This result supports our hypothesis that the video signal is most useful as a gate to filter out non-intent candidates from the textual signal. The SlowFast representations prove especially beneficial for creative intents, as seen in row 9 in Table 4. With the use of multimodal pretrained models like HERO and ClipBERT, we observe significant improvements in prediction of tool intents and smaller improvements for creative intents with a simple adaptation of the prediction head for sequence labelling (see Sec. 5.4). HERO uses video representations from pretrained encoders while ClipBERT operates on raw videos; both approaches work well with the software-based video domain yielding upto 3% and 1% improvement on tool intents respectively (rows 10, 12 in Table 4) over the unimodal RoBERTa models. Larger improvements are seen from further augmenting these models with late fusion i.e. 1% improvement on tool intents (rows 11, 12 in Table 4). The late fusion RoBERTa model using SlowFast features (row 9 in Table 4) performs best for creative intents, with 3% improvement over the text-only baseline.

We see similar trends from experiments on the validation set of the Behance Intent Discovery dataset. See results in Appendix.

8 Analysis & Discussion

In this section, we perform qualitative analysis of the late fusion approach and examine the effect of video clip length. We also discuss a semi-automated approach to creating annotations for intent extraction and use the data in combination with manual annotations for improved results. See Appendix for more analyses.

8.1 Qualitative Analysis

In order to understand the inner workings of the late fusion architecture, we examine the cross-attention and visual gate modules of the RoBERTa+Late Fusion model trained with 2D ResNet features. Each row of the attention score matrix $M \in R^{n \times f}$ (for n tokens and f video segments) in text-to-video cross-attention module corresponds to the temporal attention over video clips (represented by a sequence of ResNet feature vectors) for a given token. We plot this score matrix for the 12 attention heads in the RoBERTa model in Figures 5(a) and 7(a). The attention heads are activated in the intent region suggesting a strong interaction between two modalities in important segments of the video.

To understand how the video signal helps the prediction, we first plot the mean and standard deviation of visual gate values (S_{gate}) for each token in Figures 5(b) and 7(b). Results show that the visual gate preferentially relies on the video modality for tokens outside the intent span. Furthermore, in Fig. 6, we show example phrases where the text

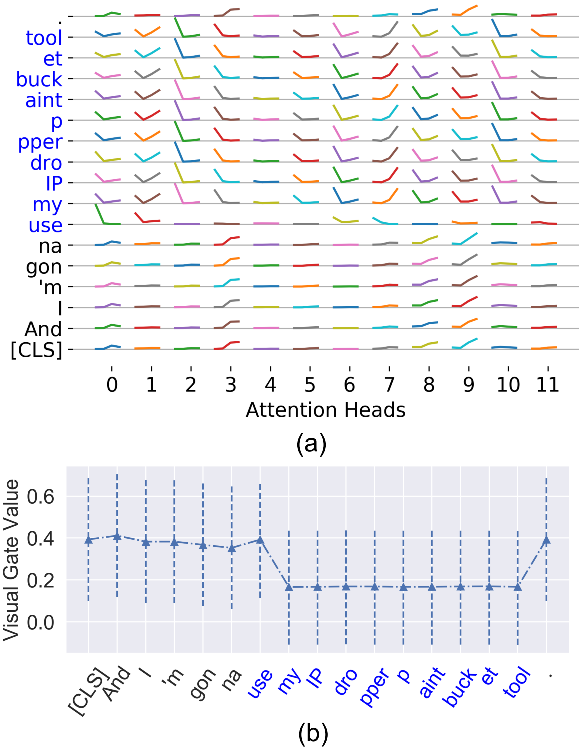

Figure 5: Visualization of (a) temporal attention over video segments from 12 attention heads and, (b) mean ± SD of visual gate values for each token (blue for intent span), using the RoBERTa+Late Fusion model.

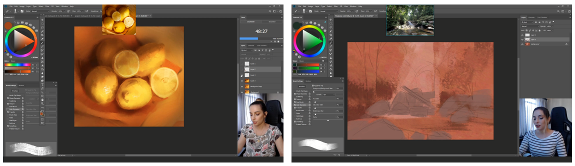
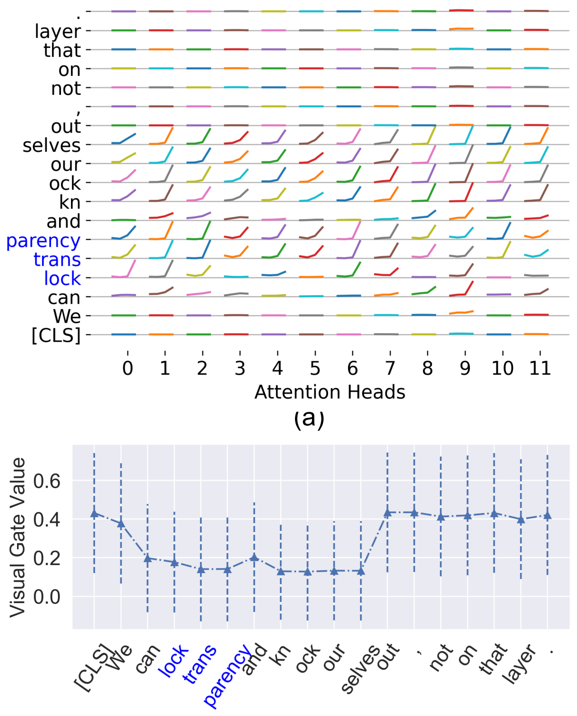


I am wondering if I should actually *paint it* in or I should try..

My workflows *change a lot of noise*..

Figure 6: Wrong predictions (red) from unimodal RoBERTa which are solved by adding video signal.



(a)

(b)

Figure 7: Visualization of (a) temporal attention over video segments from twelve attention heads and (b) mean and standard deviations for the distribution of visual gate values for each token, using the best RoBERTa+Late Fusion model.

only model classifies wrongly as intent while the joint model does not. The phrases themselves appear to be intent but the lack of action in the visual frame indicates that these are chit-chat interactions. Both analyses support our hypothesis that the late fusion model utilizes the video signal to filter intent candidates and improve precision.

8.2 Video Clip Length

As we discuss in Sec. 4, the video clip durations for the tool and creative intents are not specified. We observe that the intended action can span anywhere between 1 second to several minutes. Longer clip lengths are relevant for many creative intents like "make it into something fantasy", "add the arm to this little guy", etc. Hence, we experiment with various clip lengths (10, 20 and 60 secs), but find that larger clip lengths do not lead to further improvements. In fact, with 60 second clips the performance of RoBERTa+Late Fusion model drops below the performance of text-only RoBERTa. This issue could be alleviated with long-range video understanding models (Sener et al., 2020).

8.3 Semi-automated Intent Annotations

Since manual annotation of procedural intents is time-intensive and expensive, we explore a semi-automatic pipeline for creation of intent annotations. The Behance Livestreams corpus contains tool timelines for each livestream, which enumerates the tools used within the software at different points in the livestream. We compute the tf-idf scores for co-occurrence of 896, 287 action-object phrases (from dependency parses of sentences) and corresponding tools in the tool timelines, in order to find the phrases that are frequently used for describing particular tool actions, such as "grab the smudge tool". After filtering the phrases for those with high tf-idf scores, the pool of intent candidates was further cleaned manually, resulting in a final set of 3,697 tool intent candidates. Using this pool of candidates, 24,300 phrases from the Behance Livestreams corpus were identified as tool intent samples. Since it is not straightforward to extract creative intents using similar methods, we first identified key phrases for creative intents from the set of action-object phrases with high term frequency. We then subjected it to manual cleaning (two annotators per sample; κ=0.986) followed by embedding similarity to select creative intents (see Appendix for full pipeline). Using this method, we recovered 7,135 phrases containing creative intents.

We use these semi-automatically collected annotations as additional training data in our experiments with Late Fusion RoBERTa models. Since the manually annotated Behance Intent Discovery dataset is skewed towards negative samples i.e. $<25\%$ samples contain intent, we balance the training data by adding 5,000 samples (containing tool or creative intents) from the aforementioned semi-automatically annoated dataset to it. With this balanced data, we see upto 2% improvement in the Late Fusion RoBERTa models. See Appendix.

9 Conclusion

In this paper, we explore the novel task of video-based multimodal intent discovery. We present the unlabelled Behance Livestream corpus consisting of instructional videos for software tools, and the Behance Intent Discovery dataset annotated with tool and creative intents. We propose a late-fusion approach for integration of the video signal with the text signal in a controlled manner for this task, and show significant improvements with unimodal and multimodal pretrained models.

10 Acknowledgements

We would like to thank Tracy King for her detailed feedback and Hailin Jin for making the Behance transcript available. We would also like to thank the reviewers for their useful feedback. This work was partially done while AM was interning at Adobe Research and later extended at UNC, where it was supported by ARO Award W911NF2110220 and DARPA KAIROS Grant FA8750-19-2-1004. 11 Ethics/Broader Impacts

From an ethics standpoint, we provide a detailed overview of the methods used to create the Behance Livestreams corpus and Behance Intent Discovery dataset in Sec. 4 and more details in the Appendix. We also provide some analyses of the data in Table 3. All of the language data consists of simple English sentences. The dataset comprises livestreamed video tutorials by users of the Behance platform. Behance users grant full usage rights of their content and agree to not hold copyright claims on content in the livestreams videos or transcripts. This content is being made available for free distribution for academic research purposes only and does not allow for redistribution. Aside from the name of the instructor in each video (which is public information), real names of livestream session users or other identifying information does not appear in any of the transcripts. We provide full descriptions of the models used in this paper in Sec. 5. Detailed hyperparameters and bounds for hyperparameter search are included in the Appendix.

Video-based intent discovery serves to enhance the information exploration experience of users on any video-based platform. Since we focus on extracting procedural intent relevant to the goal of the video and in the software domain, we do not anticipate this technology to cause any harm to users, or have any unintended consequences.

A Dataset

For the semi-automatically created annotations described in Sec. 8.3, we empirically select a window of 10 seconds for computing the scores and retain intent phrases with a term frequency of 5 or higher in the corpus and tf-idf scores of 0.3 or higher with one or more tools. See the full semi-automated pipeline of dataset creation in Fig. 8.
