Contributions Based on a comprehensive typology of English quantifiers, we build a dataset of 100,000 synthetic images and 999,446 unique questions to these images. This is roughly the same size as or a little bigger than CLEVR (Johnson et al., 2017). Our questions are on average longer than previous datasets. We evaluate three baselines from Johnson et al. (2017), a text-only baseline based on BERT (Devlin et al., 2019), and MAC (Hudson and Manning, 2018) on QLEVR and analyze performance across quantifier types.

2 Related Work

Visual Question Answering Challenge Datasets Several synthetic challenge datasets for visual question answering exist: Andreas et al. (2016) presents SHAPES, a predecessor to CLEVR and QLEVR, relying also on synthetic constellations of colored geometric shapes and template-driven question generation. Pezzelle and Fernández (2019) create a similar dataset to probe visual question answering models for knowledge of adjectival semantics. A portion of the visual question answering dataset (Agrawal et al., 2017) contains synthetic cartoon imagery. Sampat et al. (2021) present an extension of CLEVR that probes for hypothetical reasoning of the form: *If someone removed three triangles from this image, how many would be left?* Malinowski and Fritz (2014) combined natural images with synthetic, template-driven question generation. Finally, Parfenova et al. (2021) recently created a dataset of three-image scenes to probe two-step reasoning.

Synthetic visual question answering datasets have several advantages over ones based on real images and questions that tend to suffer from selection biases (Liu et al., 2021), but of course they are limited in what can be induced from them. They are therefore mostly useful for probing the limitations of visual question answering architectures and off-the-shelf models. Showing results only on synthetic data is often seen as a weakness in the literature (Hassantabar, 2018), but synthetic data is useful for diagnosing the errors of visual question answering systems, in our case highlighting the challenges posed by quantifiers.

Quantifiers Quantifiers have been largely ignored in the NLP community. Question-answering datasets have been developed for numerical reasoning in English (Dua et al., 2019), and some have identified quantifier words as important sources of errors for textual entailment systems (Joshi et al., 2020). Fang and Lou (2021) recently focused on the two quantifier words *part* and *whole* in an error analysis for named entity recognition.

3 QLEVR

We design a challenge dataset called QLEVR (for Quantificational Language and Elementary Visual Reasoning) that requires more complex reasoning than previous visual question-answering datasets. QLEVR is designed to probe the visual reasoning capabilities of visual question-answering systems with respect to quantificational language, including detecting members of sets, quantifying sets, and reasoning about the relationships between sets. To this end, we automatically construct *scene graphs* (Johnson et al., 2015) and use these to generate synthetic images with ground-truth locations, attributes, and relationships for planes and objects. Each scene graph can be queried in a number of way, and we design query templates to render natural language questions involving complex reasoning about sets of such planes and objects. We describe each of these steps in detail:

Image Generation All images in QLEVR are images of objects organized in a particular way on a desk-like surface. Figure 2 shows how the images are generated. We construct a scene graph for a two-dimensional image containing areas and ob-

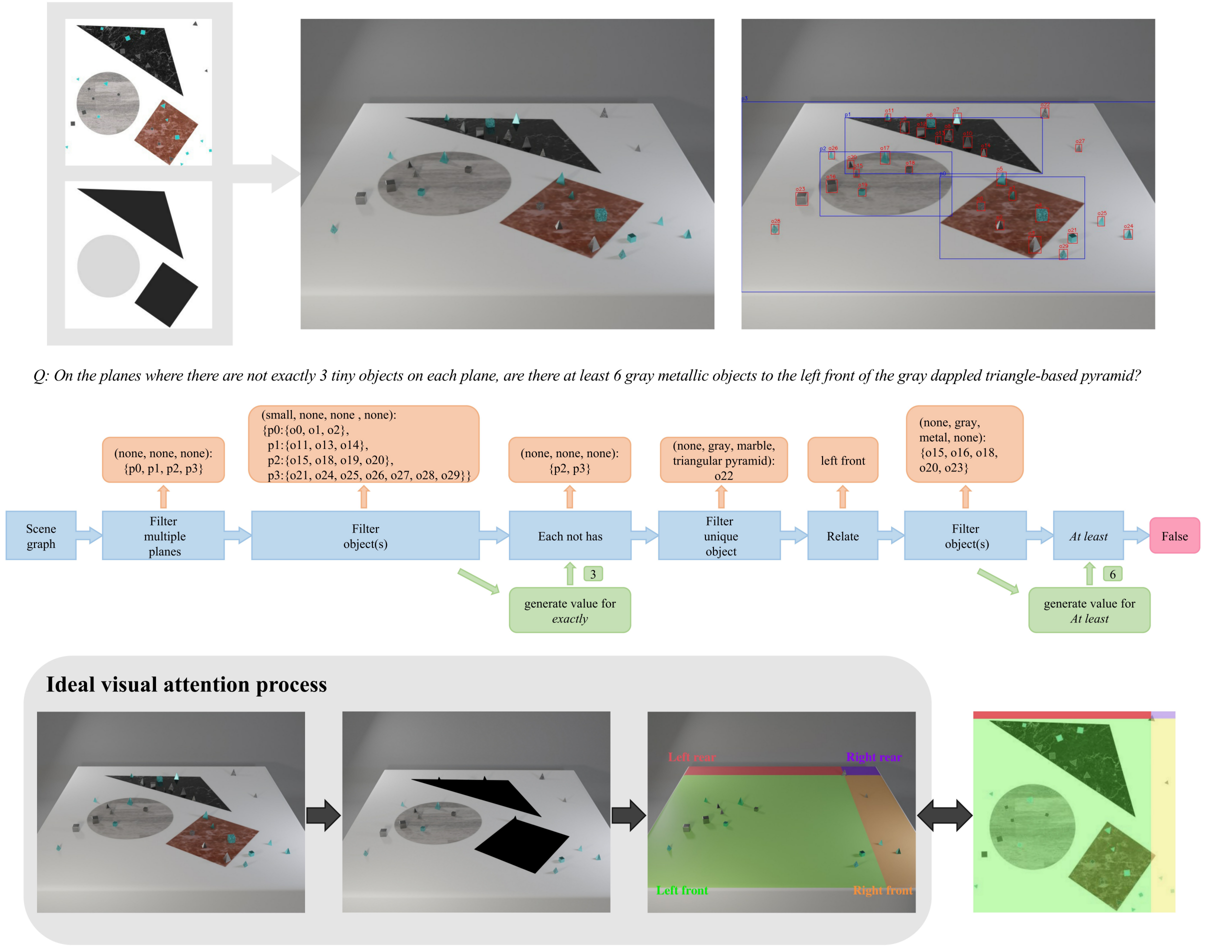

Figure 2: An overview of our dataset. **Top:** Image generation process and bounding box information. The top two-dimensional image records the scene graph, and the bottom gray-scale color map records roughness of each plane. **Center:** Examples of questions and their associated operators. **Bottom:** Ideal visual attention as the operator proceeds.

jects of different sizes and shapes. Scene graphs determine the ground-truth locations, bounding boxes, attributes and relationships for the planes and objects in the form of a graph or tree structure. Nodes are planes or objects annotated with attributes, each of which is connected to its spatially related nodes.

Each image contains one to five areas or geometric planes. These can be either triangular, rectangular or circular. The rest of the desk area we refer to as the white non-geometric plane. Geometric planes come in two materials (marble and wood), three colors (black, gray, and brown), and random sizes.

Each geometric plane contains one to ten (1–10) objects, with different sizes and shapes, and the non-geometric plane contains one to twelve (1–12) objects, with different sizes and shapes. Object come in seven shapes (cone, cube, cylinder, pentahedron, sphere, triangular prism, and tetrahedron), two absolute sizes (small and large), five materials (metal, rubber, leather, marble, and wood), and eight colors (blue, brown, cyan, gray, green, purple, red and yellow). The spatial relationships between planes and objects include *front*, *back*, *left* and *right*, as well as *right front*, *right rear*, *left front* and *left rear*.

We render three-dimensional images of the scene graphs with Blender (Community, 2018). Light settings and three preset camera positions were chosen at random, after validating that all objects were at least partially visible. Since the depth of the scene can affect the judgment of the spatial relationship in the three-dimensional image, the desk boundary is always visible as a reference for determining the depth of the scene. Minimum distances between objects and planes were kept to reduce the ambiguity of spatial relationships. See Appendix B for more details.

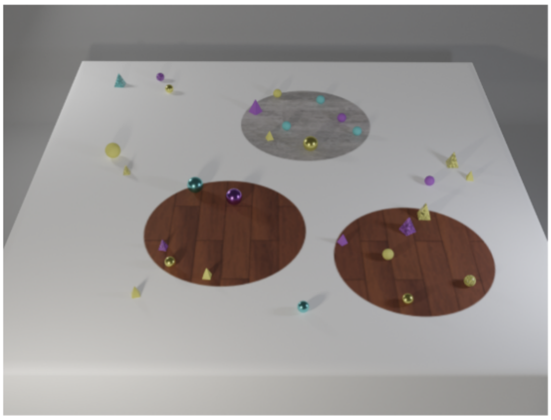
$$\mathit{all}_P(A,B) \Leftrightarrow A \subseteq B$$
$$\mathit{some}_P(A,B) \Leftrightarrow A \cap B \neq \emptyset$$
$$\mathit{no}_P(A,B) \Leftrightarrow A \cap B = \emptyset$$
$$\mathit{some\ but\ not\ all}_P(A,B) \Leftrightarrow A \cap B \neq \emptyset \neq A - B$$
$$\mathit{most}_P(A,B) \Leftrightarrow |A \cap B| > |A - B|$$
$$\mathit{more}_P(A,B) \Leftrightarrow |A| > |B|$$
$$\mathit{fewer}_P(A,B) \Leftrightarrow |A| < |B|$$
$$\mathit{equal}_P(A,B) \Leftrightarrow |A| = |B|$$
$$\mathit{exactly}\ \mathrm{n}_P(A,B) \Leftrightarrow |A| = \mathrm{n}\ \ \&\ \ A \subseteq B$$
$$\mathit{between}\ \mathrm{n}_1\ \mathit{and}\ \mathrm{n}_{2P}(A,B) \Leftrightarrow \mathrm{n}_1 \leq |A \cap B| \leq \mathrm{n}_2$$
$$\mathit{at\ most}\ \mathrm{n}_P(A,B) \Leftrightarrow |A \cap B| \leq \mathrm{n}$$
$$\mathit{more\ than}\ \mathrm{n}_P(A,B) \Leftrightarrow |A \cap B| > \mathrm{n}$$
$$\mathit{all\ but\ at\ least}\ \mathrm{n}_P(A,B) \Leftrightarrow |A - B| \geq \mathrm{n}$$
$$\mathit{at\ least}\ \frac{\mathrm{n}}{\mathrm{d}}\ \mathit{of\ the}_P(A,B) \Leftrightarrow \frac{|A \cap B|}{|A|} \geq \frac{\mathrm{n}}{\mathrm{d}}$$
$$\mathit{fewer\ than}\ \frac{\mathrm{n}}{\mathrm{d}}\ \mathit{of\ the}_P(A,B) \Leftrightarrow \frac{|A \cap B|}{|A|} < \frac{\mathrm{n}}{\mathrm{d}}$$
$$\mathit{no\ objects\ except}\ C_P(A,B) \Leftrightarrow A \cap B = \{c\}$$
$$\mathit{every\ object\ except}\ C_P(A,B) \Leftrightarrow A - B = \{c\}$$

Table 1: Quantifiers included in QLEVR. P denotes the set of all the objects on the target plane(s). A or B denotes a subset of P with the same attributes. $|A|$ is the cardinality of the set A.

Question Generation Quantifiers are often said to be among the most important and complex constructs of natural languages (Hintikka, 1977; Barwise and Cooper, 1981). As pointed out by by Bernardi and Pezzelle (2021), visual question-answering models need to master a wide range of linguistic phenomena, including negation, entailment, mutual exclusivity and so on. We add (generalized) quantifiers to this list and design a dataset to probe the ability of visual question-answering systems to handle quantifiers in combination with other linguistic phenomena. See Table 1 for the quantifiers included in QLEVR.

See Figure 2 for how questions are formed from scene graphs. In brief, we think of the scene graph as a model and evaluate various combinations of logical operators, including quantifiers, on the scene graph, i.e., performing a model checking (Clarke et al., 2009) procedure.

We introduce the notion of a *question family*, defined by a set of operators and a scene graph. Each question family is associated with 2–6 text templates and a set of synonyms (for shapes, colors, materials, and spatial relationships). The templates were written by hand. Each question template can thus generate multiple questions. For example, the template



Question: On the geometric plane whose color is different from that of other planes, all yellow spheres but 1 are smaller than fewer than 1 or more than 3 spheres; is it right?
Answer: True
Quantifiers: exactly N (all but N ¬), between (¬ between)

Figure 3: Example image-question pair

(5) Are there exactly `<OC>` `<Z>` `<C>` `<M>` `<S><os>` on the `<PC>` `<PM>` `<PS>` plane`<ps>`?

where upper-cased variables refer to words, and lower-cased variables to suffixes, can generate the question

(6) Are there exactly 2 small red rubber objects on the black wooden triangular plane?

We construct a total of 671 different templates, which are randomly constructed from 11 plane templates and 61 object templates. Our questions involve attribute recognition, counting, comparing numbers or attributes, spatial relationships, and understanding of quantifiers. Figure 2 shows the operators built in the given question family, such as *filter*, *relate*, and *at least*.

Note that many (generalized) quantifiers are related by entailment. The question

(7) Are all the red cubes on the marble planes?

is, assuming an image with red cubes, semantically equivalent to

(8) Are no red cubes not on the marble planes?

The semantics of combinations of quantifiers can be derived using *squares of opposition* (Westerståhl, 2012). We exploit these entailment relations in creating QLEVR.

Split	Images	Questions	Unique questions	Overlap with train	Overlap with val
Train	70,000	700,000	699,498	-	-
Val	15,000	150,000	149,968	199 ǀ 148	-
Test	15,000	150,000	149,980	194 ǀ 145	49 ǀ 39
Total	100,000	1,000,000	999,446	-	-

Table 2: Statistics for our dataset. In each *Overlap* column, the number on the right represents the number of overlapping questions with the same answer.

Some combinations of key values may generate unreasonable questions. We therefore define restrictions for each question family to avoid the generation of *pragmatically odd*, *ill-posed* or *trivial* questions. For example, the phrase *on the marble plane where there are at least 5 red objects* would be pragmatically odd if there was only one marble plane in the scene. The sentence

(9) On the marble plane, do between 2 and 4 cubes have the same size as most of the cylinders?

is ill-posed if there are no cubes on the marble plane. Finally, questions like *Are there more red cubes than cubes?* are trivial, because they can be answered in the absence of the image. The assertion is always true. The opposite would, for example, be true of

(10) On the plane with 8 balls, are there exactly 3 balls?

We present many examples of images and questions in the Appendix, but see also Figure 3 for a complex question with embedded quantifiers.

Dataset Characteristics QLEVR has 1,000,000 questions for 100,000 images, with each image having 10 questions generated from different question families. The dataset is balanced, preventing answering in the absence of the images. In addition, the answer distribution across question families is constrained by acceptance-rejection sampling. The data is randomly split, with 70% for training data, 15% for validation and 15% for heldout evaluation data (the test set). As shown in figure 4, QLEVR includes 27 different quantifiers. Questions contain 1–4 quantifiers. Table 2 shows the diversity and complexity of the QLEVR questions. Almost all the questions are unique. Very few questions appear in several splits, and always in conjunction with new scene graphs.

4 Experiments

In this section, we evaluate the performance of baselines and near-state-of-the-art models on the QLEVR dataset and perform detailed error analysis. We ran each each method three times with different random seeds and report the test set performance for the model that achieved the best performance on the validation data.

4.1 Models

We first present three purely text-based models, Q-type (Antol et al., 2015), LSTM (Hochreiter and Schmidhuber, 1997) and BERT (Devlin et al., 2019), to evaluate the level of visual reasoning needed for QLEVR. If these perform at random (0.5), we have successfully constructed a dataset in which questions cannot be answered in the absence of images. It is important to include text-only models as baselines in visual question answering to control for spurious correlations (Gat et al., 2020). We shall see in §4.2 that while Q-type performs at chance level, the BERT and LSTM baselines are able to pick up on some spurious correlations. We also evaluate two standard visual question answering architectures, one based on a combination of convolutional and recurrent neural networks (CNN+LSTM), and one attention-based architecture (Hudson and Manning, 2018). The latter performs best on the counting and number comparison tasks in the CLEVR dataset (Johnson et al., 2017) compared with other approaches, such as Bottom-Up-Attention and Top-Down (UpDn) (Anderson et al., 2018), Question-Conditioned Graph (QCG) (Norcliffe-Brown et al., 2018), Bilinear Attention Network (BAN) (Kim et al., 2018), Relation Network (RN) (Santoro et al., 2017) and Recurrent Aggregation of Multimodal Embeddings Network (RAMEN) (Shrestha et al., 2019). We describe each system in detail:

- **Q-type (Antol et al., 2015):** Similar to the "per Q-type prior" method in (Antol et al., 2015), this baseline predicts the most popular answer for each question type.
- **LSTM (Hochreiter and Schmidhuber, 1997):** Question words are embedded as 300-dimensional vector sand fed into an LSTM network. The last hidden state representation is passed into a multi-layer perceptron (MLP) to predict the final answer. All experiments use

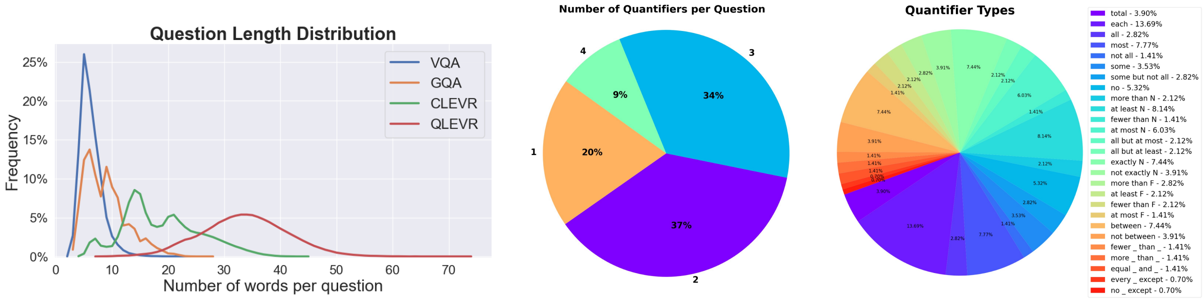


Figure 4: Statistics for our dataset. **Left:** Question length distribution for different popular VQA datasets; most of the QLEVR questions have 30 to 40 words, which is longer than other datasets. **Middle:** Distribution of the number of quantifiers in QLEVR questions. **Right:** Frequency distribution of quantifiers in QLEVR, where N stands for *Number* and F stands for *Fraction*; *each*, *total*, *no*, *at most N*, *at least N*, *exactly N*, *between*, *not between*, and *not exactly N* are also used in the plane templates, so they appear more frequently. For the quantifiers in the texts of the same question family, we consider each quantifier in square of opposition $\{Q, Q\neg, \neg Q, Q^d\}$ as quantifier Q.

a bi-directional LSTM with 512 units in the hidden layer per direction.

- **BERT (Devlin et al., 2019):** We fine-tune BERT (Devlin et al., 2019) augmented with a sentence-level classification head: The special classification token `[CLS]` is passed to a feed-forward layer and used for sentence class prediction.

- **CNN+LSTM:** The images are encoded using a convolutional neural network and questions as the last hidden state produced by an LSTM network. The convolutional network uses spatial features produced by ResNet-101 (He et al., 2015) pre-trained on ImageNet (Deng et al., 2009). We resize all images to 448x448, and use the final average pooling layer to extracts features of the shape (1, 14, 14, 2048). The question and image features are concatenated and passed to a multi-layered perceptron to predict the final answer.

- **MAC (Hudson and Manning, 2018):** The MAC network is a recurrent attention network, which uses a Memory, Attention, and Composition (MAC) cell in each attention-based reasoning step to learn to perform iterative reasoning processes. MAC learns compositional reasoning directly from the questions and the images in an end-to-end approach. The word vectors have a dimension of 300 and are initialized randomly using a standard uniform distribution. The images are resized to 448x448, and 2048-dimensional features are produced by ResNet-101. The model uses a hidden state size of 512 and a length of 12 MAC cells.

4.2 Analysis by Quantifier Type

Table 3 shows the results of the five methods described in §4.1 on the test set of QLEVR. We make the following observations.

1. Q-type exhibits performance levels around 50% for every quantifier type, showing that the answer distribution of QLEVR is uniform.

2. Text-only LSTM and BERT achieve an average accuracies of 64.6% and 65.8%, respectively. These results suggest that even if the answers of each question family are distributed uniformly, there may still be spurious correlations: Objects with more detailed attribute descriptions may be more likely to get a *false* answer. For example, the question *"Are there more than 3 small blue cubes on the black planes?"* is more likely to get a *false* answer than *"Are there more than 3 blue objects on the black planes?"*).

3. The CNN+LSTM architecture performs better than LSTM on 24 out of 27 quantifier types and on par with BERT; MAC performs better than LSTM on 26 out of 27 quantifier types, better than BERT on 24 out of 27 quantifier types and better than CNN+LSTM on 23 out of 27 quantifier types. In general, however, CNN+LSTM and MAC do not improve much over text-only LSTM and BERT, suggesting that the image features extracted by ResNet-101 contain little information relevant to counting in complex scenes.

4. Accuracies for quantifiers that present thresholds (e.g., *more than N, at least F, etc.*) are

	Q-type	LSTM	BERT	CNN+LSTM	MAC
each	50.0	63.9	65.4	65.3	66.2
total	50.0	63.4	64.7	65.1	66.3
all	50.0	59.5	60.5	60.7	61.3
most	50.0	61.7	63.6	63.5	64.0
not all	50.0	60.7	62.2	61.3	62.6
no	50.0	63.9	64.6	64.6	65.3
some	50.0	58.2	58.9	58.7	58.7
some but not all	50.0	59.9	61.5	61.0	61.7
exactly N	50.0	62.6	63.8	63.5	64.0
not exactly N	50.0	64.9	65.7	65.9	66.7
between	50.0	65.2	66.6	67.0	67.9
not between	50.0	64.4	65.8	66.0	66.0
all but at most	50.0	66.9	68.8	68.2	68.9
all but at least	50.1	62.7	63.7	63.3	65.2
more than N	50.0	65.5	67.3	67.1	67.2

more _ than _	50.0	68.0	69.4	69.1	68.7
fewer _ than _	50.0	68.9	69.9	68.8	69.0
equal _ and _	50.0	61.0	62.2	62.0	62.2
Overall	**50.0**	**64.6**	**65.8**	**65.9**	**66.5**

Table 3: Test set results of baselines and state-of-the-art models on the QLEVR dataset. Models are evaluated for both overall accuracy and accuracy per quantifier type. In quantifier type, *N* stands for *Number* and *F* stands for *Fraction*. Refer to Figure 4 for the number distribution of quantifiers.

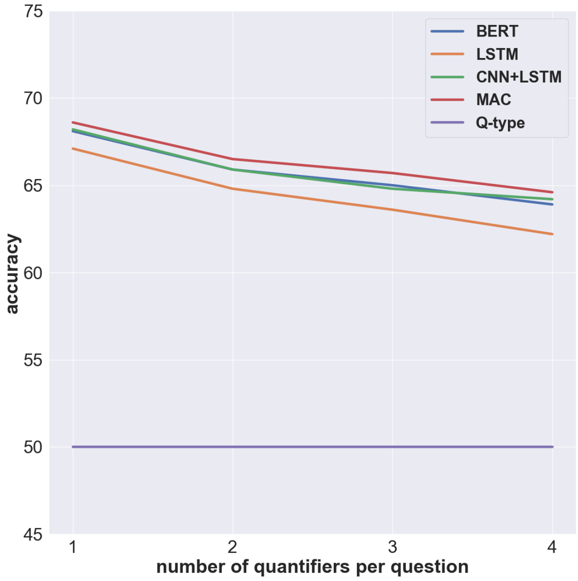

Figure 5: The effect of different number of quantifiers in questions on the accuracy of the answers. Figure 4 shows the distribution of the number of quantifiers in each QLEVR question.

higher than for quantifiers that require a number of objects to match exact values (e.g., *exactly N*).

5. Quantifiers without numerals (e.g., *all, most, not all, some* and *some but not all*) lead to lower accuracies than other quantifiers, showing that reasoning with these quantifiers is harder. This highlights the need for including such quantifiers in challenge datasets to push advancements in visual question answering.

4.3 Analysis

Number of Quantifiers in Questions Figure 5 shows how accuracy varies as the number of quantifiers in the questions increases. The more quantifiers in a question, the more complex its semantics will be.

Number of Planes We also test the visual reasoning abilities of these models by examining error across the number of planes involved in answering the question. Appendix A introduces all the plane templates in our question families. We use the plane template *"on the <PC> <PM> <PS> plane<ps>"* for our analysis, because this template has no influence of quantifiers or spatial relationships in targeting planes. QLEVR test set has 13,612 questions with this plane template. The left graph in Figure 6 shows how the accuracy varies with the increase in the number of target planes that need to be reasoned with. Among the 13,612 questions, 10,288 of them involve a single plane and 3,324 of them involve multiple planes. We can see that for language-only models Q-type, BERT and LSTM, the number of target planes does not significantly affect the accuracy. However, for CNN+LSTM and MAC, questions involving just a single plane are harder to answer than those involving multiple planes. This is because for visual models, planes enable disambiguation and thereby reduce the required reasoning. The right graph in Figure 6 compares accuracy on questions that do not refer to specific planes (*no attribute*), to questions that refer to specific planes (*with attributes*). Among the 13,612 questions, 1,340 questions do not refer to specific planes, whereas 12,272 do. This distinction has little impact on the perfor-

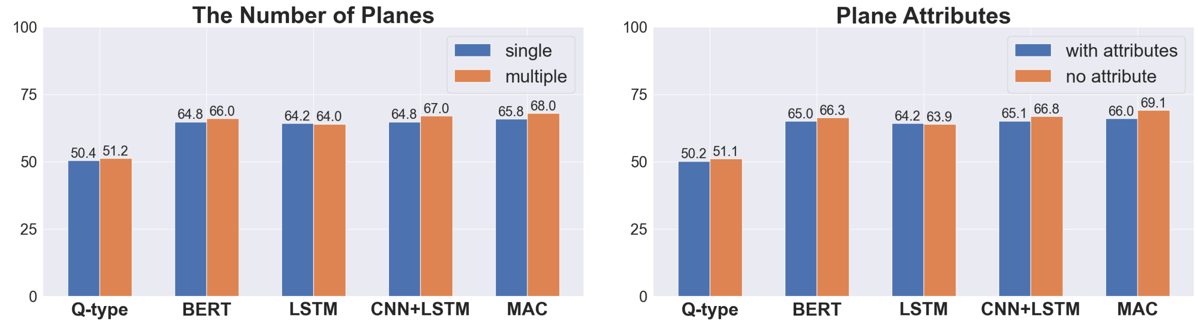

Figure 6: The results of questions contains *"on the <PC> <PM> <PS> plane<ps>"*. **Left**: The effect of different number of target planes on the accuracy of the answers; *single* means that the reasoning process basically only needs to consider one plane in the image, while *multiple* means that multiple planes need to be considered. **Right**: The effect of whether the plane has attribute description on the accuracy of the answer; *no attribute ("on the planes")* means that the reasoning process does not need to consider planes in the image and see the image as a whole, while *with attributes ("e.g., on the wooden plane")* means that specific plane(s) needs to be considered.

mance of our text-only models. For CNN+LSTM and MAC, however, examples in the *no attribute* class exhibit higher accuracies than those in *with attributes*. This, again, shows performance is better when less visual reasoning is required.

5 Discussion

In this paper, we proposed a dataset, which we call QLEVR – for Quantificational Language and Elementary Visual Reasoning. QLEVR probes the ability of visual question-answering systems to reason with quantificational language, including 27 different quantifiers and combinations thereof. It requires complex visual reasoning to locate the specific planes and understand various relationships between objects. We increase the semantic diversity of the questions by negating quantifiers and by using different templates for semantically equivalent questions. Our analysis highlights how challenging such examples are to visual question-answering systems, and we hope that QLEVR will help guide push research horizons in visual question-answering by zooming in on the challenges posed by quantificational language.

One fundamental limitation is that QLEVR only considers English questions, and we plan to extent it to other, typologically unrelated languages. Besides, QLEVR can easily be extended by adding new question families, and questions whose answers are not limited to true or false, e.g., with numbers or attributes as answer types. In addition to the three-dimensional images, we also provide two-dimensional images and scene graphs recording the ground-truth information (see Figure 2). It is also possible to generate questions about 2D images by simply modifying our question families. We hope these two datasets can be used for transfer learning for visual question answering in the future.

Supplementary Material

A Question Templates

As described in Section 3, QLEVR question templates are composed of 11 plane templates and 61 object templates randomly paired. In this section we detail the difference between these templates.

Plane Templates. The role of the plane templates is to raise our question for specific planes (regions) in the image through some restrictions (attributes, spatial relations and explicitly restricted quantifier phrases). Basically, the plane templates can generate questions with following types:

- On the white non-geometric planes.
- On the geometric plane with a different shape (color/material) from other planes.
- On the black planes to the left rear of the circular plane.
- On the planes where there are at least 3 red cubes on each plane.
- On the quadrilateral plane where there are at most 5 blue balls.
- On the brown planes where there are between 1 and 4 triangular prisms on each plane.
- On the triangular plane where there is exactly 1 leathery object.
- On the plane where there are not 2 to 4 triangular prisms.
- On the gray planes where there are not exactly 3 items on each plane.
- On the marble plane where there are not any wooden cones.
- On the wooden plane where there is a total of 7 small rubber objects.

To avoid pragmatically odd questions, we ensure that the number of planes obtained by the plane templates with restrictions of spatial relations and explicitly restricted quantifier phrases (e.g. *On the brown planes behind the gray plane*, or *On the brown plane where there are exactly 3 balls*) is less than the number of planes obtained by the templates without these restrictions (e.g. *On the brown planes*) for the same scene graph.

Object Templates. We can use the *operators* representation of the questions templates to analyze model performance on the following forms of reasoning:

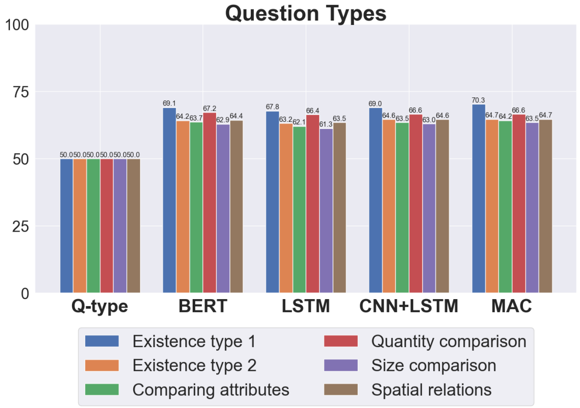

Figure 7: Accuracy per question type on the QLEVR dataset.

- **Existence type 1:** Questions ask whether a certain type of quantifier-restricted object exists on one or some specific planes (*e.g.*, *"Whether all the cyan cubes* [Plane Template]*?"*).

- **Existence type 2:** Questions ask whether a certain type of quantifier-restricted object exists in a certain direction of a unique object (*e.g.*, "[Plane Template]*, are there fewer than 3 balls behind the cyan cube?"*).

- **Comparing attributes:** Questions ask whether two types of quantifier-restricted objects have the same value for some attributes (*e.g.*, "[Plane Template]*, is there any small cylinders that has the same color as most leathery tetrahedrons?"*).

- **Quantity comparison:** Questions compare the size of two sets of objects (*e.g.*, "[Plane Template]*, are there more big blocks than rubber balls?"*).

- **Size comparison:** Questions ask which of two quantifier-restricted objects has a larger size (*e.g.*, "[Plane Template]*, some red cones are larger than some but not all of the metal cones; is it right?"*).

- **Spatial relations:** Questions involves the spatial relationship between objects (*e.g.*, "[Plane Template]*, are there more big blocks in front of the yellow cylinder than rubber balls to the left rear of the small block?"*).

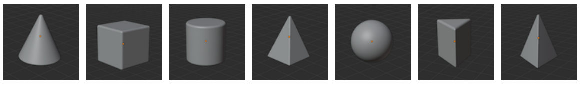
Figure 7 shows the performance on above question types. As can be seen, MAC outperforms other models on most question types. The only exception is: on quantity comparison task, BERT performs slightly better than MAC, showing that MAC has better reasoning ability in complex scenes. Questions of *Existence type 1* obtain better results than *Existence type 2* for vision-language model CNN+LSTM and MAC, suggesting that the position relationship between object and plane is easier to be inferred by the models than the spatial relationship between the objects. For questions of *Quantity comparison*, MAC and CNN+LSTM performs on par with LSTM, suggesting that the image features extracted by ResNet-101 may contain little information related to counting in complex scenes.

B 3D Modeling and Design

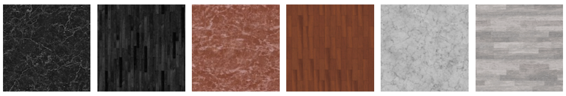
Figure 8 shows the materials and object models made through Blender (Community, 2018), as well as the performance of different colors on these materials. Two different materials of leather, marble, and wood were made respectively to further enrich the diversity of objects in the dataset. The images of the plane materials were made by modifying the images under CC0 1.0 Universal.[1] Note that after the overall scene rendering, objects of certain materials will produce different effects according to the color and material of the plane in contact with them, as well as the position of the camera and lights.

C Example Images and Questions

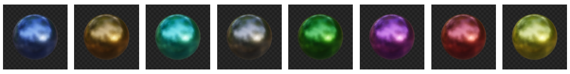
The remaining pages show some images and questions generated by the combination of our different plane templates and object templates. Each question is annotated with its answer and contained quantifiers, where *N* stands for *Number*, *F* stands for *Fraction* and *O* stands for *Object*.



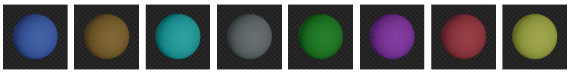
(a) object shapes



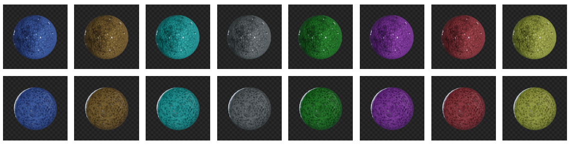
(b) materials and colors of the planes



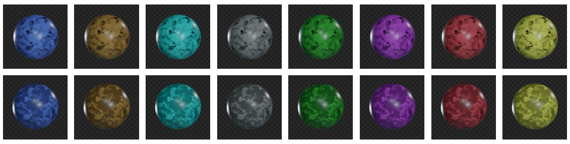
(c) metal



(d) rubber



(e) leather



(f) marble

(g) wood

Figure 8: From left to right, the object shapes in (**a**) are cone, cube, cylinder, pentahedron, sphere, triangular prism, and tetrahedron; the plane attributes in (**b**) are black marble, black wood, brown marble, brown wood, gray marble and gray wood; the colors in (**c**) ~(**g**) are blue, brown, cyan, gray, green, purple, red and yellow.

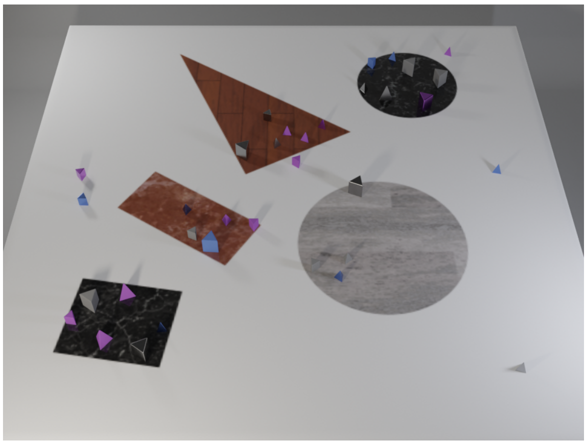
Question: Whether all the large brown objects are on the white plane?
Answer: False
Quantifiers: all

Question: Some large rubber tetrahedron is not on the gray marble plane; is it right?
Answer: True
Quantifiers: not all (some ¬)

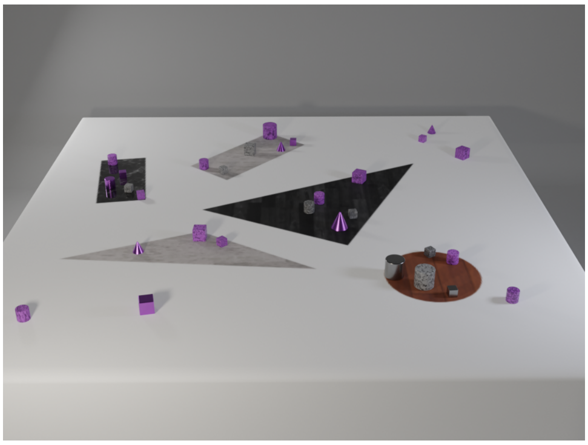
Question: It is not the case that all the big blue rubbery spheres are not on the gray rectangular plane; is it right?
Answer: False
Quantifiers: some (¬ all ¬)



Question: It's not the case that some large purple metallic triangular prism is on the planes where there are 9 items in total; is it right?
Answer: True
Quantifiers: total, no (¬ some)

Question: Whether some but not all of the large purple rubber objects are on the marble planes where there are 4 blue objects in total?
Answer: False
Quantifiers: total, some but not all

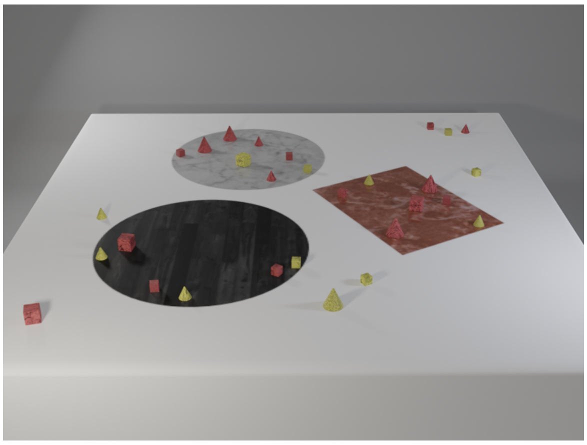
Question: Are there at most 3 small blue objects on the dappled planes where there are 5 big triangular prisms in total?
Answer: True
Quantifiers: total, at most N



Question: All the big wooden blocks but at least 2 are not on the planes where there are exactly 2 cylinders on each plane; is it right?
Answer: True
Quantifiers: each, exactly N, at least N (all but at least N ¬)

Question: It is not the case that at most 2 wood cylinders are on the quadrilateral plane where there are exactly 2 purple wood cylinders; is it right?
Answer: False
Quantifiers: each, exactly N, more than N (¬ at most N)

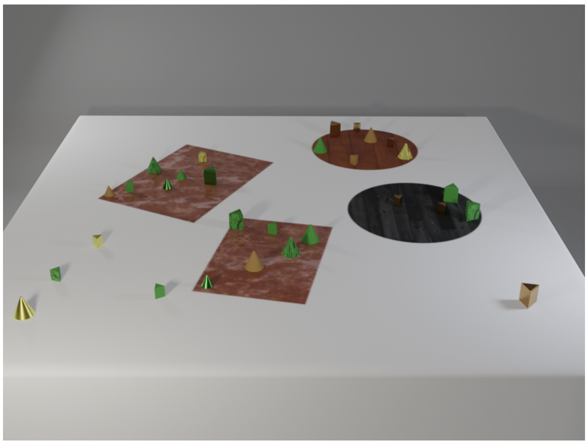
Question: Are there fewer than 2 small purple dappled cylinders on the planes where there is exactly 1 purple block on each plane?
Answer: True
Quantifiers: each, exactly N, fewer than N



Question: All the tiny red wood objects but 1 are not on the non-white plane where the shape of the plane is different from that of other planes; is it right?
Answer: True
Quantifiers: exactly N (all but N ¬)

Question: Are there between 1 and 3 small red leathery cubes on the circular plane to the left rear of the brown quadrilateral plane?
Answer: True
Quantifiers: between

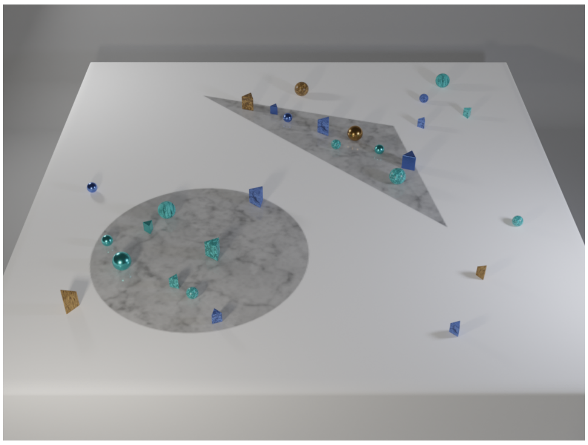
Question: All the red leather objects but at most 3 are on the geometric plane where the material of the plane is different from that of other planes; is it right?
Answer: False
Quantifiers: all but at most N



Question: More than two thirds of the green objects are on the brown marble plane to the left front of the black wood plane; is it right?
Answer: False
Quantifiers: more than F

Question: Are most brown metallic objects on the geometric plane on the right side of the brown wooden round plane?
Answer: False
Quantifiers: most

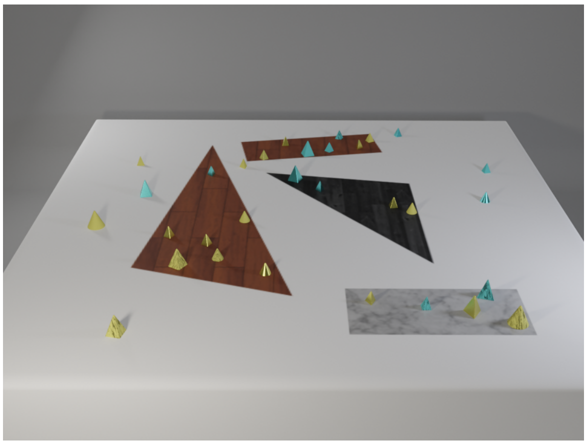
Question: It is not the case that fewer than 4 brown metallic triangular prisms are not on the non-white plane where the color of the plane is different from that of other planes; is it right?
Answer: True
Quantifiers: all but at least N (¬ fewer than N ¬)



Question: On the gray marble plane where there are between 3 and 5 tiny cyan objects, is there any wooden triangular prism that has the same size as most metallic objects?
Answer: False
Quantifiers: between, some (any), most

Question: On the gray plane where there are between 1 and 4 cyan triangular prisms, 2 to 5 cyan items are the same material as most small items; is it right?
Answer: True
Quantifiers: between, between, most

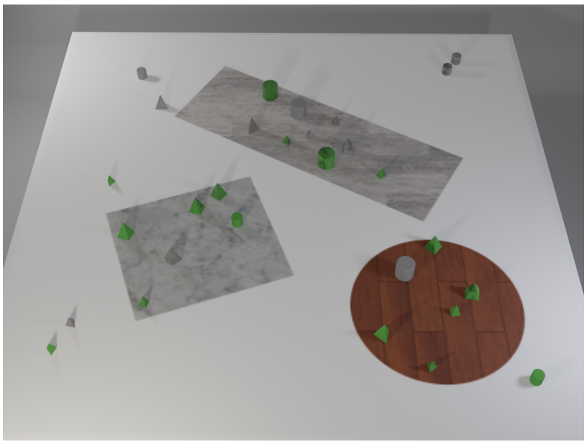
Question: On the planes where there are between 3 and 6 cyan items on each plane, are there exactly 3 small triangular prisms that have the same color as most small metallic spheres?
Answer: True
Quantifiers: each, between, exactly N, most



Question: Fewer than three-quarters of the small yellow objects are on the wood three-sided plane where there are not any large metallic square-based pyramids; is it right?
Answer: True
Quantifiers: no (¬ any), fewer than F

Question: It is not the case that fewer than 11/15 of the metallic items are on the planes where there are 0 tiny rubbery tetrahedrons on each plane; is it right?
Answer: True
Quantifiers: each, no (0), at least F (¬ fewer than F)

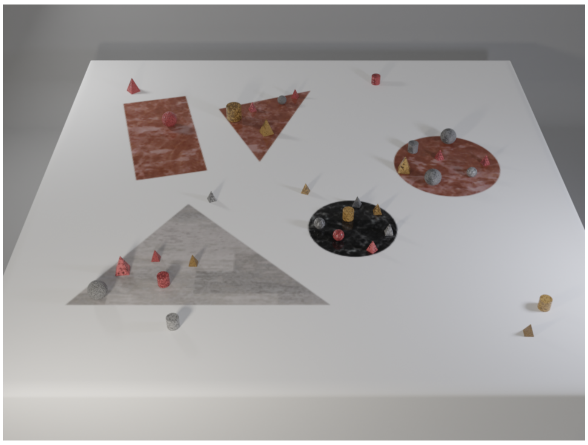
Question: At most 7/8 of the yellow rubber triangular pyramids are on the planes where there is no big yellow wooden cone on each plane; is it right?
Answer: False
Quantifiers: each, no, at most F



Question: On the gray quadrilateral plane where there are not between 1 and 3 small gray items, are all the large items but at most 1 the same color as most leather items?
Answer: True
Quantifiers: not between, all but at most N, most

Question: On the plane where there are not between 2 and 4 green leather objects, fewer than a half of the gray cylinders are the same size as most gray rubbery objects; is it right?
Answer: False
Quantifiers: not between, fewer than F, most

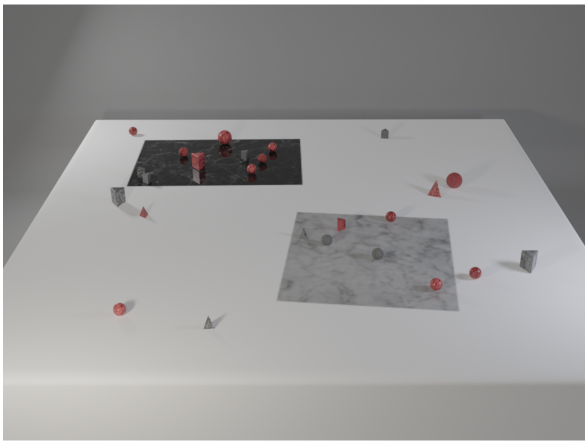
Question: On the planes where there are not between 0 and 3 big objects on each plane, more than five twelfths of the big gray objects have the same shape as most gray rubber objects; is it right?
Answer: False
Quantifiers: each, not between, more than F, most



Question: On the planes where there are not exactly 2 spheres on each plane, at most 4 red leather objects are the same shape as most objects; is it right?
Answer: True
Quantifiers: each, not exactly N, at most N, most

Question: On the triangular plane where there is not exactly 1 small marbled square-based pyramid, at least 2 red marbled items have the same size as most red items; is it right?
Answer: False
Quantifiers: not exactly N, at least N, most

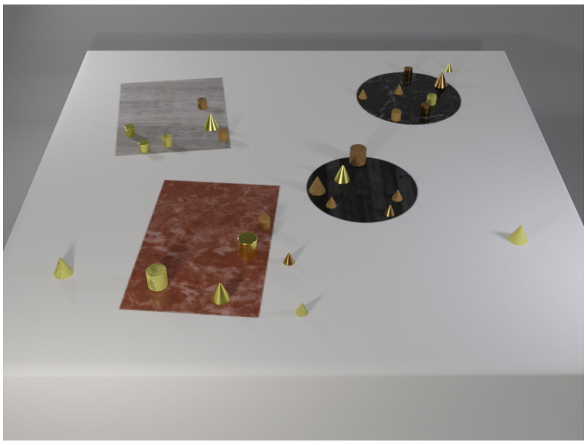
Question: On the marbled planes where there is at least 1 large marbled item on each plane, at least 2 large items are not the same material as most gray items; is it right?
Answer: True
Quantifiers: each, at least N, all but at least N (at least N ¬), most



Question: On the dappled planes, is there the same number of tiny objects on the left side of the big sphere and tiny red spheres right of the red leathery triangular prism?
Answer: False
Quantifiers: equal O_1 and O_2

Question: On the white non-geometric plane, are there fewer big objects to the right rear of the big red dappled object than tiny spheres in front of the big red dappled object?
Answer: True
Quantifiers: fewer O_1 than O_2

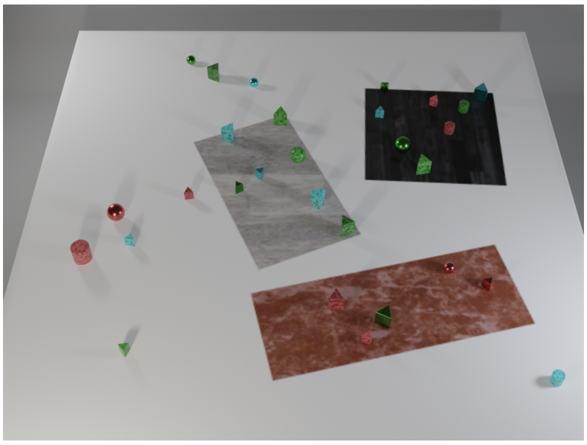
Question: On the planes, is the number of triangular prisms to the right front of the red leathery tetrahedron greater than the number of leathery tetrahedrons on the left side of the large marble sphere?
Answer: True
Quantifiers: more O_1 than O_2



Question: On the planes where there are more than or equal to 2 cylinders on each plane, are there more brown metallic cones than brown leathery cylinders?
Answer: False
Quantifiers: each, at least N, more O_1 than O_2

Question: On the wood plane where there is not exactly 1 small yellow leathery object, is the number of small objects less than the number of brown leathery cones?
Answer: False
Quantifiers: not exactly N, fewer O_1 than O_2

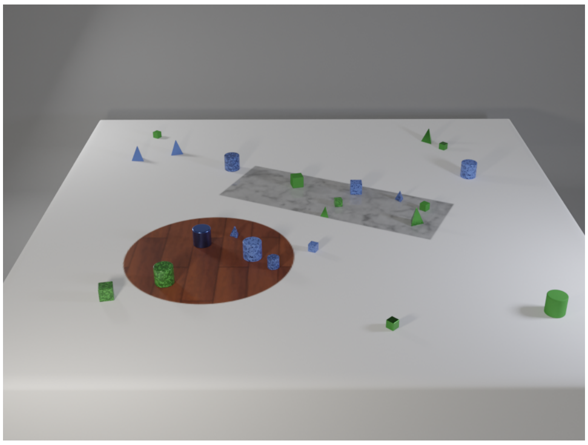
Question: On the planes where there are no fewer than 2 big cones on each plane, is the number of circular cylinders the same as the number of big circular cylinders?
Answer: True
Quantifiers: each, at least N, equal O_1 and O_2



Question: On the planes where there are no more than 3 tiny marbled objects on each plane, all the tiny marbled objects are in front of the red metallic triangular prism; is it right?
Answer: True
Quantifiers: each, at most N, all

Question: On the plane where there are at most 4 marble items, is there any tiny ball in front of the tiny red metal three-sided prism?
Answer: False
Quantifiers: at most N, some

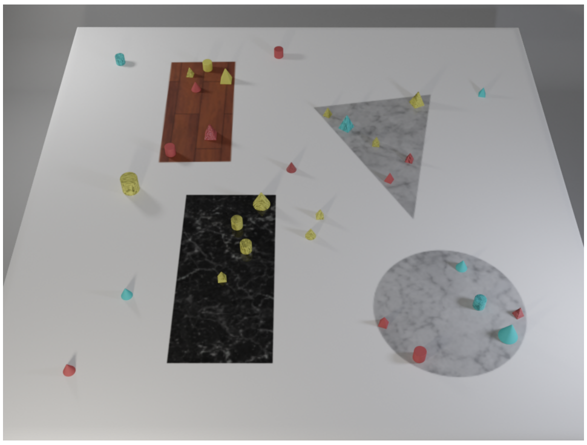
Question: On the wood plane where there are fewer than or equal to 3 small marble objects, it is not the case that no large marble triangular prism is not on the left side of the green sphere; is it right?
Answer: True
Quantifiers: at most N, not all (¬ no ¬)



Question: On the planes where there is exactly 1 small blue marbled object on each plane, every green metal object is not behind the green rubber cylinder; is it right?
Answer: False
Quantifiers: each, exactly N, no (every ¬)

Question: On the plane where there is not exactly 1 big green metal tetrahedron, some but not all of the marble objects are to the right of the blue tetrahedron; is it right?
Answer: True
Quantifiers: not exactly N, some but not all

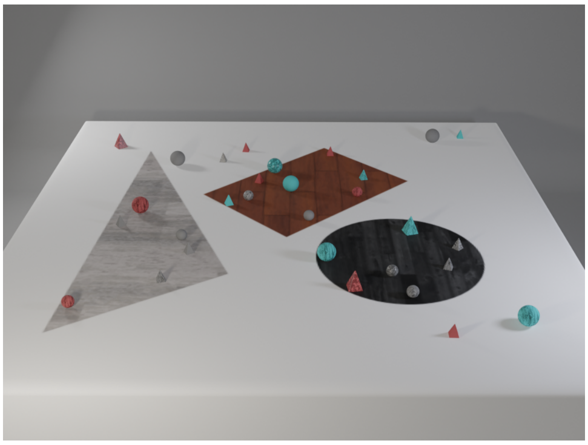
Question: On the planes where there is a total of 5 big green items, all the tiny green blocks but at most 1 are not right rear of the big green marble block; is it right?
Answer: False
Quantifiers: total, at most N (all but at most N ¬)



Question: On the planes where there are at least 2 cyan items on each plane, all the tiny cones but at least 4 are not right rear of the tiny red rubbery pentahedron; is it right?
Answer: False
Quantifiers: each, at least N, at least N (all but at least N ¬)

Question: On the quadrilateral plane where there is at most 1 yellow circular cylinder, it is not the case that at most 1 red rubber object is left rear of the leather object; is it right?
Answer: False
Quantifiers: at most N, more than N (¬ at most N)

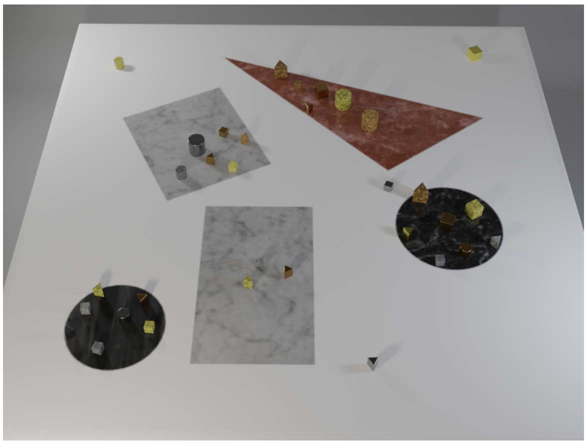
Question: On the geometric plane whose material is different from that of other planes, it is not the case that all the red items but at least 2 are not right front of the tiny yellow cylinder; is it right?
Answer: True
Quantifiers: fewer than N (¬ all but at least N ¬)



Question: On the planes where there are not any small red rubber objects on each plane, there are exactly 2 small gray pentahedrons left rear of the large cyan pentahedron; is it right?
Answer: False
Quantifiers: each, no (¬ any), exactly N

Question: On the planes where there is not exactly 1 wood ball on each plane, are there 1 to 3 wood objects to the left front of the gray marbled square-based pyramid?
Answer: False
Quantifiers: each, not exactly N, between

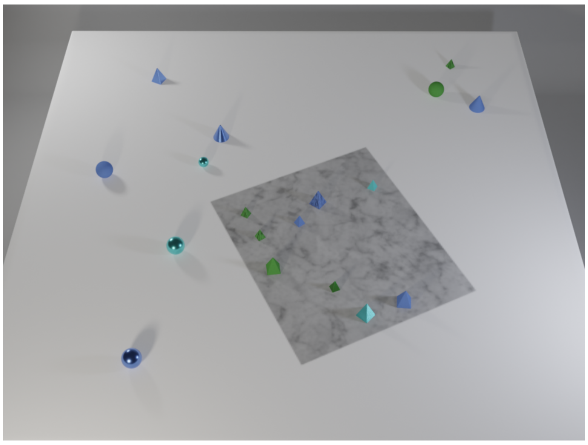
Question: On the wooden planes where there are not between 1 and 3 red rubber items on each plane, at most 3 small items are not on the right front side of the big red sphere; is it right?
Answer: True
Quantifiers: each, not between, all but at most N (at most N ¬)



Question: On the planes where there are between 1 and 3 tiny gray items on each plane, are all the tiny items but at least 5 right of the large gray metal circular cylinder?
Answer: False
Quantifiers: each, between, all but at least N

Question: On the round plane to the left of the brown dappled three-cornered plane, most items are behind the small yellow dappled block; is it right?
Answer: True
Quantifiers: most

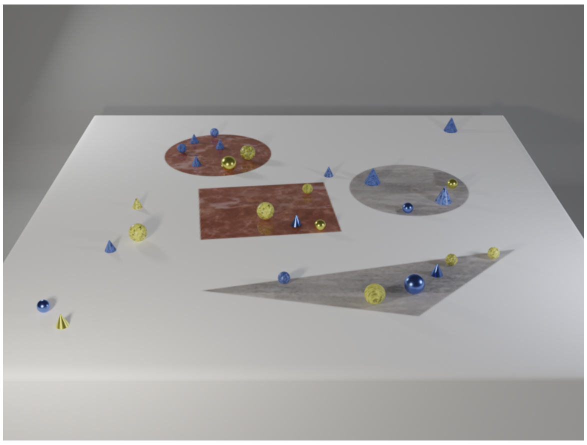
Question: On the marble planes where there is a total of 7 tiny triangular prisms, it is not the case that fewer than 2/3 of the big items are to the left of the tiny gray cube; is it right?
Answer: False
Quantifiers: total, at least F (¬ fewer than F)



Question: On the gray marble plane, it is not the case that more than 5/8 of the pentahedrons are to the right of the tiny metallic pentahedron; is it right?
Answer: True
Quantifiers: at most F (¬ more than F)

Question: On the rectangular plane, all the blue wood square pyramids are larger than some rubber square pyramid; is it right?
Answer: True
Quantifiers: all, some

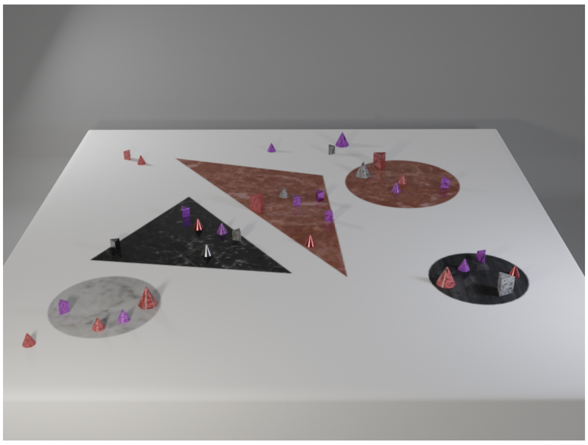
Question: On the non-geometric plane, are all the green square-based pyramids smaller than some but not all of the square-based pyramids?
Answer: True
Quantifiers: all, some but not all



Question: On the planes where there are 0 large metal balls on each plane, it is not the case that no blue cone is larger than some but not all of the yellow cones; is it right?
Answer: False
Quantifiers: each, no (0), some (¬ no), some but not all

Question: On the planes where there are not exactly 3 tiny blue objects on each plane, exactly 3 blue cones are larger than at least 2 blue wood cones; is it right?
Answer: False
Quantifiers: each, not exactly N, exactly N, at least N

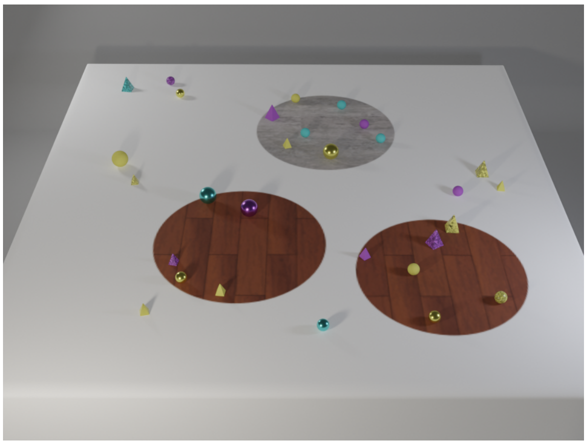
Question: On the planes where there are not between 1 and 4 tiny marbled spheres on each plane, all the spheres but at least 2 are larger than at most 1 yellow sphere; is it right?
Answer: True
Quantifiers: each, not between, at least N (all but at least N ¬), more than N (¬ at most)



Question: On the circular planes where there are exactly 2 big objects on each plane, 1 to 3 marbled cones are smaller than more than 3/7 of the red marbled cones; is it right?
Answer: True
Quantifiers: each, exactly N, between, more than F

Question: On the brown plane where there are between 1 and 3 red marbled objects, at least one-ninth of the marbled cones are larger than at least 2 cones; is it right?
Answer: True
Quantifiers: between, at least N, at least F

Question: On the marble planes where there is a total of 5 marble items, all the cones but at least 2 are smaller than fewer than 3/4 of the gray cones; is it right?
Answer: False
Quantifiers: total, at least N (all but at least N ¬), at least F (¬ fewer than F)



Question: On the geometric plane whose color is different from that of other planes, all yellow spheres but 1 are smaller than fewer than 1 or more than 3 spheres; is it right?
Answer: True
Quantifiers: exactly N (all but N ¬), between (¬ between)

Question: On the wooden planes where there are no fewer than 2 tiny balls on each plane, every item except the marble ball is not a tiny item; is it right?
Answer: False
Quantifiers: each, at least N, no _ except (every _ except ¬)

Question: On the brown plane where there is no more than 1 dappled square pyramid, no objects except the metal ones are not square pyramids; is it right?
Answer: True
Quantifiers: at most N, every _ except (no _ except ¬)

MWP-BERT: Numeracy-Augmented Pre-training for Math Word Problem Solving

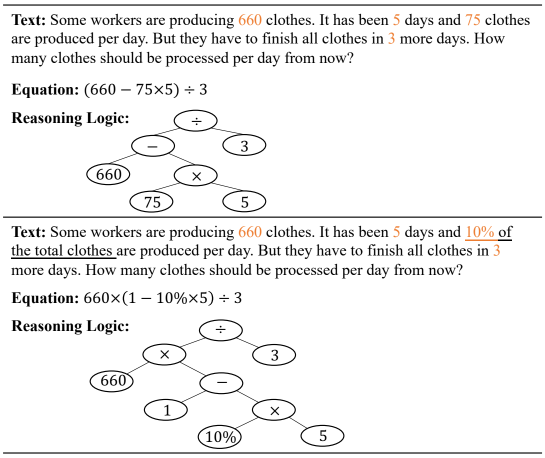
Abstract

Math word problem (MWP) solving faces a dilemma in number representation learning. In order to avoid the number representation issue and reduce the search space of feasible solutions, existing works striving for MWP solving usually replace real numbers with symbolic placeholders to focus on logic reasoning. However, different from common symbolic reasoning tasks like program synthesis and knowledge graph reasoning, MWP solving has extra requirements in numerical reasoning. In other words, instead of the number value itself, it is the reusable numerical property that matters more in numerical reasoning. Therefore, we argue that injecting numerical properties into symbolic placeholders with contextualized representation learning schema can provide a way out of the dilemma in the number representation issue here. In this work, we introduce this idea to the popular pre-training language model (PLM) techniques and build MWP-BERT, an effective contextual number representation PLM. We demonstrate the effectiveness of our MWP-BERT on MWP solving and several MWP-specific understanding tasks on both English and Chinese benchmarks.

1 Introduction

Recent works in math word problem (MWP) solving (Wang et al., 2018, 2019; Liu et al., 2019a; Li et al., 2019; Xie and Sun, 2019; Zhang et al., 2020b; Wu et al., 2020; Qin et al., 2021; Huang et al., 2021; Wu et al., 2021a; Yu et al., 2021; Shen et al., 2021) arrange the pipeline into a sequence-to-sequence framework. In brief, they use deep representation and gradient optimization as well as symbolic constraints to discover discrete symbolic combinations of operators and variants. Fundamentally, MWP solving system aims to perform symbolic reasoning by searching through a combinatorial solution space given the text description evidences. Thus, these neurosymbolic methods mainly focus on getting more effective semantic representations (Li et al., 2019; Zhang et al., 2020b; Wu et al., 2020, 2021a; Yu et al., 2021), injecting symbolic constraints (Wang et al., 2018, 2019; Liu et al., 2019a; Xie and Sun, 2019) and how to align semantic space (text descriptions) and huge combinatorial symbolic space (symbolic solutions) (Qin et al., 2021; Shen et al., 2021; Huang et al., 2021). This line of methods has achieved great success and is still holding the lead in various MWP solving benchmarks (Wang et al., 2017; Zhao et al., 2020; Koncel-Kedziorski et al., 2016).



Text: Some workers are producing 660 clothes. It has been 5 days and 75 clothes are produced per day. But they have to finish all clothes in 3 more days. How many clothes should be processed per day from now?

Equation: $(660 - 75\times5) \div 3$

Reasoning Logic:

Text: Some workers are producing 660 clothes. It has been 5 days and 10% of the total clothes are produced per day. But they have to finish all clothes in 3 more days. How many clothes should be processed per day from now?

Equation: $660\times(1 - 10\%\times5) \div 3$

Reasoning Logic:

Figure 1: The second question is obtained from the first one by minor modifications. However, their solution equation and corresponding equation tree structure are different from each other. This demonstrates the importance of considering numerical value information and reasoning logic (equation tree) in contextual modeling.

Despite the great performance achieved by the previous methods, there still exists fundamental challenges in number representation for MWP solving. More exactly, number values are required to be considered as vital evidence in solution exploration but existing works are known to be inefficient in

Findings of the Association for Computational Linguistics: NAACL 2022, pages 997 - 1009
July 10-15, 2022

capturing numeracy information (Wallace et al., 2019). Intuitively, we could simply treat explicit numbers in the same way with words, i.e., assign position for all numbers in the vocabulary. However, there would be an infinite number of candidates during prediction and it would be impossible to learn their deep representations. In other words, the solution space will be extremely large and the complexity is unacceptable. Therefore, almost all existing works follow the number mapping technique Wang et al. (2017) to replace all numbers with symbolic placeholders (e.g., "x1", "x2"). The core idea here is to get a reasonable solution space by restricting neural networks to leave out numerical characteristics and focus on logic reasoning. However, most of the current MWP solvers do not consider the background knowledge in the context and are usually inefficient in capturing numeracy properties. An example is shown in Fig. 1. Small perturbations in the problem description actually bring large variations in reasoning logic and equation. If the model simply regards "75" and "10%" as the same placeholder "x3", and does not notice the small variation in the context, a wrong solution will be generated.

To this end, we incorporate several numeracy grounded pre-training objectives to inject inductive bias about numerical constraints into dynamic representations. Compared with word candidate sets, useful points in number candidate space are scattered sparsely. However, we identify that during prediction, what matters is the reusable numerical properties of number values. What's more, these properties do not suffer from the sparsity issues of specific values in MWPs. Therefore, compared with assigning a prototype vector for each single number value like (Wu et al., 2021b), it is more reasonable to inject the reusable numerical properties in deep representations, e.g., magnitude and number type. In this work, we propose to design numeracy grounded pre-training objectives to implement soft constraints between symbolic placeholders and numbers in deep representation.

Contributions. We present a suite of numeracy-augmented pre-training tasks with consideration of reasoning logic and numerical properties. More exactly, we introduce several novel pre-training tasks with access to different levels of supervision signals to make use of more available MWP data.

- One basic group of pre-training tasks is designed for the self-supervised setting. Except for masked language modeling (MLM), we give extra consideration to number-related context information by designing related objectives.
- Another set of pre-training objectives is for the weakly-supervised setting that has only answer annotations but no equation solutions. With access to the answer value, we introduce several tasks to determine the type and the value of the answer.
- The final set is for the fully-supervised setting, where both solution equation and answer are available for the MWPs.

Besides, a group of numeracy grounded pre-training objectives is designed to leverage the corpus of MWP and encourage the contextual representation to capture numerical information. Experiments conducted on both Chinese and English benchmarks show the significant improvement of our proposed approach over all competitors. To our knowledge, this is the first approach that surpasses human performance (Wang et al., 2019) in terms of MWP solving.

2 Related Works

Math Word Problems Solving. There exist two major types of MWP, equation set MWP (Wang et al., 2017; Zhao et al., 2020) and arithmetic MWP (Qin et al., 2020; Huang et al., 2016). This work focuses on arithmetic MWP, which is usually paired with one unknown variable. Along the path of the MWP solver's development, the pioneer studies use traditional rule-based methods, machine learning methods and statistical methods (Yuhui et al., 2010; Kushman et al., 2014; Shi et al., 2015; Koncel-Kedziorski et al., 2015). Afterwards, inspired by the development of sequence-to-sequence (Seq2Seq) models, MWP solving has been formulated as a neurosymbolic reasoning pipeline of translating language descriptions to mathematical equations with encoder-decoder framework (Wang et al., 2018, 2019; Li et al., 2019; Zhang et al., 2020b; Yu et al., 2021; Wu et al., 2021a). By fusing hard constraints into decoder (Chiang and Chen, 2018; Liu et al., 2019a; Xie and Sun, 2019; Shen and Jin, 2020; Zhang et al., 2020a), MWP solvers achieve much better performance then. Several works propose to utilize multi-stage frameworks (Wang et al., 2019; Huang et al., 2021; Shen et al., 2021; Liang and Zhang, 2021) to make more robust solvers. Also, several new works made attempts to improve MWP solver beyond supervised settings (Hong et al., 2021a,b).

Among all these previous studies, the most relevant ones to our work can be categorized into two groups. First, it has been noted that number values and mathematical constraints play a significant role in supporting numerical reasoning. Wu et al. (2021b) proposed several number value features to enhance encoder and Qin et al. (2021) designed new auxiliary tasks to enhance neural MWP solvers. Compared with their work, we first introduce pre-training language model (PLM) and concentrate on representation learning to resolve numerical understanding challenges. Second, regarding the usage of pre-training techniques for MWP solving, Shen et al. (2021) introduced BART-based (Lewis et al., 2020) MWP solver and incorporated specialized multi-task training for obtaining more effective pre-training Seq2Seq models for MWP. Compared with them, our work focuses on the number representation learning issue of MWP and achieves a more flexible pre-training representation module for MWP solving, which can be applied in various MWP related tasks other than solution generation.

Numeracy-aware Pre-training Models. Number representation has been recognized as one of the main issues in word representation learning. Existing methods make use of value, exponent, subword and character methods (Thawani et al., 2021) to obtain number representations for explicit number values. These methods are known to be less effective in extrapolation cases like testing with numbers not appearing in the training corpus.

Previous related works (Andor et al., 2019; Wallace et al., 2019; Geva et al., 2020) mainly focus on shallow numerical reasoning tasks shown in DROP dataset (Dua et al., 2019), which usually serves as a benchmark for evaluating numerical machine reading comprehension (Num-MRC) performance. Compared with MWP solving, Num-MRC's main focus is laid on extracting answer spans from a paragraph, which are more fault-tolerant with no needs to predict number tokens. Besides, their solution generation tasks only contain simple computations like addition/subtraction and there are only integers in DROP. More exactly, several research efforts have been made to deal with this kind of math-related reading comprehension task by synthesizing new training examples (Geva et al., 2020), incorporating special modules considering the numerical operation (Andor et al., 2019) and designing specific tokenization strategies (Zhang et al., 2020c). Since MWP solving requires further consideration of the complex composition of reasoning logics in MWP text, the symbolic placeholder is more effective in MWP solving. Thus, instead of dealing with explicit number values, our work focuses on improving representation for symbolic placeholders by injecting numerical properties in a probabilistic way.

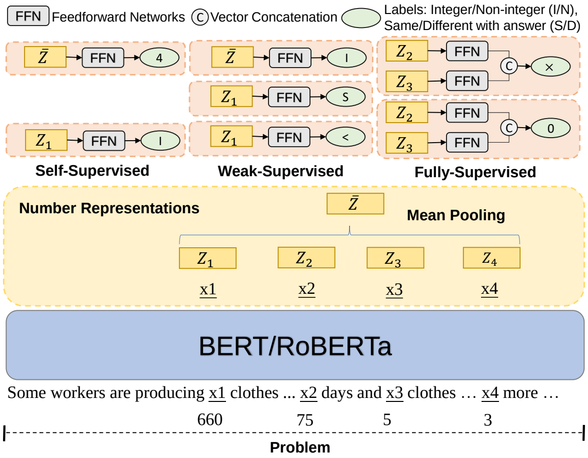


Figure 2: The overall architecture of our BERT-based MWP solver. Our method enables the solver to learn from unlabeled, incompletely labeled and fully labeled MWPs by different pre-training tasks.

3 Methodology

3.1 Problem Statement

The input to an MWP solver is a textual description, we denote it as W with length m, thus $W = \{w_1, w_2, ..., w_m\}$. We also define a subset W_q of W which contains all the quantities appeared in W. The output is an equation showing how to get the final answer. We denote it as A with length n, where $A = \{a_1, a_2, ..., a_n\}$. The vocabulary of A contains three parts, namely V_{op}, V_{num} and V_{cons}. V_{op} is the vocabulary for all operators, i.e. $+$, $-$, $\times$, $\div$ and ^. The vocabulary of quantities V_{num} is constructed by number mapping (Wang et al., 2017), which transforms quantities in different MWPs into a unified representation. More specifically, V_{num} does not contain the actual value of quantities appeared in W, and those quantities are denoted as $\{n_1, n_2, ..., n_k\}$, where n_i means the i-th number from W and k is the maximum number of quantities in V_{num} in order to fix the size of it. V_{cons} contains necessary constant values e.g., π.

3.2 PLM Encoder

Our PLM encoder maps the problem description W into a representation matrix $Z \in \mathbb{R}^{m*h}$ where h is the dimension of the hidden feature.

$$Z = encoder(W). \tag{1}$$

The representation vector corresponding to each word in Z will be used in the decoding process for generating the solution.

An overview of pre-training objectives and our model architecture is shown in Figure 2. In general, pre-training objectives are designed to inject contextual priori and numerical properties as soft constraints for representation learning. They are categorized into three types given provided training signals, i.e., self-supervised, weakly-supervised, and fully-supervised.

3.3 Self-supervised Objectives

In this part, we only consider input text descriptions for each example. Also, these objectives can alleviate the costs of collecting MWP corpus by constructing supervision signals without solution answers and equations.

Masked Language Modeling. We follow Devlin et al. (2019) and introduce masked language modeling (MLM) for basic contextual representation modeling. Specially, we apply masks on 10% of tokens, randomly replace 10% of tokens with other tokens and keep 80% of tokens unchanged. Later, the manipulated sentence is utilized to reconstruct the original sentence.

Number Counting. Another pre-training objective is to predict the amount of numbers that appeared in MWP description. The amount of a number corresponds with the cardinality of variable sets. This also reflects the basic understanding about the difficulty of an MWP and can act as a key contextual MWP number understanding feature. Here, we introduce a regression objective with the following formulated loss function:

$$L_{NumCount} = MSE(FFN(\bar{Z}), |W_q|), \tag{2}$$

where MSE stands for mean-squared-error and FFN stands for the feed-forward network which is made up of two fully-connected (FC) layers and one ReLU activation. We build a two-FC-layer block for each pre-training task (except MLM) and discard them during fine-tuning. $\bar{Z} \in \mathbb{R}^h$ is the mean vector of Z and represents the encoder's overall understanding of a single MWP text description. $|W_q|$ is the number of quantities shown in the problem description W.

Number Type Grounding. This objective aims at linking contextual number representations with corresponding number types to tell the difference between discrete and continuous concepts/entities. For numerical reasoning in MWP solving, we only need to handle whole numbers as well as non-integer numbers (decimal, fraction and percentage). Ideas here are that whole numbers usually associate with discrete entities (for example, desks, chairs and seats) while non-integer numbers often connect with continuous concepts (for example, proportions, rate, velocity). Besides, comparisons among whole numbers got different issues compared with rational numbers. Therefore, we propose a classification objective to predict if a number is a whole number or non-integer number:

$$L_{NTGround} = \sum_{i:W_i \in W_q} CE(FFN(Z_i), y_i), \tag{3}$$

where W_q contains all the numbers that appeared in W, and CE is the cross-entropy loss for binary classification. Here, i is the index when W_i is a quantity, Z_i is the corresponding representation vector, and y_i is a binary label indicating if W_i is a whole number or non-integer number.

3.4 Weakly-supervised Objectives

Given both text descriptions of MWPs and corresponding answers, we can model dependencies among answer number and numbers in text descriptions so that contextual representation perceive the existence of the target variable number that does not appear in the text descriptions. In detail, we design 3 novel pre-training objectives specializing in value-annotated MWPs to improve number representation in our MWP-BERT.

Answer Type Prediction. Determining the type of answer number can provide us discrete/continuous nature of target entity/concept. Thus, we want to predict type (whole/non-integer) of the answer value given global representations of an MWP (embedded in Z):

$$L_{ATPred} = CE(FFN(\bar{Z}), y_s), \tag{4}$$

where y_s is the ground truth label indicating the type of answer number.

Context-Answer Type Comparison. Besides the global context feature, an MWP-BERT also needs to associate context numbers and answer number (the target number does not explicitly appear in the text). Thus, another objective is proposed to predict if the quantities appeared in the MWP text fall into the same category as the answer (i.e. they are all whole or non-integer):

$$L_{CATComp} = \sum_{i:W_i \in W_q} CE(FFN(Z_i), y_i \oplus y_s), \tag{5}$$

where $\oplus$ stands for the exclusive-or operator between two binary labels to check if they are the same, the label of a quantity y_i and the label of the solution value y_s.

Number Magnitude Comparison. Beyond type, the magnitude of a number serves as the foundation of numerical reasoning. By associating magnitudes evaluation with contextual representation, the model can get a better perception about variance over key reasoning cues like time, size, intensity and speed. Let $\dot{y}_i$ indicate if the current quantity W_i is greater than the solution value or not. Moreover, the loss function is formulated as:

$$L_{NumMComp} = \sum_{i:W_i \in W_q} CE(FFN(Z_i), \dot{y}_i). \tag{6}$$

3.5 Fully-supervised Objectives

Given both equations and answers for MWPs, we can design fully-supervised training tasks to associate number representation with reasoning flows (solution equation). Mathematical equations are known to be binary tree structures with operators on root nodes and numbers on leaf nodes. The motivation is to encourage models to learn structure-aware number representations that encode the information on how to make combinations over atomic operators and numbers. We incorporate two pre-training objectives based on the solution equation tree.

Operation Prediction. The first one is a quantity-pair relation prediction task that focuses on the local feature of the equation tree. The goal is to predict the operator between two quantity nodes in the solution tree. This is in fact a classification task with 5 potential targets, i.e., $+, -, \times, \div$ and $\wedge$. The loss function of this task is:

$$L_{OPred} = \sum_{i,j} CE(FFN([Z_i; Z_j]), op(W_i, W_j)), \tag{7}$$

where i, j are two indexes that satisfy $W_i, W_j \in W_q$ and $[Z_i; Z_j] \in \mathbb{R}^{2h}$ is the concatenation of Z_i and Z_j for the quantity W_i and W_j. $op(W_i, W_j)$ returns the operator between W_i and W_j.

Tree Distance Prediction. Another pre-training objective is to incorporate the global structure of the equation tree in a quantitative way. Inspired by Hewitt and Manning (2019), we consider the depth of each number and operator on the corresponding binary equation tree to be the key structure priori. Thus, we design another fully-supervised objective to utilize this information. More exactly, given the representation of two number nodes in an equation tree, this is a regression problem that predicts the distance (difference of their depth) between them. The loss is formulated as:

$$L_{TPred} = \sum_{i,j} MSE(FFN([Z_i; Z_j]), d(W_i, W_j)), \tag{8}$$

where $d(W_i, W_j)$ is the distance between quantity W_i and W_j in the solution tree.

The final pre-training objective is the summation of Equation 2~8 and the masked language model.

3.6 Fine-Tuning

To investigate the mathematical understanding ability of our pre-training MWP-BERT, we evaluate our model of MWP solving, quantity tagging and 7 probing tasks. Moreover, we not only use BERT but also RoBERTa (Liu et al., 2019b) as the backbone of our encoder to show the adaptiveness of proposed method.

4 Experiments

We present several empirical results with octopus evaluation settings (Bender and Koller, 2020) to prove the superiority of MWP-BERT and MWP-RoBERTa solver. In section 4.1, we illustrate the application of both solvers in the generation scenario, MWP solving, by fine-tuning them with a specific decoder (Xie and Sun, 2019). Next, we present MWP probing tasks in section 4.3 to evaluate the capability of MWP-BERT and MWP-RoBERTa on "understanding" or "capturing the meanings" of MWPs. Finally, results and analysis about ablation study are illustrated in section 4.4.

Implementation Details. We pre-train our model on 4 NVIDIA TESLA V100 graphic cards and fine-tune on 1 card. The model was pre-trained for 50 epochs (2 days) and fine-tuned for 80 epochs (1 day) with a batch size of 32. Adam optimizer (Kingma and Ba, 2014) is applied with an initial learning rate of 5e-5, which would be halved every 30 epochs. Dropout rate of 0.5 is set during training to prevent over-fitting. During testing, we use 5-beam search to get reasonable solutions. The hyper-parameters setting of our BERT and RoBERTa is 12 layers of depth, 12 heads of attention and 768 dimensions of hidden features. For the Chinese pre-training model, we use an upgrade patch of Chinese BERT and RoBERTa which are pre-trained with the whole word masking (WWM)[1] (Cui et al., 2020). For the English pre-training models, we use the official source on this website[2]. Our code and data have been open-sourced on Github [3].

4.1 MWP Solving

Experiment Settings and Datasets. Given a textual description of a mathematical problem, which contains several known variables, MWP solving targets at getting the correct answer for the corresponding question. A solver is expected to be able to predict an equation that can exactly reach the answer value. We conduct experiment based on these benchmarks, Math23k (Wang et al., 2017), MathQA (Amini et al., 2019) and Ape-210k (Zhao et al., 2020). Since there exist many noisy examples in Ape-210k, e.g., examples without equation annotations or answer values, we re-organize Ape-210k to Ape-clean and Ape-unsolvable, where the training set of Ape-clean and the whole Ape-unsolvable are used for pre-training. For the English MWP, we use the training set of MathQA (Amini et al., 2019) to perform pre-training. For the implementation of our solver, MWP-BERT is adapted as an encoder to generate intermediate MWP representation for the tree-based decoder in Xie and Sun (2019).

4.2 The Ape-clean Dataset

Ape210k is a recently released large MWPs dataset, including 210,488 problems. The problems in Ape210k are more diverse and difficult than those in Math23k as shown in 1. Not only the stronger requirement of common-sense knowledge for getting solutions, but also the missing of ground-truth solution equations or answers, will take extra obstacles for MWP solving. Among all these cases, the problems without answers can not be used for fully-supervised setting. Besides, the problems without annotated equations but only answer values can be used in the weakly-supervised learning setting. Therefore, we follow the rules below to select the usable problems from Ape210k to construct an Ape-clean dataset, which can be used for the fully-supervised learning setting. (i). We remove all MWPs that have no answer values nor equations. (ii). We remove all MWPs that only have answer values without equations. (iii). We remove all MWPs with a problem length $m > 100$ or an answer equation length $n > 20$, as they will bring obstacles for training. (iv). We remove all MWPs requiring external constants except 1 and π. (v). We remove all duplicated problems with the MWPs in Math23k, because almost all problems in Math23k can be found in Ape-210k. After data filtering, the *Ape-clean* dataset contains 81,225 MWPs, including 79,388 training problems and 1,837 testing problems. The remaining 129,263 problems in Ape210k are regarded as *Ape-unsolvable*, which can be used in the pre-training tasks in the settings of self-supervised and weakly-supervised learning.

Unsolvable problem 1:	The price of a ball is 6 yuan, and the price of a basketball is less than 13 times of the ball's price. How much might the price of the basketball be?
Answer:	?
Unsolvable problem 2:	x is a single digit and the quotient of x72/47 is also a single digit, what is x at most?
Answer:	3
Unsolvable problem 3:	In the yard there were 25 chickens and rabbits. Together they had 80 legs. How many rabbits were in the yard?
Answer:	(80-25)*2/(4-2) = 15

Table 1: This table shows three kinds of discarded MWPs in Ape210k. The first one does not have a certain answer, and the solution of the second one cannot be represented by equations. Solving the third problem requires external constants. Thus we filter those problems out in our Ape-clean dataset.

Model Comparison. We first compare our approach with the most recent representative baselines on the benchmark Math23k dataset. The first baseline is *DNS* which is the pioneering work us-

Table 2: Comparison of answer accuracy (%) among our proposed models and different baselines. Math23k column shows the results on the public test set and Math23k* is 5-fold cross validation on Math23k dataset. MathQA is adapated from Li et al. (2021); Tan et al. (2021). "RoBERTa" and "BERT" represent results without pre-training. "MWP-RoBERTa" and "MWP-BERT" represent first pre-training with proposed tasks and then fine-tuning.

ing the Seq2Seq model to solve MWPs. *Math-EN* (Wang et al., 2018) proposes an equation-normalization method and uses vanilla Seq2Seq model to get solutions. *GTS* (Xie and Sun, 2019) proposes a goal-driven tree-based decoder and achieves great results. *Graph2Tree* (Zhang et al., 2020b) constructs two graphs during data preprocessing to extract extra relationships from text descriptions. *KA-S2T* (Wu et al., 2020) proposes a novel knowledge-aware model that can incorporate background knowledge. *NS-Solver* (Qin et al., 2021) designs several auxiliary tasks to help training. *NumS2T* (Wu et al., 2021b) uses explicit numerical values instead of symbol placeholder to encode quantities. *RPKHS* (Yu et al., 2021) builds hierarchical reasoning encoder in parallel with PLM encoder. *REAL* (Huang et al., 2021) proposes a human-like analogical auxiliary learning strategy. *EEH-G2T* (Wu et al., 2021a) injects edge label information and the long-range word relationship into graph network. *Gen&Rank* (Shen et al., 2021) designs a multi-task learning framework for adapting BART in MWP solving. *BERT-CL* (Li et al., 2021) incorporates contrastive learning strategy with PLM. To avoid the implementation error that may cause unreproducible results of baseline models, we reported the results of these baselines from the papers where they were published, as many previous papers (Zhang et al., 2020b; Shen and Jin, 2020) did.

As shown in Table 2, our MWP-BERT achieves competitive results. It is worth noting that we perform strict pre-training paradigm in MWP solving, i.e., our results come from pre-training on the different annotated MWP examples that will be applied in further fine-tuning. Here, our pre-training only uses Ape-clean and Ape-unsolvable and fine-tuning only uses Math23k/MathQA.

RPKHS, *REAL* and *BERT-CL* all incorporate BERT in their model architecture, which are orthogonal to our work. Our MWP-BERT can be utilized as an MWP-specific checkpoint for their encoder part to improve their performance. Besides, *REAL*, *BERT-CL* and *Gen & Rank* are all trying to make Seq2Seq pre-training (Lewis et al., 2020), which adapt both pre-training encoder as well as pre-training decoder for MWP solving. Compared with them, our model focuses on encoder pre-training and aims at obtaining better MWP representation that can be widely applied across various MWP related tasks (like quantity tagging, MWP question generation).

Another interesting observation is that BERT-based models perform better on Chinese MWP datasets while RoBERTa-based models are good at English MWP datasets. Because the Chinese RoBERTa used in this paper is actually a BERT model that uses BERT tokenization but is trained like RoBERTa (drops the Next Sentence Prediction task). Similar behaviors can be observed in Cui et al. (2020). For English setting, RoBERTa performs better than BERT, which is consistent with conclusions raised in Liu et al. (2019b).

Evaluation on Ape-clean and Math23k when being trained by a Joint MWP Set. Moreover, we combine the training set of Math23k and Ape-clean to train MWP-BERT, and then measure the accuracy on the testing set of Math23k and Ape-clean separately. Results shown in Table 2 con-

Model	Math23k		Ape-clean	
	Equ	Ans	Equ	Ans
DNS	50.2	50.3	66.2	66.2
GTS	70.1	81.4	60.4	73.2
RoBERTa	75.8	88.8	66.7	80.2
BERT	76.7	89.4	67.0	80.4
MWP-RoBERTa	77.1	90.2	67.1	80.8
MWP-BERT	**77.5**	**91.2**	**67.5**	**81.3**

Table 3: Comparison of answer accuracy (%) between our proposed models and baselines when they are all trained by the combination of the training set from Ape-clean and Math23k dataset.

vey interesting evaluation observations. Surprisingly, the accuracy of our models on Math23k reaches above 90%, which is marvelously high (previous state-of-the-art methods can hardly reach 80% (Shen and Jin, 2020)). Compared to the results in Table 2, even *GTS* has a higher accuracy when trained with the big joint MWP set of Ape-clean and Math23k.

By comparing the performance of corresponding groups between Table 2 and Table 3, we can learn that our proposed MWP-BERT pre-training paradigm can achieve more significant boosting with more training examples, which proves the effectiveness of our proposed representation learning techniques.

4.3 Other MWP Understanding Tasks

Standard MWP solving is an equation generation task. To make a sufficient validation of the effectiveness of our model on number representations learning, MWP-specific understanding tasks are further considered. Following Hewitt and Manning (2019); Wallace et al. (2019), we design several number probing tasks and incorporate quantity tagging (Zou and Lu, 2019b) to enlarge the MWP understanding evaluation task.

Following the motivation mentioned in section 3.2, we re-run all the pre-training tasks as probing tasks to evaluate our modeling's understanding ability and test MWP-BERT in a zero-shot scenario, i.e. without fine-tuning the parameters of MWP-BERT and MWP-RoBERTa for the sake of fair comparison. We perform the probing evaluation on both Ape-clean and Ape-unsolvable, except that "OPred" and "TPred" are only evaluated on Ape-clean because they require equation solutions as the ground truth.

Model	Accuracy
QT(S)	87.3
QT(R)	88.7
QT(fix)	87.7
QT	90.8
BERT	84.5
RoBERTa	84.6
MWP-BERT	91.0
MWP-RoBERTa	**91.5**

Table 5: Comparison of tagging accuracy (%) between our proposed models and baselines.

Table 4 shows the performances of 4 different PLMs on the above mentioned MWP-specific understanding tasks. Significant improvements can be observed in all the tasks, and demonstrate the effectiveness of our proposed pre-training techniques in improving number representation of PLMs.

Besides, we borrow an MWP-specific sequence labeling task, quantity tagging (Zou and Lu, 2019b) ("QT"), to further compose MWP understanding evaluation settings. Quantity tagging (Zou and Lu, 2019a) is firstly proposed to solve MWP examples with only addition and subtraction operators in their solutions. Briefly speaking, this task requires the model to assign "+", "-" or "None" for every quantity in the problem description and can serve as an MWP understanding evaluation tool to examine the model's understanding of each variable's logic role in the reasoning flow. More exactly, this is also a classification task with 3 possible targets. We extract the corresponding vectors of all quantities according to their positions in encoded problem Z from Equation 1. Next, a 2-layer feed-forward block is connected to output the final prediction.

Following the setting in baseline method *QT* (Zou and Lu, 2019a), we perform 3-fold cross-validation and the results are given in Table 5, which shows that PLMs benefits from the proposed mathematical pre-training and outperforms the baselines.

4.4 Ablation Study

We run ablation study over the proposed training objectives to investigate the necessity for each of them. As Table 6 shows, all the proposed objectives can achieve improvements individually. Moreover, only using MLM results in weaker MWP solvers on Math23k (1.4% less) and Ape-clean (1.2% less),

	NumCount	NTGround	ATPred	CATComp	NumMComp	OPred	TPred	QT
Metric	MSE ↓	Acc ↑	Acc ↑	Acc ↑	Acc ↑	Acc ↑	MSE ↓	Acc ↑
BERT	3.08	0.87	0.75	0.77	0.77	0.50	0.97	84.5
RoBERTa	3.20	0.86	0.76	0.78	0.77	0.51	0.99	84.6
MWP-RoBERTa	0.69	0.92	0.86	0.87	0.86	0.86	0.44	91.0
MWP-BERT	0.67	0.92	0.85	0.87	0.86	0.87	0.45	91.5

Table 4: The evaluation results on MWP-specific understanding tasks. All tasks correspond to the tasks mentioned in section 4. Note that the metric for 2 tasks is mean-squared-error, while others use classification accuracy. "QT" stands for quantity tagging.

	Math23k	Ape-clean
Only MLM	89.8	80.1
Only self-supervised	90.4	80.9
w/o MLM	90.1	80.6
w/o $NumCount$	89.9	80.5
w/o $NTGround$	90.1	80.4
Only weakly-supervised	90.1	80.8
w/o $ATPred$	89.7	80.2
w/o $CATComp$	89.7	80.4
w/o $NumMComp$	89.6	80.5
Only fully-supervised	91.0	80.5
w/o $OPred$	90.5	80.3
w/o $TPred$	90.6	80.5
MWP-BERT	**91.2**	**81.3**

Table 6: The experimental results show the effectiveness of every pre-trained task. "Only self-supervised" means we only apply 3 tasks of self-supervised pre-training on the BERT encoder. We also investigate the influence of each task. For example, "w/o MLM" means only performing self-supervised pre-training and discarding the MLM pre-training task.

which again proves the effectiveness of our proposed pre-training tasks. Since the difficulty level of MWPs is usually in proportion to their solution length, we can easily identify that a set of MWPs exhibit a long-tail distribution over solution length, as well as the difficulty level, as shown in. Fig 3 of the Appendix. Thus, the 87% accuracy of human-level performance in Math23k (Wang et al., 2019) indicates that 13% of the MWPs are difficult to solve. Any solvers that can improve the accuracy above 87% are making significant contribution on solving the extremely difficult cases, such as MWPs whose solutions contain ≥ 4 variables or single variable being used multiple times. As neural models are known to be limited at dealing with these combinational and symbolic reasoning cases (Lee et al., 2020), we exam our model on these specially difficult cases. Due to the space limit, we attach several examples of these difficult cases, statistics about solution length distribution and performance for increasing length of solution equations in the Appendix. Besides, it is worth noting that even without MLM objective, our model is able to promote the PLM competitor. Besides, we can observe that linking equation structure and number during pre-training is certainly beneficial for solving MWPs.

5 Conclusion

We propose MWP-BERT, an MWP-specific PLM model with 8 pre-training objectives to solve the number representation issue in MWP. Also, a new dataset Ape-clean is curated by filtering out unsolvable problems from Ape210k, and the filtered MWPs are useful for self- and weakly-supervised pre-training. Experimental results show the superiority of our proposed MWP-BERT across various downstream tasks on generation and understanding. In terms of the most representative task MWP solving, our approach achieves the highest accuracy, and firstly beats human performance. Better numerical understanding ability is also demonstrated in the probing evaluation. We believe that our study can serve as a useful pre-trained pipeline and a strong baseline in the MWP community.

A Appendix

A.1 Accuracy w.r.t. Solution Length

To better understand the improvement of the MWP solving performance of our model, we evaluate the problems with different lengths of solutions separately. The solution distribution details can be found in Figure 3 It is expected that getting longer solutions requires more comprehensive understanding and complex reasoning, like the three difficult examples shown in Table 7. The results in Table 8 demonstrate that our proposed MWP-BERT overcomes more difficult problems than the vanilla BERT model. Although the statistical improvement from BERT to MWP-BERT is marginal, our method really enhances the mathematical understanding and reasoning ability of PLMs.

A.2 Case Study

We perform case study as shown in Table 9. Firstly, we choose a difficult problem from Math23k dataset and use 3 different solvers to solve it. Both GTS (Xie and Sun, 2019) and Graph2Tree (Zhang et al., 2020b) fail to generate the right solution for it, while our proposed MWP-BERT solves it correctly. This example shows that our encoder has a stronger capability to understand complex MWPs to guide the tree-based decoder generate correct solutions. Secondly, when solving a pair of 2 similar problems (i.e., problem 1 and problem 2 in Table 9), GTS, Graph2Tree and our MWP-BERT successfully solve the former problem. However, the baseline methods GTS and Graph2Tree both fail to solve the latter one. Our MWP-BERT generates the correct answer. This example proves that our probing tasks help the encoder to capture minor variations inside the problem description, leading to more accurate solutions.

Difficult Problem:	There are totally 48 cars and motorcycles in a parking lot. Each car has 4 wheels and each motorcycle has 3 wheels. If they have 172 wheels in total. How many motorcycles are there in the parking lot?
GTS:	$x = 48 + (172 - 48)/(4 - 3)$ (✗)
Graph2Tree :	$x = 48 - (48 - 172)/3$ (✗)
MWP-BERT:	$x = (48 * 4 - 172)/(4 - 3)$ (✓)
Problem 1:	Team A and team B are working on a project together. Team A finished (4/15) of the project, and team B finished (2/15) more than Team A . How many percentage did the two teams finish in total?
GTS:	$x = (4/15) + (2/15) + (4/15)$ (✓)
Graph2Tree :	$x = (4/15) + (2/15) + (4/15)$ (✓)
MWP-BERT:	$x = (4/15) + (2/15) + (4/15)$ (✓)
Problem 2:	Team A and team B are building a road. Team A builds (4/9), and team B builds (1/9) more than team A. How many percentage does Team B build?
GTS:	$x = (4/9) + (1/9) + (4/9)$ (✗)
Graph2Tree :	$x = (4/9) + (1/9) + (4/9)$ (✗)
MWP-BERT:	$x = (4/9) + (1/9)$ (✓)

Table 9: Our case study.

Restoring Hebrew Diacritics Without a Dictionary

Abstract

We demonstrate that it is feasible to accurately diacritize Hebrew script without any human-curated resources other than plain diacritized text.

We present NAKDIMON, a two-layer character-level LSTM, that performs on par with much more complicated curation-dependent systems, across a diverse array of modern Hebrew sources. The model is accompanied by a training set and a test set, collected from diverse sources.

	המטוס נחת ברכות
(a)	hamatos naxat ????
	‘The plane landed (unspecified)’
	הַמָּטוֹס נָחַת בְּרַכּוּת
(b)	hamatos naxat b-rakut
	‘The plane landed softly’
	הַמָּטוֹס נָחַת בְּרָכוֹת
(c)	hamatos naxat braxot
	‘The plane landed congratulations’

Table 1: An example of an undotted Hebrew text (a) (written right to left) which can be interpreted in at least two different ways (b,c), dotted and pronounced differently, but only (b) makes grammatical sense.

1 Introduction

The vast majority of modern Hebrew texts are written in a letter-only version of the Hebrew script, one which omits the diacritics present in the full diacritized, or *dotted* variant.[1] Since most vowels are encoded via diacritics, the pronunciation of words in the text is left underspecified, and a considerable mass of tokens becomes ambiguous. This ambiguity forces readers and learners to infer the intended reading using syntactic and semantic context, as well as common sense (Bentin and Frost, 1987; Abu-Rabia, 2001). In NLP systems, recovering such signals is difficult, and indeed their performance on Hebrew tasks is adversely affected by the presence of undotted text (Shacham and Wintner, 2007; Goldberg and Elhadad, 2010; Tsarfaty et al., 2019).

As an example, the sentence in Table 1 (a) will be resolved by a typical reader as (b) in most reasonable contexts, knowing that the word “softly” may characterize landings. In contrast, an automatic system processing Hebrew text may not be as sensitive to this kind of grammatical knowledge and instead interpret the undotted token as the more frequent word in (c), harming downstream performance.

One possible way to overcome this problem is by adding diacritics to undotted text, or *dotting*, implemented using data-driven algorithms trained on dotted text. Obtaining such data is not trivial, even given correct pronunciation: the standard Tiberian diacritic system contains several sets of identically-vocalized forms, so while most Hebrew speakers easily read dotted text, they are unable to produce it. Moreover, the process of manually adding diacritics in either handwritten script or through digital input devices is mechanically cumbersome. Thus, the overwhelming majority of modern Hebrew text is undotted, and manually dotting it requires expertise. The resulting scarcity of available dotted text in modern Hebrew contrasts with Biblical and Rabbinical texts which, while dotted, manifest a very different language register. This state of affairs allows individuals and companies to offer dotting as paid services, either by experts or automatically, e.g. the Morfix engine by Melingo.[2] Such usage practices also force a disconnect in the NLP pipeline, requiring an API call into an external

---

[1] Also known as *pointed* text, or via the Hebrew term for the diacritic marks, *nikkud/niqqud*.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1010 - 1018
July 10-15, 2022 ©2022 Association for Computational Linguistics

service whose parameters cannot be updated.

Existing computational approaches to dotting are manifested as complex, multi-resourced systems which perform morphological analysis on the undotted text and look undotted words up in handcrafted dictionaries as part of the dotting process. Dicta's Nakdan (Shmidman et al., 2020), the current state-of-the-art, applies such methods in addition to applying multiple neural networks over different levels of the text, requiring manual annotation not only for dotting but also for morphology. Among the resources it uses are a diacritized corpus of 3M tokens and a POS-tagged corpus of 300K tokens. Training the model takes several weeks.[3]

In this work, we set out to simplify the dotting task as much as possible to standard modules. We introduce a large corpus of semi-automatically dotted Hebrew, collected from various sources, and use it to train an RNN-based model. Our system, NAKDIMON, accepts the undotted character sequence as its input, consults no external resources or lexical components, and produces diacritics for each character, resulting in dotted text whose quality is comparable to that of the commercial Morfix, on both character-level and word-level accuracy. Our model is easy to integrate within larger systems that perform end-to-end Hebrew processing tasks, as opposed to the existing proprietary dotters. To our knowledge, this is the first attempt at a "light" model for Hebrew dotting since early HMM-based systems (Kontorovich, 2001; Gal, 2002).

We introduce a novel test set for Modern Hebrew dotting, derived from larger and more diverse sources than existing datasets. In experiments over our dataset, we show that our system is particularly useful in the main use case of modern dotting, which is to convey the desired pronunciation to a reader, and that the errors it makes should be more easily detectable by non-professionals than Dicta's.[4]

2 Task and Datasets

2.1 Dotting as Sequence Labeling

The input to the dotting task consists of a sequence of characters. Each of the characters is assigned three values, from three separate diacritic categories: one category for the dot distinguishing *shin* (שׁ) from *sin* (שׂ), two consonants sharing a base character ש; another for the presence of *dagesh/mappiq*, a central dot affecting pronunciation of some consonants, e.g. פּ /p/ from פ /f/, but also present elsewhere; and one for all other diacritic marks, which mostly determine vocalization, e.g. דָ /da/ vs. דֶ /de/. Diacritics of different categories may co-occur on single letters, e.g. שָּׁ, or may be absent altogether.

Full script Hebrew script written without intention of dotting typically employs a compensatory variant known colloquially as full script (*ktiv male*, כתיב מלא), which adds instances of the letters י and ו in some places where they can aid pronunciation, but are incompatible with the rules for dotted script. In our formulation of dotting as a sequence tagging problem, and in collecting our test set from raw text, these added letters may conflict with the dotting standard. For the sake of input integrity, and unlike some other systems, we opt not to remove these characters, but instead employ a dotting policy consistent with full script. See Appendix A for further details.

2.2 Training corpora

Dotted modern Hebrew text is scarce, since speakers usually read and write undotted text, with the occasional diacritic added for disambiguation when context does not suffice. As we are unaware of legally-obtainable dotted modern corpora, we use a combination of dotted pre-modern texts as well as automatically and semi-automatically dotted modern sources to train NAKDIMON:

The PRE-MODERN portion is obtained from two main sources: A combination of late pre-modern text from Project Ben-Yehuda, mostly texts from the late 19th century and the early 20th century;[5] rabbinical texts from the medieval period, the most important of which is Mishneh Torah (obtained from Project Mamre);[6] and 23 short stories from the short story project.[7] This portion contains roughly 1.81M Hebrew tokens, most of which are dotted, with a varying level of accuracy, varying dotting styles, and varying degree of similarity to Modern Hebrew.

The AUTOMATIC portion contains 547 short stories taken from the short story project. The stories are dotted using Dicta *without* manual validation.

	Total		493	326,683

Table 2: Data sources for our MODERN Hebrew training set. Rows marked with * were automatically dotted via the Dicta API and corrected manually. Rows with † were dotted at low quality, requiring manual correction. The rest were available with professional dotting.

The corpus contains roughly 1.27M Hebrew tokens.

Lastly, the MODERN portion contains manually collected text in Modern Hebrew, mostly from undotted sources, which we dot using Dicta and follow up by manually fixing errors, either using Dicta's API or via automated scripts which catch common mistakes. We made an effort to collect a diverse set of sources: news, opinion columns, paragraphs from books, short stories, Wikipedia articles, governmental publications, blog posts and forums expressing various domains and voices, and more. Our MODERN corpus contains roughly 326K Hebrew tokens, and is much more consistent and similar to the expectation of a native Hebrew speaker than the PRE-MODERN or the AUTOMATIC corpora, and more accurately dotted than the AUTOMATIC corpus. The sources and statistics of this dataset are presented in Table 2.

2.3 New test set

Shmidman et al. (2020) provide a benchmark dataset for dotting modern Hebrew documents. However, it is relatively small and non-diverse: all 22 documents in the dataset originate in a single source, namely Hebrew Wikipedia articles.

Therefore, we created a new test set[8] from a larger variety of texts, including high-quality Wikipedia articles and edited news stories, as well as user-generated blog posts. This set consists of ten documents from each of eleven sources (5x Dicta's test set), and totals 20,474 Hebrew tokens, roughly 3.5x Dicta's. We use the same technique and style for dotting this corpus as we do for the MODERN corpus (§2.2), but the documents were collected in different ways.

3 Nakdimon

NAKDIMON embeds the input characters and passes them through a two-layer Bi-LSTM (Hochreiter and Schmidhuber, 1997). The LSTM output is fed into a single linear layer, which then feeds three linear layers, one for each diacritic category (see §2). Each character then receives a prediction for each category independently and all predicted marks are added to it as output.

Decoding is performed greedily, with no validation of readability or any other dependence between character-level decisions.

The input is pre-processed by removing all but Hebrew characters, spaces and punctuation; digits are converted to a dedicated symbol, as are Latin characters. All existing diacritic marks are stripped, and each document is split into chunks bounded at whitespace, ignoring sentence boundaries.

We train NAKDIMON first over PRE-MODERN, then over the AUTOMATIC corpus, and then by over the MODERN corpus. During training, the loss is the sum of the cross-entropy loss from all three categories. Trivial decisions, such as the label for the *shin/sin* diacritic for any non-ש letter, are masked.

Tuning experiments are detailed in Appendix B; an evaluation of a preliminary version of NAKDIMON over the Dicta test set is in Appendix C, and Hyperparameters are detailed in Appendix D.

4 Experiments

We compare the performance of NAKDIMON on our new test set (§2.3) against Dicta,[9] Snopi,[10] and Morfix (Kamir et al., 2002). as well as a MAJORITY baseline which returns the most common dotting for each word seen in our full training set.

Metrics We report four metrics: **decision accuracy (DEC)** is computed over the entire set of individual possible decisions: *dagesh/mappiq* for letters that allow it, *sin/shin* dot for the letter ש, and all other diacritics for letters that allow them; **character accuracy (CHA)** is the portion of characters in the text that end up in their intended final form (which may combine two or three decisions, e.g. *dagesh* + vowel); **word accuracy (WOR)** is the portion of words with no mistakes; and **vocalization**

System	DEC	CHA	WOR	VOC
MAJORITY	93.79	90.01	84.87	86.19
SNOPI	91.29	85.84	76.45	78.91
MORFIX	96.84	94.92	90.38	92.39
DICTA	**97.95**	**96.77**	**94.11**	**94.92**
NAKDIMON	97.91	96.37	89.75	91.64

Table 3: Document-level macro % accuracy.

accuracy (**VOC**) is the portion of words where any dotting errors do not cause incorrect pronunciation among mainstream Israeli Hebrew speakers.[11]

4.1 Results

We provide document-level macro-averaged accuracy percentage results for a single run over our test set in Table 3. All systems, except Snopi, substantially outperform the majority-dotting baseline on all metrics. NAKDIMON outperforms Morfix on character-level metrics but not on word-level metrics, mostly since Morfix ignores certain words altogether, incurring errors on multiple characters.

We note the substantial improvement our model achieves on the VOC metric compared to the WOR metric: 18.43% of word-level errors are attributable to vocalization-agnostic dotting, compared to 13.80% for Dicta and 10.41% for Snopi (but 20.91% for Morfix). Considering that the central use case for dotting modern Hebrew text is to facilitate pronunciation to learners and for reading, and that undotted homograph ambiguity typically comes with pronunciation differences, we believe this measure to be no less important than WOR.

Results on Dicta's test set (Shmidman et al., 2020) are presented in Appendix C.

4.2 Error analysis

In Table 4 we present examples of words dotted incorrectly, or correctly, only by NAKDIMON, compared with Morfix and Dicta. The largest category for NAKDIMON-only errors (∼18% of 90 sampled) are ones where a fused preposition+determiner character is dotted to only include the preposition, perhaps due to its inability to detect the explicit determiner clitic ה in neighboring words, on which the complex systems apply morphological segmentation. In other cases (∼15%), NAKDIMON creates unreadable vocalization sequences, as it has no lexical component and is decoded greedily. These types of errors are more friendly to the typical use cases of a dotting system, as they are likely to stand out to a reader. In contrast, a large portion of cases where only NAKDIMON was correct (∼13% of 152) are foreign names and terms. This may be the result of such words not yet appearing in dictionaries, or not being easily separable from an adjoining clitic, while character-level information can capture pronunciation patterns from similar words (e.g. טֶלֶפוֹן 'telephone', for the example האייפון).

Context	Correct	Incorrect
... וצריך להסתכל לה בעיניים. '...and we need to look her **in the eyes (/in eyes)**.'	בָּעֵינַיִם	בְּעֵינַיִם
... יענו לך בסבלנות... '...**you.sg.f (/unreadable)** will be answered patiently...'	לָךְ	לְךְ
... משתמשי האייפון הראשונים... '...the first **iPhone (/*ee-pon*)** users...'	הָאַיְפוֹן	הָאִייפּוֹן

Table 4: Examples of words dotted incorrectly (top) or correctly (bottom) only by NAKDIMON.

OOVs To further quantify the strengths of NAKDIMON's architecture and training abilities, we evaluate the systems' results pertaining only to those words in the test set which do not appear in our training sets. We follow common practice by calling them OOVs ("out of vocabulary"), but emphasize that NAKDIMON does not consult an explicit vocabulary, and the other systems are not evaluated against their own vocabularies (which are unknown to us).

We find that NAKDIMON's performance on this subset is substantially **worse** compared with the other systems than on the full set: 15 percentage points below Dicta and seven below Morfix on the VOC metric (see full results in Appendix C).

These results might be counter-intuitive considering the proven utility of character-level models in OOV contexts (e.g., Plank et al., 2016), and so we offer several possible explanations: First, many "OOVs" consist in fact of known words coupled with an unseen combination of prefix clitics and/or suffix possessive markers, which other systems explicitly remove using morphological analyzers before dotting. Second, mirroring the last finding from the overall analysis, some "OOVs" are proper names which appear in dictionaries but are absent from the training set, due to corpus effects such as time and domain, or simply chance.

---

[11] These are: the *sin*/*shin* dot, vowel distinctions across the a/e/i/o/u/null sets, and *dagesh* in the ב/כ/פ characters. We do not distinguish between *kamatz gadol*/*kamatz katan*, and *schwa* is assumed to always be null.

5 Related Work

Existing work on diacritizing Hebrew is not common, and all efforts build on word-level features.

Kontorovich (2001) trains an HMM on a vocalized and morphologically-tagged portion of the Hebrew Bible containing 30,743 words, and evaluates the result on a test set containing 2,852 words, achieving 81% WOR accuracy. Note that Biblical Hebrew is very different from Modern Hebrew in both vocabulary, grammatical structure, and diacritization, and also has many words with unique diacritization. In our system, we exclude the Bible altogether from the training set, as its inclusion actively hurts performance on the validation set, which consists of Modern Hebrew.

Tomer (2012) designs a diacritization system for Hebrew verbs consisting of a combination of a verb inflection system, a syllable boundary detector, and an SVM model for classifying verb inflection paradigms. The focus on verbs in a type-level setup makes this work incomparable to ours or to others in this survey.

In Arabic, diacritization serves a comparable purpose to that in Hebrew, but not exclusively: most diacritic marks differentiate consonantal phonemes from each other, e.g. ب /b/ vs. ت /t/ (which only the sin/shin dot does in Hebrew), whereas vocalization marks are in a one-to-one relationship with their phonetic realizations, e.g. only the *fatha* as in بَ /ba/ encodes the /a/ vowel.

Dictionary-less Arabic diacritization has been attempted using a 3-layer Bi-LSTM (Belinkov and Glass, 2015). Abandah et al. (2015) use a Bi-LSTM where characters are assigned either one or more diacritic symbols. Our system differs from theirs by virtue of separating the diacritization categories. Mubarak et al. (2019) tackled Arabic diacritization as a sequence-to-sequence problem, tasking the model with reproducing the characters as well as the marks.

Zalmout and Habash (2017) have made the case against RNN-only systems, arguing for the importance of morphological analyzers in Arabic NLP systems. We concede that well-curated systems may perform better than uncurated ones, particularly on low-resource languages such as Hebrew, but we note that they are difficult to train for individual use cases and are burdensome to incorporate within larger systems.

Diacritics restoration in Latin-based scripts, applicable mostly to European languages, forms a substantially different problem from the one in Hebrew given the highly lexicalized nature of diacritic usage in these languages and the very low rate of characters requiring diacritics. The state-of-the-art systems in such languages employ transformer models in a sequence-to-sequence setup (Náplava et al., 2021; Stankevičius et al., 2022), supplanting character-RNN sequence prediction architectures reminiscent of ours (Náplava et al., 2018). Indeed, the authors of this latter work note the only non-European in their dataset, Vietnamese, as a special outlier.

6 Conclusion

Learning directly from plain diacritized text can go a long way, even with relatively limited resources. NAKDIMON demonstrates that a simple architecture for diacritizing Hebrew text as a sequence tagging problem can achieve performance on par with much more complex systems. We also introduce and release a corpus of dotted Hebrew text, as well as a source-balanced test set.

In the future, we wish to evaluate the utility of dotting as a feature for downstream tasks such as question answering, machine translation, and speech generation, taking advantage of the fact that our simplified model can be easily integrated in an end-to-end Hebrew processing system.

Ethical Considerations

We collected the data for our training set and test sets from open online sources, while making sure their terms allow research application and privacy is not impugned. NAKDIMON's architecture does not encourage memorization of training data and the system is not trained for generating text.

We consider a main use case for our system to be assisting Hebrew learners in reading. We therefore expect NAKDIMON to facilitate life in Israel for immigrants still struggling with Hebrew, among other underprivileged groups. Automatic dotting can increase inclusion in Hebrew-prominent societies for literacy-challenged individuals, and derivative improvements in text-to-speech applications can assist those with impaired vision. Lastly, dotting can help researchers with limited understanding of Hebrew access resources in the language.

Hebrew is a gendered language. Orthographically, in many cases the lack of dots masks gender ambiguity, allowing both masculine and feminine readings for a given word (e.g. שָׁלַחְתְּ / שָׁלַחְתָּ 'you.fem sent' / 'you.masc sent'). While well-performing automatic dotting can help alleviate these ambiguities and reduce the amount of potentially prejudiced readings, we recognize the large body of work on gender bias in NLP (Blodgett et al., 2020), including in Hebrew NLP (Moryossef et al., 2019), and the findings that an imbalanced training set may result in an even more skewed distribution of gender bias in applications (Zhao et al., 2017). We believe our unlexicalized approach is more robust to such bias compared with other systems, and have already started quantifying and addressing these issues as we find them in ongoing work. In the meantime, we offer this paragraph as a disclaimer.

Acknowledgments

We would like to thank Avi Shmidman for details about Dicta's Nakdan and other suggestions. We thank Sara Gershuni for lengthy and fruitful discussions, and for her linguistic insights and advice. We thank Yoav Goldberg, Reut Tsarfaty, Ian Stewart, Sarah Wiegreffe, Kyle Gorman and many anonymous reviewers for their comments and suggestions in discussions and on earlier drafts.

Table 5: Document-level macro % accuracy on the test set from Shmidman et al. (2020) and on our new test set. We cannot report our full Nakdimon's performance on the former, as we use the test set for parts of its training. MajAll is reported as Majority in the main text; MajMod only considers text in the Modern portion of our training set.

A Full Script Reconciliation

We apply the following resolution tactics for added letters in undotted text: (a) We almost never remove or add letters to the original text (unless it is completely undiacritizable). (b) We keep *dagesh* in letters that follow a *shuruk* which replaces a *kubuts*, and similarly for yod (*hirik male* replacing *hirik haser*). (c) When we have double *vav* or double *yod*, the second letter is usually left undotted, except when it is impossible to have the correct vocalization this way.

Resolving *ktiv haser* discrepancies from Morfix outputs is done by adding missing vowel letters, or removing superfluous vowel letters, in such a way that would not count as an error if it is correct according to Academy regulations.

B Development Experiments

We tried to further improve Nakdimon by initializing its parameters from a language model trained to predict masked characters in a large undotted Wikipedia corpus (440MB, 30% mask rate), but were only able to achieve an improvement of 0.07%. Attempted architectural modifications, including substituting a Transformer (Vaswani et al., 2017) for the LSTM; adding a CRF layer to the decoding process; and adding a residual connection between the character LSTM layers, yielded no substantial benefits in these experiments. Similarly, varying the number of LSTM layers between 2 and 5 (keeping the total number of parameters roughly constant, close to the 5,313,223 parameters of our final model) had little to no impact on the accuracy on the validation set.

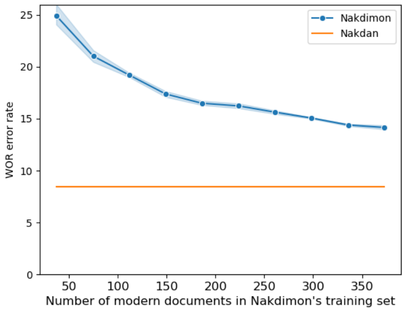

Figure 1: WOR error rate on validation set as a function of training set size vs. Dicta, over five runs. Other metrics show similar trends.

Figure 1 shows the favorable effect of training Nakdimon over an increasing amount of Modern text.

C Dicta Test Set

We present results for the Dicta test set in Table 5. In order to provide fair comparison and to preempt overfitting on this test data, we ran this test in a preliminary setup on a variant of Nakdimon which was not tuned or otherwise unfairly trained. This system, Nakdimon$_0$, differs from our final variant in three main aspects: it is not trained on the Dicta portion of our training corpus (§2.2), it is not trained on the Automatic corpus, and it employs a residual connection between the two character Bi-LSTM layers. Testing on the Dicta test set required some minimal evaluation adaptations resulting from encoding constraints (for example, we do not distinguish between *kamatz katan* and *kamatz gadol*). Thus, we copy the results reported in

Shmidman et al. (2020) as well as our replication.

We see that the untuned NAKDIMON$_0$ performs on par with the proprietary Morfix, which uses word-level dictionary data, consistent with our main results on our novel test set.

D Hyperparameters

We tuned hyperparameters and architecture over a held-out validation set of 40 documents with 27,681 tokens, on which Dicta performs at 91.56% WOR accuracy.

In our chosen setup, we train NAKDIMON over PRE-MODERN for a single epoch, followed by two epochs over the AUTOMATIC corpus, and then by three epochs over the MODERN corpus. We optimize using Adam (Kingma and Ba, 2014). For the PRE-MODERN corpus we use a cyclical learning rate schedule (Smith, 2017), varying linearly from $3 \cdot 10^{-3}$ through $8 \cdot 10^{-3}$ and down to 10^{-4}, which we found to be more useful than a constant learning rate. For each of AUTOMATIC and MODERN corpora we use epoch-wise decreasing learning rate: $(3 \cdot 10^{-3}, 10^{-3})$ and $(10^{-3}, 10^{-3}, 3 \cdot 10^{-4})$ respectively. We set maximum chunk size to 80 characters, and use batch size of 128. We set both character embedding and LSTM hidden dimensions to 400, and apply a dropout rate of 0.1.

Masked Summarization to Generate Factually Inconsistent Summaries for Improved Factual Consistency Checking

Abstract

Despite the recent advances in abstractive summarization systems, it is still difficult to determine whether a generated summary is factual consistent with the source text. To this end, the latest approach is to train a factual consistency classifier on factually consistent and inconsistent summaries. Luckily, the former is readily available as reference summaries in existing summarization datasets. However, generating the latter remains a challenge, as they need to be factually inconsistent, yet closely relevant to the source text to be effective. In this paper, we propose to generate factually inconsistent summaries using source texts and reference summaries with key information masked. Experiments on seven benchmark datasets demonstrate that factual consistency classifiers trained on summaries generated using our method generally outperform existing models and show a competitive correlation with human judgments. We also analyze the characteristics of the summaries generated using our method. We will release the pre-trained model and the code at `https://github.com/hwanheelee1993/MFMA`.

1 Introduction

As textual content available on- and offline explodes, automated text summarization is becoming increasingly crucial (El-Kassas et al., 2020); with the advances in neural text generation methods, abstractive summarization systems that generate paraphrases are quickly replacing extractive ones that simply select essential sentences from the source text (Nallapati et al., 2017). While abstractive summaries can be more coherent and informative (given the same length) than their extractive counterparts, they frequently contain information inconsistent with the source text. This is a critical issue, as it directly affects the reliability of the generated summaries. (Cao et al., 2018; Zhao et al., 2020; Maynez et al., 2020).

Article: Guus Hiddink, the Russia and Chelsea coach, has had much to smile about in his 22-year managerial career. ,. . . , Enjoying success around the world – at different levels with different players in different cultures – has made Guus Hiddink one of the most admired bosses around. ,. . . , Hiddink's resume includes stints in other high-pressure jobs such as Fenerbahce, Valencia and Real Madrid. ,. . . , But the straight-speaking Dutchman is loyal to the project he has in charge of the Russian national side and insists he will leave Chelsea at the end of the season regardless.

Reference Summary: Born in 1946, Hiddink has become one of the best managers in the world . Dutchman has enjoyed huge success at club and international level. He's currently coach of Russia and is in charge of Chelsea until end of the season.

Mask-and-fill Summary Without Article:
Born in 1946, *Dutchman* has become one of *the most respected politicians* in the world. Dutchman is enjoyed *success at the Olympics and World Cup*. He's currently the *President of Russia* and is in charge of *the country* until the end of the season.

Mask-and-fill Summary With Masked Article:
Born in 1946, *Hiddink* has become one of *the most admired managers* in the world. Dutchman has enjoyed *successful spells* at *Chelsea and Real Madrid*. He's currently *manager of Russia* and is in charge of *the country* until the end of the season.

Figure 1: An example of generated negative summary using masked article. Spans that are highlighted are masked when generating the negative summary. Note that red spans are factually inconsistent with the given article and blue spans are factually consistent.

Unfortunately, existing approaches to identify such factual inconsistency without constructing new resources have not been satisfactory. Directly measured similarity between the summary and its source text—using popular n-gram similarity metrics such as ROUGE (Lin, 2004) and BLEU (Papineni et al., 2002)—exhibits low correlation with

human judgments for factual consistency. Also, leveraging related tasks—such as natural language inference (NLI) (Bowman et al., 2015) and fact verification (Thorne et al., 2018)—is not ideal. This is because these tasks aim to identify relations between two sentences, whereas factual consistency checking involves a multi-sentence summary and an even longer source text (Bora-Kathariya and Haribhakta, 2018; Falke et al., 2019).

A remaining solution is to train a factual consistency classifier with a dataset specifically constructed for this purpose. Note that ***positive summaries*** are readily available. That is, the reference summaries from existing text summarization datasets can be assumed to be factually consistent with the respective source texts. Thus, the main challenge is in generating effective ***negative summaries***, i.e., summaries that are factually inconsistent with the source text. Recent works generate negative summaries by simply replacing keywords in the reference summaries or sentences extracted from the source texts (Kryscinski et al., 2020; Yin et al., 2021). This, however, results in negative summaries that significantly diverge from the source texts and positive summaries, which is not ideal for training factual consistency classifiers. For instance, Figure 1 shows that *coach* in the reference summary is changed to *President of Russia*, which is an inconsistency that is too obvious.

In this paper, we propose a novel method, Masked-and-Fill with Masked Article (MFMA), where parts of the source text and reference summary are masked and later inferred to generate a plausible but factually inconsistent summary. Experiments on seven benchmark datasets demonstrate that factual consistency classifiers trained on negative summaries generated with our method mostly outperform existing models and show a competitive correlation with human judgment. We also analyze the characteristics of the negative summaries generated. Our main contributions are as follows:

- We propose a novel negative summary generation method for training factual consistency classifiers for abstractive summaries.
- We show the efficacy of our method on seven benchmark datasets using classification performance and correlation with human judgment.
- We analyze the characteristics, such as affinity and diversity, of the negative summaries generated using our method.

2 Related Work

2.1 Factual Inconsistency in Summarization Systems

Previous works (Maynez et al., 2020; Zhao et al., 2020; Cao et al., 2018) have studied the factual inconsistency in abstractive summarization systems. Especially, (Cao et al., 2018) demonstrates that 30% of the model generated summaries have at least one factual error, and this obstacle the practical usage. (Maynez et al., 2020) specifies these factual errors in the abstractive summarization system into two types: *intrinsic errors* and *extrinsic errors*. Intrinsic errors occur using the contents present in the source article like "Switzerland" and "England" in the negative summary example in Figure 2. On the other hand, extrinsic errors are the errors generated by ignoring the source article when generating summaries. "in the second half" in Figure 2, which is not included in the source article, is an example of extrinsic errors.

In this work, we propose a system for detecting these various factual errors that are necessary for developing a summarization system. We propose a unified method for intentionally modeling both types of errors to build a dataset for training this system.

2.2 Measuring Factual Consistency

As a better way to evaluate the factual consistency, recent works such as QAGS (Wang et al., 2020) and QuestEval (Scialom et al., 2021) adopt question generation and question answering frameworks to evaluate the factual consistency. Both methods firstly generate questions using entities or noun phrases in the candidate summary and then compare the answers of these questions between the source and the summary. Although these methods do not require any reference summaries, they have a higher correlation with human judgments than previous metrics in consistency checking. Also, the generated questions and their answers are easily interpretable. But due to their complicated structure, the computational complexity of these methods is relatively heavy and the errors in each component can be cascaded.

Following the idea that all of the contents in the summaries should be entailed by source document, models from the related tasks such as Natural Language Inference(NLI) (Bowman et al., 2015; Williams et al., 2018; Falke et al., 2019) are also used to verify the factual consistency of the sum-

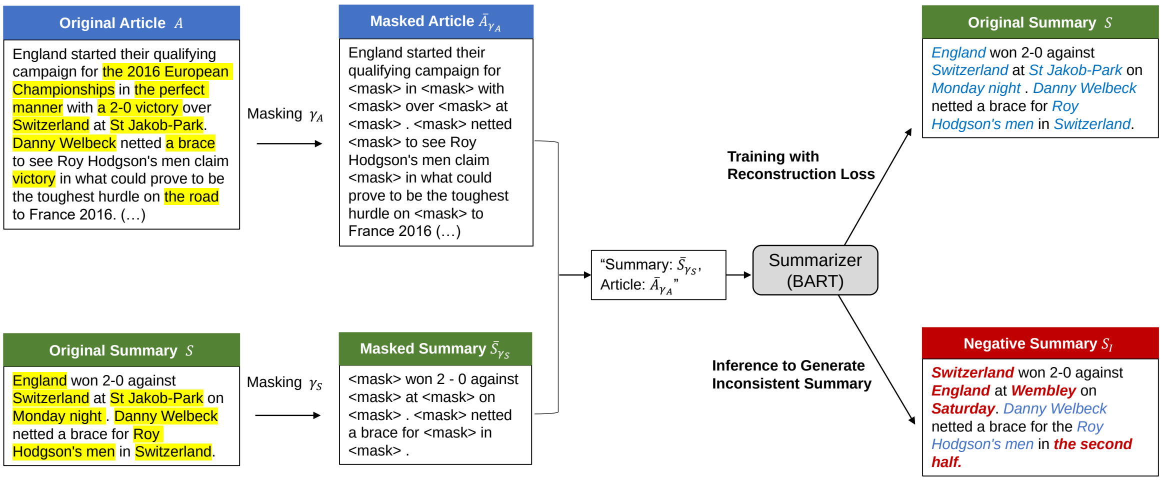

Figure 2: Overall flow of our proposed negative summary generation method Mask-and-Fill-with-Masked Article.

maries. These approaches are simpler and more intuitive than QA-based metrics. But the data pairs in these datasets are usually composed of single sentences, and this makes it difficult to be directly used for factual consistency checking in summarization where the task requires multi-sentence level reasoning. For this reason, two recent studies FactCC (Kryscinski et al., 2020) and DocNLI (Yin et al., 2021) have studied ways to make synthetic datasets for training factual consistency checking model. Both works create synthetic negative summaries using the pre-defined rules such as entity substitution or mask-and-fill. In this paper, we propose a more general negative summary generation method additionally using the masked source.

CoCo (Xie et al., 2021) compares the likelihood of the generated summaries using the original source and the masked source to estimate the counterfactual samples. Different from CoCo, our work directly augments the negative summaries and train the classifier using them.

3 Methods

For a given article A and a summary S, we aim to develop a factual consistency checking system that can evaluate whether S is factual consistent with A. In other words, the system is required to discriminate a factual consistent summary S_C with the factual inconsistent summary S_I that consists of at least one factual error. We consider this problem as a classification task between S_C and S_I. However, large-scale human-annotated training datasets for this task have not been constructed yet, especially for the inconsistent summaries S_I.

In this paper, we focus on effective augmentation methods of the inconsistent summaries. In order for that, there are two crucial conditions: 1) guarantee of inconsistency; the generated summaries should be indeed inconsistent with the source article, 2) relevance to the source article; the generated summaries should include contents related to the article. These two factors are in trade-off relations, which means that when the generated summaries are strongly inconsistent they might not be related to the article and vice versa. Therefore appropriate negative summary augmentation is required to improve the factual consistency classifier.

To generate confusing and hard negative summaries, we propose a summary generation using a masked article and a masked reference summary where some salient information is hidden. By doing so, we let the summarizer model infer hidden information through the masked article to generate plausible negative summaries. Note that, previous works such as FactCC and DocNLI generate negative summaries S_I by changing positive summaries S_C through entity replacements or mask-and-fill methods without referring to the source article. We observe that previous methods can easily guarantee negativeness, but they often generate summaries that are very irrelevant to the source article or unnatural as shown in Figure 1.

3.1 Mask-and-Fill with Masked Article

To model inconsistent summaries but related to the article, we propose a method, **M**ask-and-**F**ill with **M**asked **A**rticle (MFMA), which generates negative summaries with masked articles and masked reference summaries, as shown in Figure 2.

Specifically, we assumed *noun phrases* and *entities* in the articles are salient information, and mask them with the ratio of γ_A, resulting in masked article $\overline{A}_{\gamma_A}$. Similarly, we also mask the salient spans in the positive summary, i.e., reference summary, with the ratio of γ_S to form a masked summary $\overline{S}_{\gamma_S}$. Then, we concatenate $\overline{A}_{\gamma_A}$ and $\overline{S}_{\gamma_S}$ by prepending prefix token for each input text (i.e., "Summary: $\overline{S}_{\gamma_S}$, Article: $\overline{A}_{\gamma_A}$") as shown in Figure 2. Next, we train a summarizer based on an encoder-decoder model, BART (Lewis et al., 2020), to reconstruct the original summary S with the following loss:

$$\mathcal{L} = \sum_t -\log P(S_t|S_{<t}, [\overline{S}_{\gamma_S}; \overline{A}_{\gamma_A}]). \quad (1)$$

After training, we generate negative summaries of unseen and masked article-summary pairs through inference. Obviously, if the mask ratio is high enough, the model is hard to correctly fill the masked contents from the erased article and reference summary. However, we assume the trained reconstruction model is able to fill the masks with plausible contents by inferring the related contents with the masked article.

3.2 Masked Summarization

As a variant of MFMA, we also study another negative summary generation model, **M**asked **S**u**M**marization(MSM). The model aims to generate summaries using masked articles $\overline{A}_{\gamma_A}$ but without masked reference summaries as follows:

$$\mathcal{L} = \sum_t -\log P(S_t|S_{<t}, \overline{A}_{\gamma_A}). \quad (2)$$

The MSM model is trained to generate the entire summaries without the information guidance of masked reference summaries, so MSM has merits in generating more diverse summaries than MFMA.

3.3 Training Factual Consistency Checking Model

Finally, for the factual consistency checking model, we train a binary classifier of consistent summaries and inconsistent generated summaries. The pair of summary and the corresponding article are concatenated and then fed into the classification model as an input. We fine-tuned the pre-trained ELECTRA (Clark et al., 2019) by adding a classifier head with binary cross-entropy loss.

4 Experiments

4.1 Implementation Details

Negative Summary Generation We randomly split the training set of CNN/DM dataset (Nallapati et al., 2016) in half and use half for training negative summarizer and the other half for generating negative summary after training. We use *spaCy* for finding entities and noun phrases in both summaries and articles. We train *bart-base*[1] for five epochs to train MFMA, and use *bart-base* model without fine-tuning for MF. We use *t5-small* (Raffel et al., 2020)[2] for MSM, which shows better results than *bart-base* for this task. We attach the further details in Appendix.

Training Classifier We train *google/electra-base-discriminator*[3] for five epochs with learning rate 2e-5, batch size of 96 using adam optimizer (Kingma and Ba, 2015) with the dataset we generate using MF, MFMA and MSM. For DocNLI and FactCC, we get the original training dataset that each author release, and we train a model with the same setting as our method except for the training datasets for a fair comparison. We choose model using the balanced accuracy on validation set of FactCC (Kryscinski et al., 2020) which consists of 1k human annotated summaries.

4.2 Benchmark Datasets

For evaluating the performance of factual consistency checking system, it is necessary to compare the human judgments of the consistency for the summary with the system. And these human judgment exist in two forms, binary level(*consistent*, *inconsistent*) or numerical levels such as likert scale. In general, in the case of binary level data, performance is measured through accuracy with human judgments. For the case of numerical levels, correlation with human judgments is measured. In addition to using the results for the existing benchmark dataset in this way, we also report the accuracy by casting these numerical level datasets to the binary level dataset since we develop classifier based system. We report the results on the following datasets.

FC-Test (Kryscinski et al., 2020) release a human-annotated factual consistency for the model generated summaries for CNN/DM Dataset in

binary-level to test the performance of FactCC. There are 513 instances in this dataset.

XSumHall (Maynez et al., 2020) study the types of hallucination in the generated summaries and collect the annotation on the errors in the 2K model generated summary for BBC XSum dataset (Narayan et al., 2018). We use the datasets as binary level benchmark for XSum dataset as in (Kryscinski et al., 2020).

SummEval (Fabbri et al., 2021) collect the likert scale human judgments for the 1600 summaries generated from sixteen abstactive summarizer on CNN/DM testset. This dataset provides human judgments scores in terms of *"coherence"*, *"consistency", "fluency", and "relevance"* by three expert annotators in likert scale. We only use *"consistency"* score of three annotators, for evaluating our proposed metric. For casting this score to binary level, we let the cases where at least one annotators give less than 5 points for *"consistency"* as *inconsistent*, otherwise *consistent*.

QAGS-CNN/DM & XSum (Wang et al., 2020) release a human judgments for factual consistency on the model generated summaries for 235 summaries on CNN/DM testset and 239 summaries on XSum testset. Each summary is annotated by three annotators. We also cast the dataset to binary level by assigning *inconsistent* if at least one annotators give *inconsistent* label, otherwise *consistent*.

FRANK-CNN/DM & XSum (Pagnoni et al., 2021) releases a benchmark dataset FRANK for summarization factual metrics which consists of 2246 summaries on the model generated summaries for 1250 summaries in CNN/DM and 996 summaries XSum. Three annotators evaluated factual consistency of the generated summaries in this dataset. We also convert this dataset to binary level as same as QAGS-CNN/DM and QAGS-XSum.

4.3 Baseline Metrics

We compare our methods with the following metrics. For all of the baseline metrics, we manually compute the score using the official repository which each author provided or reproducing the model for a fair comparison.

Table 3: Summary level Pearson Correlation(r) and Spearman's Correlation(ρ) between various automatic metrics and human judgments of factual consistency for the model generated summaries. Note that we use the confidence of consistency label for entailment based metrics.

Entailment Based Metrics We adopt the model trained on MNLI (Bowman et al., 2015) and FEVER (Thorne et al., 2018) for factual consistency checking as in (Kryscinski et al., 2020). FactCC (Kryscinski et al., 2020) and DocNLI (Yin et al., 2021) are also entailment based models trained on synthetic dataset as in our work.

QA-Based Metrics QuestEval (Scialom et al., 2021) uses the question generation and answering framework for evaluating the factual consistency of the summaries. QuestEval generates the question both the generated summaries and the source article, and then compare the answers of them with both summaries and the article to compute the factuality score of the summary.

N-gram Similarity Metrics BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and METEOR (Banerjee and Lavie, 2005) are widely used for evaluating the summaries. Among them, ROUGE-L, which uses F-measure based on the longest common subsequence between a candidate summary an the reference is the most widely used.

Other Metrics BERTScore (Zhang et al., 2020) utilizes cosine similarity of BERT (Devlin et al., 2019) embeddings between the reference and the generated summary. CoCo (Xie et al., 2021) computes the difference of likelihood of the summarizer between the summary with the original source and the summary with the masked source.

4.4 Results

Classification Accuracy Due to the imbalance in each dataset, we report the macro-F1 and class balanced accuracy in Table 1 and Table 2. We observe that macro-F1 score of our proposed methods MFMA outperforms baseline entailment metrics in five of seven benchmark datasets. MFMA shows better performances than other methods in especially for CNN/DM benchmarks, and shows similar performance to other baseline in XSum datasets. We explain that this is because we only use training set of CNN/DM to construct training set. On the other hand, DocNLI additionally uses the human annotated datasets from related tasks such as ANLI (Nie et al., 2020) and SQuAD (Rajpurkar et al., 2016) except for synthetic negative summaries. Another proposed method MSM also shows competitive performance for CNN/DM benchmarks, but relatively lower performance in XSum based benchmark datasets. We explain the performance gap between MSM and MFMA is due to the properties that directly generates summaries, resulting in many noisy samples that are relatively easy to be distinguished.

Correlation with Human Judgments To compare with general metrics that are not classification level, we also report the correlation with human judgments for five datasets in Table 3. We demonstrate that our proposed method has higher pearson correlation coefficient with human judgments in three of five benchmark datasets and competitive with the best results results in the spearman correlation coefficient. Especially, entailment based methods, which are relatively easy to compute, including our proposed methods show better results than QA-based QuestEval or likelihood based CoCo. Also, reference based methods such as ROUGE-L show very lower performance than other methods that do not require any references.

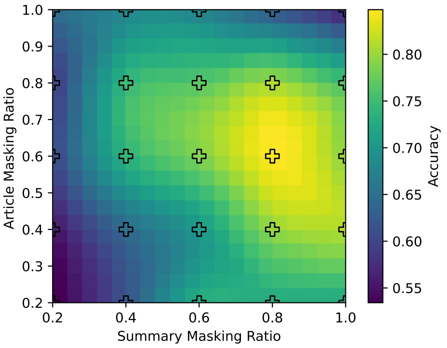

Figure 3: Validation Performance among Masked Ratio for Mask-and-Fill with Masked Article. We experiment with each of the five combinations of article mask ratio and summary mask ratio, and then plot the interpolated results.

4.5 Analysis and Discussion

Performance among Masked Ratio We analyze the effects of the mask ratio for both source article and summary in our proposed method MFMA and present results using the validation set in Figure 3. Through this experiment, we investigate the tradeoff in adjusting both the article masking ratio and summary masking ratio for generating negative summaries. As shown in Figure 3, we find that too high masking ratio decreases performance by sacrificing affinity. On the other hand, if the masking ratio is insufficient, the generated negative sample is often not really negative. In other words, too lower masking ratio leads to generate positive samples that are almost same as the original summary, and this degrades the performance of factual consistency checking model. Also, we can infer that there is an optimal masking ratio combination where the performance of factual consistency checking model is maximized.

Generated Samples among Masking Ratio We visualize the generated negative summaries through our proposed method MFMA and MSM using CNN/DM in Figure 4. We also visualize the example through MF, which simply fills in the mask without the article. We observe that if the article masking ratio γ_A is too low, the generated summaries become almost similar to the original summary since there are enough information to fill the mask. However, if the γ_A is too high, the generated examples are too far from the article, resulting in too negative summary similar to filling the mask without article.

Article: Tropical Storm Andrea formed in the Gulf of Mexico on Wednesday, marking the first storm of the 2013 Atlantic hurricane season. The storm was about 270 miles west-southwest of Tampa, Florida, and moving north at 6 mph, said the National Hurricane Center. It had maximum sustained winds of 40 mph. ,..., Thursday afternoon and move over southeastern Georgia and eastern South Carolina Thursday night and Friday. Little change in strength is expected over the next 48 hours.

Reference Summary: Storm moving north at faster rate (6 mph) A storm warning is issued for parts of the Florida coast . Little change in strength is forecast for the next 48 hours . Andrea the first storm of the 2013 Atlantic hurricane season .

MF: Storm moving north at 6 mph (11 kph) A storm warning is issued for parts of the Carolinas. Little change in strength is forecast for the Carolines. Andrea the first storm of the season.

MFMA $\gamma_A = 0.4$**:** Andea moving north at faster rate (6 mph) A storm warning is issued for parts of the Florida coast. Little change in strength is forecast for the next 48 hours. Andea the first storm of the 2013 Atlantic hurricane season.

MFMA $\gamma_A = 0.6$**:** Storm moving north at faster rate (6 mph) Tropical storm watch is issued for west coast of Florida. Little change in strength is forecast for next 48 hours. Storm the first storm of the 2013 Atlantic hurricane season.

MFMA $\gamma_A = 0.8$**:** Andrea moving north at 12 mph (6 mph) A tropical storm warning is issued for parts of the East Coast. A significant increase in strength is forecast for Thursday. Andrea the first storm of the Atlantic hurricane season.

MFMA $\gamma_A = 1.0$**:** Storm moving north at 6 mph (10 kph) A tropical storm watch is issued for the west coast of Florida. A hurricane watch in effect is forecast for the East Coast. The center of the storm forms.

MSM $\gamma_A = 0.4$**:** The storm is about 270 miles west-southwest of Fort Myers, Florida. NEW: The storm is in effect for the west coast of Florida. The storm is the first of the 2013 Atlantic hurricane season.

Figure 4: Generated negative summaries among various masking ratio in CNN/DM dataset. For MFMA and MF, we fix the summary masking $\gamma_S = 0.6$:

Table 4: Balanced accuracy of the human annotated factual consistency among masking unit. NP/Ent denotes *noun phrases* and *entities*.

Dataset	**Avg-CNN/DM**	**Avg-XSum**
NP/Ent	**73.9**	**60.9**
Token	58.6	53.9
Sentence	53.5	53.4

Performance among Masking Unit We basically perform masking operation in the *noun phrases* and *entities* units for both summary and article. In order to see the effect of the masking

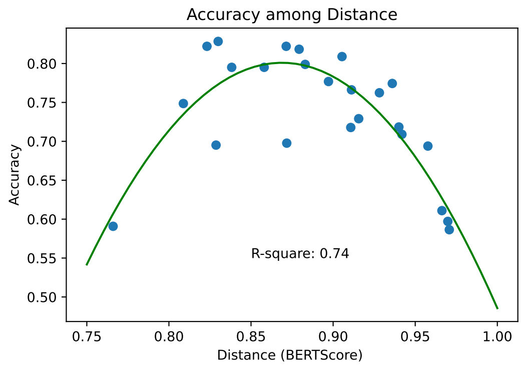

Figure 5: Validation Set Performance among BERTScore between the original reference summaries and the negative summaries we generate using the various combinations of article and summary masking ratios.

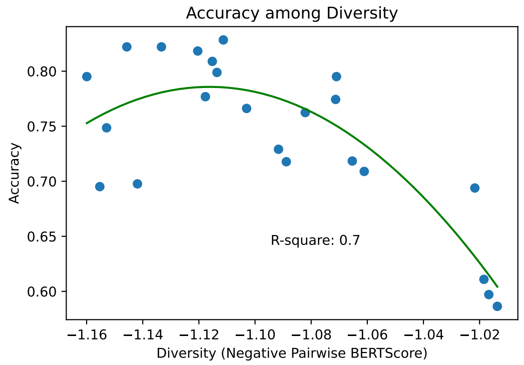

Figure 6: Validation Set Performance among diversity among various combinations of article masking ratio and summary masking ratio. Diversity is computed as negative of the pairwise BERTScore between four negative samples generated by each masking ratio.

unit, we also conduct an experiment on word level masking and sentence level masking, and present the classification level results in Table 4. We observe that *noun phrases* level masking shows the best results following the work (Goyal and Durrett, 2021) where many errors in summarization system are related to *noun phrases* and *entities*.

Distance from Original Reference Summary Using the results on various combinations of article masking ratio and summary masking ratio for MFMA as presented in Figure 3, we also investigate the relation between the average distance from the reference summary on each mask ratio combination and the performance. We compute BERTScore between original reference summary and the negative summary generated using the reference summary to get the distance. Interestingly, as shown in Figure 5, we observe the distribution in which performance is maximized within the appropriate distance around 0.8 as the two-dimensional distribution with an R^2 of 0.74. This result shows how far the synthetic negative summaries must be from the reference summaries to help training the factual consistency checking model.

Article: Nkaissery told reporters the university will be able to confirm Saturday if everyone has been accounted for. Thursday's attack by al-Shabaab militants killed 147 people, three security officers and two university security personnel. The attack left 104 people injured, including 19 who are in critical condition, Nkaissery said.,...,

Figure 7: Case study on entailment based models. First example comes from and FactCC-Test and second example comes from XSumHall.

Diversity among Masked Ratio Our proposed method can generate various samples depending on the location of the mask for the same summary-article pair with the fixed mask ratio. Hence, we analyze the diversity of the generated negative summaries among the combinations of mask ratio for MFMA and present the result using validation set in Figure 6. We define the diversity of each mask ratio combination as the negation of pairwise similarity score for each sample following (Tevet and Berant, 2021). We sample four negative summaries using the given article for each method and then compute the pairwise similarity scores for all of the combinations. We also use BERTScore as a similarity measure. Similar to the distance, we observe that diversity has also similar to a two-dimensional form with an R^2 of 0.7, in which the accuracy is maximized at an appropriate point.

Case Study To understand the pros and cons of our proposed factual consistency checking system, we conduct a case study and illustrate the representative success and failure cases in Figure 7. We observe that our system is good at judging the facts themselves in the summary like the first example, but still not perfect in examples that require high-level reasoning like the second example. We expect the system can be improved by adopting MFMA and MSM to the datasets that have more abstractive summaries which require more reasoning to check the factual consistency.

5 Conclusion

In this paper, we proposed an effective generation method of factually inconsistent summaries, called MFMA. In this method, some proportion of the source text and corresponding reference summaries is hidden, then a summarization model generates plausible but factually inconsistent summaries by inferring the masked contents. Experiments on seven benchmark datasets demonstrate that factual consistency classifiers trained using our method generally outperform existing models and show a competitive correlation with human judgment.

Ethical Considerations

Our approach creates a synthetic dataset using a public dataset to train a factual consistency checking model. Therefore, in the process of generating such samples, ethically problematic datasets can be generated due to the bias of the pre-trained models, similar to other text generation tasks. For this reason, once the training process is completed, we remove the generated sample. And, we will not release the synthetic dataset itself, and will release only the trained factual consistency checking model.

A Experimental Details

A.1 Reproducibility Checklist

Source Code We attach the source in the submission and we will release the pre-trained factual consistency checking model.

Computing Infrastructure We use Intel(R) Xeon(R) Silver 4210R CPU (2.40 GHz) with NVIDIA RTX A5000 24GB for the experiments. The software environments are Python 3.8.8 and PyTorch 1.10.1.

Dataset Statistics We use the training of CNN/DM dataset that consists of 287113 examples. We divide it in half randomly and use one for MSM or MFMA training and the other for generating negative summaries. Then, we merge the generated article-negative summaries pairs and the article-positive summaries we used for training MFMA and MSM to construct the training set for factual consistency checking model.

Average runtime for each approach For training MFMA and MSM, it takes 10 hours to train the whole model. And it takes 3 hours to generate whole negative summaries that is to be used for training factual consistency checking. For training factual consistency checking model, it takes 7 hours using a single GPU.

Hyperparameters We train five epochs for MFMA and MSM using *bart-base* for MFMA and *t5-small* for MSM respectively. We train the model with batch size of 48, max input sequence size of 1024, and max target sequence size of 140. We conduct experiment with various article masking γ_A ratio-summary masking ratio γ_S combinations, at 0.2 intervals from (0.2, 0.2) to (1.0, 1.0). For the case of training classifier, we train *google/electra-base-discriminator* for five epochs with learning rate 2e-5 and batch size of 96. We choose the best parameters using the validation set provided by the (Kryscinski et al., 2020). The best mask ratio combination is γ_A = 0.6 and γ_S = 0.8.

Number of Model Parameters The number of parameters for negative summary generation model is 139M for MFMA, is 0.6M (t5-small) and the factual consistency classifier is 109M.

A.2 Computing Baseline Metrics

Even with the same dataset, the results may be different due to some factors such as type of tokenizer or case, so we calculate baseline ourselves as follows. For n-gram similarity metrics BLEU-4, ROUGE-L and METEOR, we compute the scores using the package *language evaluation*[4] which is based on COCOeval[5]. For BERTScore[6], QuestEval[7] and CoCO[8], we use the official repository with the default setting. For MNLI, we use *roberta-large-mnli*[9] and use tals/albert-base-vitaminc-fever[10] for FEVER.

A.3 Significance Test

We adopt standard way to test the significance of the correlation coefficient for all of the reported related correlation coefficients in Table 3. We compute the p-value for each coefficient with a t-test that uses a null hypothesis, which is an absence of association.

Probing the Role of Positional Information in Vision-Language Models

Philipp J. Rösch[1] and **Jindřich Libovický**[2]

Abstract

In most Vision-Language models (VL), the understanding of the image structure is enabled by injecting the position information (PI) about objects in the image. In our case study of LXMERT, a state-of-the-art VL model, we probe the use of the PI in the representation and study its effect on Visual Question Answering. We show that the model is not capable of leveraging the PI for the image-text matching task on a challenge set where only position differs. Yet, our experiments with probing confirm that the PI is indeed present in the representation. We introduce two strategies to tackle this: (*i*) Positional Information Pre-training and (*ii*) Contrastive Learning on PI using Cross-Modality Matching. Doing so, the model can correctly classify if images with detailed PI statements match. Additionally to the 2D information from bounding boxes, we introduce the object's depth as new feature for a better object localization in the space. Even though we were able to improve the model properties as defined by our probes, it only has a negligible effect on the downstream performance. Our results thus highlight an important issue of multimodal modeling: the mere presence of information detectable by a probing classifier is not a guarantee that the information is available in a cross-modal setup.

1 Introduction

Pre-trained Vision-Language models (Tan and Bansal, 2019; Lu et al., 2019; Yu et al., 2021; Chen et al., 2020) reached strong performance in many multimodal tasks such as Visual Question Answering (Antol et al., 2015; Hudson and Manning, 2019; Bigham et al., 2010) or Visual Inference (Johnson et al., 2017; Suhr et al., 2019). All these models use the Transformer architecture (Vaswani et al., 2017) and make use of several pre-training strategies like *Masked Cross-Modality Language Modeling* (MM) and *Cross-Modality Matching* (CMM) similar to masked language modeling and next sentence prediction (Devlin et al., 2019) in NLP.

Because the attention mechanism treats its inputs as unordered sets, Transformer-based NLP models need to use position encodings to represent the mutual position of the tokens, so that the models can grasp the sentence structure. The mutual position of objects is equally important for understanding the structure of an image. VL models differ in how they represent objects in the image, typically represented as sets of object features and PI. Therefore, object detectors are used to obtain bounding box information for all objects. In many models, the upper left and lower right corners of the object's bounding box are used as 2D information to create a learnable positional encoding. In addition to the spatial but flat 2D values, we determine the depth of the objects in the image and make it available as an additional feature. Until now, VL models recognize the objects on a flat map but not in the real three-dimensional context.

We found that the current LXMERT model is capable of forwarding PI through the model but is not capable to use it to solve image-text matching tasks where positional keywords are replaced by their counterparts. Introducing two new pre-training strategies, we target these unimodal and multimodal evaluation schemes and improve probing results. Yet, we did not get any perfomance increase on the downstream tasks. This is most likely due to the small fraction of position-related text in the pre-training corpus and suboptimal results of the object detector. Regarding PI type, it seems to be sufficient to input object center values which is far less than most VL model input today.

2 Positional Information in VL Models

In NLP, the importance of word order is given great attention (Ke et al., 2021; Wang and Chen, 2020). Different methods exist, including analytical position encodings (Vaswani et al., 2017), learnable

PI Type	Models
$\emptyset$	CLIP
$x1, y1, x2, y2$	LXMERT, M4C
$x1, y1, x2, y2, \frac{a}{wh}$	ViLBERT, Unicoder-VL, ERNIE-ViL
$x1, y1, x2, y2, w, h$	OSCAR
$x1, y1, x2, y2, w, h, a$	UNITER

Table 1: Positional information in Vision-Language models. Most models use the upper left and lower right of the object's bounding box $(x1, y1, x2, y2)$. Some models add the absolute (a) or relative object area $(\frac{a}{wh})$ in combination with the image width (w) and height (h). The object depth (d) is not used and $\emptyset$ denotes no PI.

additive embeddings (Devlin et al., 2019) or the relative the attention query (Shaw et al., 2018). There is no equivalent research that would specifically approach PI in VL models. However, the position of the objects is considered in almost all common Transformer-based approaches.

In LXMERT (Tan and Bansal, 2019) the upper left and lower right corners of the object are used to encode its position. The same is true for M4C (Hu et al., 2020). Other models also use the relative area fraction of the objects as an additional feature. Although the network should be able to determine this feature, it is explicitly added, as in case of ViLBERT (Lu et al., 2019), Unicoder-VL (Li et al., 2020a), and ERNIE-ViL (Yu et al., 2021). UNITER (Chen et al., 2020) uses – in addition to the objects' corners – the absolute object area and the image width and height. OSCAR (Li et al., 2020b) uses bounding box and image height and width. Only CLIP (Radford et al., 2021) does not use PI, although they use another pre-training concept. See Table 1 for an overview. To our knowledge, there is no structured analysis of PI in VL models.

Current models use only 2D object information. By introducing depth as a new feature, we represent objects in the 3D space. This is not only important to be able to define the distances between objects but also to have a more meaningful understanding of the object sizes. Using the area of the bounding box without depth information does not add the actual object size information since the sizes depend on the depth localization of the object.

3 Evaluation of Positional Information

To determine the capability of current models with regard to PI, we experiment with three evaluation methods. Firstly, we perform an intrinsic evaluation to determine whether the PI passes through the model. Secondly, we test if the models are capable of utilizing PI using the CMM task. Lastly, we report extrinsic results for GQA downstream task (Hudson and Manning, 2019) on different data subsets. We report the results of the probing experiment in Section 5.

For our experiments, we use four types of PI. An empty set ($\emptyset$) acts as a baseline. Object center values (x, y) act as a coarse identification of where the object is located. Moreover, we evaluate $x1, y1, x2, y2$, which is the standard representation of bounding boxes and is also often used in VL models. This PI description contains information about object width, height, and area. Therefore, we ignore further settings that add these types to the input in our evaluation. Since we are also interested in analyzing depth, we investigate the setting $x1, y1, x2, y2, d$ as well.

Mutual Position Evaluation. In the intrinsic evaluation task, we test if PI is forwarded through the whole model. We use nine different pairwise classifiers for different mutual positions, which are applied to all detected objects. LXMERT uses a fixed number of 36 objects as its input. This leads to a total number of $9 \times 36 \times 36 = 11,664$ classifications for each input image.

We use six classifiers for 2D spatial relations (operate on X and Y coordinates) and three for depth information (Z coordinate). The tasks are (1) whether the center of one object is more to the left than that of another object, (2) the same if the center is closer to the bottom, (3) whether one object is completely left of the other object (without an overlap), (4) and the same for being completely below the other object, (5) whether one object is completely inside the other bounding box, (6) and if there is no overlap in the X and Y dimension. Regarding depth, the model needs to correctly classify (7) if one object is more in the foreground regarding the median value, (8) if one object is in between the inner 50% of the other object using all pixel values, and (9) if all depth values of one object are significantly smaller than the values of the other object at a significance level of 0.05 using a t-test.

Original caption: "A student works on an academic paper at her desk, computer screen glowing in the background."

Figure 1: Pre-training data with image and description with a PI keyword. For contrastive evaluation the keyword is replaced by its counterpart (i.e. "foreground").

These classification tasks have the same inputs as the *Masked Object Prediction* task (see Section 4.1.1) and are also constructed in the same manner (see Appendix A.1). An overview of the visual pre-training tasks is provided in Figure 3. Because this is a probing task, the classification head (PI head) is not updated during pre-training. After the training process has finished, all model parameters are frozen and only the weights in the PI heads are updated for 1 epoch. The average accuracy of all 11,664 classification tasks is reported on the MS COCO validation dataset. In doing so, we evaluate the unimodal capabilities of the model to forward information through the whole Transformer. The detailed results are presented in Appendix A.6.

Contrastive Evaluation on PI using CMM. The CMM classifier can successfully match images and captions (91% accuracy on the balanced pre-training validation data). However, this says little about the type of information considered during the classification. To better assess if PI is used by the model, we build a challenge set consisting of pairs of contrastive examples. We filter the validation data for samples with keywords indicating spatial relation between objects and only keep those which are replaceable by antonyms (see Appendix A.2).

We run two evaluation setups: (1) We replace all image descriptions with a random caption of a different image (following the LXMERT pre-training strategy). (2) We take the image and for all captions we replace the PI keyword with its antonym, e.g., substitute *background* with *foreground* and vice versa. See Figure 1 for an example. This task determines if the model is able to understand PI in a multimodal fashion. In both cases, we only have samples with "no match" ground truth values (which is our positive class)[1], and consequently we report recall only.

Downstream Task Evaluation. Finally, we determine the performance of the model on a downstream task. We use GQA, since it is a carefully balanced image question answering dataset, where PI plays a role. We report the 1- and 5-best accuracy. Moreover, we evaluate (top 1) accuracy of data subsets where X, Y, and Z coordinates are important. We do this by selecting questions where specific PI keywords are present (see Appendix A.3).

Since keyword search does not work perfectly (e.g., *Which color is the bag on the back of the woman?*), we employ zero-shot text classification using a BART model[2] (Lewis et al., 2020). For zero-shot classification we need a candidate label, which is used as input to determine if both texts (i.e. caption and candidate label) fit together. We experimented with different labels and found that the simple keyword "position" works best for our use case.

Downstream evaluation is done on the GQA *test-dev* split, which has 12,578 samples, hence, an change of 0.1% is equivalent with approximately 13 more correctly classified samples. For the subsets where X, Y, Z keywords are present, the dataset size is 2,050, 1,203 and 1,349 respectively. For the zero-shot subset (indicated with P) the sample size is 1,349.

4 Model and Data

4.1 Model

Our experiments are built upon LXMERT – a Transformer-based model with two separate encoders for image and text modality and one cross-encoder to join both. LXMERT was the only model in the top-3 leaderboard in both the VQA v2.0 2019 and GQA 2019 challenge, which is why we use this model as the basis for our work. Details are provided in Section 4.1.1. A detailed description of how the object's depth feature is determined is provided in Section 4.1.2.

4.1.1 Base Model

LXMERT uses Faster R-CNN with ResNet-101 for the object detection task, originally introduced by Anderson et al. (2018). The object detector is trained on Visual Genome (Krishna et al., 2017) predicting 1,600 objects with 400 different attributes (mostly adjectives). For LXMERT the model extracts the 36 most confident objects with

---

[1] Hence, we have $FP = TN = 0$.

[2] `https://huggingface.co/facebook/bart-large-mnli`

the region-of-interest features f_j, the object class c_j, attribute a_j and the positional information p_j, where j indicates the object indexes $j = 1, \dots, 36$. The feature map ($\mathbb{R}^{36\times 2048}$) and the bounding box coordinates ($\mathbb{R}^{36\times 4}$) are passed to two separate linear models with weight matrix W and bias b. The output is further processed by two layer normalizations (LN) and finally both results are averaged:

$$\hat{f}_j = \mathrm{LN}(W_F f_j + b_F) \qquad \hat{p}_j = \mathrm{LN}(W_P p_j + b_P)$$

$$v_j = (\hat{f}_j + \hat{p}_j)/2$$

This leads to a unified embedding $v_j \in \mathbb{R}^{36\times 768}$ representing the content of the objects and the positions at the same time. The image data is further processed in a BERT-style encoder.

On the language side, the text input is processed in a BERT-style encoder as well. Both outputs are merged in a cross-modality encoder (X-Enc) and passed to the output heads, where the losses for each pre-training strategy are calculated. The LXMERT architecture can be investigated in Figure 2.

The same pre-training strategies are used, namely *Masked Cross-Modality Language Modeling (MM)*, *Cross-Modality Matching* (CMM), *Visual Question Answering* (VQA), and *Masked Object Prediction*. The last one is composed of three tasks: two classification tasks to predict the object classes and attributes (*ObjClassif*, *AttrClassif*), and a regression task to predict the feature vector (*FeatRegr*). See Tan and Bansal (2019) for all details. Note that all pre-training strategies explicitly focus on the object features f_j, c_j, and a_j and not on the PI. The same is true for other VL models listed in Table 1. See Figure 3 for an illustration of all visual pre-training tasks.

We used the original implementation of LXMERT[3] and only made minor changes. We introduced dropout with $p = 0.1$ in the IQA head. Further, we tested different training hyperparameters to find a good ratio between model performance and training time. Our final pre-training model setup has a batch size of 2048 with a learning rate of 10^{-4} (with the same learning rate scheduler), the fine-tuning model has a batch size of 32 and a learning rate of 10^{-5}. Introducing PyTorch's *DistributedDataParallel* in the code and using 8 instead of 4 GPUs reduced the pre-training time from approximately 8.5 days to 41 hours. We used the pre-training weights reported in the paper and not in the corresponding repository (see Appendix A.4).

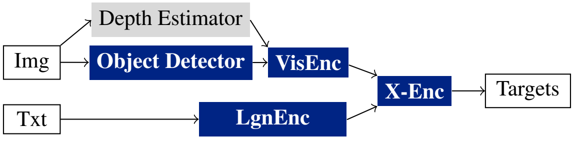

Figure 2: Architecture of the LXMERT model (blue) with depth information extension (gray). LXMERT uses object detection from Anderson et al. (2018) and has 5 visual, 9 language and 5 cross-modality (X-Enc) layers.

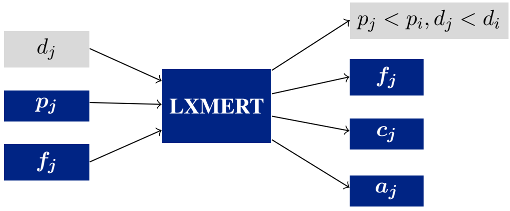

Figure 3: Visual components for the pre-training phase (text components omitted). Input data (f_j, p_j) to the visual encoder and training targets (f_j, c_j, a_j) for LXMERT's pre-training strategies are indicated in blue. Our additional depth data d_j and PI pre-training labels (PIP) are colored gray.

4.1.2 Depth Information

The datasets used for training LXMERT do not provide any depth information. To obtain depth values for each pixel in the image, we used MiDaS v2.1[4] (Ranftl et al., 2020) – a state-of-the-art algorithm for monocular depth estimations. It is trained on diverse datasets from indoor and outdoor environments, containing static and dynamic images and images of different quality. Hence, it fits the various picture types in our datasets. See Figure 4a for an original COCO image and Figure 4b for the depth information provided by the MiDaS model.

The depth predictions from MiDaS can be any real number. Large numbers indicate close objects, and small numbers refers to distant objects. We linearly normalized each pixel x_i with $1 - \frac{x_i - min(x)}{max(x)}$ to obtain 0 for the closest pixel and 1 for the most distant one for each individual image.

Since the rectangular bounding boxes do not surround the objects perfectly, we experimented with the object's center value, the mean and median as heuristic. We finally used the median, due to its robustness. Furthermore, it would be conceivable

(a) Original image (b) Depth estimation

Figure 4: We use a monocular depth estimator to obtain a pixel-level depth prediction. We normalize the output that 0 (yellow) indicates the value that is at the very front and 1 for the furthest pixel (violet).

to additionally take the standard deviation as a measure for uncertainty if the object is on specific depth plane or spans over a larger distance. This issue can be avoided with panoptic segmentation (Kirillov et al., 2019), which we leave to the future work.

4.2 Data

Following the original LXMERT setup, our models are pre-trained using the MS COCO (Lin et al., 2014) and Visual Genome (VG; Krishna et al., 2017) data in conjunction with some Visual Question Answering task (VQA). There are in total 9.18M image-caption pairs with 180K unique images. The average sentence length per caption is 10.6 words for MS COCO and 6.2 words for VG. The sentences are short and do not provide many details. Using 10 words, only the main occurrence of the image can be described. See examples in Appendix A.5.

In Table 2, we show the relative occurrence of PI keywords (see Appendix A.3). Pre-training data do not have a lot of PI in the captions or questions. Only Y keywords appear more often (11.2%) in MS COCO and X keywords in VQA (10.7%). This is different in GQA, which we use for downstream evaluation. In the *train* part, there are many X keywords, but only a few Y and Z keywords. The distribution in the *testdev* set is different. Here, the number of X, Y, and Z questions is high.

LXMERT was also evaluated on VQA v2.0 (Goyal et al., 2017) and NLVR2 (Suhr et al., 2019). VQA v2.0 has PI relations (under 3%), so we do not run an analysis on this dataset. NLVR2 has positional relations, but PI keywords are often part of the left/right image assignment and do not indicate objects within an image according to our definition of PI. Moreover, the presence of multiple images rules out a clean analysis of PI.

Dataset	**X**	**Y**	**Z**
MS COCO	2.9	11.2	6.5
VG	3.4	3.8	4.6
VQA	10.7	3.3	4.0
GQA *train*	28.4	5.3	4.9
GQA *testdev*	16.3	9.6	10.7

Table 2: Occurrence of positional keywords in percent in pre-training (top lines) and downstream datasets (bottom lines).

5 Probing Results

This section shows the results of the experiments described in Section 3.

Mutual Position Evaluation. We determine whether PI can be passed through the model using the classifications of the PI head. Results are shown in Table 3 (top lines). The accuracy is only 80.0% for no PI, but over 88% for the remaining types. This confirms that the model is able to forward PI through the whole Transformer layer stack.

Interestingly, the model is often capable of correctly classifying the mutual position of objects, although PI is not used as the model input. This is most likely due to the high correlation between the object categories and their positions. For example, "shoes" are usually at the bottom and in the foreground. The object detector is not powerful enough to detect small objects in the background in general. "Sky" and "clouds" are usually at the top and in the background of the image. Detected objects such as "kitchen" or "office" often span the whole image width and therefore have their center in the middle of the X axis. The latent image representation f_j can be used as a proxy for object types.

In addition to that, we can see that with more PI the accuracy of this task increases by more than eight percent points and has a peak at 89.7% for the input setting $x1, y1, x2, y2, d$. Switching from object centers to bounding boxes only has a minor impact. Yet, adding depth improves accuracy on the three Z related tasks (see Appendix A.6), which boost the overall performance.

Contrastive Evaluation on PI using CMM. To further evaluate the use of PI in VL models, we test if the model can utilize the information using the CMM task. Table 4 (top lines) shows that the original setting with dissimilar image-text pairs can be predicted almost perfectly – the recall is always above 96%. Hence, this pre-training strategy be-

	PI Input	XYZ Acc	XY Acc	Z Acc
Probing	$\emptyset$	80.0	81.5	77.1
	x, y	88.5	92.1	81.1
	$x1, y1, x2, y2$	88.7	92.4	81.3
	$x1, y1, x2, y2, d$	89.7	92.2	84.7
Pre-training	$\emptyset$	88.2	88.9	82.1
	x, y	91.6	94.4	86.0
	$x1, y1, x2, y2$	92.1	94.9	86.5
	$x1, y1, x2, y2, d$	93.9	94.8	92.2

Table 3: Mutual Position Classification Evaluation: Mean accuracy of all 9 mutual classification tasks (XYZ), 6 XY tasks, and 3 Z tasks for pre-trained models for different PI inputs. Upper lines for plain LXMERT and lower lines with our version (PIP, CL; see Section 6).

	PI Input	Permuted caption	Permuted PI words
Probing	$\emptyset$	97.4	1.4
	x, y	96.5	0.3
	$x1, y1, x2, y2$	96.8	1.7
	$x1, y1, x2, y2, d$	97.1	1.2
Pre-training	$\emptyset$	96.8	78.1
	x, y	97.7	79.5
	$x1, y1, x2, y2$	97.7	79.3
	$x1, y1, x2, y2, d$	97.1	79.5

Table 4: Contrastive Evaluation: Recall of the original CMM tasks with random captions (left) and text-image pairs with substituted PI antonyms (right). Upper lines for plain LXMERT and lower lines with our version (PIP, CL; see Section 6).

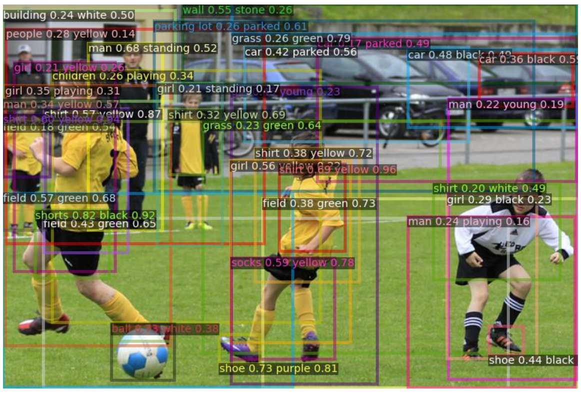

Figure 5: Bounding box predictions for the 36 objects used in LXMERT. Descriptions contain predicted label and attribute with confidence scores.

haves as expected for the normal data provided. Yet, the model cannot apply fine-grained details from textual PI. It is not capable of correctly rejecting that, for example, *“A student works on an academic paper at her desk, computer screen glowing in the foreground.”* does not fit to the image from Figure 1. The recall is steadily below 2%.

The model is able to pass through PI in the visual Transformer part but is not able to use it in a cross-modal fashion for solving problems. This is probably due to the fact that fine-grained matching does not play a role during pre-training. CMM is not constructed as indicated above (i.e., *background* vs. *foreground*) but to select completely dissimilar statements like *"A man sits before a light meal served on the table of a travel trailer”* to the image in Figure 1. To overcome this problem, we need more advanced negative sampling, i.e. captions that are closer to the original image-text pairs.

Downstream Task Evaluation. We evaluate downstream performance on GQA *testdev* with four different subsets targeting X, Y, Z keywords and general positional (P) samples. The results (in Table 5 top lines) reveal that using any type of PI is better or equally good than not using it (except for Y in $x1, y1, x2, y2$). Although the improvements are small, they indicate that PI is indeed helpful in this downstream task.

The best top 1 and X subset results are achieved by x, y input type. This might be due to the fact that most object relations are distinct and center values are sufficient to track this relationship. For example, the question “*Is the boy in white left or right of the ball?*” is more common than asking ambiguous questions, for example, where bounding boxes intersect (“*Is the left boy in yellow left or right of the ball?*”, see Figure 5).

The PI input $x1, y1, x2, y2, d$ received the best results for the Y and Z subsets. Although the improvements are small, it shows that our new depth feature can help solve the Z task. But also, the improvement on Y can be attributed to the depth input. Due to the graphical perspective, objects at the top correlate with the background and objects at the bottom with the foreground (see Figure 4b). Here, object depth can act as a top/down proxy.

For the downstream evaluation, we need to keep in mind that the underlining object detector is not perfect. Therefore, we face the issue that objects asked for in the questions are not always a part of LXMERT’s visual input. Moreover, our contrastive evaluation scheme shows that LXMERT has difficulties to properly matching image and text representation in a multimodal fashion. This can explain the small margin of improvements. The increase of top-1 accuracy is not reflected in the top-5 accuracy.

6 From Probing to Pre-training

In the previous section, we evaluated the role of PI in pre-trained LXMERT. In this section, we use the probing tasks as a part of model pre-training to improve weaknesses that we identified in the previous section. Alongside the established strategies, we add two tasks to learn mutual positions and fine-grained PI details in captions utilizing the CMM task. These strategies are elaborated below.

Positional Information Pre-training (PIP). Currently, all pre-training strategies rely on the visual features (f_j, c_j, a_j) rather than on the PI. Only in a small fraction of the pre-training captions and questions positional keywords are present, as Table 2 shows. Hence, we add a new pre-training strategy which exclusively focuses on PI.

We take the PI head used in Mutual Position Evaluation and add it as a new classification task which is updated during pre-training. We weight PIP by 10, since the initial loss is noticeably lower than the losses of the other strategies. Until now only visual representation of the object features, labels and attributes was part of pre-training. Using PIP, we introduce an explicit unimodal connection between the PI input and the PI output, which was not previously available (see Figure 3).

Contrastive Learning using CMM (CL). During pre-training in classical CMM in 50% of all cases the caption is replaced with another random image description. This is similar to the main pre-training concept of CLIP. Yet, doing so, the model only learns to distinguish dissimilar text and images. There are no small differences in the captions that the model needs to be aware.

In line with Contrastive Evaluation on PI using CMM, we make CMM more complex. In 50% of all captions with PI keywords the word is replaced by its counterpart, so that it has to learn fine-grained PI differences during pre-training. Dissimilar to PIP, this pre-training strategy only affects a small portion of the pre-training samples, since PI keywords are rare. Yet, it operates on both modalities and hence is able to connect both data types. This idea can also be extended to other attributes (such as color, material, shape using VG's Scene Graph).

Results. Using both pre-training strategies, we train new models for all four PI input types. We assess the models using the same three evaluation schemes as the plain LXMERT model before.

Results of Mutual Position Evaluation are shown in Table 3 (bottom lines). We observe an increase in accuracy for all input types. The largest is for the empty input type with an accuracy of 88.2%, indicating the high correlation between feature f_j and position p_j. For the other versions improvements are smaller. In Table 9 in the Appendix, the accuracies for each of the nine classification tasks are displayed. The largest increase can be seen for the empty input type with up to 23.1 percent points for task (1) of the 9 mutual position classification tasks. For classifications based on depth, the best improvements are 9.7 percent points for task (7) and 8.0 percent point for task (9) utilizing $x1, y1, x2, y2, d$. This shows that the presence of depth is useful as expected.

In the original LXMERT version, the probe on Contrastive Evaluation on PI using CMM showed that the model is not able to solve this task successfully. Recall was steadily below 2 percent. Introducing the CL pre-training strategy increases matching accuracy to over 78 percent, as shown in Table 4 (bottom lines). In CMM, we are now able to perform matching between visual and textual representations regarding PI. As a consequence, we successfully force the model to connect both types in a multimodal manner.

Downstream Task Evaluation. The third evaluation is the downstream task and results are shown in Table 5 (bottom lines). In the two former probes, our extended pre-training helped the model to solve these tasks. However, interestingly, this is not the case for GQA evaluation. The best results for the top 1 and subset tasks are obtained by plain LXMERT. Only in the (not official) best 5 accuracy, evaluation our version achieves better results. One reason for this may be that our PIP weight is too high and needs to be tuned in further studies.

We found that PI has much less impact on downstream results as previously thought. Simple object centers are often sufficient. Bounding box data, which add object width, height and area, do not add the desired information that the models can utilize. Adding depth is marginally useful on the Z task, which suggests that this feature is useful.

	PI Input	**Top 1**	**X**	**Y**	**Z**	**P**	**Top 5**
Probing	$\emptyset$	58.1	65.7	62.0	46.4	58.0	85.0
	x, y	**59.4**	**69.6**	62.0	49.6	**60.2**	85.0
	$x1, y1, x2, y2$	59.0	66.2	61.8	49.4	58.9	**85.3**
	$x1, y1, x2, y2, d$	58.6	66.0	**62.4**	**50.0**	58.4	85.1
Pre-training	$\emptyset$	**58.8**	**68.7**	60.4	48.5	**59.0**	85.1
	$x1, y1$	**58.8**	**68.7**	60.4	48.5	**59.0**	85.1
	$x1, y1, x2, y2,$	58.7	67.6	61.5	48.3	58.6	85.4
	$x1, y1, x2, y2, d$	58.7	67.8	**62.0**	**49.1**	**59.0**	**85.8**

Table 5: Evaluation on GQA *testdev*: Model comparison of plain LXMERT models (top lines) and our version with PIP and CL pre-training (bottom lines) for different PI Input types. Evaluation on Top 1 and Top 5 accuracy, moreover on subsets focusing on X, Y, and, Z keywords only and questions that focus on position (P) using zero-shot classification. Underlined numbers indicate the best overall model per column and bold numbers indicate the best model per block and column.

7 Conclusions

Current VL models make use of different PI inputs without evaluating their impact. In our work, we inspect the effect of such PI input types and investigate depth as a new input extension. In the original setting, the model is able to forward the positional information through the whole Transformer layer stack, but it cannot utilize it in the contrastive evaluation and only marginally in the downstream task. Overall, having any type of PI is helpful, though object-center values are often sufficient. However, object features f_j are already good proxies for where objects are located. Because this can be based on spurious correlations, we propose pre-training methods that should make the model rely on PI directly.

We introduced two new pre-training strategies. Firstly, Positional Information Pre-training to ensure that data is passed through the model properly and does not need to rely on feature correlations. This operates on visual component only and increases performance on the corresponding intrinsic evaluation task. Moreover, we introduce Contrastive Learning on PI using CMM. In doing so, we connect PI in the textual and visual modality. As a result, the model is now able to succeed in the contrastive evaluation task. However, these improvements do not affect the downstream performance on GQA.

It is not enough to add different features unchecked, trusting they are properly utilized by the Transformer. In line with BERTology (Rogers et al., 2020; Clark et al., 2019; Tenney et al., 2019), studies are important to understand better what a model is capable. The same is true for pre-training strategies. It is not sufficient to add new pre-training strategies, although they look promising. With our probing experiments, we tried to receive a better understanding of the inner workings of LXMERT. We see the importance to investigate differences between general concepts and impact on a downstream task.

We see two major issues for PI in VL models. Firstly, the pre-training data contains too little fraction of sentences with PI content. Hence, especially the CL pre-training strategy has not enough samples to learn from. Secondly, the used object detector is not very powerful (see predictions in Figure 5). Newer detection models like VinVL (Zhang et al., 2021) might help to have a better image representation, which consequently leverages performance regarding PI context.

A Appendix

A.1 PI Classification Head

The PI head is build up in the same manner as the other visual heads, i.e. `Dense` → `Activation` → `Layer Normalization` → `Dropout` → `Dense`.

A.2 PI Antonyms

For Contrastive Evaluation, we replace some PI keywords with its antonyms.

We substitute *left* with *right*, *above* with *below*, *under* with *over*, *foreground* with *background*, *before* with *behind* and vice versa.

A.3 PI Keywords

In Table 6 we list all PI keywords used in our evaluations.

Dim.	**Keywords**
X	left, right, beside, besides, alongside, side
Y	top, down, above, below, under, beneath, underneath, over, beyond, overhead
Z	behind, front, rear, back, ahead, before, foreground, background, before, forepart, far end, hindquarters

Table 6: Overview of positional keywords regarding dimension.

A.4 Pre-training Weights

In Table 7 we compare pre-training weights from LXMERT paper (Tan and Bansal, 2019) and the repository version (`https://github.com/airsplay/lxmert/`).

Version	**MLM**	**CMM**	**ObjClassif**	**AttrClassif**	**FeatRegr**	**VQA**
Paper	1	1	1	1	1	1
Repository	1	1	$6.\overline{6}$	$6.\overline{6}$	$6.\overline{6}$	1

Table 7: Overview of pre-training weights in publication and GitHub version.

A.5 Text Examples

In Table 8 we provide examples from pre-training and downstream tasks with highlighted keywords.

Dataset	**Example**	**Length**
MS COCO	A very clean and well decorated empty bathroom	8
	A panoramic view of a kitchen and all of its appliances.	11
	Surfers waiting for the *right* wave to ride.	8
	Two dogs are laying *down* **next** to each other.	9
	A red stop sign with a Bush bumper sticker **under** the word stop.	13
VG	separate kitchen areas in a home	6
	older red Volkswagen Beetle car	5
	a woman walking *down* the sidewalk	6
	A bag in the woman's **left** hand	7
	stones **under** wood bench	4
GQA	Are there both a television and a chair in the picture?	11
	That car is what color?	5
	On which **side** of the picture is the lamp?	9
	Is the table to the **left** or to the **right** of the appliance in the center?	16
	Is there a bookcase **behind** the yellow flowers?	8

Table 8: Text examples from different datasets with word counts. Italic stands for PI keywords that are wrongly selected and bold words are correctly detected.

PI Input	**(1)**	**(2)**	**(3)**	**(4)**	**(5)**	**(6)**	**(7)**	**(8)**	**(9)**
$\emptyset$	65.0	84.1	82.1	89.9	95.6	72.3	77.7	75.3	78.4

Abstract

Few-shot transfer often shows substantial gain over zero-shot transfer (Lauscher et al., 2020), which is a practically useful trade-off between fully supervised and unsupervised learning approaches for multilingual pretained model-based systems. This paper explores various strategies for selecting data for annotation that can result in a better few-shot transfer. The proposed approaches rely on multiple measures such as data entropy using n-gram language model, predictive entropy, and gradient embedding. We propose a loss embedding method for sequence labeling tasks, which induces diversity and uncertainty sampling similar to gradient embedding. The proposed data selection strategies are evaluated and compared for POS tagging, NER, and NLI tasks for up to 20 languages. Our experiments show that the gradient and loss embedding-based strategies consistently outperform random data selection baselines, with gains varying with the initial performance of the zero-shot transfer. Furthermore, the proposed method shows similar trends in improvement even when the model is fine-tuned using a lower proportion of the original task-specific labeled training data for zero-shot transfer.

1 Introduction

Language resource distribution, for both labeled and unlabeled data, across the world’s languages is extremely skewed, with more than 95% of the languages having hardly any task-specific labeled data (Joshi et al., 2020). Therefore, *cross-lingual zero-shot transfer* using pretrained deep multilingual language models has received significant attention from the NLP community. During cross-lingual zero-shot transfer, first a multilingual model (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020; Liu et al., 2020; Xue et al., 2020; Ouyang et al., 2020) is created using only unlabelled data from a large number of languages (typically in the range of 100) with some self-supervised learning objectives. These pretrained models are then fine-tuned with task-specific labeled data from one or more languages (we refer to these as the *pivot* languages) and tested on all the other languages (here referred to as the *target* languages) for which no annotated data was used during fine-tuning.

Many recent work (Pires et al., 2019; Karthikeyan et al., 2019; Wu and Dredze, 2019; Artetxe et al., 2020; Lauscher et al., 2020) have studied the efficacy of zero-shot cross-lingual transfer across languages and factors influencing it. Other work have shown that a few-shot transfer, where very little labeled data in the *target* language is also used during fine-tuning, can result in substantial gains over the zero-shot transfer. For instance, Lauscher et al. (2020) show that zero-shot transfer does not hold much promise for transfer across typologically different languages or when there is not enough unlabeled data in the target language during model pretraining. In such cases, the gap in the cross-lingual transfer can be effectively reduced by fine-tuning it on a little annotated data in the target language. However, very few languages have readily available annotated resources for different NLP tasks, and collecting annotated data for a large set of target languages can be expensive and time-consuming (Dandapat et al., 2009; Sabou et al., 2012; Fort, 2016). Therefore, it is essential to carefully select and annotate target language data for a few-shot transfer, reducing the transfer gap effectively.

Training data selection has been investigated for several NLP tasks, especially for domain adaptation (Blitzer et al., 2007; Søgaard, 2011; Liu et al., 2019). The majority of these approaches use different techniques to rank the entire data and use top n data points to train the system (Moore and Lewis, 2010). In addition, active learning (Fu et al., 2013; Settles and Craven, 2008) has been widely used to

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1042 - 1055
July 10-15, 2022 ©2022 Association for Computational Linguistics

improve annotation efficiently by using model predictions to select informative data. Active learning is generally used in an iterative setting, in which a model is learned at each iteration, and samples are selected for labeling to improve performance. However, in this paper, we are trying to select a few samples. Hence we are limiting the training to one iteration. In the past, Chaudhary et al. (2019) have used active learning to annotate only uncertain entity spans for Dutch and Hindi languages. However, to the best of our knowledge, none of these approaches have been studied for a large set of languages in a cross-lingual few-shot transfer setting.

The central goal of this work is to propose specific strategies for data selection (and subsequent annotation) for few-shot learning so that the performance in a target language is maximized, given a data budget. The main contributions of this work are: [1] We propose different data selection strategies based on the notions of cross-entropy, predictive entropy, gradient embedding and loss embedding, and perform various reliability analyses of these strategies. [2] We conduct experiments on a set of 20 typologically diverse languages including some syntactically divergent from the pivot language – English & Chinese. [3] We propose a loss embedding-based method for sequence labeling tasks which incorporates both diversity and uncertainty sampling. [4] Through experiments on three NLP tasks, we show that embedding-based strategies perform consistently better than random data selection baselines, with gains varying with the initial performance of the zero-shot transfer. We also observe several language and data-size dependent trends in the performance across different data selection strategies. [5] Finally, we provide a concrete set of recommendations for data selection based on features such as zero-shot performance and the amount of unlabeled data available for a target-language.

The rest of the paper is organized as follows. The next section introduces the novel data sampling strategies. Section 3, 4, and 5 present the experimental setup, results and related research in the area, respectively. Concluding remarks are made in Section 6.

2 Data Sampling Strategies

Assuming we have a pre-trained multilingual language model and enough labelled data in a particular language such as English (EN) for fine-tuning on a task. We can measure the zero-shot performance on a set of target languages. We observe that zero-shot performances are not uniform and often vary with the tYpological similarity between the target and pivot language as stated by (Pires et al., 2019; Lauscher et al., 2020). Nevertheless, all the target languages show a drop in zero-shot performance compared to the performance achieved in the pivot language. Hence, there is a cross-lingual transfer gap for all the target languages. This gap can be attributed to the inherent linguistic property of the target languages however, Lauscher et al. (2020) have shown that the cross-lingual transfer gap can be reduced by fine-tuning on a little annotated data in a target language.

Consequently, few-shot performance can reduce the transfer gap for all the languages. Given a fixed budget, let say k examples, we want to maximize the few-shot performance in a target language by carefully choosing the effective k examples. To this end, we are proposing several data selection strategies in this section. We compare them with random sampling where k target language examples are randomly selected from task-specific fine-tuning data collection. Note that the sampling strategies are oblivious to the actual labels of the data points, as annotation would follow the data selection step in practice.

2.1 Data Cross-Entropy (DCE)

Cross-entropy (Moore and Lewis, 2010; Axelrod et al., 2011; Dara et al., 2014) has been widely used for domain adaptation by selecting in-domain data from a large non-domain-specific (contains both in- and out-domain data) corpus. In our scenario, like Dara et al. (2014), the target language labeled data acts as the large non-domain-specific corpus and using cross-entropy, novel and diverse data is selected from it. Assuming that there is little overlap between the tokens of the pivot and target language during the zero-shot cross-lingual transfer, we presume that *no* in-domain labeled data for a particular target language is available initially. We further assume that we have access to a non-domain-specific collection of data points, the entire target language unlabeled corpus (may or may not be distinct from the pretraining corpus).

First, two N-gram language models $\mathbf{M_I}$ and $\mathbf{M_O}$ are trained on the sentences selected L_I (initially an *empty set*) and sentences left in the target language corpus L_O (staring with the entire corpus), respectively. We use SRILM[1] (Stolcke, 2002) to build the N-gram (for N=3) language models. We do not want to select sentences which are similar to already picked L_I; hence we measure data cross entropy (DCE) and select sentences from L_O that have high entropy with respect to L_I and low entropy with respect to L_O.

$$H_I(x) = H(\mathbf{M_I}(x)) \tag{1}$$

$$H_O(x) = H(\mathbf{M_O}(x)) \tag{2}$$

$$\text{DCE}(x) = \frac{H_O(x)}{\sum_{s \in L_O} H_O(s)} - \frac{H_I(x)}{\sum_{s \in L_O} H_I(s)} \tag{3}$$

where $H(x)$ is the measure entropy of a sentence x using a N-gram language model. The size of L_O and L_I will vary across the iterations, therefore we appropriately normalize the entropy H_I and H_O for calculating cross-entropy.

Algorithm 1 Sentence Selection using DCE

```
Input: Target Language Corpus $D^t$, $g$, $k$
$L_I \leftarrow \{\}$, $L_O \leftarrow D^t$
while size($L_I$) $< k$ AND $L_O \neq \phi$ do
    $\mathbf{M_I} \leftarrow$ TrainLM($L_I$)
    $\mathbf{M_O} \leftarrow$ TrainLM($L_O$)
    for each $s \in L_O$ do
        $H_I(s) \leftarrow H(\mathbf{M_I}(s))$
        $H_O(s) \leftarrow H(\mathbf{M_O}(s))$
    end for
    for each $s \in L_O$ do
        Calculate DCE($s$)
    end for
    $L_g \leftarrow$ Select top $g$ sentences ranked by DCE($\cdot$)
    $L_I \leftarrow L_I \cup L_g$
    $L_O \leftarrow L_O - L_g$
end while
```

Algorithm 1 describes the data selection method using data cross-entropy, where g is the number of data points to be selected in one iteration, and k is the total number of sentences to be selected. The overall time complexity of this method is $\mathcal{O}(nk/g)$, where $n = |D^t|$. For reducing the computation time, we can increase g, which we set to 10 in our experiments.

2.2 Predictive Entropy (PE)

We employ predictive entropy to measure the task-specific knowledge of a fine-tuned model. For a sequence labelling task, we define the predictive entropy $E(x_i)$ of a token x_i of a sentence x given a fine-tuned model $\mathbf{M}$ as follows:

$$p(y_i|x_i) = \mathbf{M}(x_i) \tag{4}$$

$$E(x_i) = -\sum_{j=1}^{C} p(y_i = c_j|x_i) * \log p(y_i = c_j|x_i) \tag{5}$$

where $c_1, c_2, \ldots c_C$ are the class labels.

We define the predictive entropy of the sentence using the equation (6):

$$\text{PE}(x) = \frac{1}{N_x} \sum_{i=1}^{N_x} E(x_i) \tag{6}$$

where N_x is the number of tokens in sentence x. For classification tasks, N_x will be 1.

To define the scoring function for data selection using predictive entropy that can generalize to the corpus with different domain-shift, we use the statistics of the predictive entropy from the entire target language corpus. We use μ_{PE} mean and σ_{PE} standard deviation of the predictive entropy of all the sentences in the corpus. Selecting sentences with very low predictive entropy will not help improve the performance as they have less novel information to enhance the knowledge of the model. Furthermore, picking sentences with very high predictive entropy can be harmful to training. It can be high due to either noise or out-of-domain data. As we want to select very few data instances for few-shot learning and improve further upon the zero-shot performance, we consider selection around μ_{PE}, the mean of the predictive entropy. But if the zero-shot performance is excellent, then μ_{PE} will be very low, and selecting data closer to mean may not improve over the zero-shot performance. Therefore, we add σ_{PE}. We formally define the scoring function in equation (7).

$$\text{score}_{PE}(x) = |\text{PE}(x) - (\mu_{PE} + \lambda * \sigma_{PE})| \tag{7}$$

Here, λ controls the distance of the preferred selection zone from μ_{PE}.

2.3 Gradient Embedding (GE)

Most of the data selection strategies use either representative sampling such as DCE or uncertainty

Table 1: We report the zero-shot cross-lingual transfer performance drops relative to EN for all the languages on POS, NER, and XNLI tasks with mBERT (**B**) and XLM-R (**X**). The results are medians over three RAND initialization (seeds). The darkness of the cell indicates the drops in zero-shot performance.

sampling such as PE. Recently, Ash et al. (2019) proposed BADGE that combines both diversity and uncertainty sampling. BADGE uses gradient embedding to capture uncertainty from the model, assuming the norm of the gradients will be smaller if the model is highly certain about its predictions and vice versa. As we don't have access to the ground truth labels, the gradient embedding $g_{x_i} \in \mathbb{R}^d$ is computed for a input sentence x_i by taking model's (M) prediction as the true label $\hat{y}_i$.

$$\hat{y}_i = \arg\max \mathbf{M}(x_i) \tag{8}$$

$$g_{x_i} = \frac{\partial}{\partial \theta_{out}} l_{CE}(\mathbf{M}(x_i), \hat{y}_i) \tag{9}$$

where l_{CE} is the cross-entropy loss function, $\theta_{out} \in \mathbb{R}^d$ refers to the parameters of last layer and d is the number of parameters. We have used hidden states of the [CLS] token from last layer classification tasks, hence we have computed the gradients with θ_{out} as the last layer of the pre-trained models.

BADGE selects samples by applying k-MEANS++ (Arthur and Vassilvitskii, 2006) clustering on the gradient embedding. The selection is made on the assumption that examples with gradient embedding of small magnitude will tend to cluster together and not be selected repeatedly. k-MEANS++ tend to select samples that are diverse and highly uncertain. For simplicity, we will call BADGE method as GE.

As we want to select very few data instances for few-shot learning and improve further upon the zero-shot performance, we consider applying GE selection on examples satisfying the following criteria:

$$\text{GE}(\lambda) = \text{GE}(\{x \colon g_x > \mu_g + \lambda * \sigma_g\}) \tag{10}$$

where μ_g and σ_g are the mean and standard deviation of magnitude of the gradient embedding of all the examples in the corpus. λ controls the final value of the selection criteria.

We noticed that in certain cases selecting samples sharing similar context but having different true labels may be more helpful for few-shot learning. To incorporate this, we propose **GE(γ)**, which adds γ similar examples for each k sample selected using the GE method. As gradient embedding loses information about the sentence, we use Multilingual Sentence XLM-R (Reimers and Gurevych, 2020) for calculating similarity based on sentences. We do not apply any constraints to ensure similar examples have different true labels but the gradient embedding can be used for ensuring it.

2.4 Loss Embedding (LE)

Sequence labelling tasks require prediction over all the tokens of a sentence, and therefore we have to calculate the gradient embedding for each token classification. Considering the maximum number of allowed tokens in a sentence to be m, the resulting gradient embedding g_{x_i} will of dimension $d \times m$. Due to its high dimensionality, applying k-MEANS++ will be expensive. We solve this dimensionality issue by proposing the Loss Embedding method, which has a dimension of m, considering lm is usually less than d.

Instead of calculating gradient, we consider only using classification loss at each token. For a sentence x_i, we compute loss embedding $l_{x_i} \in \mathbb{R}^m$ by computing cross-entropy loss for each token by taking the model's prediction as actual labels. As the norm of loss embedding will be smaller if the model is highly certain about its predictions and vice-versa, it satisfies the primary assumption of BADGE method. Another property preferable for sequential tasks is that the sentences with similar syntax will have a similar structure in the loss embedding as it depends upon the position of tokens in a sentence. Therefore applying k-MEANS++ clustering on the loss embedding will induce both diversity and uncertainty sampling.

Similar to GE, we also experiment with selection of examples satisfying the following criteria:

$$\mathrm{LE}(\lambda) = \mathrm{LE}(\{x\colon l_x > \mu_l + \lambda * \sigma_l\}) \quad (11)$$

where μ_l and σ_l are the mean and standard deviation of magnitude of the loss embedding of all the examples in the corpus.

3 Experimental Setup

We conduct various experiments to evaluate effectiveness of our proposed data sampling techniques in a few-shot transfer setting with up to 20 languages from various language families on two different sequential tasks and one classification task.

3.1 Datasets

We evaluate our methods on three benchmarks datasets on POS-tagging, NER, and NLI. The complete statistics of training and test data available in each language is provided in Appendix A.

Named Entity Recognition (NER). We perform NER experiments using NER Wikiann dataset (Rahimi et al., 2019) on 20 languages. We also remove duplicates data points from the training corpus as these will hinder data selection.

Part-of-speech Tagging (POS). We perform POS experiments using Universal Dependency treebanks (Nivre et al., 2016) on the same set of languages of NER except French (FR), Thai (TH), and, Vietnamese (VI) due to unavailability of substantial amount of training data after removing duplicates.

Cross-lingual Natural Language Inference (XNLI). The XNLI dataset (Conneau et al., 2018) consists of translated train, dev and test sets in 14 languages of English hypothesis-premise pairs.

3.2 Training Details

We conduct all our experiment using the 12 layer multilingual mBERT *Base cased* (Devlin et al., 2019) and XLM-R (Conneau et al., 2020). We use the standard fine-tuning technique as described in (Devlin et al., 2019; Pires et al., 2019) for all the experiments. We limit the sentence length to 128 subword tokens and set the batch size as 32. Following (Lauscher et al., 2020), we fix the number of training epochs to 20 and the learning rate as 2.10^{-5} for NER and POS. For XNLI, we set the training epochs to 3 for zero-shot and 1 for few-shot training, and learning rate as 3.10^{-5}. We report F_1-score for NER and POS, and accuracy for XNLI. All the reported results are medians over three random initializations (seeds).

3.3 Zero-Shot Transfer

Throughout our experiments, we assume EN as the pivot language. We report the zero-shot cross-lingual transfer results in Table 1. We observe similar trends in zero-shot performance as reported in (Lauscher et al., 2020), where there are significant drops in performance for TH, JA, AR, ZH, UR, KO, VI. In TH, we observe the highest transfer gap with nearly 0 F_1-score, which indicates no cross-lingual transfer has happened.

3.4 Few-Shot Transfer

We add k additional examples from a target language and report the improvement of few-shot performance over the zero-shot performance reported in Section 3.3, where k examples are chosen according to the proposed strategies in Section 3, namely random sampling (RAND), DCE, PE, GE, and LE. We use similar training and evaluation setups for the few-shot transfer experiments as we used in the zero-shot setting and repeat the experiments with three random seeds. We consider three RAND baselines and report the average for all the data selection experiments.

4 Results

We calculated the difference between the F_1-scores of few-shot and zero-shot setups, *deltas*($\triangle$), for each language separately, but we observed different sampling strategies to work better depending upon the cross-lingual transfer gap. Therefore, we present the experimental results after categorizing languages by the transfer gap as indicated by the zero-shot performance, shown in Table 1. We categorize the languages in three groups: C_1, C_2 and C_3, and are coloured as light grey, dark grey and very dark grey respectively in Table 1. For NER task, groups are defined as $C_1 \in$ {BG, DE, EL, ES, EU, FI, FR, HI, RU, SV, TR, VI}, $C_2 \in$ {AR, HE, JA, KO, UR, ZH}, and $C_3 \in$ {TH}. For POS, groups are defined as $C_1 \in$ {BG, DE, ES, EL, FI, RU, SV, TR}, and $C_2 \in$ {AR, EU, HE, HI, JA, KO, JA, UR, ZH}. For XNLI, the groups are different for XLM-R and mBERT, hence we have mentioned them in the Appendix.

We report the *deltas*, for NER and POS tasks in Table 2 and 3, respectively. The reported deltas are averaged across all the target languages for each language group. All the reported values are positive, which means in all cases, performance for the few-shot is higher than that for the zero-shot. The proposed methods require two parameters λ

and γ for data selection. We perform experiments for $\lambda \in \{0, 0.5, 1\}$ and $\gamma \in \{1, 2, 3\}$, which are reported in Appendix B. In Table 2 and 3, we are reporting the best setups for PE and LE, where we observe the highest gains for NER and POS tasks, respectively. The methods based on PE and LE consistently outperform the baseline RAND and DCE for all values of k on POS task, and most of the cases in the case of NER. DCE performs worse compared to RAND for all the languages from groups C_1 and C_2. In general, the gains obtained through PE and LE compared to RAND are higher for C_1 than C_2. Similarly, the proposed approaches are more useful compared to RAND for small values k, and the advantage of our sampling strategies diminishes as k approaches to 1000. For TH ($\in C_3$), due to deficient zero-shot transfer performance in NER, the gains are not consistent across models. However, all three approaches outperform RAND for small values of k.

Table 4: Averaged few-shot performance on XNLI tasks with varying number of target language examples k using EN as the pivot language.

For XNLI, the averaged deltas across all languages are reported in Table 4. As DCE requires a sentence to train n-gram language model, hence we represent a sentence in XNLI by joining the hypothesis and the premise of an instance with a separator (-). The few-shot improvements are less pronounced than the sequence labeling tasks; noticeable gains start after seeing $k = 500$ target-language examples. As the size of the target-language corpus in XNLI is enormous compared to POS and NER, we also evaluated the methods for $k = 10000$. Surprisingly, GE ($\gamma = 1$) and DCE outperforms RAND. As DCE selects examples in batches of 10, it selects examples having similar contexts similar to GE ($\gamma = 1$), which benefits the few-shot learning. Since GE ($\gamma = 1$) also includes uncertainty sampling, it outperforms DCE for most of the values of k. Due to the large corpus size of XNLI, diversity becomes crucial during sampling.

We observe low few-shot gains for PE as it does not induce diversity. To measure the impact of pivot size, we trained a zero-shot model with 40k EN examples and observe similar trends for both DCE and GE (see Table 13 in Appendix).

	XNLI		NER		POS	
Method	C_1 (24)	C_2 (4)	C_1 (24)	C_2 (12)	C_1 (16)	C_2 (16)
PE	1	1	8	1	1	7
LE	-	-	**15**	**5**	**3**	**10**
GE	**18**	**2**	-	-	-	-

Table 5: Pairwise t-Test is performed using the proposed methods against RAND. We have reported the number of languages in each group having significance level of 0.1 using both XLM-R and mBERT models.

4.1 Effect of λ and γ parameters

In Appendix B, we have provided detailed results by varying λ and γ. For LE, a higher value of λ is required for the POS task due to the higher number of class labels than NER. The number of classes is 18 for POS and 7 for the NER task. Due to the higher number of class labels, the norm of loss embedding distribution has a higher tail. Hence, a higher value of λ is required for POS. We limited the value of λ to 0.5 as beyond that, very few examples were left for selection.

We incorporate γ parameter to include examples similar in context. As sentences with similar context will also have similar class labels in the case of POS and NER tasks, further decreasing the diversity in samples. Hence, we only consider experimenting with γ for XNLI. We observe that $\gamma = 1$ provides the best performance on average, suggesting that having two samples of similar contexts provides better few-shot learning.

4.2 Statistical Significance Test

We perform a pairwise t-Test for measuring the statistical significance of the proposed methods against the RAND baseline. We perform t-test for each language using both mBERT and XLM-R and have reported the number of languages having p-value less than the critical point (which is 0.1 in our case) for each language group. We have considered the following methods in our tests: GE ($\gamma = 1$) for XNLI, LE for NER, LE ($\lambda = 0.5$) for POS and PE ($\lambda = 1$) for all the tasks.

In Table 5, we notice that for XNLI, GE provides significant gains than RAND for 18 out of 24 cases from C_1 group, and 2 out of 4 cases from C_2 group. For NER, the gains are significant for 20 out of 32 cases while using LE, but only 9 cases have significant gains using PE. For POS, we observe LE provide significant gains for cases compared to PE. We can conclude that the embedding-based methods provide better gains than uncertainty-based methods for most languages.

	Method	10	50	100	500	1000
mBERT	RAND	3.9	8.8	10.5	18.6	21.2
	DCE	1.8	5.5	6.5	15.3	19.2
	LE	**5.0**	**11.0**	**12.2**	**19.8**	**22.0**
XLM-R	RAND	7.3	15.3	**17.1**	**26.5**	**29.3**
	DCE	-0.8	8.6	10.5	22.9	26.9
	LE	**8.7**	**15.9**	**17.1**	26.1	29.1

Table 6: △ Delta between Few-shot and zero-shot performance on NER tasks using **ZH** as the pivot language, averaged across all languages.

5 Impact of Pivot Language

We conduct few-shot experiments considering ZH as the pivot language to validate the effectiveness of our method across different pivots. The delta between the gains using ZH as the pivot have been reported in Table 6 on the NER task. The delta has been averaged across all the languages. LE provides consistent gains over RAND, and gains saturate beyond 500 examples.

5.1 Embedding Visualization

We visualize the loss embeddings for DE language using t-SNE (Van der Maaten and Hinton, 2008) in Figure 1. Most of the samples using RAND (▼) tend to have lower norm of loss embedding, which may not be ideal for few-shot learning. We notice that examples having lower norm of loss embedding are clustered together and highlighted with ocean colour. Hence, samples selected via LE (×) are more likely to have higher norm or higher uncertainty estimates. It is also evident that the samples from LE (cluster centre) will have higher diversity than RAND for few-shot learning.

5.2 Qualitative Analysis of Samples

We have compared sentences selected using RAND and LE for the NER task in Table 7. Random sampling has no constraints due to which it may select examples having very few entities which might not improve the few-shot performance. Since LE uses loss as the measure of uncertainty, it selects

sentences with a higher number of entities often miss-classified by the zero-shot model. Hence, LE will most probably improve the few-shot performance compared to RAND. Similarly, we observe in Table 8 that for POS, LE selects sentences containing class labels that are often incorrectly tagged by the zero-shot model. In the case of XNLI, we found that the GE-based method selects more competing examples (similar hypotheses for different premises leading to different labels), which effectively can enhance the model capability. Selected examples using different methods for POS and XNLI tasks can be found in Appendix C.

6 Related Work

6.1 Cross-lingual Transfer

In recent years, several pre-trained multilingual language models have been proposed including mBERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019), XLM-R (Conneau et al., 2020), mBART (Liu et al., 2020), mT5 (Xue et al., 2020) and ERNIE-M (Ouyang et al., 2020) for cross-lingual transfer. Pires et al. (2019) show mBERT to have good zero-shot performance on NER and POS tagging tasks and attributed the effectiveness of transfer to the typological similarity between the languages. In contrast, several works (Karthikeyan et al., 2019; Wu and Dredze, 2019) have shown that cross-lingual transfer does not depend on subword vocabulary overlap and joint training across languages. Lauscher et al. (2020) empirically demonstrate that both pre-training corpora sizes and linguistic similarity are strongly correlated with the zero-shot transfer. Target languages with smaller pretraining corpora or higher linguistic dissimilarity with the pivot language have a low zero-shot transfer. Furthermore, they have shown that the gap can be reduced significantly by fine-tuning with a small number of target-language examples. Nooralahzadeh et al. (2020) study the cross-lingual transfer in meta-learning setting and demonstrate improvement in zero-shot and few-shot settings. While (Lauscher et al., 2020; Nooralahzadeh et al., 2020) focus on reducing zero-shot transfer gap us-

Table 8: Percentage of tokens from sentences sampled using RAND and LE($\lambda = 0.5$) for $k = 10$ from POS task. We calculated the percentage of tokens from class labels that are mispredicted using the zero-shot model for more than 40% on the whole language corpus. We observe that the LE method selects sentences containing more incorrect class labels without access to the ground truth labels. The languages from C_1 group are not considered as the gains are not relatively low.

ing few-shot learning, in this work, we explore the data selection methods to get better cross-lingual transfer than the often used random sampling.

6.2 Training Data Selection

The problem of training data selection has been extensively studied for several NLP tasks, with the most notable ones from area of Machine Translation systems where target-domain data is limited and large non-domain-specific data is available. The task is to pick sentences that are closer to the target domain and also penalize the sentences which are out-of-domain. Moore and Lewis (2010) and Axelrod et al. (2011) address this problem by ranking sentences using the cross-entropy of target-domain-specific and non-domain-specific n-gram language models. Dara et al. (2014) employ an extension of the cross-entropy difference by including a vocabulary saturation filter which removes selection of very similar sentences. Song et al. (2012) have shown the effectiveness of cross-entropy selecting in-domain data for word segmentation and POS tagging tasks. We also use an extension of cross-entropy for selecting training data from the target language corpus for effective few-shot transfer using multilingual transformer models and compare with the proposed methods.

6.3 Active Learning

Active Learning has been widely used to reduce the amount of labeling to learn good models, (Yoo and Kweon, 2019; Fu et al., 2013). Uncertainty sampling methods have been commonly used in AL, where the most uncertain samples are selected for labeling. Various metrics have defined uncertainty using least confidence, sample margin, and predictive entropy. On the other hand, diversity sampling methods (Sener and Savarese, 2018; Gissin and Shalev-Shwartz, 2019) select examples which can act as a surrogate for the entire dataset. Chaudhary et al. (2019) used AL-based approaches to select entity spans for labeling in a cross-lingual transfer learning setting. However, this work was limited to only two languages. Our work focuses on data selection for cross-lingual transfer on a large and diverse set of target languages.

7 Discussion and Conclusion

This work explored various data sampling strategies for few-shot learning for two sequence labeling and a semantic tasks on 20 target languages. Our study shows that the embedding-based strategies, LE and GE, consistently outperform random sampling baseline across languages and sample sizes. Some of the salient observations are as follows. On NER and POS tasks, languages of the group C_2 show significant improvements in few-shot performance, suggesting that the gains from few-shot learning are strongly correlated to the zero-shot transfer gap. LE and GE-based data selection methods show consistent gains over the RAND strategy for each target language group, but these gains saturate as the sample size, k, increases beyond 500. The saturation occurs due to the relatively smaller target-language corpus size (varies between 5k and 20k for NER and POS, respectively) effectively reducing the diversity in the total sample. LE provides better few-shot performance than PE in terms of statistical significance. DCE only performs better than RAND for Thai. As DCE does not use any form of information from the fine-tuned model and if the target-language corpus size is small, it fails to select novel target language examples any better than RAND. However, in TH, for which zero-shot performance is close to zero, DCE selects the highly representative and diverse training examples for small values of k. The trends for XNLI are different from that of the sequence labeling tasks. GE and DCE outperform all other methods, with gains increasing with the value of k, which suggests that the size of the target-language corpus is crucial for data selection. XNLI has about 400k examples in each target-language corpus, much larger than that of NER and POS, signifying the importance of diversity sampling.

Based on our observations, we recommend the LE-based sampling strategy for data selection for cross-lingual few-shot transfer for sequence labeling tasks and GE-based sampling for classification tasks. While the optimal parameter setting for the LE sampling algorithm varies across tasks, we recommend the vanilla LE method without any parameter for most of the tasks. For tasks having higher number of class labels, we recommend using LE variant with λ such as 0 or 0.5.

In future the work can be extended to other high-level tasks such as cross-lingual QA and Machine translation. We would also like to extend this work in a reinforcement learning (Liu et al., 2019) or meta-learning (Tseng et al., 2020) framework, where the parameters can be automatically learnt for various tasks and settings.

Table 10: We report the statistics of training and test data available in each language for XNLI.

B Study of λ and γ parameters on few-shot transfer

We conduct experiments using the following set of values for $\lambda \in \{0, 0.5, 1\}$ for NER and POS tasks. We have reported the results in Table 14 and 15. We find the parameter $\lambda = 1$ to be providing highest performance on average for PE, while $\lambda = 0.5$ show better performance for C_2 language group when $k = 10$. For LE methods, we observe $\lambda = 0.5$ provides the highest gains in POS tasks. However for NER task, LE method any λ parameter provides best gains on average. The gains start diminishing with higher λ values in general, but for C_2 language group, $\lambda = 0.5$ provides best gains for smaller values of k.

In Table 13, we observe that increasing the value γ beyond 1 hurts the performance for mBERT. $\gamma = 3$ provides higher gains in few cases for XLM-R. But overall, we consider $\gamma = 1$ to provide consistent gains across models.

C Qualitative Analysis of Samples

We have compared sentences selected using RAND and LE for POS task in Table 11. The comparison of examples from XNLI task selected using RAND and GE is shown in Table 12.

RAND	Study: Domestic violence in the United States affects 25% of women and 7.5 of men
	The Lebanese authorities, led by the Command of the Emergency Force, contacted the Command and asked them to move to prevent and prevent the violations of Israel, which is carrying out works inside the Lebanese territories, including especially unloading sand or paving slopes, according to what was announced by an official source.
LE	It was also agreed to participate in the Maqama cultural festivals held on both sides by the two sides and to exchange and exchange musical, folk bands, artists, painters, playwrights, and others.
	Arafat is also scheduled to visit Kuala Lumpur, Jakarta, and Tokyo, according to Palestinian sources.

Table 11: Sample sentences in AR from POS task using RAND and LE ($\lambda = 0.5$) methods for $k = 10$ using XLM-R. The tokens are highlighted having ground truth class labels that are mispredicted using the zero-shot model. In case for AR, we noticed following class labeled are wrongly predicted: Other, Interjection, Particle, Adjective, Determiner, Pronoun and Adverb. LE ($\gamma = 0.5$) select sentences containing these class labels more frequently than RAND.

	Translated Premise	Translated Hypothesis

Abstract

Pretrained language models such as BERT have been successfully applied to a wide range of natural language processing tasks and also achieved impressive performance in document reranking tasks. Recent works indicate that further pretraining the language models on the task-specific datasets before fine-tuning helps improve reranking performance. However, the pre-training tasks like masked language model and next sentence prediction were based on the context of documents instead of encouraging the model to understand the content of queries in document reranking task. In this paper, we propose a new self-supervised joint training framework (SJTF) with a self-supervised method called Masked Query Prediction (MQP) to establish semantic relations between given queries and positive documents. The framework randomly masks a token of query and encode the masked query paired with positive documents, and use a linear layer as a decoder to predict the masked token. In addition, the MQP is used to jointly optimize the models with supervised ranking objective during fine-tuning stage without an extra further pre-training stage. Extensive experiments on the MS MARCO passage ranking and TREC Robust datasets show that models trained with our framework obtain significant improvements compared to original models.

1 Introduction

The document ranking task is to generate a ranked list of candidate documents based on their relevance scores to a given query posed in natural language, which has been a longstanding problem that has been widely studied over natural language processing (NLP) and question answering. Pre-trained language models (PLMs) such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and ELECTRA (Clark et al., 2020), have achieved impressive results on various NLP tasks and have outperformed conventional document ranking methods (Hui et al., 2018; Mitra and Craswell, 2019) for powerful contextual representation capability. In recent years, several studies (Karpukhin et al., 2020; Qu et al., 2021) have used pre-trained language models as dual-encoder to separately encode queries and documents for dense document retrieval. One of the most common approaches (Nogueira and Cho, 2019) uses a PLMs as an interaction-based reranker for passage ranking, which fine-tunes BERT simply with an extra linear layer on the top of BERT and using a special vector $[CLS]$ to produce relevance score for each query document pair. Inspired by the fact that contextualized embeddings produced by PLMs are essential for the success of pre-trained models, CEDR (MacAvaney et al., 2019) employed the classification vector into existing neural ranking models and PARADE (Li et al., 2020) used a transformer module for passage-level representation aggregation to obtain performance improvements.

In contrast to the approaches of using contextual representation for reranking, prior works (Sun et al., 2019; Gururangan et al., 2020) suggest that further pre-train the PLMs on within-task training unsupervised data is able to learn domain-specific and task-specific language patterns effectively. To better understand the complex sentence relations, UED (Yan et al., 2021) transformed original next sentence prediction (NSP) task in BERT to a new sentence relation prediction (NSR) task. Gu et al. (2020) proposed a novel selective masking strategy to focus on masking the important tokens and then train a model to reconstruct input for further pre-training the PLMs to learn task-specific patterns. However, these approaches typically perform the pre-training task on task-specific corpus to understand the context of passages, while fail to consider the passages as the context of the given query to capture semantic consistency. In addition, further

pre-training on task-specific domain datasets entails additional time cost and computational cost.

Therefore, this paper proposes a self-supervised joint training framework for encouraging the model to understand the content of queries based on the context of passages, where the auxiliary self-supervised method is combined with the ranking task to fine-tune pre-trained model. Specifically, the self-supervised joint training framework (SJTF) extends the typical reranking pipeline with the auxiliary self-supervised method MQP and a decoder for predicting the masked token after the pre-trained model. On the one hand, the self-supervised approach enables the model to establish semantic relations between queries and positive passages to better identify relevant passages from a large number of candidate passages. On the other hand, the proposed training framework reduces the training time by simultaneously performing the self-supervised method and the ranking task in the fine-tuning stage, while the time of the ranking model is not increased in the inference stage. We evaluate the proposed training framework on two widely used document ranking datasets MS MARCO and Robust04. The experimental results indicate that the models trained with the proposed SJTF framework obtain a performance improvement against original models.

In summary, the contributions of our paper are as follows:

- A self-supervised joint training framework (SJTF) is proposed to improve the representation learning without additional pre-training.
- A strategy to integrate the SJTF to existing passage reranking methods is proposed without architecture modification and inference time increasing.
- Experiments on standard datasets show that reranking models with SJTF integration achieve significant performance improvement.

2 Related Work

In recent years, pretrained language models such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and ELECTRA (Clark et al., 2020) had substantially outperformed the traditional neural ranking models like DRMM (Guo et al., 2016), Co-PACRR (Hui et al., 2018) and Conv-KNRM (Dai et al., 2018). Nogueira and Cho (2019) first employed the pretrained language model BERT to passage reranking tasks using the classification vector $[CLS]$. CEDR (MacAvaney et al., 2019) incorporated the contextualized embeddings of BERT into existing IR models for document ranking. PARADE (Li et al., 2020) utilized Transformer (Vaswani et al., 2017) blocks to aggregate relevance passage-level representations to predict a document ranking. These approaches provided different perspectives on score prediction using the relevance representation vectors produced by pre-trained language models.

To better improve the representation learning of pre-trained language models in the target domain, Sun et al. (2019) further pre-trained BERT with masked language model (MLM)and next sentence prediction (NSP). Gururangan et al. (2020) observed that the less relevant the pre-trained corpus was to the target corpus, the more the pre-trained language model would benefit from further pre-training. In this paper, the proposed joint training framework could be used in conjunction with those reranking models in the fine-tuning phase, which reduced the time spent in further pre-training.

Representation learning has been shown to be critical on natural language tasks and has a significant influence on downstream tasks (Devlin et al., 2019; Peters et al., 2018; Yan et al., 2021). Devlin et al. (2019) adopted the self-supervised MLM task to encourage the model to learn contextual representations by predicting the masked token from the context. From the perspective of optimizing the masking strategy, RoBERTa (Liu et al., 2019) modified the static masking strategy by dynamically masking the input examples during the training stage, while (Gu et al., 2020) proposed a selective masking strategy that masked important words rather than any word in the sentence.

For understanding the content of documents, Cross-Thought (Wang et al., 2020) proposed a method for recovering masked words from documents that contain the most important information in a nearby sequence. However, understanding the content of both the query and the document is crucial in the question answering tasks (Zhang et al., 2019; Mudrakarta et al., 2018; Nogueira et al., 2019b), while these methods focused on representation learning for understanding the content of the document. The aim of our self-supervised task MQP is to predict the masked query word based on the semantic consistency of the query and the

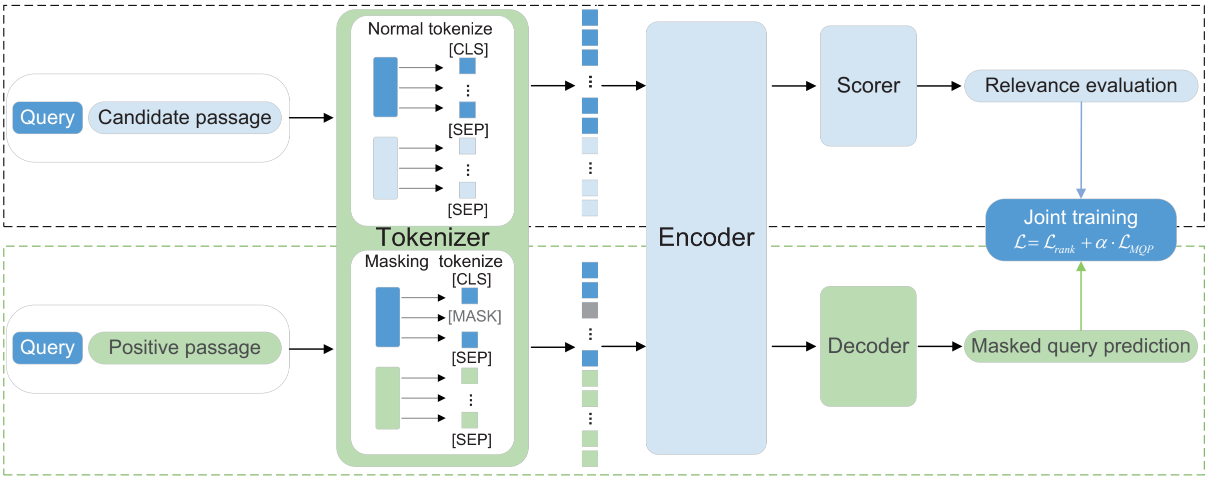

Figure 1: The architecture of joint training with Masked Query Prediction (MQP) task during fine-tuning stage.

positive passages, which forces the model to consider the positive passages as the context of the given query. The MQP differs from the standard self-supervised approaches of using unsupervised data (He et al., 2021; Hendrycks et al., 2019; You et al., 2021) in that the supervised signal is used to select relevant passage as the context of the query.

Multi-task learning (MTL) is an effective training setting for allowing model to obtain shared knowledge from several related supervised tasks in document ranking. Fun et al. (2021) enhanced the common representation learning using a retrieval optimized multi-task framework (ROM) for jointly training the retriever, reader and self-supervised tasks with a single encoder. UED (Yan et al., 2021) jointly trained both the ranking and query generation tasks to exploit the task relationships for enhancing the neural re-ranker. Liu et al. (2019) and Maillard et al. (2021) leveraged supervised data from related tasks to enhance the robustness of the model and generic knowledge representation learning. Although the datasets of related tasks are available, there may be differences in language patterns and data distribution between datasets. Our proposed joint training framework uses relevance labels to construct data on the target domain of ranking tasks without the requirement of external data, which is achievable on any of the question answering datasets.

3 The Approach

This section describes the proposed self-supervised joint training framework (SJTF), which employs a self-supervised method (MQP) to jointly fine-tune reranking models with the ranking task. In general, the whole model consists of three parts: a pretrained encoder for producing interaction-based representation of the given query and passages, a scorer for calculating a precise relevance score for each query-passage pair and an extra decoder to predict the masked query token based on the interaction-based representation. The overall framework of our approach is shown in Figure 1.

In the task of passage reranking, a natural language question and a list of candidate passages retrieved by traditional methods or dense retriever are provided. The question is denoted as a k-length sequence of tokens $Q{=}{<}q_1, q_2, \cdots, q_k>$, while each candidate passage can be denoted by an m-length sequence of tokens $P \;=<p_1, p_2, \cdots, p_m>$. The passage reranking task requires the model to learn informative representation and produce a precise relevance score for each query-passage pairs to return the best permutation of candidate passages.

3.1 Radom Masking

In contrast to the MLM task that random masks the tokens of the passage, we assume that understanding the content of the given query is necessary and the semantic information of the positive passage can be used to infer the masked token in the query, which finally allows the model to learn the semantic relation between the query and the positive passage. The tokens to be masked in the query are selected randomly following a uniform distribution and replaced with special token [MASK], and for simplicity, each query token is considered here to have the same importance. Then the masked query and positive passage are concatenated and preprocessed into a sequence $I_{mask} =< [CLS], q_1, \cdots, [MASK], \cdots, q_k, [SEP], p_1, \cdots p_m, [SEP] >$, where special token $[CLS]$ indicates the start of a sentence, token $[MASK]$ indicates the masked token and token $[SEP]$ is a separator symbol.

The reason for masking the query is that the original query can be reconstructed by understanding the content of the processed query and the positive passage. However, if the goal is to predict the masked tokens in the passage, the semantic information of the query is redundant as it can be inferred from the context of the passages alone. Without requiring extra data augmentation, the framework SJTF only utilizes the relevance label and a simple masking strategy to construct the masked input sequence I_{mask},which can be easily implemented in question-answering tasks.

3.2 Masked Query Prediction

The pre-trained language model BERT (Devlin et al., 2019) uses the MLM task to learn contextual language representations of individual texts in a large corpus. However, establishing contextual semantic relations between queries and candidate passages is critical in the question-answering domain. To achieve this, we propose a self-supervised auxiliary approach called Masked Query Prediction (MQP) so that the model uses positive passages as the context of the query and predicts masked token in conjunction with visible query tokens, which allows the model to extract semantic relation between the query and positive passage, thus pick relevant passages out of a large number of candidate passages.

After passing the masked input sequence I_{mask} constructed in section 3.1 through the BERT-like encoder which is shared with a passage reranking task, the representation vector $T_{mask} \in \mathbb{R}^d$ of the masked query token in the last layer is obtained as:

$$T_{masked} = Encoder(q_{masked}, p_{pos}) \qquad (1)$$

Finally, the masked token representation vector T_{masked} is fed into a decoder implemented by a neural linear layer to predict the original token.The parameters of MQP module are optimized by the cross-entropy loss function $\mathcal{L}_{MQP}$ which is defined as :

$$\mathcal{L}_{MQP} = -\sum_{m=1}^{M} \log P(t_m), \qquad (2)$$

where M is the number of masked token and $P(t_m)$ denotes the probability that the token t_m is predicted over the whole vocabulary. For each query and positive passage pair, a single query token is replaced with the special token $[MASK]$ for the self-supervised method. Note that the MQP decoder is only used for predicting the masked token during the fine-tuning stage, while in the inference phrase only the encoder and scorer are used for reranking passages. The decoder for the MQP task is implemented with one linear layer, meaning that this requires only a small number of additional neural network parameters to be trained, which makes the MQP task easy to be extended to the existing passage reranking methods without significant modifications to the model architecture.

3.3 Passage Ranking

Following the settings of Nogueira and Cho (2019), a pair of query q and candidate passage p_i is packed as an input sequence $I =< [CLS], q_1, \cdots, q_k, [SEP], p_1, \cdots p_m, [SEP] >$, and the BERT-like pretrained language model is employed as a passage encoder *E* that produces a relevance representation vector for each QA pair. During fine-tuning the model, the $[CLS]$ vector $T_{cls} \in \mathbb{R}^d$ from the last layer of encoder is regarded as the final interaction-based representation:

$$T^i_{cls} = Encoder(q, p_i) \qquad (3)$$

For passage reranking task, the representation vector T_{cls} of query-passage pairs is calculate by a scorer S_{ranker} which generates a relevance score to quantify their relevance. The relevance score of *i-th* pairs of query q and candidate passage P_i is denoted as:

$$Score^i_{cls} = S_{ranker}(T^i_{cls}; \theta), \qquad (4)$$

where the scorer S_{ranker} can be implemented by a linear layer at top of the BERT or by an elaborate scoring module such as KNRM (Dai et al., 2018) , SAN (Kingma and Ba, 2015) or PARADE (Li et al., 2020), and θ contains the set of parameters of the scorer module.

Compared with the point-wise ranking loss used in (Nogueira and Cho, 2019), the pair-wise margin ranking loss discriminates the positive and negative examples by relative distance, allowing the model to learn the margins between the positive and negative examples to give an appropriate relevance score. Therefore, the reranking module is optimized by the ranking loss $\mathcal{L}_{rank}$ as Equation (5):

$$\begin{aligned}&\mathcal{L}_{rank}\\&=\max(0, y\cdot(Score_{cls}^{k}-Score_{cls}^{k+1})+\gamma),\end{aligned}\tag{5}$$

where $y=-1$ if the $Score_{cls}^{k}$ is higher than $Score_{cls}^{k+1}$, and vice-versa for $y=1$. γ is a hyperparameter that controls the margin of positive and negative examples.

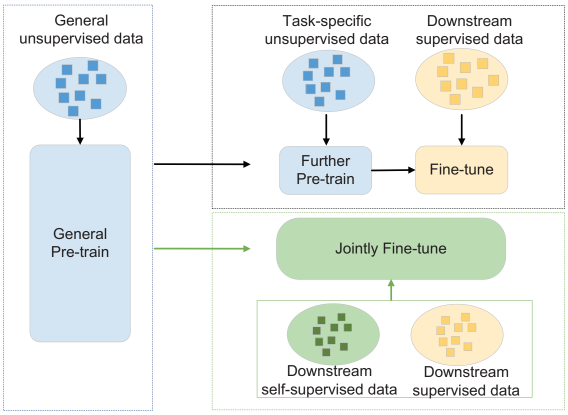

Figure 2: The overall self-supervised jointly training framework SJTF.

3.4 Joint Training

Different from the self-supervised tasks that are used for further pre-training on the downstream dataset (Fun et al., 2021; Liu et al., 2019), our proposed self-supervised method MQP is combined with the ranking task in the fine-tuning phase, since it utilizes the relevance label information to construct masked input sequences. As shown in Figure 2, the joint training strategy simplifies the training procedure without further pre-training phases and training resources required. In the fine-tuning stage, the loss is defined as a linear combination of passage reranking loss and masked query prediction loss as:

$$\mathcal{L}=\mathcal{L}_{rank}+\alpha\cdot\mathcal{L}_{MQP}\tag{6}$$

The hyperparameter α is assigned by different values to tradeoff between passage reranking and masked query prediction. As the MQP is a secondary task used to help the model understand the query content, where the loss weight α is usually set to a lower value, resulting in the parameters of the reranking model still being optimized primarily by the passage reranking task.

4 Experiments and Results

4.1 Dataset

The proposed method is extended to existing ranking models and evaluated on two widely used datasets: MS MARCO Passage Ranking (Nguyen et al., 2016) and TREC Robust 2004 (Voorhees). The statistics of these two datasets are shown in Table 1.

MS MARCO Passage Ranking dataset is a large-scale dataset consisting of real anonymous questions from the Bing search engine and 8.8 million candidate passages for passage reranking task. The training set contains about 500 thousand positive query-passage pairs and each query has one relevant passage on average. The development set and evaluation set contains 6980 queries and 6837 queries respectively, where the relevance labels are provided for the development set only.

Robust04 dataset is a newswire collection used by TREC 2004 Robust track, which comprises 250 queries and 0.5 million documents (TREC Disks 4 and 5). Following the setting of CEDR (MacAvaney et al., 2019), we use the same five folds cross-validation with three folds for training, one fold for validation and one fold for testing.

4.2 Evaluation Metrics

Following the previous works, three widely used evaluation metrics are adopted to measure the performance of the proposed approach, including MRR@10 for the MS MARCO Passage Ranking dataset, P@20 and NDCG@20 evaluated by trec_eval[1] for the Robust04 dataset. The result reported for model performance are averaged over all test folds on the Robust04 dataset.

MRR@10(Mean Reciprocal Rank) This metric considers the reciprocal rank of the first relevant passage in ranked list to a given query as the precision. For MS MARCO passage ranking task only provides binary label and does not specify relative ranking order between passages, thus the MRR metric is used for evaluation.

P@20 The top-20 precision is defined as the proportion of relevant documents which are ranked in the top 20 candidate documents.

NDCG@20 NDCG is used to measure the discrepancy between the ranked list and the correct ranking list, which evaluates the ranking performance of models.

---

[1] `https://trec.nist.gov/trec_eval`

Table 1: The statistics of datasets MS MARCO Passage Ranking and TREC Robust04.

Datasets	Queries	Avg. of word length	Passages	Avg. of word length
MS MARCO	516,756	5.97	8,841,823	56.58
Robust04	250	2.65	528,155	577.82

4.3 Baselines

The proposed training framework is integrated with the following methods and compared the reranking results with the original methods:

BM25+BERT (Nogueira and Cho, 2019) utilizes the traditional unsupervised ranking method BM25 as a first-stage retriever to generate a ranked list of candidate passages, and the relevance scores between query and candidate passages are produced by the BERT-base model with a linear layer.

BM25+BERT+FP (Gururangan et al., 2020) further pretrains the language model BERT with MLM objective on the target datasets before fine-tuning to learn the specific domain language patterns for document reranking task.

BERT+PACRR (MacAvaney et al., 2019) constructs query-document term similarity matrix in PACRR (Hui et al., 2018) using the interaction-based representation vectors generated by BERT.

PARADE (Li et al., 2020) aggregates passage-level relevance representations to predict a document relevance score, where the long document is split into several passages and each passage is encoded with a given query.

CEDR-KNRM (MacAvaney et al., 2019) incorporates the classification vector of a fine-tuned BERT into existing neural models KNRM (Dai et al., 2018) and leverage contextual information to improve ad-hoc document ranking.

4.4 Implementation Detail

For both datasets, following the setting of the first retrieval stage (Nogueira et al., 2019a) , we employ BM25 (Robertson et al., 2009) as the retriever at the first stage to obtain a list of top-k candidate documents/passages for next reranking stage. The reranking models are optimized by Adam (Kingma and Ba, 2015) with a learning rate of 3e-6 and a batch size of 8. The maximum sequence length is limited to 128 tokens for MS MARCO passage ranking dataset, while the documents are truncated to 800 tokens for Robust04 dataset. The encoder of CEDR and PARADE are the base-size pre-trained language model which consists of 12 transformer blocks, the hidden size as 768, and 12 self-attention heads. For Robust04 dataset, the dropout function is used with the rate of 0.1 for improving model robustness. We set the value of margin hyperparameter γ of pairwise ranking loss to 1. A uniform distribution is used to random mask a token in a given query, where all query tokens are assumed to be of equal importance. Since the MQP loss serves as an auxiliary loss to enhance the interactive-based representation learning for encoder, the weight hyperparameter α is assigned to 0.2 for MS MARCO and 0.05 for Robust04 respectively. The experiments are conducted on a single GeForce RTX 3090 GPU.

4.5 Results

The experimental results of model+SJTF on the MS MARCO passage ranking and Robust04 datasets are presented in Table 2, where model+SJTF refers to the joint training of different reranking models applying to SJTF during the fine-tuning stage. From Table 2, the reranking models adopting SJTF have obtained significant improvements using paired t-test ($p < 0.05$) compared to original models.

Compared with BM25+BERT-base, the further pretraining method BM25+BERT+FP improves MRR@10 by 0.5% on the MS MARCO and NDCG@20 by 0.8% on the Robust04 datasets for better capturing the domain-specific language patterns. By Jointly training the BERT-base model with SJTF framework during the fine-tuning stage, BERT+SJTF achieves a 1.3% improvement in terms of MRR@10 on the MS MARCO and 1.1% improvement of NDCG@20 on the Robust04, The experimental results suggest that learning the semantic dependencies of queries and relevant documents is more effective than further learning the contextual semantic information of documents. BERT+PACRR+SJTF outperforms the original approach by 0.5% on the MS MARCO dataset and 1.3% on the Robust04 dataset,which indicates that the performance of traditional reranking methods would benefit from an improved contextual representation. The results show that the models fine-tuned with the joint training framework yields a

Table 2: Performance comparison of all methods on the MS MARCO Passage Ranking and Robust04. '-' means that the PARADE method is not applicable because PARADE aggregates information from multiple overlapping passages. Significant paired t-test ($p < 0.05$) improvements over the original models are marked with †.

	MS MARCO Passage Ranking		**TREC Robust04**	
Method	**MRR@10(Dev)**	**MRR@10(Eval)**	**P@20**	**NDCG@20**
BM25+BERT	0.345	0.342	0.4042	0.4541
BM25+BERT+FP	0.355	0.347	0.4024	0.4624
BM25+BERT+SJTF	$0.362^{\dagger}$	0.355	$0.4291^{\dagger}$	$0.4657^{\dagger}$
BERT+PACRR	0.328	0.326	0.3969	0.4599
BERT+PACRR+SJTF	$0.333^{\dagger}$	0.331	$0.4122^{\dagger}$	$0.4735^{\dagger}$
PARADE	-	-	0.4604	0.5399
PARADE+SJTF	-	-	$0.4701^{\dagger}$	0.5455
CEDR-KNRM	0.337	0.331	0.4729	0.5388
CEDR-KNRM+SJTF	$0.347^{\dagger}$	0.337	$0.4851^{\dagger}$	$0.5565^{\dagger}$

better interaction-based representation based on the semantic relationships between the query and candidate passages, which leads to a significant performance improvement without the model structure change.

The improvement of PARADE by splitting a long document into overlapping passages via sliding windows is less, increased by 0.55% on Robust04 datasets, suggesting that the semantic blocks in long documents are not all tightly semantically associated with queries and using these to predict masked query tokens only slightly enhances representation learning. In comparison with the results of PARADE, CEDR has been significantly improved by applying the SJTF framework, which indicates that the document-level semantic relations captured by the SJTF framework are beneficial for representation learning. The overall experimental results verify the effectiveness and generality of the training framework of encouraging the models to adopt the positive passage as the semantically consistent context for a given query.

4.6 Ablation Study

Inspired by the observations from previous works (Gu et al., 2020; Liu et al., 2019; Gururangan et al., 2020) that different masking strategies enable a model to learn various perspective knowledge during pre-training stage, we design three different self-supervised methods in terms of focusing on understanding the content of query or passages and using the query or passage as the context for masking prediction task.

Similar to the traditional MLM approach, we randomly mask a token of a positive document and use a corresponding query and the remaining documents as contexts to predict the masked token, and this strategy is denoted as MPP. The aim of MPP is to encourage the model to learn task-specific language patterns and understand that the corresponding query and the positive documents are semantically consistent. However, it is possible to reconstruct the masked token based on the content of document itself without demanding the semantic information of the query. In addition, since MPP is a simple task for pre-trained models, it cannot effectively improve the ranking performance of models.

Table 3: The performance of BERT-base and CEDR-KNRM models by integrating different masking strategies on Robust04 dataset.

Method	**NDCG@20**	**P@20**
BM25+BERT	0.4541	0.4042
+ MPP	0.4539	0.4026
+ MQP$_{ALL}$	0.4567	0.3979
+ MQP	**0.4657**	**0.4291**
CEDR-KNRM	0.5388	0.4729
+ MPP	0.5433	0.4738
+ MQP$_{ALL}$	0.5464	0.4784
+ MQP	**0.5565**	**0.4851**

Considering that the documents retrieved by BM25 are relevant or partially relevant to the query at the word level, the second strategy is to treat each retrieved document (regardless of positive and negative documents) as the context of the masked query for the MQP task, which does not utilize the supervised signal and is denoted as MQP$_{ALL}$. In contrast to the first strategy, MQP$_{ALL}$ allows the models to focus on understanding the content of query and capture the semantic relationships between queries and documents. Table 3 illustrates the slight improvement achieved by MQP$_{ALL}$ compared to the original model and the first strategy.

The self-supervised method MQP proposed in this paper is based on the assumption that although the documents retrieved by BM25 have word-level relevance to the query, the documents containing the query terms are not always relevant. Therefore, we use supervised signals to consider only positive documents as the context of masked queries, since the semantic information of negative documents is equal to noise for the queries. As shown in table 3, after filtering out negative documents by supervised signals, BERT-base and CEDR-KNRM achieve a significant improvement on NDCG@20 and P@20 metrics. Experimental results illustrate that the reasonable use of label informations to construct a self-supervised approach enables the models to obtain more accurate knowledges of the downstream task, which helps the models to identify correct documents for each question from a large collection.

4.7 Hyper-parameter Study

As a hyper-parameter described in Equation (6), the setting of α value controls the influence of the self-supervised approach on the representation learning of models. Figure 3 shows the result of different hyper-parameters setting on the Robust04 dataset. In general, a larger value α allows an excessive effect of the self-supervised method, which reduces the influence of the reranking task in optimizing models while achieving sub-optimal performance. Therefore, with α value greater than 0.05, the ranking performance of all three methods show a decreasing trend. For the CEDR method, a stable performance improvement is obtained using the proposed training framework, indicating that considering the positive documents as the contextual features of the query can significantly enhance the representation learning of the CEDR model. By gradually raising the α value from 0.01 to 0.05, the performance of both BERT-base and BERT+PACRR also gradually achieves the highest NDCG@20, which suggests that encouraging these models to focus on query understanding can lead to better reranking performance. From Figure 3, it can be seen that the α value of 0.05 is more robust for most of the models.

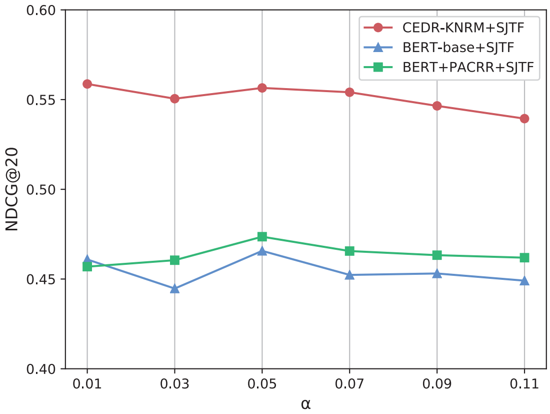

Figure 3: Performance of various rerankers with different configurations of α on the Robust04 dataset using the metric nDCG@20.

5 Conclusion

This paper proposes a self-supervised joint training framework SJTF to improve the representation learning for document ranking. By integrating with this training framework, models are able to better understand the content of queries and capture the semantic relation between queries and positive documents, which guides the models to identify the relevant documents among a large number of candidate documents. Experimental results show that our proposed framework enhances the representation learning of reranking models and achieves better performance compared with baselines in the document reranking task.

Abstract

Recent years have witnessed increasing interest in code representation learning, which aims to represent the semantics of source code into distributed vectors. Currently, various works have been proposed to represent the complex semantics of source code from different views, including plain text, Abstract Syntax Tree (AST), and several kinds of code graphs (e.g., Control/Data Flow Graph). However, most of them only consider a single view of source code independently, ignoring the correspondences among different views. In this paper, we propose to integrate different views with the natural-language description of source code into a unified framework with **M**ulti-**V**iew contrastive **P**re-training, and name our model as CODE-MVP. Specifically, we first extract multiple code views using compiler tools, and learn the complementary information among them under a contrastive learning framework. Inspired by the type checking in compilation, we also design a fine-grained type inference objective in the pre-training. Experiments on three downstream tasks over five datasets demonstrate the superiority of CODE-MVP when compared with several state-of-the-art baselines. For example, we achieve 2.4/2.3/1.1 gain in terms of MRR/MAP/Accuracy metrics on natural language code retrieval, code similarity, and code defect detection tasks, respectively.

1 Introduction

Code intelligence that utilizes machine learning techniques to promote the productivity of software developers, has attracted increasing interest in both communities of software engineering and artificial intelligence (Lu et al., 2021; Feng et al., 2020; Wang et al., 2022; Wan et al., 2022a; Wu et al., 2021). To achieve code intelligence, one fundamental task is code representation learning (also known as code embedding), which aims to preserve the semantics of source code in distributed vectors (Alon et al., 2019). It can support various downstream tasks about code intelligence, including code defect detection (Omri and Sinz, 2020; Zhao et al., 2021b,a), code summarization (Wan et al., 2018), code retrieval (Wan et al., 2019), and code clone detection (White et al., 2016).

Table 1: Comparison with current pre-trained code models. PT: Program Transformation.

Current approaches to code representation borrow ideas from the successful deep learning methods in natural language processing, mainly attributed to the *naturalness hypothesis* in source code (Allamanis et al., 2018). From our investigation, existing approaches mainly represent the source code from different views of code, including code token in plain text (Iyer et al., 2016), Abstract Syntax Tree (AST) (Bui et al., 2021a), and Control/Data Flow Graphs (CFGs/DFGs) of code (Cummins et al., 2020; Wang and Su, 2020). Recently, many attempts have been made to pre-train a masked language model for source code, such as CodeBERT (Feng et al., 2020), GraphCodeBERT (Guo et al., 2021), SynCoBERT (Wang et al., 2021), CodeGPT (Lu et al., 2021), PLBART (Ahmad et al., 2021), CoTexT (Phan et al., 2021), and CodeT5 (Wang et al., 2021b). Table 1 shows the contribution of our work when compared with current pre-trained language models for source code.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1066 - 1077
July 10-15, 2022

Despite much progress in code representation learning, most of them only consider a single view of source code independently, ignoring the consistency among different views (Feng et al., 2020; Lu et al., 2021; Ahmad et al., 2021; Wang et al., 2021b). Usually, a program, accompanied by a corresponding natural-language comment (NL), can be parsed into multiple views, e.g., the source code tokens, AST, and CFG. We argue that these different views contain complementary semantics of the program. For example, the source code tokens (e.g., method name identifiers) and natural-language comments always reveal the *lexical* semantics of code, while the intermediate structures of code (e.g., AST and CFG) always reveal the *syntactic* and *executive* information of code. In addition, a program can also be transformed (or rewritten) into different variants that have equivalent functionality. We think that different variants of the same program reveal the *functional* information of code. That is, those different program variants with the same functionality are expected to represent the same semantics.

Inspired by the aforementioned insights, this paper proposes a novel Code-MVP for code representation, which aims to integrate multiple views of the code into a unified framework with multi-view contrastive pre-training. Concretely, we first extract multiple views of code using several compiler tools, and learn the complementary information among them under a multi-view contrastive learning framework. Meanwhile, inspired by the type checking in compilation process, we also introduce fine-grained type inference as an auxiliary task in the pre-training process to encourage the model to learn more fine-grained type information.

To summarize, the contributions of this paper are two-fold: (1) We are the first to represent source code from multiple views, including the code tokens, AST, CFG, and various program equivalents, under a unified multi-view contrastive pre-training framework. Meanwhile, we also introduce an auxiliary task of inferring type annotations for variables. (2) We extensively evaluate Code-MVP on three program comprehension tasks. Experimental results demonstrate the superiority of Code-MVP when compared with several state-of-the-art baselines. Specifically, Code-MVP achieves 2.4/2.3/1.1 gain on MRR/MAP/Accuracy metrics in natural language code retrieval, code similarity, and code defect detection tasks, respectively.

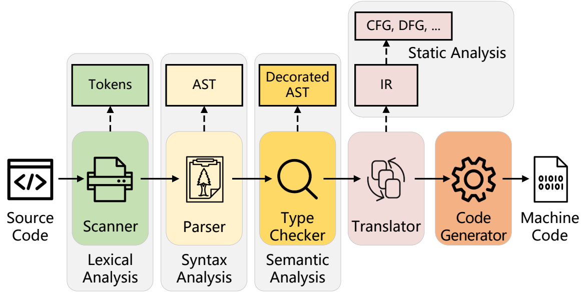

Figure 1: An example of converting a program from source code into machine code in compilation process.

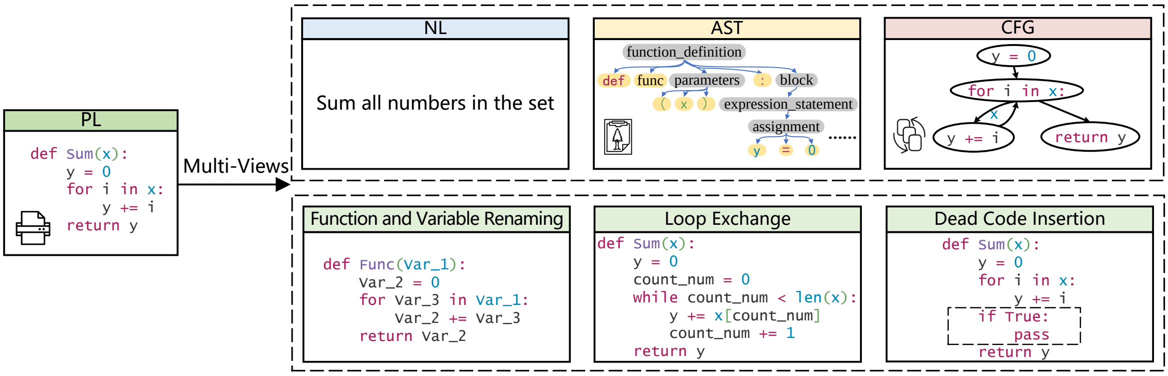
2 Multiple Views of Code

We borrow ideas from the way that computers process the source code in compilation, where a program would be converted into multiple views. Figure 1 shows the process of converting a program from source code to machine code. During this process, the compiler would automatically utilize some program analysis techniques to verify the correctness of source code, including lexical, syntax, and semantic analyses. In the lexical analysis, a program is treated as a sequence of tokens and checked for spelling problems. In the syntax analysis, syntactic rules of programs are defined by the context-free grammar (Javed et al., 2004). Then the program could be parsed as an AST, based on which many program transformation heuristics can be applied to rewrite the program while maintaining the same desired functionality. In the semantic analysis, semantic rules of the program are defined by the attribute grammar (Paakki, 1995). Then the compiler could check the types of code tokens, and a decorated AST could be obtained. After the three stages above, a translator will convert the source code to its Intermediate Representation (IR), which is then considered as the basis for building Control/Data Flow Graphs (CFGs/DFGs) for further optimizations in the static analysis. Finally, the IR of the source code should be converted into machine code to execute through a code generator. Next, we introduce how we extract different views of the source code. Figure 2 illustrates multiple views of source code with an example.

Abstract Syntax Tree (AST). An AST, which is composed of leaf nodes, non-leaf nodes and edges between them, contains rich syntactic structural information of source code. In the AST, an assignment statement `y = 0` can be represented by a non-leaf node `assignment` that points to three



```
def Sum(x):
    y = 0
    for i in x:
        y += i
    return y
```

```
def Func(Var_1):
    Var_2 = 0
    for Var_3 in Var_1:
        Var_2 += Var_3
    return Var_2
```

```
def Sum(x):
    y = 0
    count_num = 0
    while count_num < len(x):
        y += x[count_num]
        count_num += 1
    return y
```

```
def Sum(x):
    y = 0
    for i in x:
        y += i
    if True:
        pass
    return y
```

Figure 2: Multiple views of source code.

leaf nodes (`0`, `y`, and `=`). In this paper, we parse a snippet of source code into an AST using a standard compiler tool `tree-sitter`.[1]. To feed an AST into our model, we apply depth-first traversal to convert it into a sequence of AST tokens (Kim et al., 2021).

Control Flow Graph (CFG). CFG, which represents the execution semantics of the program in the form of a graph, is one intermediate representation of programs. A CFG consists of basic blocks and directed edges between them, where each directed edge reflects the execution order of the two basic blocks in the program. We can easily traverse the CFG along directed edges to parse it into a token sequence, which reveals the execution semantics of the program. In this paper, we use a static analyzer `Scalpel`[2] (Li et al., 2022) to construct the CFGs for Python code snippets.

Program Transformation (PT). The program transformation operations aim to produce multiple variants for a given program that satisfy the same desired functionality (Rabin et al., 2020). These different variants of a program can help the model capture functional semantics. In this work, we employ the following program transformation heuristics on ASTs and rewrite one program into another equivalent variant.

- **Function and Variable Renaming.** We randomly take new names from a set of candidates, such as `VAR_i`, `FUNC_i`, to rename the names of variables and functions in a program. This heuristic will not change the AST structure of the program, except for the textual appearance of variable and function names in the AST.
- **Loop Exchange.** The `for` and `while` loops represent the same functionality in a program. We traverse the AST to identify the `for` and `while` loop nodes, and replace `for` loops with `while` loops or vice versa. We also modify the initialization, condition and afterthought simultaneously.
- **Dead Code Insertion.** We first traverse the AST to identify several basic blocks (Mendis et al., 2019), and then randomly select a basic block and insert dead code snippets into it. Note that the dead code snippets are predefined and selected from a set of candidates.

3 CODE-MVP

3.1 Tasks and Notations

We define the set of program samples in multiple views (i.e. NL, PL, AST, CFG, PT) as $S = \{S^1, \dots, S^m\}$, where m represents the number of views, $s_i^a \in S^a$ represents a program in the view of a. Given a program, the PL view denotes its textual appearance, the NL view denotes its corresponding natural-language comment, and the PT denotes the variants of this program based on program transformation. The AST and CFG are extracted from a program using several compiler tools. CODE-MVP adopts two forms of input, i.e., single-view input $x_i^a = \{\texttt{<CLS>}, s_i^a\}$ and dual-view input $x_i^{ab} = \{\texttt{<CLS>}, s_i^a, \texttt{<SEP>}, s_i^b\}$, where a and b denote two different views of the program. Following (Devlin et al., 2019), a special token `<CLS>` is appended at the beginning of each input sequence, and `<SEP>` is used to concatenate two sequences. Subsequently, the representation of `<CLS>` is used to represent the entire sequence, and `<SEP>` is used to split two views of sub-sequences. Given a set of programs with their corresponding multiple

[2] https://github.com/SMAT-Lab/Scalpel

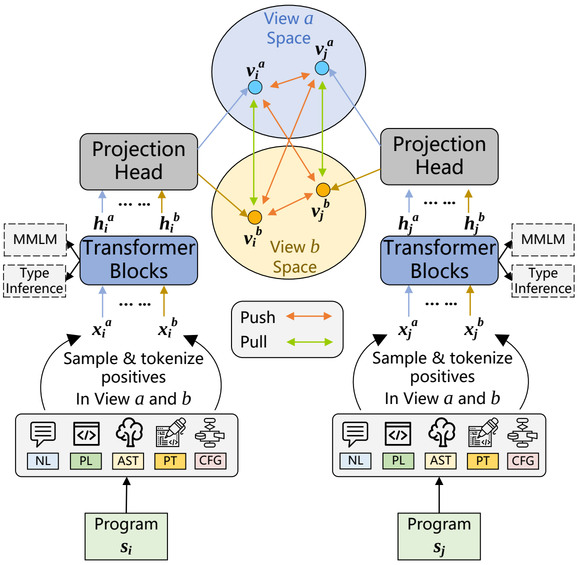

Figure 3: An illustration of our proposed multi-view contrastive pre-training framework.

views, we aim to learn the code representation by utilizing the mutual information existing in different views. Our intuition is to learn complementary information from multiple views of code by pulling the code under different views together and pushing the dissimilar ones apart.

3.2 Framework Overview

Figure 3 shows a simple example of our multi-view contrastive pre-training framework. Given a program s_i, we use the same program to construct a pair of positive samples ($x_i^a = \{\texttt{<CLS>}, s_i^a\}$ *vs* $x_i^b = \{\texttt{<CLS>}, s_i^b\}$) in the form of views a and b, as described above. We take x_i^a and x_i^b as the input of Code-MVP respectively. The last hidden representations of `<CLS>` tokens in the two inputs can be formulated as $\boldsymbol{h}_i^a = \text{Code-MVP}(x_i^a)$ and $\boldsymbol{h}_i^b = \text{Code-MVP}(x_i^b)$. We utilize a projection head (a two-layer MLP) to map hidden representations to a space, i.e., $\boldsymbol{v}_i^a = f(\boldsymbol{h}_i^a)$, $\boldsymbol{v}_i^b = f(\boldsymbol{h}_i^b)$. Then the multi-view contrastive objective can be performed. During the pre-training process, we also design other two pre-training tasks, i.e., fined-grained type inference (FGTI) task and multi-view masked language modeling (MMLM).

3.3 Multi-View Contrastive Learning

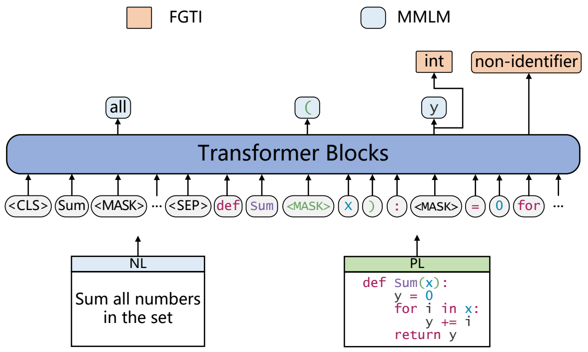
We train Code-MVP with *paired data* and *unpaired data*. Paired data refers to those program samples with paired NL, while unpaired data stands for those isolated program samples without paired NL. Next, we explain how we construct positive and negative samples for these two cases.

Multi-View Positive Sampling. We design *Single-View* (for paired and unpaired data) and *Dual-View* (for paired data only, which needs the NL) methods to construct multi-view positive samples for the MVCL objective:

- **Single-View.** To bridge the gap between different views of a same program, we consider the view of a program x_i^a as a positive sample w.r.t another view x_i^b. That is, ($x_i^a = \{\texttt{<CLS>}, s_i^a\}$ *vs* $x_i^b = \{\texttt{<CLS>}, s_i^b\}$) forms an inter-view positive pair, since x_i^a and x_i^b are two different views of a same program x_i.
- **Dual-View.** There are a total of C_m^2 combinations for two views of a same program. For efficiency, we focus on the features of the program itself, and propose the *NL-conditional* dual-view contrastive pre-training strategy, freezing the position of NL. Concretely, we construct a *NL*-conditional inter-view positive pair by replacing the second view in the input $\{\texttt{<CLS>}, s_i^{\text{NL}}, \texttt{<SEP>}, s_i^a\}$ to be $\{\texttt{<CLS>}, s_i^{\text{NL}}, \texttt{<SEP>}, s_i^b\}$, where $\forall a, b \neq \text{NL}$.

It is worth mentioning that there are many combinations to construct positive pairs. Some combinations are not considered in this work, such as the AST *vs* PT of the same program, and the CFG *vs* PT of the same program. Simultaneously, for training efficiency and downstream applications, we comprehensively consider eight combinations. They are (1) single-view: (NL *vs* PL), (NL *vs* PT), (PL *vs* AST), (PL *vs* CFG), and (PL *vs* PT); and (2) dual-view: (NL-PL *vs* NL-AST), (NL-PL *vs* NL-CFG), and (NL-PL *vs* NL-PT).

Multi-View Negative Sampling. Since the processes of unpaired data and paired data are similar, here we take the unpaired data as an example. We leverage *in mini-batch* and *cross mini-batch* sampling strategies (Chen et al., 2020) to construct intra-view and inter-view negative samples, respectively. Given a mini-batch of training data $b_1 = [x_1^a, \ldots, x_n^a]$ in the view of a with size n, we can easily get another positive mini-batch data $b_2 = [x_1^b, \ldots, x_n^b]$ in the view of b, where (x_i^a *vs* x_i^b) denotes an inter-view positive pair. For x_i^a, the intra-view negative samples are $\{x_j^a\}, \forall i \neq j$, and the inter-view negative samples are $\{x_j^b\}, \forall i \neq j$. Finally, for each x_i, we can get a set of $2n - 2$ negative samples.



```
def Sum(x):
    y = 0
    for i in x:
        y += i
    return y
```

Figure 4: Pre-training with fine-grained type inference and multi-view masked language modeling.

For an input x_i^a with representation v_i^a under the view of a, it has one positive sample x_i^b with representation v_i^b under the view of b. It also has a negative sample set $\mathbf{V}^- = \{\boldsymbol{v}_1^-, \ldots, \boldsymbol{v}_{2n-2}^-\}$ with size $2n-2$, which consists of two types of negative sample subsets, e.g., intra-view negative sample set $\mathbf{V_1^-}$ with size $n-1$, where $\boldsymbol{v}_j^a \in \mathbf{V_1^-}, \forall j \neq i$, and the inter-view negative sample set $\mathbf{V_2^-}$ with size $n-1$, where $\boldsymbol{v}_j^b \in \mathbf{V_2^-}, \forall j \neq i$. We define the similarity of a pair of samples as the dot product of their representations. Then the loss function for a positive pair (x_i^a, x_i^b) can be defined as:

$$l(x_i^a, x_i^b) = -\ln \frac{\exp(\boldsymbol{v}_i^a \cdot \boldsymbol{v}_i^b)}{\exp(\boldsymbol{v}_i^a \cdot \boldsymbol{v}_i^b) + \sum_{k=1}^{2n-2} \exp(\boldsymbol{v}_i^a \cdot \boldsymbol{v}_k^-)} . \quad (1)$$

We calculate the loss for the same pair twice with order switched, i.e., (x_i^a, x_i^b) is changed to (x_i^b, x_i^a) as the dot product with negative samples for x_i^a and x_i^b are different. Overall, the MVCL loss function is defined as follows:

$$\mathcal{L}_{\text{MVCL}} = -\frac{1}{|\mathcal{N}|} \sum_{i}^{|\mathcal{N}|} \left[l(x_i^a, x_i^b) + l(x_i^b, x_i^a) \right] , \quad (2)$$

where $\mathcal{N}$ denotes the set of all program samples covering all different views.

3.4 Pre-Training with Type Inference

Figure 4 shows the other two pre-training tasks, including fine-grained type inference and multi-view masked language modeling.

Fine-Grained Type Inference. Several previous works (Wang et al., 2021; Wang et al., 2021b) have proven the importance of symbolic properties in programming languages. Two concurrent works, SynCoBERT (Wang et al., 2021) and CodeT5 (Wang et al., 2021b) let the model divide the code token types into `identifier` or `non-identifier`. Inspired by the type checking in compilation process, we propose a fine-grained type inference (FGTI) objective to capture the fine-grained type information of variables (Li et al., 2022; An et al., 2011). First, we parse all source codes into ASTs. Then, we traverse the AST and use the type checker to obtain fine-grained identifier types. We employ BPE tokenizer (Sennrich et al., 2016) to tokenize tokens and let sub-tokens inherit the type information of the token. Finally, we define the loss function as follows:

$$\mathcal{L}_{\text{FGTI}} = -\frac{1}{|\mathcal{Z}|} \sum_{i}^{|\mathcal{Z}|} \sum_{j}^{|\mathcal{T}|} Y_{ij} \log P_{ij} , \quad (3)$$

where $\mathcal{Z}$ denotes the set of all tokens that need to inference types, $\mathcal{T}$ represents the set of all types contained in the pre-training corpus, Y_{ij} denotes the label of token i in type j, and P_{ij} denotes the predicted probability of token i in type j.

Multi-View Masked Language Modeling. In addition to the multi-view contrastive learning objective and fine-grained type inference objective, we also extend the Masked Language Modeling (MLM) to the multi-view program corpus, named MMLM. Given a data point x, we randomly select 15% of tokens in x and replace them with a special token `<MASK>`, following the same settings in (Devlin et al., 2019). The MMLM objective aims to predict original tokens which are masked out. We calculate the MMLM loss as follows:

$$\mathcal{L}_{\text{MMLM}} = -\frac{1}{|\mathcal{M}|} \sum_{i}^{|\mathcal{M}|} \sum_{j}^{|\mathcal{V}|} Y_{ij} \log P_{ij} , \quad (4)$$

where $\mathcal{M}$ denotes the set of masked tokens, $\mathcal{V}$ represents the vocabulary, Y_{ij} denotes the label of the masked token i in class j, and P_{ij} denotes the predicted probability of token i in class j.

3.5 Overall Training Objective

The overall loss function in CODE-MVP is the integration of several components we have defined before.

$$\mathcal{L} = \mathcal{L}_{\text{MVCL}} + \mathcal{L}_{\text{FGTI}} + \mathcal{L}_{\text{MMLM}} + \lambda \|\Theta\|^2 , \quad (5)$$

where Θ contains all trainable parameters of the model, and λ is the coefficient of L_2 regularizer.

Tasks	Datasets	Train	Valid	Test
Natural Language Code Retrieval	AdvTest	251K	9.6K	19.2K
	CosQA	19.6K	0.5K	0.5K
	CoNaLa	2.4K	-	0.5K
Code-to-Code Retrieval	Python800	72K	4K	4K
Code Clone Detection	Python800	144K	8K	8K
Code Defect Detection	GREAT	100K	5K	5K

Table 2: Statistics of datasets for downstream tasks.

4 Experimental Setup

We conduct experiments to answer the following research questions: (1) *How effective is* CODE-MVP *compared with the state-of-the-art baselines?* (2) *How do different components and different views affect our* CODE-MVP*?*

4.1 Pre-Training Dataset and Settings

Different programming languages often require different program analyzers. Existing program analysis tools rarely support multiple programming languages and multi-view program transformations. For convenience, we choose Python for our experiments, as it is very popular and used in many projects. We pre-train CODE-MVP on the Python corpus of CodeSearchNet dataset (Husain et al., 2019), which consists of 0.5M bimodal Python functions with their corresponding natural-language comments, as well as 1.1M unimodal Python functions.

CODE-MVP is built on the top of Transformer (Vaswani et al., 2017), and consists of a 12-layer encoder with 768 hidden sizes and 12 attention heads. The pre-training procedure is conducted on 8 NVIDIA V100 GPUs for 600K steps, with each mini-batch containing 128 sequences up to 512 tokens including special tokens. According to the length distribution of samples in the training corpus, we set the lengths of PL/AST/CFG/PT in unpaired data to 512, and set the lengths of NL and PL/AST/CFG/PT in paired data to 96 and 416 respectively. The learning rate of CODE-MVP is set to $1e$-4 with a linear warm up over the first 30K steps and a linear decay. CODE-MVP is trained with a dropout rate of 0.1 on all layers and attention weights. We initialize the parameters of CODE-MVP by GraphCodeBERT (Guo et al., 2021) and utilize a BPE tokenizer (Sennrich et al., 2016).

4.2 Evaluation Tasks, Datasets and Metrics

We select several program comprehension tasks to evaluate CODE-MVP, including natural language code retrieval, code similarity, and code defect detection. We pre-train CODE-MVP on Python corpus, and choose several public Python datasets to evaluate it, as shown in Table 2.

Natural Language Code Retrieval. This task aims to find the most relevant code snippet from a collection of candidates, given a natural language query. We choose three datasets to evaluate this task, including AdvTest (Lu et al., 2021), CoNaLa (Yin et al., 2018), and CoSQA (Huang et al., 2021). We adopt the Mean Reciprocal Rank (MRR) metric to evaluate the performance of code retrieval. In AdvTest dataset, we set the learning rate as $5e$-5, the batch size as 32, the maximum fine-tuning epoch as 20, the maximum length of both query and code sequence as 256. In CoNaLa and CoSQA datasets, we set the learning rate as $5e$-5, the batch size as 32, the maximum fine-tuning epoch as 30, the maximum length of query and code sequence as 128. In AdvTest and CoSQA datasets, we save the optimal checkpoint on the validation set, and test it on the testing set. In CoNaLa dataset, we report the best results on the testing set.

Code Similarity. This task is always categorized into two groups: code-to-code retrieval and code clone detection. We conduct experiments on the Python800 dataset (Puri et al., 2021), which is composed of 800 problems with each problem having 300 unique Python solution files. We remove those files not in UTF-8 encoding formats and randomly select 100 solutions for each problem. In code-to-code retrieval, the filtered dataset is split to 720/40/40 problems for training, validation, and testing. Given a program, this task aims to retrieve other programs that solve the same problem; we evaluate using Mean Average Precision (MAP). Regarding the task of code clone detection, we treat it as binary classification and evaluate it using the Accuracy score, following (Puri et al., 2021).

To train these two tasks, we set the learning rate as $2e$-5, the batch size as 32, the epoch number as 20. In code-to-code retrieval, we set the maximum length of both query and code sequence as 256. In code clone detection, we set the maximum concatenation sequence length of the two code snippets to 512. We save the optimal checkpoint on the validation set, and test it on the testing set.

Models	AdvTest	CoNaLa	CoSQA	Average
RoBERTa	18.3	30.7	57.6	35.5
CodeBERT	27.2	38.9	64.2	43.4
GraphCodeBERT	35.2	47.3	68.2	50.2
PLBART	34.3	45.5	65.3	48.4
CodeT5	36.5	47.7	67.7	50.6
SynCoBERT	38.1	48.4	69.6	52.0
CODE-MVP	**40.4**	**50.6**	**72.1**	**54.4**

Table 3: Results on the natural language code retrieval task evaluating with MRR, using the AdvTest, CoNaLa, and CoSQA datasets.

Models	MAP@R	Accuracy
RoBERTa	82.9	94.4
CodeBERT	86.1	95.2
GraphCodeBERT	88.8	95.9
PLBART	86.7	95.5
CodeT5	88.1	95.7
SynCoBERT	89.2	96.1
CODE-MVP	**91.5**	**97.4**

Table 4: Results on the code-to-code retrieval and code clone detection tasks evaluating with MAP and Accuracy score, using the Python800 dataset.

Code Defect Detection. This task aims to identify whether a given piece of code snippet is vulnerable or not, which is usually treated as a binary classification task. We evaluate all models on the GREAT dataset (Hellendoorn et al., 2020), which is originally built from the ETH Py150 dataset (Raychev et al., 2016). We evaluate the performance of code defect detection using the Accuracy score. We randomly select 100K samples for training, 5K samples for validation and 5K samples for testing, respectively. We set the learning rate as $5e$-5, the batch size as 32, the maximum fine-tuning epoch as 50, the maximum length of both query and code sequence as 256. We save the optimal checkpoint on the validation set, and test it on the testing set.

4.3 Baselines

We compare CODE-MVP with various state-of-the-art models. **RoBERTa** (Liu et al., 2019) is a robustly optimized BERT (Devlin et al., 2019), which is originally pre-trained on a large-scale natural-language corpus. We fine-tune it on source code datasets of downstream tasks. **CodeBERT** (Feng et al., 2020) is pre-trained on NL-PL pairs using both masked language modeling (Devlin et al., 2019) and replaced token detection (Clark et al., 2020) objectives. **GraphCodeBERT** (Guo et al., 2021) is a pre-trained language model of source code which incorporates the data flow information of source code. **PLBART** (Ahmad et al., 2021) is based on the BART (Lewis et al., 2020) architecture and pre-trained on Python and Java functions using denoising autoencoding. **CodeT5** (Wang et al., 2021b) is based on the T5 (Raffel et al., 2020) architecture and employs denoising sequence-to-sequence pre-training on seven programming languages. **SynCoBERT** (Wang et al., 2021) incorporates AST by edge prediction and uses contrastive learning to maximize the mutual information among programs, documents, and ASTs.

5 Results and Analysis

5.1 Performance on Downstream Tasks (RQ1)

Natural Language Code Retrieval. Table 3 shows the results of natural language code retrieval on three datasets. We can observe that CODE-MVP outperforms all baseline models on all datasets. Specifically, it outperforms CodeT5 by 3.8 points on average. Compared to the previous state-of-the-art SynCoBERT, CODE-MVP also performs better with an average improvement of 2.4 points. This significant performance improvement indicates that the code representation learned by CODE-MVP preserves more code semantics. We attribute this improvement to our introduced multi-view contrastive pre-training strategy.

Code Similarity. Table 4 presents the results for code similarity calculation, including code-to-code retrieval and code clone detection. We can see that CODE-MVP significantly outperforms all baseline models on these two tasks. In the task of code-to-code retrieval, CODE-MVP outperforms CodeT5 and SynCoBERT by 3.4 points and 2.3 points, respectively. In the task of code clone detection, CODE-MVP achieves 1.5 and 1.3 points higher compared to GraphCodeBERT and SynCoBERT, respectively. These results show that CODE-MVP can better identify those programs with the same semantics and distinguish those programs with different semantics.

Code Defect Detection. Table 5 shows the experimental results of code defect detection. CODE-MVP consistently outperforms all models. Specifically, it outperforms GraphCodeBERT and SynCoBERT by 1.8 and 1.1 points, respectively. These results indicate that CODE-MVP can effectively preserve the semantics of programs, which is beneficial for code defect detection.

Models	Accuracy
RoBERTa	81.9
CodeBERT	85.5
GraphCodeBERT	87.5
PLBART	86.8
CodeT5	87.4
SynCoBERT	88.2
CODE-MVP	**89.3**

Table 5: Results on the code defect detection task evaluating with Accuracy score, using the GREAT dataset.

Models	AdvTest	CoNaLa	CoSQA	Average
CODE-MVP	**40.4**	**50.6**	**72.1**	**54.4**
w/o MVCL	36.2	47.7	69.2	51.0
w/o FGTI	38.0	48.9	70.8	52.6
w/o AST	39.1	48.5	71.3	53.0
w/o PT	38.2	48.6	70.8	52.5
w/o CFG	37.8	47.9	70.5	52.1

Table 6: Ablation study on the task of natural language code retrieval, evaluated using MRR.

5.2 Ablation Study (RQ2)

We empirically study several simplified variants of CODE-MVP to understand the contributions of each component, including the Multi-View Contrastive Learning (MVCL), Fine-Grained Type Inference (FGTI), Abstract Syntax Tree (AST), Program Transformation (PT), and Control Flow Graph (CFG). Taking the natural language code retrieval task as an example, Table 6 shows the experimental results of each variant on that task. The setting of w/o (MVCL, FGTI) indicates that these pre-training objectives are removed from CODE-MVP respectively. The setting of w/o (AST, PT, CFG) indicates that different views of programs are removed from CODE-MVP respectively. From Table 6, several meaningful observations can be drawn. (1) Both MVCL and FGTI effectively increase the performance, which confirms that the two proposed pre-training objectives can indeed improve the ability of the model for program comprehension. (2) Exploiting different views of programs can bring performance improvements to the model as arbitrarily discarding any view of programs degrades the performance. Additionally, the introduction of CFG brings more performance improvements, indicating the importance of execution information for program understanding.

6 Related Work

Pre-Trained Models for Source Code. Benefiting from the strong power of pre-trained models in natural language processing (Liu et al., 2019; Devlin et al., 2019; Wang et al., 2021a, 2020a,b), several recent works attempt to use the pre-training techniques on programs (Svyatkovskiy et al., 2020). Kanade et al. (2020) proposed CuBERT which follows the architecture of BERT (Devlin et al., 2019), and is pre-trained with a masked language modeling objective on a large-scale Python corpus. Feng et al. (2020) proposed CodeBERT, which is pre-trained on NL-PL pairs in six programming languages, introducing the replaced token detection objective (Clark et al., 2020). Furthermore, Guo et al. (2021) proposed GraphCodeBERT, which incorporates the data flow of programs into the model pre-training process. Wang et al. (2021) proposed SynCoBERT, which incorporates ASTs via edge prediction to enhance the structural information of programs. They also used contrastive learning to maximize the mutual information among programs, documents, and ASTs. Lu et al. (2021) proposed CodeGPT for code completion, which is pre-trained using a unidirectional language modeling objective. Ahmad et al. (2021) proposed PLBART based on BART (Lewis et al., 2020), which is pre-trained on a large-scale corpus of Java and Python programs paired with their corresponding comments via denoising autoencoding. Wang et al. (2021b) proposed CodeT5 following the architecture of T5 (Raffel et al., 2020). It employs denoising sequence-to-sequence pre-training on seven programming languages. Recently, Wan et al. (2022b) conducted a thorough structural analysis aiming to provide an interpretation of pre-trained language models for source code (e.g., CodeBERT and GraphCodeBERT).

Program Analysis for Code Intelligence. In addition to the lexical information of programs, many recent works attempt to leverage program analysis techniques to capture the structural and syntactic representations of programs (Cummins et al., 2020). Kim et al. (2021) designed several strategies to feed the ASTs of programs into Transformer (Vaswani et al., 2017). Li et al. (2019) proposed a graph matching network, which utilizes the CFG of the program to deal with the challenge of binary function similarity search. Ling et al. (2021) proposed a deep graph matching and searching model based on graph neural networks (Kipf and Welling, 2017; Wang et al., 2021b,a; Yu et al., 2022; Zhao et al., 2022) for code retrieval. They represented both natural language queries and code snippets based on the unified graph-structured data. Iyer et al. (2020) presented the program-derived semantic graph to capture the semantics of programs at multiple levels of abstraction. Ben-Nun et al. (2018) presented inst2vec, which locally embeds individual statement in LLVM intermediate representations by processing a contextual flow graph with a context prediction objective (Mikolov et al., 2013).

Contrastive Learning on Programs. Recently, several attempts have been made to leverage contrastive learning for better code semantics. ContraCode (Jain et al., 2021) and Corder (Bui et al., 2021b) first utilized semantic-preserving program transformations such as identifier renaming, dead code insertion, to build positive instances. Then a contrastive learning objective is designed to maximize the mutual information among the positive and negative instances. Ding et al. (2021) presented a self-supervised pre-training technique called BOOST based on contrastive learning. They inject real-world bugs to build hard negative pairs. In CODE-MVP, we construct the positive pairs throughout the compilation process of programs, including lexical analysis, syntax analysis, semantic analysis, and static analysis. It is the first pre-trained model that integrates multi-views of programs for program comprehension.

7 Conclusion

In this paper, we have proposed CODE-MVP, a novel approach to represent the source code with multi-view contrastive pre-training learning. We extract multiple code views with compiler tools and learn the complement among them under a contrastive learning framework. We also propose a fine-grained type inference task in the pre-training process. Comprehensive experiments on three downstream tasks over five datasets verify the effectiveness of CODE-MVP when compared with several state-of-the-art baselines.

Abstract

Pre-trained language models (PLMs) can provide a good starting point for downstream applications. However, it is difficult to generalize PLMs to new tasks given a few labeled samples. In this work, we show that Relation Graph augmented Learning (RGL) can improve the performance of few-shot natural language understanding tasks. During learning, RGL constructs a relation graph based on the label consistency between samples in the same batch, and learns to solve the resultant node classification and link prediction problems on the relation graph. In this way, RGL fully exploits the limited supervised information, which can boost the tuning effectiveness. Extensive experimental results show that RGL consistently improves the performance of prompt-based tuning strategies.[1]

1 Introduction

Pre-trained language models (PLMs), such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), have become the standard workhorse for nowadays natural language processing tasks. A direct way of leveraging these PLMs is to fine-tune them by taking gradient descent w.r.t. the objective of downstream tasks. However, tuning the large PLM by a few labeled samples has a high risk of overfitting (Dodge et al., 2020; Zhang et al., 2021; Gunel et al., 2020). Besides, as PLMs are trained by an objective different from the downstream tasks, the ability of PLM may not be fully exploited. Recently, prompt-based tuning methods emerge and obtain promising results on tuning PLMs to new tasks with a few labeled samples (Liu et al., 2021). In particular, these methods use prompts to reformulate the downstream tasks into the same form of pre-training tasks such that the gap between pre-training and fine-tuning is reduced (Brown et al., 2020; Schick and Schütze, 2021a). Concretely, prompt-based tuning strategies rewrite the input sequence into a cloze question with masks (Schick and Schütze, 2021a). The input sequence is rewritten as prompts, while the corresponding label is replaced by answer tokens. Some methods use hard prompts and answers which use text strings with certain semantic meaning (Schick and Schütze, 2021b; Tam et al., 2021; Gao et al., 2021), while others take learnable parameters as soft prompts and answers (Liu et al., 2021; Li and Liang, 2021; Lester et al., 2021). One can use multiple prompts to boost the performance of prompt-based tuning (Brown et al., 2020; Schick and Schütze, 2021b). While the above strategies improve few-shot performance, they pay less attention to exploiting the relations among the limited number of labeled samples.

In this work, we propose a simple yet effective relation graph augmented approach which can enhance the performance of prompt-based tuning strategies PLM in few-shot natural language understanding tasks. Specifically, our proposal aims at fully exploiting the limited supervised information via **R**elation **G**raph augmented **L**earning, we thus call the proposed method RGL. RGL first constructs a batch-wise relation graph, where every node refers to a labeled sample and the edge between nodes refers to the similarity between the two samples. RGL establishes the edge in the relation graph w.r.t whether the two samples are from the same class and regularizes the similarity of representations learned by PLMs between every two samples to fit the edge of the relation graph. RGL can easily scale up as the relation graph is constructed w.r.t. only a mini-batch of sampled data points per iteration. Empirical results on benchmark datasets show that RGL can

consistently improve the performance of prompt-based tuning.

2 Related Works

The related works are briefly reviewed below.

Few-Shot Learning. Few-shot learning (FSL) targets at generalizing to new tasks with a few labeled samples (Wang et al., 2020). FSL has been applied to many natural language processing applications such as text classification (Bao et al., 2020) and named entity typing (Yang and Katiyar, 2020). Typical solutions in FSL include data augmentation which directly generate more labeled samples (Dopierre et al., 2021), metric learning which learns to embed samples into a space where samples can be easily discriminated (Geng et al., 2020), and meta-learning which learns a good initialized model from a set of related tasks which is then fine-tune to each task (Bao et al., 2020). Recently, several methods propose to tune pre-trained language models to downstream few-shot tasks (Liu et al., 2021). We follow this line, and further propose to conduct model tuning on learned relation graphs. Our approach can be incorporated into existing prompt-based tuning strategies, increasing the effectiveness of supervised signals and bringing in performance gains.

Graph Structure Learning. Graph structure learning methods target at jointly learning graph structure and node embeddings of input samples (Zhu et al., 2021). Usually, these methods iterate over two steps: (i) estimate the adjacency matrix which encodes graph structure using node embeddings; and (ii) apply graph neural networks (GNNs) on this updated graph to obtain new node embeddings. Recently, graph structure learning has been used to estimate relation graphs among samples to facilitate effective propagation of label information (Satorras and Estrach, 2018; Rodríguez et al., 2020; Wang et al., 2021a,b). These methods estimate relation graphs which encode the similarity between sample embeddings. In contrast, our RGL models similarity between samples by class prediction vectors without introducing extra parameters.

3 Background

Following the problem definition of (Schick and Schütze, 2021b; Gao et al., 2021), the target of this paper is to generalize a pre-trained language model (PLM) to text classification tasks with a few labeled examples. Each task $\mathcal{T}$ with label space $\mathcal{Y}$ consists of three datasets: (i) training dataset $\mathcal{D}_{\text{train}} = \{(\mathbf{x}_i, y_i)\}$ containing a few labeled examples where $\mathbf{x}_i$ is the sequence and y_i is the corresponding label, (ii) development(validation) dataset $\mathcal{D}_{\text{dev}}$ containing the same number of samples as $\mathcal{D}_{\text{train}}$ and is used for model selection, and (iii) testing dataset $\mathcal{D}_{\text{test}}$ containing unlabeled samples to be predicted.

In prompt-based tuning, each input sample $(\mathbf{x}_i, y_i)$ is reformulated as a pattern-verbalizer pair (PVP) (Schick and Schütze, 2021a) in terms of $(p(\mathbf{x}_i), v(y_i))$. The pattern mapping function $p(\cdot)$ maps $\mathbf{x}_i$ to a cloze question with masks. For example, a single sentence

$$\text{“}\mathbf{x}_i = \text{[CLS]}s\text{[SEP]”}$$

can be mapped as

$$\text{“}p(\mathbf{x}_i) = \text{[CLS]}s \text{ It was [MASK].[SEP]”},$$

where [CLS] and [SEP] are special start and end tokens. And a sentence pair

$$\text{“}\mathbf{x}_i = \text{[CLS]}s_1\text{[SEP]}s_2\text{[SEP]”}$$

can be mapped as

$$\text{“}p(\mathbf{x}_i) = \text{[CLS]}s_1\text{[MASK]}, s_2\text{[SEP]”}.$$

The verbalizer $v(\cdot)$ maps y_i to tokens expressing the semantic meaning of y_i. For examples, “positive/negative” can be mapped as “good/bad”. With PVPs, the token embedding $\mathbf{h}_i^{\text{[MASK]}}$ of [MASK] is taken as the representation of $\mathbf{x}_i$. The class prediction $\hat{\mathbf{y}}_i$ contains the conditional probability distribution of each possible class label given $\mathbf{x}_i$, whose entry corresponds to y_i is estimated as

$$\begin{aligned} q(y_i|\mathbf{x}_i) &= \frac{\exp(p(\text{[MASK]}=v(y_i)|p(\mathbf{x}_i)))}{\sum_{y_j\in\mathcal{Y}}\exp(p(\text{[MASK]}=v(y_j)|p(\mathbf{x}_i)))} \\ &= \frac{\exp(\mathbf{w}_{v(y_i)}^\top \cdot \mathbf{h}_i^{\text{[MASK]}})}{\sum_{y_j\in\mathcal{Y}}\exp(\mathbf{w}_{v(y_j)}^\top \cdot \mathbf{h}_i^{\text{[MASK]}})}, \end{aligned} \tag{1}$$

where $\mathbf{w}_v$ is the logit vector of token v existing in the vocabulary. Let $\mathbf{y}_i$ be a one-hot vector with all 0s but a single one denoting the index of the ground truth class label $y_i \in \{1, \ldots, C\}$. The model is optimized w.r.t. the loss $\mathcal{L}_{\text{CE}}$ defined as

$$\mathcal{L}_{\text{CE}} = \sum\nolimits_{i=1}^{N} -\log(\hat{\mathbf{y}}_i)^\top \mathbf{y}_i, \tag{2}$$

where $(\cdot)^\top$ denotes the transpose operation.

4 RGL: Our Proposed Method

In this section, we present the proposed RGL (Figure 1). We manage to exploit more supervised signals out of the training samples by constructing and learning on batch-wise relation graphs, which can boost the effectiveness of prompt-based tuning.

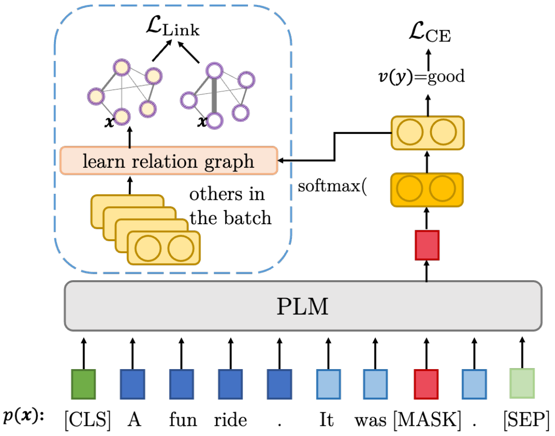

Figure 1: A high-level illustration of prompt-based tuning with the proposed RGL (marked by the square with blue dotted lines).

4.1 Defining the Relation Graphs

Consider a mini-batch $\mathcal{B} = \{(\mathbf{x}_i, y_i)\}_{i=1}^{N}$ containing N randomly sampled sequence-label pairs, whose indexes are kept in $\mathcal{I} = \{1, \ldots, N\}$. We try to exploit more supervised information by modeling its relation graph. Let $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$ denotes the relation graph among the N training samples in $\mathcal{B}$. In particular, $\mathcal{V}$ is a set of nodes where each node $v_i \in \mathcal{V}$ corresponds to one training sample $\mathbf{x}_i$, and $\mathcal{E} = \{e_{ij}\}$ is a set of edges between the N training samples. In this paper, we mainly consider text classification tasks. Hence, we establish the edge e_{ij} between a node v_i and another node v_j if these nodes come from the same class. Formally, e_{ij} is set to

$$e_{ij} = \begin{cases} 1 & \text{if } y_j = y_i \\ 0 & \text{otherwise} \end{cases}. \quad (3)$$

Note that (3) is just an example of defining e_{ij} in classification tasks, which is simple but already enough to obtain good performance. One can also define e_{ij} in other ways flexibly, such as modeling both the intra-class and inter-class relations (Kim et al., 2019), using auxiliary information to calculate it, and defining real-valued e_{ij} for regression tasks.

4.2 Learning with Relation Graphs

On the relation graph $\mathcal{G}$ of mini-batch $\mathcal{B}$, we expand the origin classification task into two problems: (i) a node classification problem to predict the correct class of each node, and (ii) a link prediction problem to connect nodes of the same classes and disconnect nodes from different classes.

The node classification problem corresponds exactly to the original classification task. Therefore, we obtain class prediction $\hat{\mathbf{y}}_i$ of v_i (corresponding to $\mathbf{x}_i$) by (1) and calculate $\mathcal{L}_{\text{CE}}$ loss by (2).

As for the link prediction problem, we establish $\hat{e}_{ij}$ between v_i and v_j based on the relevance between $\hat{\mathbf{y}}_i$ and $\hat{\mathbf{y}}_j$:

$$\hat{e}_{ij} = g(\hat{\mathbf{y}}_i, \hat{\mathbf{y}}_j), \quad (4)$$

where $\hat{\mathbf{y}}_i, \hat{\mathbf{y}}_j$ are obtained by (1), and $g(\cdot, \cdot)$ is simply set as cosine similarity in this paper. There exist other choices to obtain $\hat{e}_{ij}$. One can define e_{ij} and $\hat{e}_{ij}$ differently: leveraging auxiliary relation graphs or calculating based on representation similarity such as $g(\mathbf{h}_i^{[\text{CLS}]}, \mathbf{h}_j^{[\text{CLS}]})$ and $g(\mathbf{h}_i^{[\text{MASK}]}, \mathbf{h}_j^{[\text{MASK}]})$. We use $\hat{\mathbf{y}}_i, \hat{\mathbf{y}}_j$ as they carry more semantic information relevant to each class, which are more predictive and obtain better empirical performance. One may also consider using parameterized $g(\cdot, \cdot)$ instead of using cosine similarity. However, considering the limited number of labeled samples, we avoid bringing in extra parameters to reduce the risk of overfitting. To measure the losses of link prediction, We design $\mathcal{L}_{\text{Link}}$ loss as

$$-\sum_{i \in \mathcal{I}} \sum_{j \in \mathcal{A}(i)} e_{ij} \log(\hat{e}_{ij}) + (1 - e_{ij}) \log(1 - \hat{e}_{ij}), \quad (5)$$

where

$$\mathcal{A}(i) = \{j \in \mathcal{I} \text{ and } i \neq j\}. \quad (6)$$

For each mini-batch $\mathcal{B}$, we optimize the model to minimize the combination of node classification loss $\mathcal{L}_{\text{CE}}$ and link prediction loss $\mathcal{L}_{\text{Link}}$ as a whole:

$$\mathcal{L}_{\text{CE}} + \alpha \mathcal{L}_{\text{Link}}, \quad (7)$$

where α is a hyperparameter to control the contribution of this $\mathcal{L}_{\text{Link}}$.

4.3 Comparisons with SCL

The most relevant work to RGL is SCL(Gunel et al., 2020) which applies supervised contrastive learning (SCL) on a batch level while fine-tuning PLM (rather than prompt-based tuning PLM). SCL optimizes for the following objective:

$$\mathcal{L}_{\text{CE}} + \beta \mathcal{L}_{\text{SCL}}, \tag{8}$$

where $\mathcal{L}_{\text{SCL}}$ is defined as:

$$-\sum_{i \in \mathcal{I}} \sum_{j \in \mathcal{P}(i)} \log \frac{\exp(f(\mathbf{x}_i) \cdot f(\mathbf{x}_j)/\tau)}{\sum_{k \in \mathcal{A}(i)} \exp(f(\mathbf{x}_i) \cdot f(\mathbf{x}_k)/\tau)}, \tag{9}$$

where τ is a hyperparameter. $\mathcal{P}(i)$ takes the form of

$$\mathcal{P}(i) = \{j \in \mathcal{A}(i) : y_j = y_i\}, \tag{10}$$

where $\mathcal{A}(i)$ is defined in (6). $f(\mathbf{x}_i)$ in (9) refers to the representation of $\mathbf{x}_i$. In the original paper (Gunel et al., 2020), $f(\mathbf{x}_i)$ is set as token embedding $\mathbf{h}_i^{\text{[CLS]}}$ of [CLS]. While considering prompt-based tuning strategies (Liu et al., 2021), we follow routine and set $f(\mathbf{x}_i) = \mathbf{h}_i^{\text{[MASK]}}$ in SCL.

Comparing (5) to (9), it can be observed that RGL enforces more strict constraints between samples. By constructing relation graphs and learning to approximate the edge labels $\hat{e}_{ij}$ defined in (3), RGL rules samples from the same class to be connected and otherwise disconnected. While SCL does not use any precise measures (e.g., edge labels) to constrain similarities/distances between intra/inter-class samples. SCL only encourages samples from the same class to be close, without explicitly pushing those from different classes to be farther apart. Another difference is that RGL estimates edge labels $\hat{e}_{ij}$ using the prediction $\hat{\mathbf{y}}_i$ and $\hat{\mathbf{y}}_i$ to regularize the task-dependent representations, while SCL uses representation of $\mathbf{x}_i$ (outputs of PLM) which can be irrelevant to the target task.

5 Experiments

All the experiments are conducted on a 32GB NVIDIA Tesla V100 GPU.

Experimental Settings. We use RoBERTa-large[2] (Liu et al., 2019) as the PLM. We take PET[3] (Schick and Schütze, 2021b) as the basic prompt-based tuning method. Upon PET, we compare the benefits of applying the proposed RGL versus SCL (Gunel et al., 2020). All the hyperparameters are selected using the provided development set via grid search following Gao et al. (2021). We use Adam optimizer. We first select learning rate from $\{1e-5, 2e-5, 5e-5\}$ and batch size from $\{2, 4, 8\}$ for PET. Then, we select hyperparameter α in RGL and hyperparameters β and τ in SCL from $[0 : 0.2 : 1]$ separately. We train all methods for a maximum number of 1000 steps and evaluate the performance on development set every 100 steps.

Dataset. Experiments are performed on a variant of GLUE benchmarks (Wang et al., 2018) for few-shot setting, which is provided by Gao et al. (2021). Gao et al. (2021) provide 5 different training sets and developing sets where each of them consist of 16 labeled samples per class. The averaged performance over these 5 splits are reported. We also evaluate the proposed RGL on the SuperGLUE (Wang et al., 2019) variant proposed by Schick and Schütze (2021b), whose results are put in Appendix due to space limit.

Results. Table 1 shows the results. As shown, both RGL and SCL can bring in additional performance gain. In particular, RGL can improve the performance of PET by 2.38% on average, while SCL only improves PET by 1.46% on average. Moreover, RGL obtains more stable results as the variances are smaller than the others.

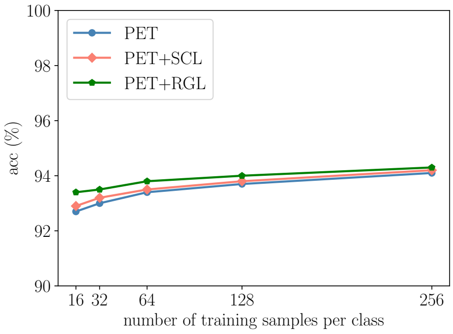

Figure 2: Effect of labeled samples.

Model Analysis. Figure 2 plots the effect of varying the number of labeled training samples. As shown, all methods obtain better performance given more training samples, while PET+RGL consistently outperforms the others. We further consider different ways of obtaining $\hat{e}_{ij}$ in (4): (i) **w/ $\mathbf{h}^{\text{[CLS]}}$** which sets $\hat{e}_{ij} = \cos(\mathbf{h}_i^{\text{[CLS]}}, \mathbf{h}_i^{\text{[CLS]}})$ where $\cos(\cdot,\cdot)$ denotes cosine similarity; (ii)**w/ $\mathbf{h}^{\text{[MASK]}}$** which sets $\hat{e}_{ij} = \cos(\mathbf{h}_i^{\text{[MASK]}}, \mathbf{h}_i^{\text{[MASK]}})$; and (iii) **w/ $\hat{\mathbf{y}}$** which is the one adopted in RGL and sets $\hat{e}_{ij} = \cos(\hat{\mathbf{y}}_i, \hat{\mathbf{y}}_j)$. Results in Figure 3 show that RGL outperforms the others. This

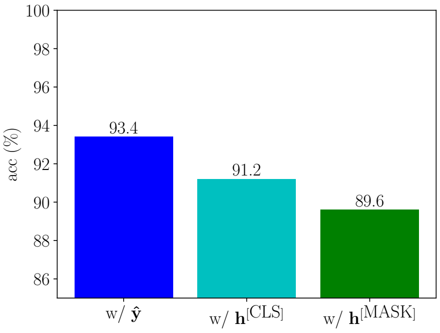

Figure 3: Estimating $\hat{e}_{ij}$ in different ways.

validates that class prediction carries more relevant information to discriminate samples.

Visualization. Figure 4 plots the t-SNE visualization of the learned sample embeddings. It apparently shows that, when combining RGL with both fine-tuning and PET, the distances of deep representations between any two inter-class samples are much longer than the intra-class distances. Furthermore, PET+RGL can separate two classes of samples with clear margin while concentrating samples of every class closely to the center of the group, resulting in better discriminate ability.

6 Conclusion

We present RGL, a simple yet effective relation graph augmented prompt-based tuning approach for few-shot natural language understanding tasks. During learning, RGL constructs batch-wise relation graphs based on label consistency between samples, and explicitly tunes the pre-trained language models to solve the resultant node classification and link prediction problems. In this way, RGL fully exploits the limited supervised information. In this paper, we provide one way of relation graph learning. This can be further extended to broader applications, where other ways of relation graph learning worth trying. In addition, one can explore how to avoid the interference of noisy samples.

A Results on SuperGLUE Variant

In addition to PET (Schick and Schütze, 2021b), we also combine the proposed RGL with other prompt-based tuning strategies. We take P-tuning[4] (Liu et al., 2021) as the representative for joint prompt and PLMtuning, and WARP[5] (Hambardzumyan et al., 2021) as the representative for prompt tuning with a fixed PLM. WARP is only evaluated on CB and RTE as in the original paper.

In the original papers, both P-tuning and WARP use SuperGLUE (Wang et al., 2019) variant proposed by Schick and Schütze (2021b) to evaluate the few-shot performance and use ALBERT[6] (Lan et al., 2020) as the PLM. We adopt their setting for fairness. Schick and Schütze (2021b) provide one training set which consists 32 samples per task and a testing set. Schick and Schütze (2021b) also use unlabeled samples, which are not used in this paper. Following Liu et al. (2021), a development set consisting of 32 samples per task are randomly drawn for model selection. As only one split is provided, we initialize the parameter with five random seeds and report the averaged results over five runs.

Abstract

Given a context knowledge base (KB) and a corresponding question, the Knowledge Base Question Answering task aims to retrieve correct answer entities from this KB. Despite sophisticated retrieval algorithms, the impact of the low-resource (incomplete) KB is not fully exploited, where contributing components (*i.e.* key entities and/or relations) may be absent for question answering. To effectively address this problem, we propose a contrastive regularization based method, which is motivated by the `learn-by-analogy` capability from human readers. Specifically, the proposed work includes two major modules: the knowledge extension and sMoCo module. The former aims at exploiting the latent knowledge from the context KB and generating auxiliary information in the form of question-answer pairs. The later module utilizes those additional pairs and applies the contrastive regularization to learn informative representations, that making `hard` positive pairs attracted and `hard` negative pairs separated. Empirically, we achieved the state-of-the-art performance on the WebQuestionsSP dataset and the effectiveness of proposed modules is also evaluated.

1 Introduction

The task of Knowledge Base Question Answering (KBQA) refers to answering a question given a background knowledge base (KB). A large number of studies on KBQA can be cast into two mainstream categories: semantic parsing (SP) and information retrieval (IR) based. The former focuses on parsing questions into symbolic logic forms, such as query graph (Hu et al., 2018) and skeleton grammar (Sun et al., 2020), before identifying final answer(s) from the KB. The IR approach, on the other hand, aims to perform semantic matching between topic entities from questions and candidate answers within the KB (Xiong et al., 2019; Sun et al., 2019; Saxena et al., 2020; Yadati et al., 2021). This paper is on a novel method for information retrieval based KBQA.

Approaches to IR-based KBQA usually follow a three-step process, including question analysis, subgraph reasoning and answer matching. At first, the question analysis is to understand reasoning instructions behind questions for extracting topic entities and involved relations, *etc*. The second step is performed to retrieve relevant entities and relations (as subgraphs of the context KB) according to reasoning instructions, and further formulate candidate answers. The last step is to identify the best answer by estimating and ranking the semantic-relationship matching score between the given question and candidates.

However, existing IR-based matching pays insufficient attention to the `low resource` (incompleteness) nature of KB, where contributing components (*i.e.* neighboring entities, key relations and/or reasoning path) may be absent. The limit or lack of enough information poses challenges for the subsequent effective question answering. Some work have been proposed to utilize auxiliary information, such as extra question-related texts (Sun et al., 2019) and pre-trained KB embeddings (Saxena et al., 2020), which unfortunately could introduce noisy and misleading facts, not to mention the extra computational cost.

Notably, when human performs QA reasoning, one could infer other cases from one similar instance. Even with a new question, experienced readers could still make a guess using similar concepts or facts from their current knowledge, and potentially discriminate candidate answers from different aspects. For instance, given a question of "`What state did Al Gore represent?`", one could infer from his working experience (*i.e.* `The Tennessean (News)`) and/or the graduate university (*i.e.* `Vanderbilt University`), to further predict the correct answer of `Tennessee`.

July 10-15, 2022 ©2022 Association for Computational Linguistics

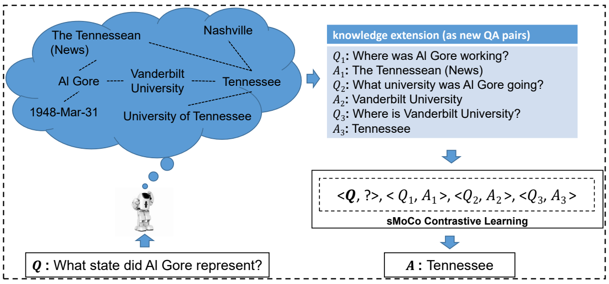

Figure 1: Overview of the proposed `learn-by-analogy` framework for KBQA, where latent knowledge is exploited and represented as the form of QA pairs. The sMoCo module is then applied to extract informative features for question answering.

Inspired from the aforementioned `learn-by-analogy` process, we propose a novel KBQA framework as illustrated in Fig. 1, which includes two major modules: knowledge extension and sMoCo. The former aims to expand knowledge from the existing KB to discover latent information. That is, hidden knowledge is exploited and manipulated in a form of question-answering pairs via making use of existing relations and entities (simulating human readers to use similar concepts/facts). The sMoCo adopts the contrastive learning mechanism, with the ultimate aim of capturing discriminative features from correct and misleading question-answering pairs (simulating human's inference skill). Furthermore, different from traditional contrast methods, the proposed sMoCo is particularly designed to utilize **hard** positive and negative pairs, which further improves the model generalizability. [1]

Our contributions are summarized as follows:

- To the best of our knowledge, we are the first to advance the contrastive learning-based algorithm to resolve the KBQA task; the proposed method is motivated by the `learn-by-analogy` capability from human readers;
- Simulating the human capability of utilizing similar facts, the proposed knowledge extension module explores the context KB to capture latent knowledge and further manipulates them as the task-related question-answer pairs;
- A novel contrast algorithm (sMoCo) is further introduced to simulate human inference capability; compared to existing methods, the proposed one mainly relies on `hard` positive and negative pairs during the training process. Related theoretical analysis is also provided for the discussion of its applicability and sensitivity;
- Experimental evaluations show that the proposed algorithm outperforms state-of-the-arts, in particular with the low-resource cases. We also conduct comprehensive ablation studies to characterize the proposed algorithm, by investigating the impact from the knowledge extension and hard positives/negatives.

2 Related work

2.1 KBQA

Knowledge Base Question Answering (KBQA) is one of the most popular and challenging research topics for machine reading comprehension (MRC). Aiming at determining correct answer(s) given the background knowledge base (KB) and one question, a large amount of research efforts have been put forward to supplement the KBQA task via either semantic parsing (SP) or information retrieval (IR) based strategies. The work from (Hu et al., 2018; Sun et al., 2020), for instance, belongs to the former, which introduced the state-transition and skeleton-based parsing approach to convert the target question into a semantic graph and structural tree, respectively, before querying answers.

Another line of studies aims to retrieve answers by following a more end-to-end training style, that is, to learn representations of the target question and candidate answers. KDReader from (Xiong et al., 2019) performed an attention-based fusion to combine the question and answer features. PullNet (Sun et al., 2019) employed the question-related content as a guideline to extract supporting components (entities and relations from KB). The work of (Saxena et al., 2020) utilized the pre-trained KB embeddings. In addition, Han *et al.* proposed a hypergraph-based reasoning strategy with dynamic relation and entity embeddings (Han et al., 2020). Similarly, RecHyperNet (Yadati et al., 2021) applied recursive hypergraphs to form groups (relations and entities with similar semantic) in the KB. With well-represented features, a matching step is usually followed to identify/rank the best candidate(s).

Despite some promising results from the afore-

---

[1] The source codes is publicly available at `https://github.com/JakeyMei/sMoCo`

mentioned feature learning and matching, less work has been put forward to explore underlying/hidden knowledge from the context KB. We argue that making full use of those existing but latent knowledge is beneficial to the subsequent QA task.

2.2 Contrastive learning

Contrastive learning (CL) has attracted a lot of attention in the recent several years, which utilizes input data itself as the additional supervision signal for training (Chen et al., 2020a; Grill et al., 2020; Chen and He, 2021; He et al., 2020; Chen et al., 2021; Zhu et al., 2021). Specifically, for an input sample (anchor) $\boldsymbol{x}_i$ and an encoder $f(\cdot)$, the overall contrastive loss is formulated as follows:

$$sim\left(f(\boldsymbol{x}_i), f(\boldsymbol{x}_i^+)\right) \gg sim\left(f(\boldsymbol{x}_i), f(\boldsymbol{x}_i^-)\right), \tag{1}$$

where $sim(\cdot,\cdot)$ is a user-defined similarity function, and $\boldsymbol{x}_i^+$ and $\boldsymbol{x}_i^-$ are contrastive pairs of positive and negative, respectively. The training purpose via the contrastive loss is to form informative features ($i.e.\boldsymbol{z}_i^{+/-} = f(\boldsymbol{x}_i)$) such that positives stay close to anchors and negatives are pushed away. Yet, existing CL methods fail to differentiate the pair significance, while the proposed method focuses on `hard` contrastive pairs.

3 Methodology

The illustration of our framework is shown in Fig 2. The KBQA task has been formulated as searching for optimal entities, given the question $\boldsymbol{q}$ and the external KB ($i.e.$ a set of triples $(\boldsymbol{e}_h, \boldsymbol{r}, \boldsymbol{e}_t)$ representing head entity, semantic relationship and tail entity, respectively).

3.1 Knowledge extension module

Most existing KBQA work, unfortunately, focuses on the inference accuracy by offering sophisticated reasoning models. They have neglected the low resource nature of KB, from which key reasoning paths could be absent. Note that, experienced human readers could still utilize knowledge from limit but similar circumstances to infer correct answers. As such, this paper argues that it is beneficial to leverage hidden knowledge, from the context KB (even incomplete), for the subsequent QA process. That is the main aim for the proposed knowledge extension module.

Notably, knowledge extension serves the same role as data argumentation. Yet, this knowledge extension task is nontrivial. In the domain of image processing, argumentation can be carried out by using randomized operations, such as image rotation, cut-off, and scaling. However, in the context of KB, it is impractical to simply randomize knowledge, which could lead to meaningless or inaccurate information.

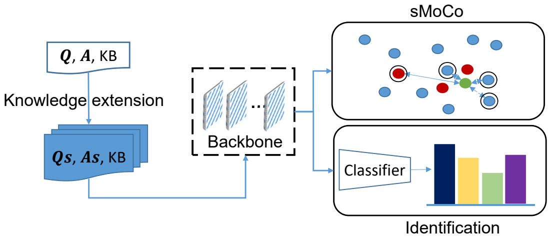

Figure 2: Overview of the proposed framework for KBQA which consists of four modules. First, the knowledge extension module is introduced to explore hidden knowledge from the context KB and produce new QA pairs. Second, a backbone module is applied to extract latent representations, after which the sMoCo module is employed, utilizing only hard contrastive pairs, to ensure that the similarity (of feature representations) between correct QA pairs is maximized by contrasting to that of inaccurate ones. At last, an overall identification module is utilized to identify the best-matching answer.

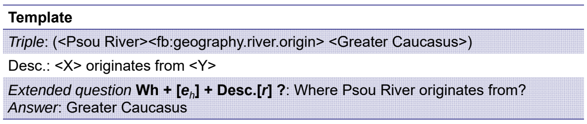
Intuitively, we propose to create new KB-relevant QA pair(s) from available triple(s) using an unsupervised manner. By doing so, we can alleviate the aforementioned challenge by not only effectively utilizing existing knowledge facts, but also providing additional samples for training the QA model. In this regard, we implement the knowledge-extension module using a *template*-oriented strategy[2].



Template

Triple: (<Psou River><fb:geography.river.origin> <Greater Caucasus>)

Desc.: <X> originates from <Y>

Extended question **Wh + [e_h] + Desc.[r] ?**: Where Psou River originates from?
Answer: Greater Caucasus

Figure 3: Example of producing the template-oriented QA pairs.

Given an known triple of $(\boldsymbol{e}_h, \boldsymbol{r}, \boldsymbol{e}_t)$, as the example illustrated in Figure 3. The relation of `fb:geography.river.origin` is associated with a factual description (`Desc.[`$\boldsymbol{r}$`]`), that can be interpreted as `[X] originates from`

---

[2] This strategy can also be viewed as the task of question generation. As such, some general generation techniques (Chen et al., 2020b; Bi et al., 2020) may help if complicated questions (with multiple hops) are preferred and we leave the investigation to future work.

`[Y]` (`[X]` and `[Y]` is the placeholder for $\boldsymbol{e}_h$ and $\boldsymbol{e}_t$ respectively). Then, we produce a template question "`[Wh]` + `[`$\boldsymbol{e}_h$`]` + `Desc.[`$\boldsymbol{r}$`]`?", where `Desc.[`$\boldsymbol{r}$`]` is the relation description. The `[Wh]` component belongs to one of the types (such as `who`, `where`, and `when`), depending on the tag of $\boldsymbol{e}_t$ (such as person, location, and time).

3.2 Backbone module

We adopt KDReader from (Xiong et al., 2019) as the backbone module. For a given question $\boldsymbol{q}$, KDReader firstly retrieves relevant entities from the context KB, according to topic entities $\boldsymbol{e}_q$ from $\boldsymbol{q}$, and further formulates entity embeddings $\mathcal{G}_{\boldsymbol{e}}$. Secondly, with the question embedding $Q_{\boldsymbol{q}}$, a classifier C is trained via optimizing the following loss function:

$$\mathcal{L}_{Matching} = SoftMax(C(\mathcal{G}_{\boldsymbol{e}}, Q_{\boldsymbol{q}})). \quad (2)$$

3.3 sMoCo module

Learning distinguishable features to match correct entities with the given question lies at the heart of KBQA, for which we accordingly propose a new contrastive learning algorithm in this module. Yet, majority contrast methods are characterized by a slow momentum encoder (E_p) and an independent queue ($\mathcal{Q}$) with thousands of negative samples. Despite its simplicity, the existing design poses the following problems: (i) the slow encoder E_p could produce `easy` positive samples (highly similar to anchors); similarly (ii) the lengthy queue $\mathcal{Q}$ may contain `easy` negative samples (highly different to anchors).

Notably, existing methods fail to differentiate `easy` and `hard` positives/negatives. We argue that the contribution of easy ones to the contrastive loss is trivial, while the significance from hard ones is the success toward the contrastive learning. As a result, we propose a screening-based Momentum Contrast method (termed **sMoCo**) via *screening* hard contrastive pairs.

To illustrate this idea, let $\mathbf{z}_i$ and $\mathcal{P}$ represent the i-th anchor feature and the set of corresponding positives. We propose to select only one `hard` positive from $\mathcal{P}$, say $\mathbf{z}_i^{h,+}$, with the lowest similarity to $\mathbf{z}_i$. On the other hand, we select `hard` negatives according to their similarity to $\mathbf{z}_i$ to form a subset $\mathcal{I}_-$ (with $\mathcal{I}_- \in \mathcal{Q}$). More precisely, $\forall \mathbf{z}_i^{h,-} \in \mathcal{I}_-$ and $\forall \mathbf{z}_n \in \mathcal{Q}$, we have

$$\begin{aligned} & s(\mathbf{z}_i^{h,-}) > s(\mathbf{z}_i^-), \forall \mathbf{z}_i^- \in \mathcal{Q},\ \ \mathbf{z}_i^- \notin \mathcal{I}_-, \\ \text{and} & \sum_{\mathbf{z}_i^{h,-} \in \mathcal{I}_-} s(\mathbf{z}_i^{h,-}) = \lambda_{\mathcal{Q}} \sum_{\mathbf{z}_n \in \mathcal{Q}} s(\mathbf{z}_n), \end{aligned} \quad (3)$$

where $s(\cdot)$ is the normalized inner product (for simplicity say $s(\mathbf{z}_i^{h,-}) = \langle \mathbf{z}_i^{h,-}, \mathbf{z}_i \rangle$), and $\lambda_{\mathcal{Q}}$ is a screening term. As such, the proposed contrastive loss for $\mathbf{z}_i$ is formulated as follows:

$$\mathcal{L}_{sMoCo} = -\log \frac{e^{\langle \mathbf{z}_i^{h,+}, \mathbf{z}_i \rangle}}{e^{\langle \mathbf{z}_i^{h,+}, \mathbf{z}_i \rangle} + \sum_{j \in \mathcal{I}_-} e^{\langle \mathbf{z}_j, \mathbf{z}_i \rangle}} \quad (4)$$

In addition to utilizing the proposed hard positive $\mathbf{z}_i^{h,+}$ and hard negatives $\mathcal{I}_-$, we further consider a liner combination of updating $\mathbf{z}_n$ from the negative queue $\mathcal{Q}$ via:

$$\mathbf{z}_n = \lambda_U \mathbf{z}_i + (1 - \lambda_U) \mathbf{z}_i^{h,+}, \quad (5)$$

where $\lambda_U \in [0, 1]$ is a hyperparameter.

Comparison with existing contrastive methods. The mainstream approaches for implementing contrastive learning include SimCLR (Chen et al., 2020a), MoCoV1/2 (He et al., 2020), MoCoFT (Zhu et al., 2021), MoCoV3 (Chen et al., 2021), SimSiam (Chen and He, 2021). Although our approach shares similar idea of utilizing positives and/or negatives as the above, our algorithm is different in the following: (i) the majority existing work neglects the difference of easy and hard contrastive pairs; for instance, MoCoV1/2/3 and SimSiam only considers one positive, while SimCLR selects the easiest one (with the highest similarity with anchors) with the presence of multiple positives; meanwhile, they take all available negatives into account. By contrast, ours is particularly interested in hard positives and negatives; (ii) MoCoFT applies feature-level transformation (FT) to generate hard positives/negatives, which in fact has no direct impact for/from encoders; another drawback then lies in the sensitivity of those FT hyperparameters, that further reduces its generalization capability; Similarly, SimSiam is also significantly impacted by the hyperparameters to produce positives, as no negative exists; and (iii) for updating the negative queue, the proposed update can be cast as a linear combination of SimCLR and MoCos, where other methods (such as MoCoFT) require one entire queue for each single anchor, that is computationally expensive. The aforementioned difference is also summarized in Table 1.

Table 1: Comparison between sMoCo and existing methods, where $|b|$, $|\mathcal{Q}|$, 1-E and 1-H represents the batch size, queue size, one easy and one hard positive, respectively.

	$\mathcal{P}$	$\mathcal{Q}$	Update $\mathcal{Q}$
SimCLR	1-E	$\|b\|$-2	$\mathbf{z}_n = \mathbf{z}_i$
MoCoV1/2	1	$\|\mathcal{Q}\|$	$\mathbf{z}_n = \mathbf{z}_i^+$
MoCoFT	1-H	$\|\mathcal{Q}\|$	$\mathbf{z}_n = \lambda \mathbf{z}_i + (1-\lambda)\mathcal{Q}$
MoCoV3	1	$\|b\|$-2	$\mathbf{z}_n = \mathbf{z}_i$
SimSiam	1	×	×
sMoCo	1-H	$\mathcal{I}_{n,-}$	$\mathbf{z}_n = \lambda_U \mathbf{z}_i + (1-\lambda_U)\mathbf{z}_i^{h,+}$

3.4 Analysis

We present the sensitivity analysis hereafter to justify the choice of the screening parameter (or $\lambda_{\mathcal{Q}}$ from Eq. (3)). Note that the traditional contrastive loss, for the i-th anchor, is defined as follows

$$\mathcal{L}_c = -\log \frac{e^{\langle \mathbf{z}_i^{h,+}, \mathbf{z}_i \rangle}}{e^{\langle \mathbf{z}_i^{h,+}, \mathbf{z}_i \rangle} + \sum_j e^{\langle \mathbf{z}_j^-, \mathbf{z}_i \rangle}}. \tag{6}$$

Denoting $s_i^+ = e^{\langle \mathbf{z}_i^{h,+}, \mathbf{z}_i \rangle}$ and $s_i^- = \sum_j e^{\langle \mathbf{z}_j^-, \mathbf{z}_i \rangle}$, Eq. (6) can be written more concisely as

$$\mathcal{L}_c = -\log \frac{s_i^+}{s_i^+ + s_i^-} = \log(1 + \frac{s_i^-}{s_i^+}). \tag{7}$$

We then quantify the screened proportion as $\epsilon \in [0, 1)$ for negative samples, and note that

$$\epsilon = 1 - \lambda_{\mathcal{Q}}.$$

By removing a given proportion of negative samples, it is equivalent to reduce s_i^- to $\tilde{s}_i^-$ by a suitable value of ϵ such that $\tilde{s}_i^- = (1-\epsilon)s_i^-$. Hence the perturbed loss function $\tilde{\mathcal{L}}_c$ becomes

$$\tilde{\mathcal{L}}_c(\epsilon | r_i) = \log\left(1 + (1-\epsilon) r_i\right), \tag{8}$$

where $r_i = \frac{s_i^-}{s_i^+}$. The perturbed loss is caused by ϵ and $\tilde{\mathcal{L}}_c(0|r_i)$ recovers the original loss in Eq. (7). Therefore the sensitivity of the function in Eq. (8) at $(\epsilon = 0)$ determines the change to the loss by introducing screening. The first order Taylor expansion shows that:

$$\tilde{\mathcal{L}}_c(\epsilon | r_i) = \tilde{\mathcal{L}}_c(0 | r_i) + \frac{\partial \tilde{\mathcal{L}}_c}{\partial \epsilon}|_{\epsilon=0}[r_i] \cdot \epsilon + O(|\epsilon|^2),$$

where $O(|\epsilon|^2)$ is the negligible higher order term when ϵ is approximate zero. Note that $\tilde{\mathcal{L}}_c(0|r_i) = \mathcal{L}_c$, *i.e.* the original loss. Plugging in the partial derivatives evaluated at $\epsilon = 0$ with r_i $(\frac{\partial \tilde{\mathcal{L}}_c}{\partial \epsilon}|_{\epsilon=0}[r_i])$, *i.e.*

$$\frac{-r_i}{r_i + 1},$$

we obtain

$$\tilde{\mathcal{L}}_c(\epsilon | r_i) \approx \mathcal{L}_c - \frac{r_i \epsilon}{r_i + 1}. \tag{9}$$

Remark 1. *The perturbation (or the difference in loss aroused by screening) is approximately* $\frac{-r_i \epsilon}{r_i + 1}$*, which is an apparent reduction to the original loss* $\mathcal{L}_c$ *as all variables in Eq. (9) are positive.*

Furthermore, it is worth noting that normalized similarities are between $[-1, 1]$*, that is,* $\langle \mathbf{z}_i^{h,+}, \mathbf{z}_i \rangle \to 1$*, and* $\langle \mathbf{z}_j^-, \mathbf{z}_i \rangle \to -1$ *at the convergence of the optimization, and hence*

$$r_i \to e^{-2} |\mathcal{Q}| > \frac{|\mathcal{Q}|}{9},$$

where $|\mathcal{Q}|$ *is the size of the negative queue or number of negative samples. In many contrast methods (He et al., 2020; Zhu et al., 2021; Chen et al., 2021),* Q *consists of thousands of negatives, which leads to* $r_i \gg 1$*.*

At last, combining $\frac{\partial \tilde{\mathcal{L}}_c}{\partial \epsilon}|_{\epsilon=0}[r_i]$ *with the value of* r_i*, we obtain*

$$\frac{\partial \tilde{\mathcal{L}}_c}{\partial \epsilon}|_{\epsilon=0}[r_i] \approx -1,$$

and the perturbation is approximately $-\epsilon$ *at convergence.*

Remark 2. *The perturbation indicates that that if we screen out a small proportion of negative samples, say* $1 - \lambda_{\mathcal{Q}}$ *(or* ϵ*), the function loss is reduced by approximately that much. In other words, the sample screening connects to the loss reduction directly. Although we discussed only ideal situation where the contrast reaches maximum, similar result exists in expectation sense as well because a large value of* $|\mathcal{Q}|$ *outweighs less contrast in negative and positive similarities.*

Notably, the above perturbation analysis is performed at 0 requiring ϵ to be small or even close to zero (say $\epsilon \in [0.01, 0.1]$), and hence satisfies this condition.The loss function change caused by screening will eventually transfer to gradients to the model parameters. Our results indicates the scaling factor in front of the final gradients. Nonetheless, when r_i is too large, it saturates the loss function to the "plateau" stage where gradients are small and hence the aforementioned analysis results hold.

3.5 Overall identification

With the matching and contrastive loss from the Backbone and sMoCo modules, we propose the following *joint* loss for the overall identification:

$$\mathcal{L}_{Identification} = \mathcal{L}_{Matching} + \lambda_{sMoCo}\mathcal{L}_{sMoCo}, \tag{10}$$

where λ_{sMoCo} is a penalty term[3].

4 Experiment

4.1 Setup

The WebQuestionsSP datasets is employed (Yih et al., 2016) with a total of 4737 questions, that are answerable through the Freebase KB. This entire KB consists of 601,145 distinct entities, 568 different relations, 1,261,849 unique triples. Followed by the work from (Xiong et al., 2019; Saxena et al., 2020), the low-resource KB settings have been constructed by down-sampling a percentage of facts in the background KB (we randomly retain a triple with probability of 0.1, 0.3, and 0.5). Accordingly, the resultant datasets are referred as KB0.1, KB0.3, KB0.5 and KBFull (original), respectively, and Table 2 shows the statistics of those four datasets.

Table 2: Summary of four adopted datasets, where **#e**, **#r** and **#triples** is the averaged number of entities, relations, and triples per question, respectively.

Dataset	#e	#r	#triples
KB0.1	152.5	51.3	184.8
KB0.3	182.3	54.8	567.1
KB0.5	183.5	56.1	837.3
KBFull	191.2	56.7	1484.2

To make a fair comparison, the hyperparameter setting of the backbone module is adopted explicitly from (Xiong et al., 2019), such as implementing the 300-d GloVe embeddings for question entities, maximal number of neighboring entity as 50, maximal question length as 10. The matching loss has been implemented using binary cross-entropy loss with 0.1 smoothing factor. In addition, the mini-batch size is 16, the Adam optimizer with a learning rate setting of 0.001, and the number of training epoch is set as 100. For the implemented knowledge extension module, factual descriptions about entity and relation are available publicly[4]. Meanwhile, we generate three additional QA pairs for one single QA input. For the sMoCo, the momentum rate is 0.99, $\tau = 0.07$, $\lambda_{sMoCo} = 0.2$, $\lambda_Q = 0.95$, $\lambda_U = 0.4$, and the negative queue capacity is set as 10000. The proposed model is trained on a machine with four Tesla V100 GPUs. The Hits@1 score is used to measure the performance.

4.2 Main Results

We compare the proposed with different methods, including the baseline model (*i.e.* KDReader (Xiong et al., 2019)) and state-of-the-arts (*i.e.* PullNet (Sun et al., 2019), 2HR-DR (Han et al., 2020), EmbedKGQA (Saxena et al., 2020), and RecHyperNet (Yadati et al., 2021)). The comparison results over 10 trails are shown in Table 3.

Table 3: Results in Hits@1 obtained by sMoCo and existing methods re-implemented for four test sets. The number within the bracket indicates the original result reported by the paper.

Algorithm	**KB0.1**	**KB0.3**	**KB0.5**	**KBFull**
KDReader	33.5(33.6)	42.6(42.6)	52.8(52.7)	67.4(67.2)
PullNet	33.7	42.8	52.1(51.9)	68.0(68.1)
2HR-DR	33.5	42.5	52.0(52.2)	66.9(67.0)
EmbedKGQA	34.3	41.5	53.2(53.2)	67.0(66.6)
RecHyperNet	34.5	43.1	53.6(53.7)	68.4(68.4)
sMoCo	36.1	44.2	54.1	69.2

sMoCo shows superior performance compared to the state-of-the-arts via achieving a considerable margin. For instance, competing with the strongest baseline RecHyperNet, the proposed method outperforms by 2.55%, 0.93%, 1.17% with respect to KB0.3 KB0.5 and KBFull. It is also worth noting that sMoCo obtains the highest performance boost with KB0.1 (7.76% and 4.63% compared to the baseline and RecHyperNet), which demonstrates its strong capability of handling the extreme low-resource KB.

In addition, to further evaluate the improvement from sMoCo, we also compare ours with cutting-edge contrastive learning techniques, including SimCLR (Chen et al., 2020a), MoCoV1 (He et al., 2020), MocoFT (Zhu et al., 2021), MoCoV3 (Chen et al., 2021), and SimSiam (Chen and He, 2021). Again, the backbone module from KDReader is

---

[3] There are another two training strategies, including *pre-train* and *alternate*. The former is to update the model first using $\mathcal{L}_{sMoCo}$ before fine-tuning with $\mathcal{L}_{Matching}$, while the latter is to train the model with $\mathcal{L}_{Matching}$ for $(N_t - 1)$ iterations and switch to $\mathcal{L}_{sMoCo}$ once, for every N_t iterations. We leave these as the future work.

[4] Description about entities and relations can be found https://developers.google.com/freebase and https://freepal.appspot.com/, respectively

implemented for all contrastive methods for a fair comparison. In addition, hyperparameters for employed contrastive methods are set to similar as sMoCo: the momentum rate is 0.99, $\tau = 0.07$, $|\mathcal{Q}|$ = 10000, while the prediction head is implemented as a 2-layer MLP with a 512-hidden dimension.

Table 4: Average Hits@1 results (10 trials) obtained by sMoCo and other contrastive learning methods.

Algorithm	**KB0.1**	**KB0.3**	**KB0.5**	**KBFull**
SimCLR	34.5	42.9	52.9	67.3
MoCoV1	34.5	43.2	52.8	67.8
MocoFT	35.4	43.6	53.3	67.9
MoCoV3	35.0	43.4	53.3	68.1
SimSiam	34.5	43.2	52.9	67.5
sMoCo	36.1	44.2	54.1	69.2

Table 4 clearly demonstrates the superiority of applying contrastive based methods, as averaged results (over 10 trials) show all methods achieve better performance compared to the baseline model (*i.e.*, KDReader). In particular, contrastive methods perform specifically well with low-resource KBQA, as they lead to from 2.98% to 7.76% averaged improvement for KB0.1 (higher than other three cases). This result indicates the advantage of using contrastive learning for extremely low-resource KBQA tasks. Additionally, the proposed sMoCo outperforms existing methods, by achieving a notable accuracy (50.9 for overall averaged Hits@1) compared to that of SimCLR(49.4), MoCoV1(49.6), MocoFT(50.1), MoCoV3(50.0), and SimSiam(49.5), respectively.

4.3 Ablation study

Experiments are conducted to validate contributions from proposed modules, mainly the knowledge extension (KE) and sMoCo module. To highlight the low-resource nature of KG, we are particularly interested in the performance on datasets of KB0.1 and KB0.3. Again, all the results are reported as an averaged Hits@1 over 10 trials.

On knowledge extension module. To begin with, we consider the impact from the proposed knowledge extension (or data argumentation) by treating additional QA pairs as training samples, while no contrastive learning (sMoCo) is applied.

Results in terms of different numbers of additional pairs ($|Q|_a$) are then summarized in Table 5. Compared to the baseline (KDReader), the advantage of KE is observed from the performance improvement. With $|Q|_a = 3$, for instance, the model produces 38.4 for Hits@1 on average. Not surprisingly, the model performance is enhanced by the proposed KE (via providing additional training samples). In the following, we fix $|Q|_a = 3$ for KE and analyze the contrastive module.

Table 5: Performance against different numbers ($|Q|_a$) of additional QA pairs (without sMoCo).

$\|Q\|_a$	**KB0.1**	**KB0.3**
baseline	33.5	42.6
1	33.9	42.9
3	33.7	43.1

Notably, compared to traditional method (such as MoCoV1), sMoCo is different from three aspects: 1) adopting hard positive and 2) negative samples for estimating the contrastive loss, and 3) queue updating with hard positives (anchors). We accordingly perform ablation study on individual aspect to manifest their efficacy and the results are summarized in Table 6. In particular, for comparison purposes we take "KE" and "MoCoV1" to represent the result from the knowledge extension module and normal contrastive learning, as the baseline; "+hard positive" differs from MoCoV1 by using one hard positive; "+hard negative" considers a subset of hard negatives while maintaining a 95% of total sum, in addition to "+hard positive"; "+queue updating" further applies the proposed combination strategy to update negatives iteratively.

Table 6: Ablation study on hard positive, hard negative, and queue updating from the proposed sMoCo.

Model Variants	**KB0.1**	**KB0.3**
KE	33.7	43.1
MoCoV1	34.5	43.2
+hard positive	34.8(↑ 0.3)	43.4(↑ 0.2)
+hard negative	35.7(↑ 0.9)	43.8(↑ 0.4)
+queue updating	36.1(↑ 0.4)	44.2(↑ 0.4)

Results from Table 6 show contributions from individual aspect to the final performance, which evidently states their effectiveness. At first, not surprisingly, all four contrastive variants improve the overall performance compared to KE, which again demonstrate the superiority of forming discriminate features to separate positives and negatives. Additionally, we observe the step of "+hard negative" brings the biggest performance boost, followed by

"+queue updating". The result highlights the significance of maintaining and utilizing hard negatives for contrastive learning, instead of employing a large negative queue as existing methods.

On hard positives. We then consider the individual impact from hard positives by fixing the rest setting of sMoCo, such as screening hard negatives ($\lambda_Q = 0.95$) and updating $\mathcal{Q}$ with $\lambda_U = 0.4$. Precisely, four utilization, including "1-pos" (employing only one positive like MoCoV1/2), "3-pos" (with three positives), "1-easy" (picking up the most similar/easy positive like SimCLR), and "1-hard" (the proposed), are considered, while their comparison is illustrated in Fig. 4.

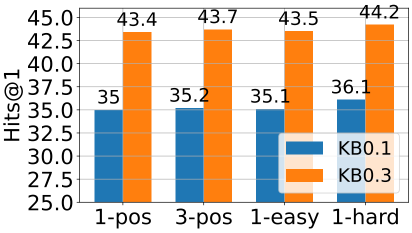


Figure 4: Comparison among four different ways of utilizing positives in sMoCo.

Notably, applying more positives (*i.e.*, "3-pos") performs competitively than cases with only one positive (either "1-pos" or "1-easy"). One reason could be the variety of positives helps in avoiding the model collapsing (that is, positives becomes very similar to anchors). Additionally, focusing on the hardest one achieves the best result, as shown in "1-hard", as it forces the model to pay attention to the positive far away from the anchor.

On hard negatives. Next we fix to use "1-hard" and evaluate the impact from negatives (by testing different λ_Q, in line with the analysis presented in Section 3.4). Note that with a large λ_Q, more negatives are included in the loss calculation. In particular, with $\lambda_Q = 100\%$, sMoCo applies all negatives (same as MoCoV1/2/FT).

Table 7: Performance comparison in terms of hard negatives as a function of λ_Q.

λ_Q	100%	99%	97%	95%	90%
KB0.1	34.5	34.7	35.2	36.1	35.5
KB0.3	43.5	43.6	43.6	44.2	43.8

Table 7 shows the improvement by utilizing hard negatives, from which the model with the full queue ($\lambda_Q = 100\%$) achieves the worst result. Additionally, the best performance is observed with $\lambda_Q = 95\%$, approximately 2000 negatives. This findings clearly suggest that it is unnecessary to have a large number of negatives for a performance gain, not to mention its computational cost with a huge queue.

On updating negatives. At last, by fixing "1-hard" and $\lambda_Q = 95\%$, we investigate the impact of updating negatives via changing λ_U. As discussed before, will a small λ_U (=0), sMoCo adopts positives directly to replace previous negatives like MoCoV1/2; on the other hand, sMoCo behaves similar to SimCLR or MoCoV3 if $\lambda_U = 1$.

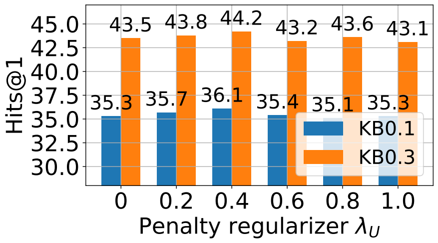

Figure 5: Model accuracy obtained from sMoCo as a function of λ_U via updating $\mathcal{Q}$.

Fig. 5 shows the model accuracy based on different settings of λ_U. Results indicate that the proposed combination of positives and anchors (with $\lambda_U = 0.4$) could bring in the performance boost (than that of $\lambda_U = 0$ or 1). Note that for KBQA, there exists QA pairs requiring same entities and relations. Using previous positives or anchors to replace previous negatives could mislead the model to separate them into different feature spaces. By contrast, the proposed updating maintains a good balance of forming hard but informative negatives.

5 Conclusion

We present a novel KBQA model that particularly tackles the low-resource (incompleteness) nature of the context knowledge bases (KBs). The proposed model is characterized by a knowledge extension and a sMoCo module, that is motivated by the learn-by-analogy capability of human readers. Precisely, the former extends existing knowledge via producing additional question-answer pairs, which are further utilized by the sMoCo module. The latter appropriately learns informative representations that grouping hard positives and pushing away hard negatives. Empirically, in comparison to existing approaches, the proposed algorithm produces the state-of-the-art performance on the WebQuestionsSP benchmark, in particular with the extreme incomplete KBs. In future work, we will extend the proposed idea to explore more contrastive behavior of utilizing hard positives and negatives. More importantly, sMoCo is agnostic to the downstream tasks, *i.e.*, we could incorporate it into other applications.

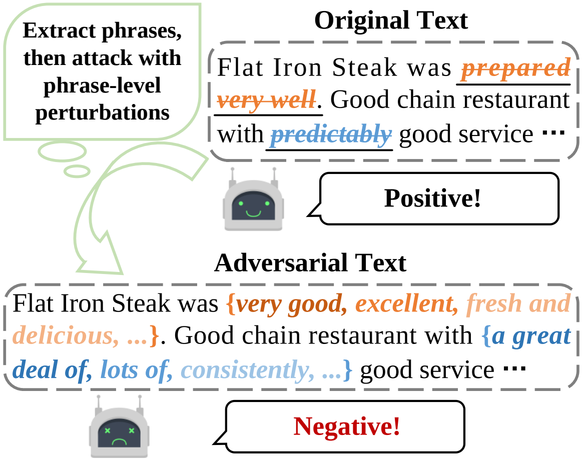
Abstract

Generating high-quality textual adversarial examples is critical for investigating the pitfalls of natural language processing (NLP) models and further promoting their robustness. Existing attacks are usually realized through word-level or sentence-level perturbations, which either limit the perturbation space or sacrifice fluency and textual quality, both affecting the attack effectiveness. In this paper, we propose **P**hrase-**L**evel Textual **A**dversarial A**T**tack (PLAT) that generates adversarial samples through phrase-level perturbations. PLAT first extracts the vulnerable phrases as attack targets by a syntactic parser, and then perturbs them by a pre-trained blank-infilling model. Such flexible perturbation design substantially expands the search space for more effective attacks without introducing too many modifications, and meanwhile maintaining the textual fluency and grammaticality via contextualized generation using surrounding texts. Moreover, we develop a label-preservation filter leveraging the likelihoods of language models fine-tuned on each class, rather than textual similarity, to rule out those perturbations that potentially alter the original class label for humans. Extensive experiments and human evaluation demonstrate that PLAT has a superior attack effectiveness as well as a better label consistency than strong baselines.[1]

1 Introduction

Despite the widespread success of deep learning in natural language processing (NLP) applications, a variety of works (Wallace et al., 2019; Jia et al., 2019; Cheng et al., 2019) discovered that neural networks can be easily fooled to produce incorrect predictions, when their input text is modified by adversarial attacks that do not necessarily alter human predictions and the true meaning of the original text. Through the lens of adversarial attacks, we can allocate the weakness of models and in turn improve their reliability and robustness (Jia and Liang, 2017; Belinkov and Bisk, 2018).



Flat Iron Steak was ~~prepared~~ ~~very well~~. Good chain restaurant with ~~predictably~~ good service ···

Flat Iron Steak was {very good, excellent, fresh and delicious, ...}. Good chain restaurant with {a great deal of, lots of, consistently, ...} good service ···

Figure 1: In PLAT, we extract phrases from the original text as attack targets, then use a blank-infilling model to obtain perturbation candidates and generate effective adversarial texts. Note that both target phrases and perturbations may contain one or multiple tokens.

However, generating high-quality adversarial texts is nontrivial due to the discrete nature of human language and its rigorous linguistic structures. While many efforts of previous works have been taken to generate word-level perturbations (Ren et al., 2019; Alzantot et al., 2018; Jin et al., 2020; Li et al., 2020; Garg and Ramakrishnan, 2020; Li et al., 2021) for the sake of simplicity, their attacks are restricted to independent perturbations on single words and thus cannot produce richer and more diverse forms of adversarial examples. To expand the search space for attacks, sentence-level attacks have been explored (Iyyer et al., 2018; Wang et al., 2020b,a; Qi et al., 2021) such as using paraphrasing, but their textual quality is usually poor due to insufficient constraints or controls on the structure and meanings of the generated texts.

To generate controllable high-quality textual adversarial examples, we propose a new phrase-level attack, PLAT, which can explore more diverse and flexible forms of perturbations than single word

July 10-15, 2022 ©2022 Association for Computational Linguistics

perturbations. Our model is able to produce phrase-level perturbations with a high success rate and preserve the textual similarity in a more controllable manner. As illustrated in Figure 1, with the help of constituency parsing, PLAT first detects and extracts the most vulnerable phrases from the text to the victim model as the attack targets. To maintain textual fluency and grammaticality, PLAT perturbs these phrases through a contextualized blank-infilling procedure by a pre-trained language model. Compared to existing textual adversarial attacks, PLAT can produce more effective attacks by searching in a larger space of phrase-level perturbation. Meanwhile, PLAT delicately controls the range and amount of modifications so the textual meaning of the original texts will not be altered significantly after attacks.

Moreover, the success of attacks can be trivial if allowed to arbitrarily distort the ground-truth label or key contents. Hence, a valid attack is required to not change the ground-truth label predicted by humans. However, the semantic similarity filters widely used in existing works to guarantee the validity of adversarial samples (Jin et al., 2020; Li et al., 2020) perform unsatisfactorily, especially in preserving the textual meaning and even flip the gold labels according to a recent study (Morris et al., 2020). To this end, we develop a label-preservation filter to maintain class-dependent properties such as sentiments. It is built upon the comparison of likelihoods of language models fine-tuned on different classes' data. Thereby, it selects the attacks that can easily fool the victim model but possibly hardly alter the original labels.

Our contributions in this paper are three-fold:

- We propose a phrase-level textual adversarial attack that employs contextualized blank-infilling to generate high-quality phrase perturbations. It expands the perturbation space of word-level attacks and thus can produce more effective attacks without notably hurting the fluency and grammaticality.

- We introduce a novel label-preservation filter, which utilizes the likelihood of class-specific language model to generate more reliable adversarial examples.

- Extensive experiments demonstrate the effectiveness of PLAT on multiple text classification and natural language inference tasks, hence presenting a new robustness challenge to existing NLP models.

2 Methodology

In this section, we first formulate the problem of phrase-level textual adversarial attack. Then we elaborate on how PLAT chooses phrase candidates to attack and how to adversarially perturb them. Finally, we discuss strategies to select the most effective perturbations with label preservation.

2.1 Problem Definition

We focus on generating textual adversarial examples for classification tasks. Given a textual sequence $\mathbf{x} = x_1 x_2 \dots x_n$ with a specific attribute label y and a victim model F (assume $F(\mathbf{x}) = y$) to attack, our goal is to generate an adversarial sample $\mathbf{x}'$ by perturbing $\mathbf{x}$. A valid adversarial example $\mathbf{x}'$ can successfully trigger a wrong prediction of the victim model, i.e. $F(\mathbf{x}') \neq y$, while the human judgement on $\mathbf{x}'$ should stay unaltered as y. To achieve this goal, $\mathbf{x}'$ needs to be sufficiently similar to $\mathbf{x}$ with reasonable fluency and correct grammaticality.

2.2 Phrase-level Attack

Phrase candidates. Given a sequence $\mathbf{x}$, PLAT allocates candidates of phrases to attack from the syntactic tree extracted by a language parser (e.g., Stanford Parser (Manning et al., 2014), etc.). The model first traverses all constituents (nodes) in the syntactic tree in a top-down manner. If a node is identified as a phrase, i.e. tagged as *NP*, *VP*, etc., the text piece in $\mathbf{x}$ associated with all nodes in the subtree that is rooted at the current node, will be regarded as an attacking candidate. For more controllable attacks, we set a maximum depth of syntactic subtree d to restrict the length of candidate phrases so the modification to $\mathbf{x}$ is limited, hence resulting in more possibly valid adversarial samples. Thereby, we obtain a set of multiple candidate phrases in the form of $\mathcal{A} = \{(\mathbf{a}, i, j)\}$, where i and j are the indices of the leftest and rightest token of a phrase $\mathbf{a}$ from $\mathbf{x}$.

Phrase importance. To produce attacks more effectively against the victim model F (e.g., fine-tuned BERT (Devlin et al., 2019)), PLAT only perturbs the phrase candidates important to the prediction as former works (Jin et al., 2020; Ren et al., 2019). Specifically, we consider to replace a phrase $\{(\mathbf{a}, i, j)\}$ in $\mathbf{x}$ with a series of special symbol [MASK][2] with

---

[2] We empirically found this is better than single-mask replacement.

the same length as $\mathbf{a}$, which results in $\tilde{\mathbf{x}} = x_1 \ldots x_{i-1}, \text{[MASK]} \ldots \text{[MASK]}, x_{j+1} \ldots x_n$. The importance for phrase $\mathbf{a}$ is measured by

$$I(\mathbf{a}) = P_F(y \mid \mathbf{x}) - P_F(y \mid \tilde{\mathbf{x}}),$$

where $P_F(y|\cdot)$ is the probability of the ground truth label y predicted by F given the input textual sequence. Larger $I(\mathbf{a})$ indicates that the phrase $\mathbf{a}$ has more significant contribution to the prediction of y. PLAT manipulates each *target phrase* in candidate sets $\mathcal{A}$ by following a descending order of their importance scores. So more effective phrase-level perturbations are applied earlier for achieving minimum modifications to $\mathbf{x}$.

Phrase perturbations. To generate phrase-level adversarial perturbations, PLAT performs a blank-infilling procedure on each target phrase. Specifically, PLAT first replaces a target phrase $\mathbf{a} \in \mathcal{A}$ with a blank (a single special [MASK] token in our implementation) from index i to j, i.e.,

$$\tilde{\mathbf{x}}_{\backslash \mathbf{a}} = x_1, \ldots, x_{i-1}, \underline{\qquad\quad}, x_{j+1}, \ldots, x_n.$$

Then a pre-trained blank-infilling language model, e.g., BART (Lewis et al., 2020) or T5 (Raffel et al., 2020), takes $\tilde{\mathbf{x}}_{\backslash \mathbf{a}}$ as the input and fills a phrase $\mathbf{b} = z_1 \ldots z_m$ having m tokens into the blank conditioned on surrounding context, i.e.,

$$\tilde{\mathbf{x}}_{\mathbf{b}} = x_1 \ldots x_{i-1}, z_1 \ldots z_m, x_{j+1} \ldots x_n.$$

In contrast to paraphrasing each phrase independently, such contextualized infilling procedure can produce more fluent and grammatically correct perturbations fitting into the rest context.

For attacking each target phrase, PLAT samples N candidates of perturbed phrases $\mathcal{B} = \{\mathbf{b}\}$ with varying lengths. During the generation, PLAT tends to sample tokens of higher probability at every step so that the outputs are more appropriate with the surrounding context. In addition, we keep the maximum length of perturbations not greater than the length of original phrases plus a threshold l (e.g., $|\mathbf{b}| \leq |\mathbf{a}| + l$). The most effective perturbation in $\mathcal{B}$ is then selected to replace the target phrase $\mathbf{a}$, resulting in a perturbed text $\tilde{\mathbf{x}}_{\mathbf{b}}$ (The details of selection will be discussed in §2.3).

We apply the above phrase perturbation sequentially to all target phrases from $\mathcal{A}$[3] until (1) a valid adversarial sample $\mathbf{x}^{(t)}$ is found when perturbing the t^{th} target phrase, i.e., $F(\mathbf{x}^{(t)}) \neq y$; or (2) the maximum number of perturbations T is reached. We summarize the above procedure in Algorithm 1.

Algorithm 1 Adversarial Attack by PLAT

```
Input: Original text $\mathbf{x}$, the gold label $y$, victim model $F$, maximum number of perturbation $T$, importance score $I$, likelihood ratio threshold $\delta$. Two filter functions: class-conditioned likelihood function $R(\cdot)$, effectiveness score function $S(\cdot)$
Output: An adversarial example $\mathbf{x}'$
Extract phrase candidates from $\mathbf{x}$ to form the set $\mathcal{A}$
$\mathbf{x}^{(0)} \leftarrow \mathbf{x}$
for $1 \leq t \leq T$ do
    $\mathbf{a} \leftarrow$ target phrase with highest $I$ in $\mathcal{A}$
    $\mathcal{B} \leftarrow$ a set of phrases perturbations generated by blank-infilling $\tilde{\mathbf{x}}_{\backslash \mathbf{a}}^{(t-1)}$
    $\mathcal{B} \leftarrow$ filtering $\mathcal{B}$ by $R(\mathbf{x}^{(t-1)}, \mathbf{b}', y) < \delta$
    if $\mathcal{B} = \varnothing$ then $\mathbf{x}^{(t)} = \mathbf{x}^{(t-1)}$, continue
    end if
    $\mathbf{b} \leftarrow \operatorname{argmax}_{\mathbf{b}' \in \mathcal{B}} S(\mathbf{x}^{(t-1)}, \mathbf{b}')$
    $\mathbf{x}^{(t)} \leftarrow \tilde{\mathbf{x}}_{\mathbf{b}}^{(t-1)}$(replace $\mathbf{a}$ with $\mathbf{b}$ in $\mathbf{x}^{(t-1)}$)
    if $F(\mathbf{x}^{(t)}) \neq y$ then return $\mathbf{x}^{(t)}$
    end if
end for
return NONE
```

2.3 Label Preservation and Effective Perturbation.

Label preservation filter. Although existing works (Jin et al., 2020; Chen et al., 2021) usually employ a semantic similarity constraint (e.g., USE (Cer et al., 2018)) to encourage the validity of adversarial samples, it has been observed that such constraint is unreliable to preserve the textual meaning (Morris et al., 2020). Moreover, existing approaches rarely preserve class-dependent contents, e.g., sentiments, and might produce invalid adversarial examples with human-annotated labels flipped. Such a drawback is commonly observed in our human evaluation in §3.3.

In order to retain the class-related characteristics most critical to classification tasks, inspired by Malmi et al., 2020, PLAT directly filters phrase perturbations using likelihoods provided by class-conditioned masked language models (CMLMs). Specifically, given a sequence $\tilde{\mathbf{x}}_{\mathbf{b}} =$

---

[3] If a phrase $\mathbf{b}$ is perturbed, phrases that overlap $\mathbf{b}$ in the remaining phrases of $\mathcal{A}$ will be ignored.

$x_1, \ldots, x_{i-1}, z_1, \ldots, z_m, x_{j+1}, \ldots, x_n$, the class-conditioned likelihood of the adversarially perturbed phrase $\mathbf{b} = z_1, \ldots, z_m$ for phrase $(\mathbf{a}, i, j)$ in $\mathbf{x}$ can be calculated as

$$L(\mathbf{x}, \mathbf{b}, y) = \prod_{k=1}^{m} P_{\text{CMLM}}\left(z_k \mid \tilde{\mathbf{x}}_{\mathbf{b}\setminus z_k}; \Theta_y\right).$$

Here, m is the length of $\mathbf{b}$, $\tilde{\mathbf{x}}_{\mathbf{b}\setminus z_k}$ is the perturbed sequence $\tilde{\mathbf{x}}_{\mathbf{b}}$ with token z_k masked, P_{CMLM} is the likelihood of z_k given $\tilde{\mathbf{x}}_{\mathbf{b}\setminus z_k}$, which is produced by a class-conditioned masked language model Θ_y conditioned on class y. The conditional language model is first initialized as a pre-trained model and then fine-tuned with the pre-training objective on the data from the dataset that belonging to the class y. Therefore, a larger likelihood indicates that $\mathbf{b}$ is more likely to match the corresponding class distribution given the surrounding context.[4]

To avoid label flipping of human prediction, the phrase perturbations should enjoy a higher likelihood on the original class's distribution but a lower likelihood on other classes. This property can be measured by the following likelihood ratio:

$$R(\mathbf{x}, \mathbf{b}, y) = L(\mathbf{x}, \mathbf{b}, y) / \max_{\tilde{y} \in \mathcal{Y}, \tilde{y} \neq y} L(\mathbf{x}, \mathbf{b}, \tilde{y}),$$

where $\mathcal{Y}$ denotes the set of all classes in the task. A higher likelihood ratio suggests the perturbation is more correlated to the original label in contrast to other labels. For better label preservation, the committed phrase perturbations are required to have a likelihood ratio larger than certain threshold δ, i.e. $R(\mathbf{x}, \mathbf{b}, y) \geq \delta$ for $\mathbf{b} \in \mathcal{B}$. As shown in §3.3, our method outperforms other baselines on label-preservation according to human evaluation.

Selection of the most effective perturbation. To generate $\mathbf{x}'$ with sufficient global textual-similarity to $\mathbf{x}$, PLAT selects target phrases with syntactic tree depth no deeper than d and restricts their perturbations' lengths to be no larger than their length by l . Moreover, PLAT aims at utilizing minimum perturbations to perform effective adversarial attacks, so the textual similarity can be preserved. Minimum perturbations can in return help maintain reasonable fluency and grammaticality of the generated texts.

To achieve the above goals, PLAT selects the most effective phrase perturbation at each step as the one that minimizes the probability of the gold label y predicted by F. We use a score to measure each phrase $\mathbf{b}$ in terms of how likely it can successfully fool the model, i.e. the negative probability of the gold label y for the original $\mathbf{x}$ associated with the perturbation $\mathbf{b}$, i.e.,

$$S(\mathbf{x}, \mathbf{b}) = -P_F(y \mid \tilde{\mathbf{x}}_{\mathbf{b}}).$$

When attacking a target phrase, PLAT only chooses one phrase perturbation $\mathbf{b} \in \mathcal{B}$ with the highest score. The resulted perturbed-sequence is retained and then used as the initial sequence for the next time of perturbation.

2.4 Discussion

A primary novelty of PLAT is the phrase-level perturbation. Compared to the widely studied word-level perturbations (Ren et al., 2019; Jin et al., 2020; Li et al., 2021) that can only independently perturb a single word every time, PLAT can perturb a text span of varying lengths by replacing it with phrases of possibly unequal lengths. Hence, it produces a more flexible attack by searching it in a larger perturbation space. Although the textual phrase-level attack has been studied by a concurrent work MAYA (Chen et al., 2021), there are several critical differences of PLAT, i.e.,

(1) The phrase-level attack by PLAT is a more general attack model that covers both word-level and phrase-level perturbations in one framework, while MAYA builds separate sub-modules for different levels of perturbations.

(2) PLAT adopts a blank-infilling strategy and leverages language models to generate phrase perturbations in a context-aware manner, leading to more fluent and grammatical adversarial examples. On the contrary, MAYA applies paraphrasing to each constituent target separately without taking its surrounding context information into account.

(3) PLAT applies several constraints and filters to the phrase perturbations for more controllable attacks and better preservation of the original textual and label information, while MAYA has no such restrictions and its generated perturbations can introduce arbitrary distortions to the original text.

3 Experiments

In this section, we first elaborate on the experimental settings and implementation details of PLAT as well as the comparisons to several baselines in §3.1.

---

[4] In practice, we partition the whole text into multiple sentences and the likelihood P_{CMLM} for a phrase $\mathbf{b}$ is calculated locally using its corresponding sentence.

We then introduce the datasets and evaluation designs in §3.2. At the end, we summarize the main results in §3.3.

3.1 Setup

The implementation details are given as follows:

- We use pre-trained BART$_{\text{base}}$ (Lewis et al., 2020) as the language model for blank-infilling to generate phrase perturbations. We sample $N = 5000$ candidates as the phrase set $\mathcal{B}$ via Top-K sampling (Fan et al., 2018), while set restriction $d = 4$, $l = 3$ for each target phrase. In sections §4.1, we also report the performance comparison when using different language models.
- We use a RoBERTa$_{\text{base}}$ (Liu et al., 2019) to calculate the class-conditioned likelihood for label-preserving filters. On each dataset, the model is further fine-tuned to optimize the masked language modeling pre-training objective on each sequence with a prepending special label token indicating the current class. We set threshold $\delta = 1$ for the filtering.
- The victim model F is an MLP classifier based on a BERT$_{\text{base}}$ model (Devlin et al., 2019). It takes the representation of [CLS] token for prediction and is fine-tuned on the target datasets in advance.

Baselines. We compare PLAT with four state-of-the-art textual adversarial attack models:[5]

- **Textfooler** (Jin et al., 2020): a word-level attack model, which replaces tokens with their synonyms via counter-fitting word embeddings (Mrkšić et al., 2016). USE (Cer et al., 2018) distance is used to select adversarial texts that can mostly preserve the semantic similarity.
- **CLARE** (Li et al., 2021): instead of token replacement only, **CLARE** considers three word-level perturbations: replacement, insertion, and merging. Pre-trained masked language models are used to generate perturbations and a USE semantic similarity filter is applied.
- **MAYA** (Chen et al., 2021): a multi-granularity model that attacks the input using two separate modules for word replacement and constituent paraphrasing. It employs the embedding of Sentence-BERT (Reimers and Gurevych, 2019) for semantic similarity preservation.
- **StyleAdv** (Qi et al., 2021): a sentence-level model based on text style transfer. To launch an attack, it paraphrases the whole examples with five different text styles: tweets, bible, poetry, shaekspeare and lyrics.

Dataset	Avg. Len	#Classes	Train	Test	Acc
Yelp	130	2	560k	38k	91.8%
AG News	46	4	120k	7.6k	94.6%

QNLI	11/31	2	105k	5.4k	91.4%

Table 1: Statistics of datasets and the performance of victim models on each dataset.

3.2 Datasets and Evaluation

Datasets. We investigate the following datasets for text classification and natural language inference tasks in our experiments. The statistics and performance of the victim models evaluated on each dataset are reported in Table 1.

- **Yelp Reviews** (Zhang et al., 2015): a binary sentiment classification dataset containing restaurant reviews as samples.
- **AG News** (Zhang et al., 2015): a news articles classification dataset covering four classes: *World*, *Sport*, *Business*, and *Science and Technology*.
- **MNLI** (Williams et al., 2018): a natural language inference dataset, where each sample contains a pair of sentences whose relationship is labeled as *entailment*, *neutral*, or *contradiction*. We use the *matched* test set here.
- **QNLI** (Wang et al., 2018): a natural language inference dataset based on the question answering corpus SQuAD (Rajpurkar et al., 2016). Each sample contains a context and a question labeled as *entailed* or *not entailed*.

All attacks will be conducted on 1000 instances randomly drawn from test sets. For tasks on a pair of sentences, we attack the longer sentence.

Evaluation metrics. We evaluate models using the following automatic metrics:

- **Attack success rate (ASR)**: the percentage of successful adversarial attacks that trigger wrong predictions of the victim model.
- **Edit Distance (DIS)** (Navarro, 2001): the normalized Levenshtein distance that measures the minimum amount of word edits required to transform the original text to the adversarial one. It measures the modification rate of an adversarial sample.
- **BLEU** (Papineni et al., 2002): the BLEU score between an adversarial sample and its corresponding original sample is used to measure their n-gram overlap (textual similarity). We do not report the

Table 2: Adversarial attack performance of PLAT and baselines on four datasets, in terms of attack success rate (ASR), edit distance (DIS), BLEU, perplexity (PPL), and increased grammar errors (GER). **Bold values** indicate the best performance for each metric. ↓(↑) indicates the higher (lower) the better. Note that phrase-level attacks naturally introduce more modifications than word-level attacks so they are not directly comparable on DIS and BLEU metrics in the table.

BLEU scores of **StyleAdv**, as the BLEU scores are extremely low (on 3 of 4 tasks the BLEU scores are at the scale of 10^{-81}).

- **Perplexity (PPL)**: a pre-trained $\text{GPT2}_{\text{small}}$ (Radford et al., 2019) is used to calculate the PPL of adversarial texts, which reflects the fluency as suggested by (Kann et al., 2018; Zang et al., 2020a).
- **Grammar error (GER)**: Following Zang et al., 2020b, we employ LanguageTool[6] to calculate the average number of grammar errors newly introduced by adversarial samples.

We only evaluate the last four metrics on the successful attacks against the victim model.

3.3 Main Results

Table 2 summarizes the main experimental and comparison results. Overall, PLAT consistently achieves a better attack success rate and perplexity performance across all datasets. We attribute this to the flexible phrase-level perturbations generated using contextual information. PLAT achieves a significantly better text quality than the sentence-level model StyleAdv, in terms of modificaton rates, BLEU, and perplexity. Compared with a phrase-level model MAYA, our method is significantly better on modification rates, BLEU, and grammar scores. Hence, despite not using semantic similarity constraints, PLAT is more controllable than MAYA as we confine the modification ranges and generate perturbations by contextual blank-infilling. While word-level attacks naturally introduce fewer perturbations and thus have better textual similarity and grammaticality, its perturbation space is small and results in lower success rates. On the contrary, PLAT achieves the highest success rate while on a par with word-level attacks on textual similarity and grammaticality, hence achieving a sweet spot among all metrics.

Table 3: Human evaluation performance in percentage on the Yelp dataset.

Human evaluation. We further conduct human evaluations on Yelp dataset with 100 randomly selected successful attacks produced by PLAT, CLARE, and MAYA. We evaluate these attacks in three aspects: (1) **Meaning preservation**: whether the attacks preserve the original meaning or not; (2) **Label preservation**: whether the modifications contradict the original sentiment or not; (3) We evaluate **fluency and grammaticality** via pairwise comparison: for each instance, we pair PLAT's attack with one by CLARE or MAYA. The human annotators are asked to either select the better one or rate them as equal. We average 6 responses for each sample. More details are in Appendix D.

As shown in Table 3, PLAT significantly out-

Yelp (Negative)	The quality of the food has really plummeted over the past year. We use to love coming her to get the creamy clam chowder, not its watery and gross.
TextFooler (Positive)	The quality of the food has really **engulfed** over the past year. We use to love coming her to get the creamy clam chowder, not its watery and gross.
CLARE (Positive)	The quality of the food has really **soared** over the past year. We use to love coming her to get the creamy clam chowder, not its watery and gross.
MAYA (Positive)	The quality of the food has really last year was a big one for the fall. We use to love coming her to get the creamy clam chowder, not its watery and gross.
PLAT (Positive)	The quality of the food has **also somewhat** plummeted over the past year. We use to love coming her to get the creamy clam chowder, not its watery and gross.

Table 4: Adversarial examples generated by different models on Yelp dataset, perturbations are colored.

	Yelp	AG News	MNLI	QNLLI
1^{st}	NP / 39.9%	NP / 53.7%	NP / 57.6%	NP / 58.6%
2^{nd}	ADJP / 17.5 %	NNP / 27.0%	PP / 12.4%	NNP / 16.4%
3^{rd}	VP / 16.6%	PP / 9.5%	NNP / 27.1%	PP / 13.4%

Table 5: Top-3 phrase tags of attack phrases and their percentages on different datasets by PLAT.

performs CLARE and MAYA in terms of label consistency, i.e., 77.1% vs. 49.8%(CLARE) or 53.5%(MAYA). This demonstrates the benefit of our whole architecture that utilizes both phrase-level infilling and sufficient constraints. It's worth noting that all models struggle on preserving the textual meaning and less than 40% of samples can retain their original meaning. This is consistent with Morris et al., 2020 in that semantic similarity metrics fail to maintain the actual meaning under most conditions. On the fluency and grammaticality, PLAT is comparable to CLARE but is much better than MAYA (45% vs. 26%), since our context-aware blank-infilling is superior to paraphrasing each text piece independently. Finally, Table 4 compares adversarial attacks crafted by our model and other baselines. More case studies are provided in Appendix B.

Vulnerable phrase types. We also analyze the three mostly attacked phrase types on each dataset. As shown in Table 5, noun phrases (NP) are the most vulnerable phrases over all datasets (more than 50% on three datasets), while preposition phrases (PP) and proper noun phrases (NNP) are also commonly vulnerable.

4 Analysis

In this section, we conduct detailed analyses of PLAT, including ablation study (§4.1), discussion of controllability in blank infilling (§4.2), and attacking robust defense models (§4.3).

Module	**ASR↑**	**DIS↓**	**BLEU↑**	**PPL↓**	**GER↓**
PLAT	98.4	0.17	0.78	**56.8**	0.33
w/o PHRASE-LEVEL	97.7	**0.09**	**0.84**	92.8	0.68
w ALL CONSTITUENTS	98.2	0.16	0.79	58.1	**0.29**
$\text{BERT}_{\text{base}}$ likelihood	98.5	0.17	0.78	**56.8**	0.30
T5_{base} infilling	98.4	0.16	0.79	61.4	0.41
$\text{GPT-2}_{\text{small}}$ infilling	**98.7**	0.16	0.79	61.4	0.42

Table 6: Results of the ablation study on Yelp dataset.

4.1 Ablation Study

We evaluate the effectiveness of each key component in PLAT based on the 1,000 random Yelp samples §3.2. We first study the phrase-level perturbation by replacing it with the word-level replacement used in Textfooler (*w/o* PHRASE-LEVEL). As Table 6 shows, phrase-level perturbation has a larger attack search space which leads to better attack success rate, perplexity and grammar score. It also demonstrates that attacking the constituents that are labeled as phrases is more effective than attacking all possible constituents. This is probably because phrases contain more critical and clear information to attack in classification tasks. In addition, we have not observed a significant difference between using $\text{BERT}_{\text{base}}$ and $\text{RoBERTa}_{\text{base}}$ for class-conditioned likelihood calculation, probably due to their similar architectures and shared knowledge. Finally, we comparing different blank-infilling methods using pre-trained $\text{BART}_{\text{base}}$ (PLAT), pre-trained T5_{base} (Raffel et al., 2020) and fine-tuned $\text{GPT-2}_{\text{small}}$ (Donahue et al., 2020). Empirically, $\text{BART}_{\text{base}}$ achieves the best overall performance. Moreover, we investigate the effectiveness of the label-preservation filter in §C.1

4.2 Sensitivity and Controllability Analysis

In this section, we investigate how the outputs can be controlled by hyper-parameters in PLAT on Yelp dataset. We first study how the generated samples can be impacted by varying the candidate number

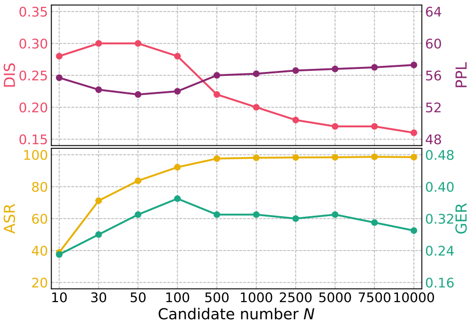

Figure 2: **ASR**, **GER**, **DIS** and **PPL** results by controlling different candidates numbers N in PLAT.

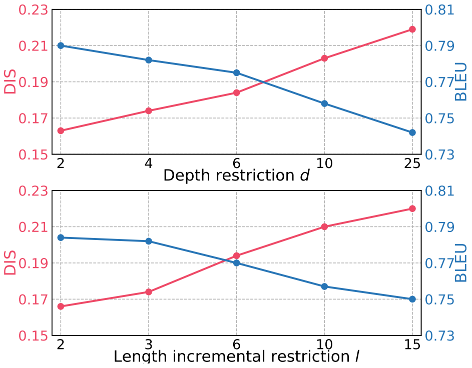

Figure 3: **DIS** and **BLEU** results by varying depth restrictions d (upper) and length increments l (bottom).

N in blank-infilling. As shown in Figure 2, the success rate (**ASR**) increases with the increase of N but starts to saturate when $N \geq 500$, while the grammar errors (**GER**) stay quite consistent. Meanwhile, the edit distance (**DIS**) drops significantly but the perplexity (**PPL**) only increases slightly when N increases. Based on these observations, we choose $N = 5000$ in our experiments for the best trade-off among these aspects.

In addition, we explore how the syntactic tree depth d in target phrases and the incremental length l for perturbed phrases can affect the modification degree. In Figure 3, with the increase of d or l, more modifications are introduced and the textual similarity decreases, which undermines the validity of adversarial samples, as larger d and l may augment the attacking space with longer but unnecessary perturbations. Hence, we choose relatively small d and l to ensure the attack is more controllable. Note that both d and l exhibit a slight impact on the success rate (Refer to Appendix C for detailed results).

4.3 Attacking Robust Defense Model

In this section, we examine whether existing robust defense models can defend PLAT attack which is beyond word-level perturbations. We apply a robust BERT$_{\text{base}}$ defense model trained via TAVAT (Li and Qiu, 2021) to defend the attacks from PLAT and baseline models, which is designed for word-level attacks. Comparing Table 7 with Table 2, both the edit distance and BLEU get worse when attacking the defense model, showing that the defense model is harder to attack. Meanwhile, two word-level attacks have a significant attack success rate drop, e.g., 94.5% to 64.2% on TextFooler. On the contrary, PLAT still can achieve the best 99.2% attack success rate with sufficient textual similarity and grammar errors, outperforming MAYA in every aspect. This suggests that PLAT raises a new robustness issue on current defense models.

Method	ASR↑	DIS↓	BLEU↑	PPL↓	GER↓
TextFooler	64.2	0.23	0.59	185.5	1.39
CLARE	92.5	**0.12**	**0.81**	76.1	**0.15**
MAYA	98.6	0.57	0.33	82.1	3.51
PLAT	**99.2**	0.28	0.67	**55.7**	0.39

Table 7: Results of PLAT and baselines attacking the robust defense model TAVAT on Yelp dataset.

5 Related Work

Textual Adversarial Attack Growing interest is devoted to generating textual adversarial samples via perturbation at various levels. Some early works use misspelling tokens in character-level (Liang et al., 2018; Ebrahimi et al., 2018; Li et al., 2019), but they can be easily defended by spell checking tools (Pruthi et al., 2019; Zhou et al., 2019; Jones et al., 2020). Recent mainstream of studies try to misguide models via word-level perturbations, e.g., synonym/semantic neighbor substitution (Alzantot et al., 2018; Jin et al., 2020; Ren et al., 2019; Zhang et al., 2019), replacement by pre-trained masked language models (Li et al., 2020; Zhang et al., 2019), or combing replacement with operations like insertion and merging (Li et al., 2021). These methods usually attempt to preserve the semantic similarity for better fluency and grammaticality, but their perturbations are limited to independent single words.

Sentence-level attacks have also been studied to generate new texts via paraphrasing or GAN-based generation (Iyyer et al., 2018; Wang et al., 2020b; Zou et al., 2020; Wang et al., 2020a; Qi et al., 2021), but their drastic modifications on the text structure make it harder to maintain a satisfactory textual quality. Very recently, phrase-level perturbations are considered in evaluating the performance of syntactic parsing (Zheng et al., 2020), or involved in a multi-granularity textual attack model MAYA (Chen et al., 2021). Unlike MAYA, PLAT only focuses on unified phrase-level attacks without multiple sub-modules, which require simpler and fewer modifications while benefiting better performance.

Blank Infilling Large-scale pre-trained language models such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) have shown their capability of filling masked single tokens (Wang and Cho, 2019; Ghazvininejad et al., 2019) but they cannot handle variable-length masks. Although autoregressive generative models such as GPT (Radford et al., 2018) or GPT2 (Radford et al., 2019) can produce outputs with arbitrary lengths, they only condition information from a single direction and ignore some surrounding texts. To enable GPT models to fill in blanks, Donahue et al. proposed to fine-tune them with sequences concatenating manually-masked texts and missing texts. Recently, autoencoder-decoder models such as T5 (Raffel et al., 2020) and BART (Lewis et al., 2020), which are trained using text infilling losses make it possible to fill the blanks within the context in a more flexible form (Shen et al., 2020).

6 Conclusion

We present a new phrase-level textual adversarial attack, PLAT, which produces richer and higher-quality phrase-level perturbations than the widely studied word-level attacks. It utilizes contextualized blank-infilling to generate perturbations by a pre-trained language model and thus well preserves the fluency, and grammaticality. We additionally develop a label-preservation filter based on the likelihood given by class-conditioned language models, trying to to keep the ground-truth labels intact. Extensive experiments show the effectiveness of PLAT and its advantages over baselines on different NLP tasks.

A Implementation Details

A.1 Details of PLAT

Basic infrastructure We use PyTorch as the backbone of our implementation, along with Huggingface-Transformers[7] for the implementation of victim models and likelihood estimation models, while Fairseq for the implementation of blank-infilling model BART[8]. We list the hyperparameters used in our model in Table 8, all of them are determined empirically based on both attack success rate and textual quality. It takes **about 160 minutes to generate 100 adversarial samples** on Yelp dataset using PLAT on a single NVIDIA GTX 1080 Ti GPU.

Select phrase candidates. We use the parser from Stanford CoreNLP[9] toolkit for the syntactic tree parsing. We consider parsed nodes with the syntactic tags in Table 9 as the possible root node of a phrase.

Depth restriction of phrase syntactic tree d	4
Length incremental restriction for substitutions l	3
Maximum perturbation number T	11
Likelihood ratio filter threshold δ	1
Substitution candidates number N	5000

Table 8: All hyperparameters used in PLAT.

Tags	ADJP, ADVP, CONJP, NP, NNP, PP, QP, VP, WHADJP, WHADVP, WHNP, WHVP

Table 9: Syntactic tags that will be selected as the root of a phrase.

Blank filling with language model. In our default setting, we directly apply the original BART$_{\text{base}}$ model[10] with 6 encoder and decoder layers and 140M parameters. During infilling, the target phrase $\mathbf{a}$ will be replaced with a special symbol "<mask>", then the model will fill this blank with variable-length context. The Top-K sampling strategy is used during generation, where we set $k = 50$ and repeat this procedure several times to collect enough phrase substitution candidates. Since BART$_{\text{base}}$ implement blank filling via reconstructing the whole sentence, where the text excluding the blank part after filling may not be the same as the original one, we simply only reserve the reconstructed sentences which keep the text excluding the blank part unchanged.

In the variations with other blank-infilling models, we use GPT-2$_{\text{small}}$ model[11] with 124M parameters or T5$_{\text{base}}$ model[12] with 220M parameters, both have 12 layers. Since the original GPT-2$_{\text{small}}$ model is not suitable for blank infilling, we enable GPT-2 model to implement this task by finetuing on Yelp training corpus using method proposed by Donahue et al., running the code provide by the authors[13].

Dataset	PPL before	PPL after
Yelp	11.44	6.29
AG News	9.33	3.64
MNLI	6.16	3.74
QNLI	5.14	5.00

Table 10: Perplexities of our fine-tuned masked language models for likelihood estimation, before and after fine-tuning on the validation set of each dataset (prepending our predefined special label token).

Models for calculating likelihood. We apply RoBERTa$_{\text{base}}$[14] model fine-tuned on the corresponding training set of each attack dataset in this stage, which has 12 layers and 125M parameter. Then we fine-tune the label-conditioned masked language models on different datasets as follows to make them better fit the specific domain.

- Classification datasets (Yelp, AG News): Since each sample is usually long, we split a sample into several short sentences as the input for fine-tuning. To avoid the conditions that some short sentences may be irrelevant or contradict the overall label y, we employ a classifier to make predictions on these sentences and only remain sentences with the confidence value of y higher than 0.99. Such a sentence along with the special label token "*<Label>*" corresponding to the overall label y will form a new sample for fine-tuning, whose input format is "*<Label> Sentence*".
- NLI datasets (MNLI, QNLI): samples in these datasets are usually a pair of short sentences, so we will not split them. The input format for these datasets is "*<Label> SentenceA </s> </s> SentenceB*", where "*</s></s>*" is the separation symbol in RoBERTa.

[13] `https://github.com/chrisdonahue/ilm`

[14] `https://huggingface.co/roberta-base`

Then we will randomly mask some tokens in these samples to fine-tune a masked language model conditioned on labels, the batch size is 8, and the learning rate is $5e^{-5}$ with AdamW optimizer. The PPL before and after fine-tuning is shown in Table 10, demonstrating the effectiveness of this procedure.

When predicting the likelihood of a perturbation, we will concatenate the label of the original sample with the masked perturbed sequence as the input, similar to samples in fine-tuning. When attacking Yelp and AG News datasets, we also only use the sub-sentence containing the perturbation, rather than the whole text.

Metrics. To obtain the edit distance (DIS) metric, we utilize the open-source tool[15] to calculate it in token-level, i.e. how many words need to be edited to transform a text into another one and then normalized by the text length. In addition, we employ Toolkit in NLTK[16] to calculate BLEU metrics between adversarial samples and the corresponding original samples.

A.2 Details of Victim Models

BERT models. All BERT victim models are based on $\text{BERT}_{\text{base}}$[17], which contains 110M parameters with 12 layers. A linear layer is added for classification, which takes the representation of "[CLS]" token in the head of a sequence as the input. We then fine-tune victim models on each dataset using batch size 32 and the learning rate $2e^{-5}$ for 3 epochs. The final model after 3 epochs will be saved and used as the victim model F on each dataset.

Train robust models using TAVAT. The robust models are also based on $\text{BERT}_{\text{base}}$ with a linear layer added for classification. We fine-tune the model using an adversarial training method TAVAT proposed by Li and Qiu which is a token-level gradient accumulation of perturbations, by running code provided by the authors[18] with all default hyper-parameters. During finetuning, perturbations guided by gradient are applied to the embedding space and models are trained using these perturbed data.

A.3 Details of baseline MAYA

MAYA has three variants: MAYA, MAYA_{π} and MAYA_{bt}. We select MAYA as our baseline since overall it obtains the best attack success rate and perplexity performance.

A.4 Possible Limitations of Our Model

The label-preservation filter in our PLAT model utilizes label-conditioned masked language models, which need to be fine-tuned on a labeled corpus with sufficient data. Therefore, the performance of PLAT may drop on datasets that have limited number of labeled samples. In addition, it takes about 1 minute for our model to generate one adversarial sample using BERT as the victim model, so PLAT is not applicable for conditions with low computational resources.

B Additional Qualitative Samples

We introduce some additional adversarial samples generated by our PLAT model, along with three baselines, TextFooler, CLARE, MAYA, on four datasets, Yelp, AG News, MNLI, QNLI, in Table 11, Table 12, and Table 13.

C Additional Results

C.1 Effectiveness of Label-Preservation Filter

Since human evaluation on ablation study of the label-preservation filter is costly, to verify its effect, we turn to use adversarial samples derived from the attack on the Yelp dataset. Here, we train models with either only adversarial examples or a combination of original and adversarial examples to evaluate the label correctness of adversarial samples. Since the labels of the Yelp test set are carefully annotated, the accuracy on the Yelp test set of each trained classifier can be regarded as a metric to reflect the label-preservation capability of the crafted adversarial examples. A better label-preservation of adversarial samples will introduce less noise during training and thus results in preferable performance on the test set. According to the results shown in Table 14, models trained using samples from our complete PLAT model with the label preservation filter shows higher accuracy than ones trained on samples derived from ablated PLAT without such a filter, especially when only training the classifiers based on adversarial samples. Therefore, it demonstrates that using the label-preservation filter can obtain adversarial examples with better label consistency.

Module	**Only Adv**	**Combined**
PLAT	88.8%	89.2%
w/o label-preservation	87.3%	88.6%

Table 14: Accuracy on the Yelp test set of models that are trained on barely adversarial examples (**Only Adv**) or a combination of original and adversarial examples (**Combined**). The adversarial samples come from our complete PLAT model, or its ablation without label-preservation filter.

C.2 Additional Results on Controllable Ability

We list the full results of §4.2 about controllable ability on Yelp dataset in Table 15, Table 16, and Table 17, for the effects of candidate number N during infilling, syntactic tree depth restriction for phrase candidates d and length incremental restriction for substitution l on our PLAT model, respectively. It can be found that all N, d, and l can control the performance of PLAT in different aspects. Surprisingly, the grammar error decreases while d is increasing. We attribute this to the fact that the modification range of the phrase is extended as d increases, such that the infilling text is less likely to be essentially conditioned on the surrounding context and fewer grammar errors occur at the boards between blanks and rest texts.

We also test the effects of different likelihood ratio threshold δ on Yelp dataset, which is illustrated in Figure 4. A larger threshold δ may result in a lower attack success rate, more modifications, and a worse textual quality.

D Details of Human Evaluation

We conducted our human evaluation via *Google Forms* on a total 60 non-expert volunteer anno-

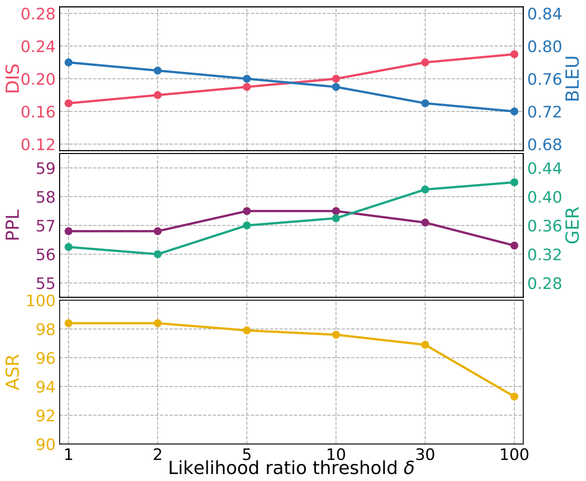

Figure 4: The performance of PLAT on Yelp dataset using different likelihood ratio threshold in label-preservation filter, in terms of all 5 metrics.

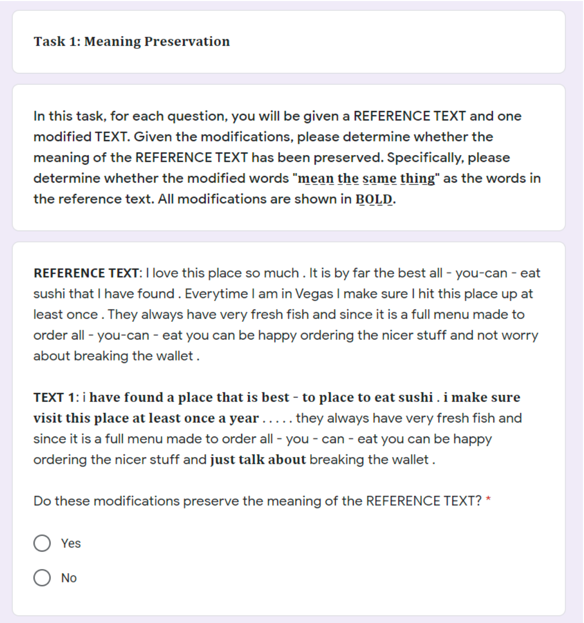
tators. Each annotator was asked to rate for 10 sets of examples, where each set contains one original sample and three corresponding adversarial samples generated by PLAT, CLARE, and MAYA respectively. We show the screenshot of our instructions and examples in Figure 5, Figure 6, and Figure 7, where the perturbed parts are in bold font. We described how we would use these collected data in the invitations for annotators, and they must agree on this usage before evaluation. All collected data go without personal information in our experiments.



Task 1: Meaning Preservation

In this task, for each question, you will be given a REFERENCE TEXT and one modified TEXT. Given the modifications, please determine whether the meaning of the REFERENCE TEXT has been preserved. Specifically, please determine whether the modified words "**mean the same thing**" as the words in the reference text. All modifications are shown in **BOLD**.

REFERENCE TEXT: I love this place so much . It is by far the best all - you-can - eat sushi that I have found . Everytime I am in Vegas I make sure I hit this place up at least once . They always have very fresh fish and since it is a full menu made to order all - you-can - eat you can be happy ordering the nicer stuff and not worry about breaking the wallet .

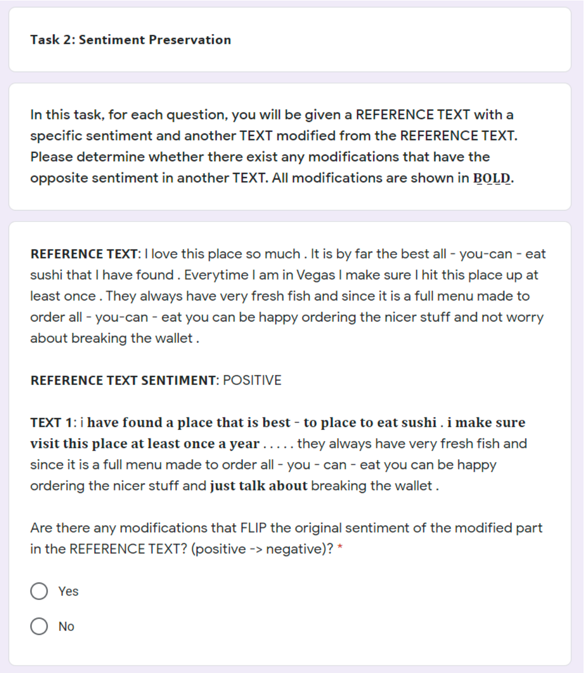
TEXT 1: i **have found a place that is best - to place to eat sushi** . **i make sure visit this place at least once a year** . . . . . they always have very fresh fish and since it is a full menu made to order all - you - can - eat you can be happy ordering the nicer stuff and **just talk about** breaking the wallet .

Do these modifications preserve the meaning of the REFERENCE TEXT? *

○ Yes

○ No

Figure 5: The instruction and an example of meaning preservation task in human evaluation.



Task 2: Sentiment Preservation

In this task, for each question, you will be given a REFERENCE TEXT with a specific sentiment and another TEXT modified from the REFERENCE TEXT. Please determine whether there exist any modifications that have the opposite sentiment in another TEXT. All modifications are shown in **BOLD**.

REFERENCE TEXT: I love this place so much . It is by far the best all - you-can - eat sushi that I have found . Everytime I am in Vegas I make sure I hit this place up at least once . They always have very fresh fish and since it is a full menu made to order all - you-can - eat you can be happy ordering the nicer stuff and not worry about breaking the wallet .

REFERENCE TEXT SENTIMENT: POSITIVE

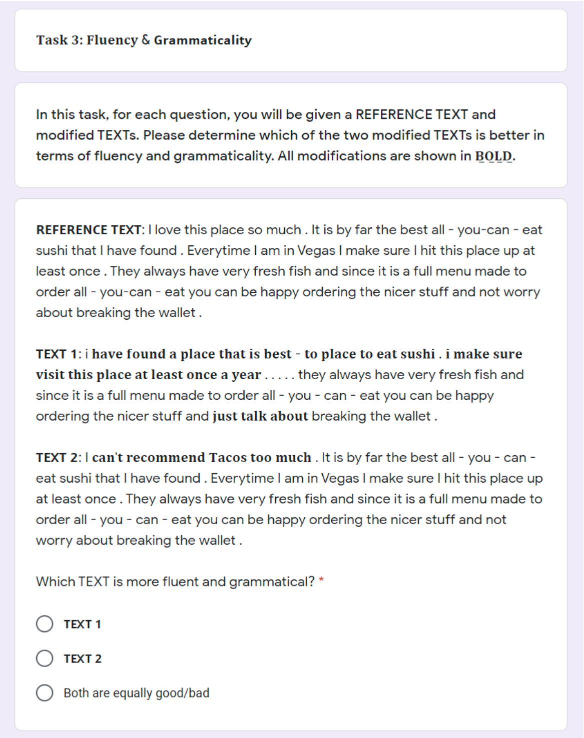
TEXT 1: i **have found a place that is best - to place to eat sushi** . **i make sure visit this place at least once a year** . . . . . they always have very fresh fish and since it is a full menu made to order all - you - can - eat you can be happy ordering the nicer stuff and **just talk about** breaking the wallet .

Are there any modifications that FLIP the original sentiment of the modified part in the REFERENCE TEXT? (positive -> negative)? *

○ Yes

○ No

Figure 6: The instruction and an example of label preservation task in human evaluation.



Task 3: Fluency & Grammaticality

In this task, for each question, you will be given a REFERENCE TEXT and modified TEXTs. Please determine which of the two modified TEXTs is better in terms of fluency and grammaticality. All modifications are shown in **BOLD**.

REFERENCE TEXT: I love this place so much . It is by far the best all - you-can - eat sushi that I have found . Everytime I am in Vegas I make sure I hit this place up at least once . They always have very fresh fish and since it is a full menu made to order all - you-can - eat you can be happy ordering the nicer stuff and not worry about breaking the wallet .

TEXT 1: i **have found a place that is best - to place to eat sushi** . **i make sure visit this place at least once a year** . . . . . they always have very fresh fish and since it is a full menu made to order all - you - can - eat you can be happy ordering the nicer stuff and **just talk about** breaking the wallet .

TEXT 2: I **can't recommend Tacos too much** . It is by far the best all - you - can - eat sushi that I have found . Everytime I am in Vegas I make sure I hit this place up at least once . They always have very fresh fish and since it is a full menu made to order all - you - can - eat you can be happy ordering the nicer stuff and not worry about breaking the wallet .

Which TEXT is more fluent and grammatical? *

○ TEXT 1

○ TEXT 2

○ Both are equally good/bad

`lovekesh.vig, gautam.shroff}@tcs.com`

Abstract

Identifying all possible user intents for a dialog system at design time is challenging even for skilled domain experts. For practical applications, novel intents may have to be inferred incrementally on the fly. This typically entails repeated retraining of the intent detector on both the existing and novel intents which can be expensive and would require storage of all past data corresponding to prior intents. In this paper, the objective is to continually train an intent detector on new intents while maintaining performance on prior intents without mandating access to prior intent data. Several data replay-based approaches have been introduced to avoid catastrophic forgetting during continual learning, including exemplar and generative replay. Current generative replay approaches struggle to generate representative samples because the generation is conditioned solely on the class/task label. Motivated by the recent work around prompt-based generation via pre-trained language models (PLMs), we employ generative replay using PLMs for incremental intent detection. Unlike exemplar replay, we only store the relevant contexts per intent in memory and use these stored contexts (with the class label) as prompts for generating intent-specific utterances. We use a common model for both generation and classification to promote optimal sharing of knowledge across both tasks. To further improve generation, we employ supervised contrastive fine-tuning of the PLM. Our proposed approach achieves state-of-the-art (SOTA) for lifelong intent detection on four public datasets and even outperforms exemplar replay-based approaches. The technique also achieves SOTA on a lifelong relation extraction task, suggesting that the approach is extendable to other continual learning tasks beyond intent detection.

1 Introduction

Modern dialog systems are reliant on user intent detection wherein the system is required to classify a user utterance into one of multiple pre-defined intents. A static intent detection model is often insufficient for real-world applications because (i) User intents evolve over time (ii) Additional functionality may be added to the system and (iii) Some intents may become obsolete.

Consider a conversational Information Technology (IT) helpdesk in an enterprise, where a ticket raised by an employee is classified into one of the multiple pre-defined intents (corresponding to different IT complaints) and accordingly routed by the system to the appropriate IT support staff. Each ticket comprises a textual IT problem description manually entered by an employee in natural language. In a typical IT enterprise, the helpdesk team provides support for every IT application from installation to maintenance. As applications get upgraded, and newer applications are introduced, the set of intents can change and the intent detection model must be updated.

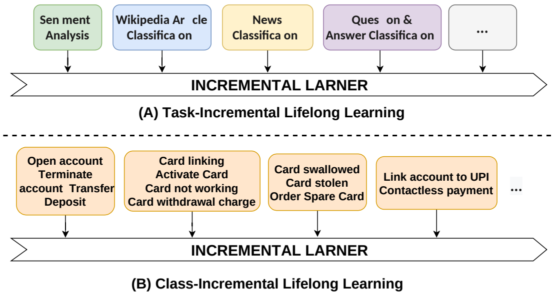

Figure 1: Task-Incremental (*Task-IL*) Vs Class-Incremental Lifelong Learning (*Class-IL*).

In the above example, the intent detection model is required to classify both old and newly introduced intents after updation. However, privacy concerns may limit access to prior intent data, and even if prior data is available, retraining the intent detection model from scratch becomes computationally expensive due to the ever-increasing data volume. An additional problem is that the data is skewed towards prior intents. Recently, there has

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1113 - 1127
July 10-15, 2022

been a lot of emphasis on continual learning to address these issues for computer vision (Parisi et al., 2018) and natural language processing (Biesialska et al., 2020), wherein the objective is to train a model on a sequence of novel tasks while maintaining performance on prior learned tasks, i.e., to prevent catastrophic forgetting (McCloskey and Cohen, 1989) with little or no data from old tasks.

Sun et al. (2020a); Wang et al. (2021); Madotto et al. (2021) formulate multiclass-text classification as a task-incremental learning (*Task-IL*) problem where the objective is to train an "incremental learner" on a sequence of tasks. As shown in Fig. 1 (A), they treat each classification task from a novel domain as a separate task introduced at each incremental step. They further assume that each task definition is complete, i.e., for each classification task they have access to all possible class labels and the set of class labels for that task remains immutable. However, in real-world applications, a task itself may evolve over time as shown in Fig. 1 (B), where, for an intent detection task in the banking domain a new set of intents are added at each incremental step based on new user needs and new functionality introduced by the service provider. Also in *Task-IL*, the task identity is provided at inference time, i.e., "Which task has to be performed for a given utterance?". This restricts the job of the "task incremental learner" to choosing one of the task-specific classes as a response. This is in contrast to lifelong intent detection, where the "incremental learner" has to consider the complete set of intents that have been added so far, independent of the number of incremental steps.

To overcome catastrophic forgetting in *Task-IL*, LAMOL (Sun et al., 2020a) uses a PLM as the task incremental learner and uses the same learner for generative replay, i.e., for generating samples of old tasks in *Task-IL*. Madotto et al. (2021) propose a residual adapter (Houlsby et al., 2019) based architecture for lifelong intent detection in task-oriented dialogue systems. Unlike existing Task-IL approaches, the authors also predict task-id, i.e., which adapter to use at test time by using an entropy-based classifier. Similar to LAMOL, they also model lifelong intent detection as Task-IL where dialogues from new domains are added to the system over a period of time. However, the task-specific adapters are trained in isolation which often results in erroneous task-id predictions due to an overlap between the intents introduced over different incremental steps. Liu et al. (2021b) propose a novel strategy based on exemplar-replay (MSR) which tries to perform knowledge distillation at prediction level and feature level and uses inter-class margin loss to minimize distance between new and old class embeddings.

In the current work, we model "lifelong intent detection" as a class-incremental learning (*Class-IL*) (Rebuffi et al., 2017) problem where a new set of intents/classes are added over a period of time, i.e., at each incremental step. To address the issue of catastrophic forgetting during "lifelong intent detection", we extend LAMOL to the *Class-IL* scenario and propose the "**P**rompt **A**ugmented **Ge**nerative **R**eplay" (**PAGeR**) model where, similar to existing approaches (de Masson d'Autume et al., 2019; Wang et al., 2020; Qian et al., 2021; Xia et al., 2021; Wang et al., 2019; Obamuyide and Vlachos, 2019; Han et al., 2020) we do not store real samples in replay memory but instead store concept words for each intent. In successive incremental steps, we generate samples for each prior intent based on the natural language intent definition and the stored intent specific concept words via PAGeR. To further improve the quality of generative replay and overall classification performance, we perform supervised contrastive fine-tuning of *PAGeR* and distill knowledge from the previous version of the "lifelong intent detector" while adapting it to the new set of intents.

Our key contributions are as follows:
(i) We propose a novel incremental learning approach using prompt based classification and generative replay via a common pre-trained language model.
(ii) Our generative replay approach uses prompt based generation guided by intent specific concept words and intent definition, yielding high quality samples.
(iii) To boost the quality of generative replay, we propose an approach for supervised contrastive fine-tuning of pre-trained Language Models (PLMs).
(iv) Our approach, *PAGeR*, outperforms exemplar replay based approaches for lifelong intent detection on three public intent classification datasets, one text classification dataset and two public multi-domain dialog intent detection datasets.
(v) We further demonstrate that *PAGeR* also outperforms the state-of-the-art on a lifelong relation extraction task by a wide margin suggesting generalizability of the proposed technique across tasks.

2 Related Work

2.1 Lifelong Learning

van de Ven and Tolias (2018) proposed three problem scenarios of increasing difficulty for evaluating continual learning algorithms based on whether the task identity is known or not and if not known whether it has to be predicted at inference time or not. The three scenarios correspond to (i) Task Incremental Learning (*Task-IL*) (ii) Domain-incremental learning (*Domain-IL*) and (iii) Class-incremental learning (*Class-IL*) respectively. Among these three scenarios, *Class-IL* is the most challenging whereas *Task-IL is* comparatively the easiest. Different approaches have been proposed to alleviate catastrophic forgetting for continual learning including *Rehearsal-based methods* where a subset of labelled training data from prior tasks is stored in a memory buffer and later replayed while training the model on the current task. Chaudhry et al. (2019b) proposed Experience Replay (*ER*) where the data from prior tasks is interleaved with data from the current task to retain performance on old tasks. *GEM* (Lopez-Paz and Ranzato, 2017) ensures that at every training step the loss of each previous task, approximated by the samples in episodic memory, does not increase. whereas *A-GEM* (Chaudhry et al., 2019a) attempt to ensure that at every training step the average episodic memory loss over previous tasks does not increase. *EWC* (Kirkpatrick et al., 2017) is an example of a *Regularization based approach* which remembers old tasks by selectively slowing down learning on the weights important for old tasks. *iCaRL* (Rebuffi et al., 2017) uses prototype rehearsal along with *Knowledge distillation* to alleviate catastrophic forgetting in a *Class-IL* scenario along with a herding (Welling, 2009) based approach for prioritized exemplar selection. *DER* (Buzzega et al., 2020) combines *rehearsal* with *knowledge distillation* and *regularization* to alleviate catastrophic forgetting in all three scenarios by matching the network's logits sampled throughout the optimization trajectory. In *architecture based approaches* the model is expanded for each new task with task-specific components (Rusu et al., 2016) or the same model is used for different tasks by identifying appropriate subnetworks (Wortsman et al., 2020). Shin et al. (2017) provide a *Generative Replay based approach* where pseudo-labelled data corresponding to the prior task is generated and interleaved with data from the current task to train a solver whereas van de Ven et al. (2020) use the same model as both a solver and generator and instead of replaying actual samples, replay latent representations.

2.2 Rehersal-based Methods

Monaikul et al. (2021); Qian et al. (2021); Cao et al. (2021) use different variants of knowledge distillation and representative sample selection methods to alleviate catastrophic forgetting for lifelong learning of NER (Monaikul et al., 2021), NMT (Qian et al., 2021) and hate speech classification on social media (Cao et al., 2021). For lifelong language learning on stream of text examples, de Masson d'Autume et al. (2019) use sparse experience replay, local adaptation during training, and inference respectively. Wang et al. (2020) extend the work of de Masson d'Autume et al. (2019) and propose a sparse experience replay augmented meta-learning based approach to learn better initialization for local adaptation. *EA-EMR* (Wang et al., 2019), *EMAR* (Han et al., 2020) are different methods for the lifelong relation extraction task described in section 6. Xia et al. (2021) propose a novel few-shot class incremental text classification task and model text classification as textual entailment.

2.3 Generative Replay based Methods

Sun et al. (2020a) propose an approach for *TASK-IL* where they generate pseudo-labelled samples corresponding to old tasks for replay and use the same model for generating a label given a sample and task identifier. Sun et al. (2020b); Chuang et al. (2020) use a common classifier-generator model LAMOL with distillation (Sun et al., 2020a) for *TASK-IL*.

2.4 Prompting PLMs

(Radford et al., 2019) demonstrate the possibility of solving multiple NLP tasks in the zero-shot setting by expressing each of them via a task specific natural language prompt where the corresponding output is generated in an autoregressive fashion. For a given task, there was still a significant performance gap between zero-shot and supervised learning. To reduce this gap, Schick and Schütze (2021) propose an approach where they express text classification and natural language inference in a cloze-style format and fine-tune the PLM in a few-shot setting. The same apprach has since been attempted for various NLP tasks (Liu et al., 2021a).

In the context of *Task-IL*, LAMOL expresses different NLP tasks in the format proposed by (McCann et al., 2018) and fine-tune GPT-2 on the entire task-specific data.

In *PAGeR*, we propose three prompts, two for expressing intent detection and one for labelled data generation for *Class-IL*. Pseudo-labelled utterance generation is guided by intent labels along with concepts words which are stored in memory instead of actual samples. We jointly fine-tune GPT-2 on an intent detection and labelled utterance generation task. To minimize the likelihood of incorrect (Utterance, label) pairs, unlike (Chen et al., 2020; Wu et al., 2020; Khosla et al., 2020; Gunel et al., 2021), we fine-tune GPT-2 on a supervised contrastive learning objective. To further alleviate catastrophic forgetting, we also use *Knowledge Distillation* (Hinton et al., 2015).

3 Preliminaries

Recent work has demonstrated how downstream tasks can be performed with PLMs using prompts (Liu et al., 2021a) in a zero shot setting. Typically, a prompting function $x' = f_{prompt}(x)$ is applied to an input x to obtain the corresponding prompt x' containing x, an (intermediate) answer z and task specific discrete or continuous tokens as task descriptors. For instance, for the sentiment analysis task, $\langle x' = [x]$ The movie is $[z]\rangle$ is an example of a prompt where $[x]$="I like this movie." and "The movie is" are task specific discrete tokens. Given a prompt, an answer z can be generated using a PLM model $p(z \mid [x]$ The movie is$; \varphi)$. Prompts with a random or true value of z are referred to as *Filled Prompts* and *Answered Prompts* respectively. Schick and Schütze (2021) propose prompt-based fine-tuning of PLMs to minimize the performance gap between supervised and zero-shot prompt approaches on downstream tasks.

Our approach is inspired by LAMOL (Sun et al., 2020a) which fine-tunes a GPT-2 PLM over a sequence of tasks. In LAMOL, each task is represented as a prompt generated via a prompt function $f_{prompt}(\mathit{Context}) = \mathit{Context}, \mathit{Question}, ANS, \mathit{Answer}, EOS))$, where *Context* corresponds to the input, *Question* acts as a task descriptor, *Answer* refers to the output and ANS, EOS refers to special tokens. LAMOL was initially used for training a single multi-task NLP model without any task-specific parameters (McCann et al., 2018). For the Sentiment Analysis task (*Context*: "I like this restaurant.", *Question*: "Is this sentence positive or negative?", *Answer*: "positive"), *Context* represents the input sentence/paragraph, *Question* includes all possible class labels and *Answer* represents the true label. Similar to generative pre-training (Radford and Narasimhan, 2018) of a transformer based decoder only model, LAMOL performs prompt based fine-tuning of GPT-2 by maximizing $P(\mathit{Answer} \mid \mathit{Context}, \mathit{Question}, ANS)$ for answer generation and $P(\mathit{Context}, \mathit{Question}, ANS, \mathit{Answer}, EOS \mid \mathit{Task})$ for generative replay. At inference time, LAMOL generates a class label given a *Context* and task-identifier, i.e., $P(\mathit{Answer} \mid \mathit{Context}, \mathit{Question}, ANS)$. In LAMOL, generative replay is conditioned solely on task-specific tokens. Similar to LAMOL, we use GPT-2 as PLM for both lifelong intent detection and generative replay.

4 Problem Description

In this paper, we model the "lifelong intent detection" problem as a class-incremental learning problem where a set of new intents are introduced at each incremental step. Consider $\mathcal{D}^i = \{\mathcal{I}_1^i, \mathcal{I}_2^i, ..., \mathcal{I}_m^i\}$ and $\mathcal{I}_j^i = \{\bigcup_{k=1}^{r} (x_{jk}^i, y_j^i)\}$ where $\mathcal{D}^i = \mathcal{D}_{train}^i \cup \mathcal{D}_{val}^i \cup \mathcal{D}_{test}^i$ represents the set of new intents and $\mathcal{I}_j^i$ represents labelled data corresponding to the j^{th} intent introduced at the i^{th} incremental step respectively. x_{jk}^i represents the k^{th} natural language utterance corresponding to the j^{th} intent introduced in the i^{th} incremental step and the corresponding intent label is represented by y_j^i. Unique intent labels introduced at the i^{th} incremental step are represented by $Y^i = \{y_1^i, y_2^i, ..., y_m^i\}$ and there will not be any overlap between the intents introduced at different incremental steps, i.e., $Y^i \cap Y^t = \emptyset$ where $t \in \{1, 2, ..., i-1\}$ and Y_{all}^i represent unique intent labels introduced so far where $Y_{all}^i = Y^i \cup Y^{i-1} \cup ... \cup Y^1$. At the i^{th} incremental step the whole labelled data corresponding to previous intents, i.e., $\mathcal{D}_{old}^i = \mathcal{D}_{train}^{i-1} \cup \mathcal{D}_{train}^{i-2} \cup ... \cup \mathcal{D}_{train}^1$ is not available for training but a fixed size memory $\mathcal{M} \ll |\mathcal{D}_{old}|$ is accessible by the incremental learner. We represent the incremental learner trained at the i^{th} incremental step by $\mathcal{IL}_i$. And the $\mathcal{IL}_i$ is evaluated on $\mathcal{D}_{test-full}^i = \mathcal{D}_{test}^i \cup \mathcal{D}_{test}^{i-1} \cup ..., \mathcal{D}_{test}^1$ which includes utterances corresponding to all the intents seen so far in addition to new intents.

$\mathcal{I}_{dist} = \{\mathcal{N}^1, \mathcal{N}^2, ..., \mathcal{N}^{\mathcal{T}}\}$ represents the number of intents introduced over each incremental step where $\mathcal{N}^i$ represents number of new intents introduced at i^{th} incremental step and $\mathcal{T}$ represents the total number of incremental steps for a dataset $\mathcal{D} = \mathcal{D}^1 \cup \mathcal{D}^2 \cup, ..., \cup \mathcal{D}^\mathcal{T}$. Thus at the $i+1^{th}$ incremental step the objective is to train a learner $\mathcal{IL}_{i+1}$ given $\mathcal{D}^{train}_{i+1}$, $\mathcal{M}$ and evaluate it on $\mathcal{D}^{i+1}_{test-full}$.

5 Proposed Approach

In *PAGeR*, we model "Lifelong Intent Detection" as a text generation problem, as shown in Fig. 2 (A), where the objective is to generate the correct label y^{i+1}_j for intents given a user utterance x^{i+1}_{jk}, while also utilizing generative replay to maintain performance on old intents. At the $i+1^{th}$ incremental step, we jointly fine-tune $\mathcal{IL}_{i+1}$ on the "Lifelong Intent Detection" *LID* and "Labelled Utterance Generation" (*LUG*) task given $\mathcal{D}^{i+1}_{train}$, $\mathcal{S}^i$ which consists of labelled ($\mathcal{D}^{i+1}_{train}$) and pseudo-labelled ($S_i$) utterances respectively. Pseudo-labelled utterances corresponding to intents present in $\mathcal{D}^i_{old}$ are generated from $\mathcal{IL}_i$ based on prompts stored in a fixed size memory, $\mathcal{M}$ as shown in Fig. 2 (B). To minimize the likelihood of incorrect (x^{i+1}_{jk},y^{i+1}_{j+1}) pairs, we do supervised contrastive fine-tuning of $\mathcal{IL}_{i+1}$, as shown in Fig. 2 (C). To alleviate catastrophic forgetting, we use knowledge distillation (Hinton et al., 2015) by fine-tuning $\mathcal{IL}_{i+1}$ on $\mathcal{S}^i$ with soft targets on *LID* and *LUG* whereas we use hard targets while fine-tuning $\mathcal{IL}_{i+1}$ on novel intents in $\mathcal{D}^{i+1}_{train}$.

For the remainder of this section, we drop the superscript $i+1$ for simplicity which indicates the $i+1^{th}$ incremental step. We use (x,y) for (x^{i+1}_{jk},y^{i+1}_j) and refer to the $i+1^{th}$ step as the current incremental step.

5.1 Lifelong Intent Detection (*LID*)

In *Task-IL* (van de Ven and Tolias, 2018), a task-identifier is provided at inference time, and the model performs the corresponding task. In *Class-IL*, no class/task information is provided apriori which makes the problem more challenging and not amenable to existing models such as LAMOL. We propose two ways of creating a prompt so that we can extend LAMOL to *Class-IL*.

(i) *Prompt without question* (*PWQ*): In *PWQ*, we convert each user utterance x in a prompt by applying a pre-defined template as mentioned in Eq 1. An *Answered Prompt* corresponding to *PWQ* is shown in Fig. 3 (A).

(ii) *Prompt with incremental question* (*PWIQ*): In *PWIQ*, we transform each user utterance x into a prompt by application of a pre-defined template as mentioned in Eq 2. where *IncQ* at the current incremental step includes all the intent labels Y^{i+1}_{all} seen so far. The *Answered Prompt* corresponding to *PWIQ* is shown in Fig. 3 (B).

$$f^{PWQ}_{prompt}(x) = (x, ANS, y, EOS) \quad (1)$$

$$f^{PWIQ}_{prompt}(x) = (x, \mathit{IncQ}, ANS, y, EOS)) \quad (2)$$

ANS, EOS refers to special tokens used during prompt creation. We perform *PWQ* based fine-tuning of $\mathcal{IL}_i$ on $\mathcal{D}^{i+1}_{train} \cup \mathcal{S}^i$ to arrive at the $\mathcal{IL}_{i+1}$ by maximizing $log(p(y, EOS \mid x, ANS; \varphi))$ or by minimizing the loss function as mentioned in Eq. 3. $(w_1, ..., w_n)$, $(y_1, ..., y_N)$ are the set of tokens present in x and y respectively. n and N represent the number of tokens in the utterance and intent label respectively.

$$L_{ID} = -log(p(y, EOS \mid x, ANS; \varphi)) \quad (3)$$

5.2 Labelled Utterance Generation (*LUG*)

To generate high quality pseudo-labelled utterances for generative replay in subsequent incremental steps, we condition our intent specific generative model on an "intent label" and the corresponding intent *Concepts*. For each intent I_j, we obtain the top-K tf-idf words $tf-idf_j$ from the utterances corresponding to intent I_j to create a prompt. We use a maximum of $K = 50$ tf-idf words per intent. Words which are part of both x and $tf-idf_j$ are referred to as intent *Concepts* and $C_j = \{c_{j1}, c_{j2}, ..., c_{jr}\}$ represents a set of *Concept* sequences one per labelled utterance present in I_j. We use the template outlined in Eq. 4 to create a prompt for *LUG* and the corresponding *Answered Prompt* as shown in Fig. 3 (C). We train $\mathcal{IL}_{i+1}$ for prompt based generation by minimizing the loss function in Eq. 5.

$$f^{LUG}_{prompt}(y, c) = (y, c, SEP, x, ANS, y, EOS) \quad (4)$$

We use $\mathcal{IL}_i$ along with $\mathcal{M}$ to generate the pseudo-labelled data $\mathcal{S}^i$ corresponding to intents present in $\mathcal{D}^i_{old}$ for training of $\mathcal{IL}_{i+1}$. Existing replay based approaches either store a few labelled utterances per intent in $\mathcal{M}$ or generate an equal number of pseudo-labelled utterances. PAGeR, instead uses the same memory to store tf-idf concept

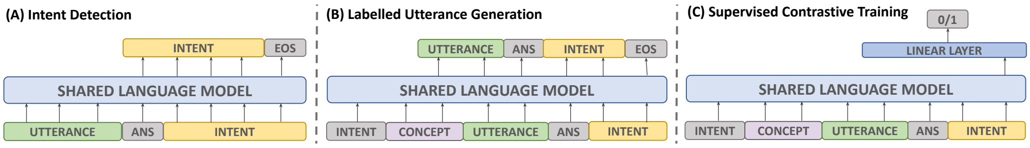

Figure 2: Proposed approach for Lifelong Intent Detection, where a PLM is jointly fine-tuned on (A) Intent detection, for generating the "intent label" corresponding to a user utterance (B) Generative replay, i.e., given a prompt consisting of the "intent" and a representative set of words from that intent, generate a user utterance along with the corresponding "intent label"(C) Supervised contrastive learning, i.e., given a valid utterance intent pair (U, I_1) and another randomly chosen intent I_2, predict whether I_1 and I_2 correspond to the same intent. For E.g., ("How do I link my new card ?","Card Linking") is an example of an (utterance,intent) pair and "Cash Withdrawal Charge" refers to a (possibly different) intent.

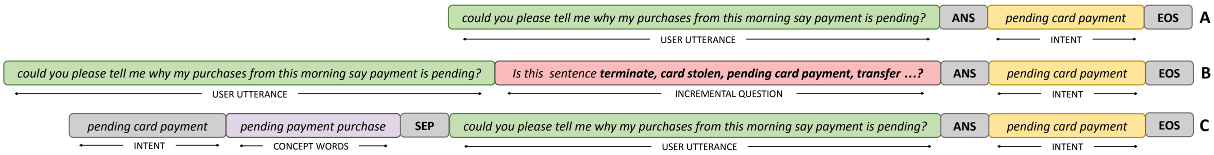

Figure 3: *Answered Prompts*: (A) Prompt without a question (*PWQ*), (B) Prompt with an incremental question (*PWIQ*), (C) Prompt for Labelled Utterance Generation (*LUG*)

words from C_j for every intent along with y_j and generates pseudo-labelled utterances corresponding to each entry in memory.

$$L_R = -(log(p(x, ANS, y, EOS \mid y, c_{jk}, SEP; \varphi))) \tag{5}$$

5.3 Supervised Contrastive Training (*SCT*)

To minimize the likelihood of incorrect utterance-label pairs during *LID* and *LUG*, we explicitly fine-tune $\mathcal{IL}_{i+1}$ on positive and negative utterance-label pairs via contrastive loss as shown in Eq. 6. A pair $((x, y), y')$ where $y' \in Y_{all}$ is positive if $y = y'$ or negative otherwise. $p_{ul} = sigmoid(W_c h_{EOS} + b_c)$, represents the probability that $((x, y), y')$ is positive and h_{EOS} is a representation of EOS token from the PLM. W_c and b_c represents the weight and bias of a linear layer respectively.

$$L_{SCT} = p_{ul} * log(p_{ul}) + (1 - p_{ul}) * log(1 - p_{ul}) \tag{6}$$

5.4 Knowledge Distillation (*KD*)

To alleviate catastrophic forgetting, we also use *KD* (Hinton et al., 2015) in the context of *LID* where instead of hard targets we use soft targets to train $\mathcal{IL}_{i+1}$ on $\mathcal{S}^i$. For intent detection, we distill the knowledge from $\mathcal{IL}_i$ while training $\mathcal{IL}_{i+1}$ by minimizing the loss function in Eq. 7 where $p'(y_{s+1})$ is obtained from $\mathcal{IL}_i$ and $y_0 = ANS$.

$$L_{KD} = -\frac{1}{N}\sum_{s=0}^{N} p'(y_{s+1}) * \\ log(p(y_{s+1} \mid x, y_0, ..., y_s; \varphi)) \tag{7}$$

At the current incremental step, we incrementally update $\mathcal{IL}_i$ based on $\mathcal{D}^{i+1}_{train} \cup \mathcal{S}^i$ by minimizing L_{total} as shown in Eq. 8 to get $\mathcal{IL}_{i+1}$.

$$L_{total} = \lambda_1 * L_{ID} + \lambda_1 * L_{KD} + \lambda_2 * L_R + \lambda_3 * L_{SCT} \tag{8}$$

where $\lambda_1, \lambda_2, \lambda_3$ are the set of hyperparameters. At inference, we use $\mathcal{IL}_{i+1}$ to generate intent labels for all utterances in $\mathcal{D}^{i+1}_{test-full}$.

We define *PAGeR-Base* as a baseline for *PAGeR*, which extends LAMOL for *Class-IL*. We train *PAGeR-Base* on $\lambda_1 * L_{ID} + \lambda_2 * L_R$ as our loss function where replay samples are generated based on the *PWQ* prompt.

6 Experimental Setup

In this section, we describe the various datasets, baseline approaches, evaluation metrics and training details. We subsequently present the results and discuss our key observations. For further training details, please refer to A.2 in appendix.

6.1 Dataset Description

Lifelong Intent Detection: **CLINC150** (Larson et al., 2019) is a crowdsourced multi-domain (10 domains such as utility, travel etc.) intent detection dataset. **HWU64** (Liu et al., 2019) is a crowdsourced multi-domain (21 domains such as alarm, cooking etc.) intent detection dataset. **BANKING77** (Casanueva et al., 2020) is an imbalanced, fine-grained intent detection dataset from the banking domain. **SGD** (Rastogi et al., 2020) and **MWOZ** (Budzianowski et al., 2018) are multi-domain dialogue datasets which consist of dialogues from 19 and 8 domains respectively.

Text Classification: **Stackoverflow** (*S20*) (Xu et al., 2017) is a multi-class classification dataset comprising of 20,000 question titles from Stackoverflow each tagged with one of 20 different tags. *Lifelong Relation Extraction*: **FewRel** (Han et al., 2018): is a relation extraction dataset where the objective is to predict a relation type between a pair of entities in a given sentence/paragraph.

For all datasets, we use standard train-test split provided by respective authors (shown in Table 5). For further dataset details, please refer to A.1 in appendix.

6.2 Baseline Approaches

We use *Upper Bound* (**UB**) where we assume that data corresponding to all incremental steps is available apriori and fine-tune $\mathcal{IL}$ on all $\mathcal{D}^i$'s together and in *Lower Bound* (**LB**), we incrementally fine-tune $\mathcal{IL}$ on $\mathcal{D}^i$'s with $|\mathcal{M}| = 0$.

6.2.1 Lifelong Intent Detection

(i) **EWC** (Kirkpatrick et al., 2017): Remembers old tasks by selectively slowing down learning on the weights important for these tasks.

(ii) **A-GEM** (Chaudhry et al., 2019a): A-GEM tries to ensure that at every training step the average episodic memory loss over the previous tasks does not increase.

(iii) **ER** (Rolnick et al., 2019): Interleaving old samples with current data in training batches.

(iv) **DER** (Buzzega et al., 2020): Rehearsal with knowledge distillation and regularization.

(v) **AdapterCL** (Madotto et al., 2021): Train a task-specific residual adapters (Houlsby et al., 2019) and uses an entropy-based classifier to select which adapter to use at test time.

6.2.2 Lifelong Relation Extraction

(i) **GEM** (Lopez-Paz and Ranzato, 2017): GEM ensures that at every training step the loss for each of the previous tasks, approximated by the samples in episodic memory, does not increase.

(ii) **EMR** (Parisi et al., 2019): Jointly train a model on current and old labelled samples stored in memory.

(iii) **EA-EMR** (Wang et al., 2019): They utilize an explicit alignment model to mitigate the sentence embedding distortion of the learned model when training on new data and new relations.

(iv) **EMAR** (Han et al., 2020): Every time neural models are activated to learn both new and memorized data, EMAR utilizes relation prototypes as a memory reconsolidation exercise to keep a stable understanding of old relations.

6.3 Evaluation Metrics

We use the following two metrics for evaluating performance on the lifelong intent detection task.

Average Accuracy (Chaudhry et al., 2018) We use $Avg_{acc}^{k'}$ to evaluate the performance after k' incremental steps where $Acc_{avg}^{k'} = \frac{1}{k'}\sum_{i=1}^{k'} A(\mathcal{IL}_{k'}(\mathcal{D}_{test}^{i}))$ and $A(\mathcal{IL}_{k'}(\mathcal{D}_{test}^{i}))$ represents classification accuracy obtained by $IL_{k'}$ after k' incremental steps on $\mathcal{D}_{test}^{i}$.

Average Forgetting (**F**) (Chaudhry et al., 2018) We use $F_{avg}^{k'}$ to measure the average drop in intent classification accuracy for intents introduced after k' incremental steps where $F_{avg}^{k'} = \frac{1}{k'}\sum_{i=1}^{k'-1} \max_{1\leq t<k'} A(\mathcal{IL}_{t}(\mathcal{D}_{test}^{i})) - A(\mathcal{IL}_{k'}(\mathcal{D}_{test}^{i}))$ and $F_{avg}^{k'} \in [-1, 1]$ (lower value of $F_{avg}^{k'}$ implies less forgetting).

7 Results and Discussion

For lifelong intent detection task, we compare *PAGeR* with SOTA approaches for *Class-IL* from the NLP and vision community on three imbalanced and one balanced intent detection dataset. The comparison was across three different sizes for $\mathcal{M}$. For a given $\mathcal{M}$, we run all baselines, including *PAGeR-Base* and *PAGeR* over four different intent permutations and report $Acc_{avg}^{\mathcal{T}}$ and $F_{avg}^{\mathcal{T}}$. As shown in Table 1, *PAGeR* outperforms the baselines for all possible dataset-$\mathcal{M}$ combinations. In low memory scenarios, i.e., $\mathcal{M} = 1\%$, *PAGeR* outperforms exemplar replay based baselines by high margins which indicates that while it's not possible to store all representative samples in a given memory, these may be generated based on concept words. Similar to (Buzzega et al., 2020), we also find *EWC* and *A-GEM* less effective in the *Class-IL* setting. With $\mathcal{M} = 1\%$, *PAGeR* also outperforms *AdapterCL* on all datasets except *C150*^{I}. We also compare *PAGeR* with MSR (Liu et al., 2021b) and

Table 1: *Average Accuracy (↑) / Average Forgetting (↓)* on four intent detection dataset, **C150^B**, **C150^I** : Balanced and Imbalanced version of **CLINC150**, **BANKING77 (B77)**, **HWU64** and on one Text Classification (**TC**) dataset.

show the results in table 8.

PAGeR also outperforms other baselines for incremental text classification on the *S20* dataset. Even with $\mathcal{M} = 1\%$, *PAGeR* gets an average accuracy, $Acc_{avg}^{\mathcal{T}}$ of 84.3% which is only 6.5% below the *UB*. For *S20*, we use numeric label ids as class labels to demonstrate that *PAGeR* also works when labels are not informative.

7.1 *PWQ* Vs *PWIQ*

As shown in Fig. 4, the length of *PWIQ* prompt depends on the number of intent labels which increases at every incremental step and leads to large sequence length whereas the length of *PWQ* prompt is independent of the number of intent labels. And large sequence length leads to more running time. Hence, *PWQ* prompt can be extended to operate over a large number of incremental steps.

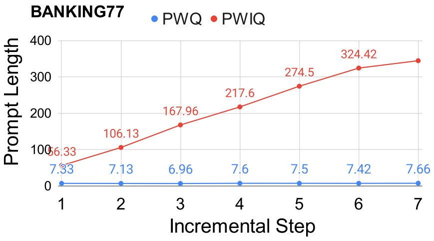

Figure 4: PWQ Vs PWIQ

7.2 How good are pseudo-labelled utterances?

To alleviate catastrophic forgetting in the *LID* and *LUG* tasks, we use pseudo-labelled utterances for generative replay. To empirically assess the quality of pseudo-labelled utterances over incremental steps, we perform the following experiment: We only consider intents that have been introduced at the first incremental step. On these intents, we train an intent detection model at each incremental step where we use pseudo labelled utterances generated by $\mathcal{IL}_i$ at i^{th} incremental step and compare it with the model trained on real labelled-utterances (Upper Bound). As shown in Fig. 5, on the B77 dataset, the drop in average accuracy is not significant for these intents over incremental steps. This suggests that pseudo-labelled utterances generated by the model are close to original utterances, i.e., generative replay plays an important role towards alleviating catastrophic forgetting in both *LID* and *LUG* tasks.

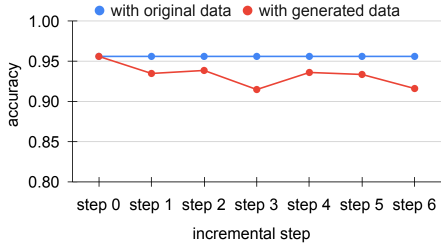

Figure 5: Accuracy for intents introduced during first incremental step at subsequent incremental steps

8 Ablation Study

We conduct ablation experiments on the B77 dataset across all memory sizes to demonstrate the efficacy of *PAGeR*'s sub-components as shown in Table 2. Individually, all three components when applied with *PAGeR-Base*, show significant improvement in performance ($Acc_{avg}^{\mathcal{T}}$). **LUG**, when applied with *PAGeR-Base* to generate better representative samples for replay, boosted the $Acc_{avg}^{\mathcal{T}}$ of *PAGeR-Base* by 4.7%, 4.9% and 5.7% in experiments where $\mathcal{M}$ is set to 10%, 5% and 1% respectively. Applying **SCT** with *PAGeR-Base* also shows significant improvement in experiments across different sizes for $\mathcal{M}$. Results of *PAGeR-Base* with **KD** only, affects the $Acc^{\mathcal{T}}_{avg}$ of *PAGeR-Base* by -0.5%, -0.4% and +1.0% in experiments when $\mathcal{M}$ is 10%, 5% and 1% respectively suggesting that usage of **KD** by itself is not effective in alleviating catastrophic forgetting.

In row *PAGeR w/o LUG*, removing LUG from the combined approach highlights the importance of LUG and how the other two components, SCT and KD, are complementary to each other. This is reflected in the improved performance of *PAGeR-Base* by 6.8%, 7.6% and 10.4% in experiments with $\mathcal{M}$ set to 10%, 5% and 1% respectively. A similar trend is proven by rows *PAGeR w/o SCT*, *PAGeR w/o KD*, suggesting how all of these components are complementary to each other. In case of small memory size ($\mathcal{M}$=1%), all three components are required to achieve good intent detection accuracy, i.e., there is a drop of 1.5%, 3.4%, and 5.3% if we remove LUG, SCT and KD from *PAGeR*.

When all components are applied together with *PAGeR-Base* to give **PAGeR**, the $Acc^{\mathcal{T}}_{avg}$ improves from 82.9% to 90.2%, 81.1% to 89.2%, and 68.1% to 80.1% with $\mathcal{M}$ set to 10%, 5% and 1% respectively.

Approach	**$\mathcal{M}$=10%**	**$\mathcal{M}$=5%**	**$\mathcal{M}$=1%**
PAGeR-Base (LAMOL) (A)	82.9	81.1	68.1
A w/ *LUG only*	87.6	86.0	73.8
A w/ *SCT only*	87.9	86.2	72.1
A w/ *KD only*	82.4	80.7	69.1
B w/o *LUG*	89.7	88.7	78.5
B w/o *SCT*	88.8	88.0	76.7
B w/o *KD*	90.0	87.7	74.8
PAGeR (B)	**90.2**	**89.2**	**80.1**

Table 2: Ablation on components of **PAGeR** on **BANKING77** dataset. In *PAGeR-Base* (LAMOL), generative replay is based on only intent labels whereas in *PAGeR-Base* (LAMOL) + *LUG*, we use intent specific concept words along with intent labels for generative replay.

9 Applications of PAGeR

$\mathcal{M}$	**Approach**	**FewRel**
50 labelled samples per incremental step	**UB**	92.7
	LB	66.2
	EWC	30.2
	GEM	59.8
	A-GEM	47.5
	EMR	65.1
	EA-EMR	69.9
	EMAR	77.9
	PAGeR	**91.3**

Table 3: Average Accuracy on Lifelong relation extraction task. Except **UB** and **LB**, we have taken all baseline results from (Han et al., 2020)

9.1 Lifelong Relation Extraction

We applied *PAGeR* on a lifelong relation extraction task with the same experimental setup as described in Han et al. (2020), where the objective is to identify the correct relation mentioned in a given sentence from a set of candidate relations. To utilize candidate relations in *PAGeR*, we use *PWID* instead of *PWD* and replace *User Utterance*, *Incremental Question* and *Intent* with sentence, candidate relations and correct relation respectively as outlined in Fig. 3 (B). *PAGeR* outperforms the state-of-the-art baseline *EMAR* by 13.4% in terms of $Acc^{\mathcal{T}}_{avg}$ and is only 1.4% below the *UB* with $\mathcal{M} = 50$ per incremental step, as shown in Table 3. These results suggest that *PAGeR* can be extended to other class incremental NLP problems.

9.2 Multi-domain Dialog

We also evaluate *PAGeR* in a scenario where new intents are added as part of new domain at each incremental step and we use *K* previous utterances along with current utterance for intent detection. We use *SGD*, *MWOZ* multi-domain dialogue datasets and compare *PAGeR* with *AdapterCL*. As shown in Table 4, in this scenario, *PAGeR* outperforms *AdapterCL*.

	SGD		**MWOZ**	
Approach	**K=0**	**K=1**	**K=0**	**K=1**
AdapterCL	65.0	77.0	94.5	**96.51**
PAGeR	**77.12**	**92.6**	**98.10**	96.0

Table 4: Average Accuracy on incremental Multi-domain intent detection task

10 Conclusion

The current paper addresses the problem of lifelong intent detection and proposes *prompt augmented generative replay* (*PAGeR*) to alleviate catastrophic forgetting. We model lifelong intent detection as a *Class-IL* problem and use a common PLM for intent detection and pseudo-labelled data generation which is jointly trained for both tasks yielding SOTA performance. Future work would involve demonstrating the versatility of PAGeR on a variety of different NLP tasks, and to apply it to real world *Class-IL* scenarios wherein the initial number of classes is large and relatively few intents are added or removed in each iteration with significant class imbalance.

A Appendix

A.1 Dataset Description

Lifelong Intent Detection: **CLINC150** (Larson et al., 2019) is a crowdsourced multi-domain (10 domains such as utility, travel etc.) intent detection dataset comprising of 23,700 queries with 22,500 in-scope queries labelled with 150 intents and 1,200 out-of-scope queries. We only use in-scope queries, with both the balanced and imbalanced versions of the provided dataset. **HWU64** (Liu et al., 2019) is a crowdsourced multi-domain (21 domains such as alarm, cooking etc.) intent detection dataset comprising of 25,716 queries labelled with 64 intents and is an imbalanced dataset. **BANKING77** (Casanueva et al., 2020) is an imbalanced, fine-grained intent detection dataset from the banking domain comprising of $13,083$ customer queries labelled with 77 intents. **SGD** (Rastogi et al., 2020) and **MWOZ** (Budzianowski et al., 2018) are multi-domain dialogue datasets which consist of dialogues from 19 and 8 domains respectively. Total number of intents in **SGD** and **MWOZ** are 39 and 5 respectively.

Text Classification: **Stackoverflow** (*S20*) (Xu et al., 2017) is a multi-class classification dataset comprising of 20,000 question titles from Stackoverflow each tagged with one of 20 different tags.

Lifelong Relation Extraction: **FewRel** (Han et al.,

2018): is a relation extraction dataset where the objective is to predict a relation type between a pair of entities in a given sentence/paragraph. It consists of $56,000$ examples tagged with 80 relations introduced incrementally at each step.
For all datasets, we use standard train-test split provided by respective authors (shown in table 5).

Table 5 contains details about different intent detection datasets $\mathcal{D}$ such as *CLINC150* with balanced (*C150*^{B}) and imbalanced version (*C150*^{I}), *BANKING77*, *HWU64 (H64)*, and one text classification dataset, i.e., *Stackoverflow (S20)*. It also contains details about *SGD*, *MWOZ* two multi-domain dialogue datasets which is used for intent detection task only. In these dialog datasets, the intent of an utterance can be determined on the basis of that utterance along with K previous history utterances from the dialog where K is hyperparameter for preprocessing during dataset creation. In our experiments, we have taken K=0 and K=1 to create the dataset for intent detection from SGD and MWOZ datasets.
Table 6 contains details about total number of incremental steps ($\mathcal{T}$), total number of intents ($Y_{all}^{\mathcal{T}}$) in an intent detection dataset ($\mathcal{D}$) and how these intents have been introduced over incremental steps, i.e., $\mathcal{I}_{dist}$. And all of these datasets are available in english language and released under creative Commons licences.

	$\mathcal{D}_{train}$	$\mathcal{D}_{val}$	$\mathcal{D}_{test}$
CLINC150 (C150^B)	15000	3000	4500
CLINC150 (C150^I)	10525	3000	4500
BANKING77 (B77)	8463	1540	3080
HWU64	8954	1076	1076
Stackoverflow (S20)	16000	-	4000
SGD	8843	1291	2421
MWOZ	2494	208	227

Table 5: Dataset Details

Dataset	Intents	$\mathcal{T}$	$\mathcal{I}_{dist}$
C150^B	150	10	{15, 15, 15, 15, 15, 15, 15, 15, 15, 15}
C150^I	150	10	{15, 15, 15, 15, 15, 15, 15, 15, 15, 15}
B77	77	7	{20, 10, 10, 10, 10, 10, 7}
H64	64	7	{10, 10, 10, 10, 10, 10, 4}
S20	20	5	{4, 4, 4, 4, 4}
SGD	39	19	{1,2,2,2,4,1,2,2,3,1,2,3,3,2,2,4,2,1,1}
MWOZ	5	5	{1,1,2,1,1}

Table 6: Dataset Details, where “Intents” ($Y_{all}^{\mathcal{T}}$) represents total number of intents introduced after $\mathcal{T}$ incremental steps.

Different shuffled versions of a dataset Same set of intents are introduced over different incremental steps to create different shuffled versions of a dataset $\mathcal{D}$, as shown in Fig. 6. We run all baselines, *PAGeR* and it's variant on four different shuffled versions of $\mathcal{I}_{dist}$ for a given $\mathcal{D}$.

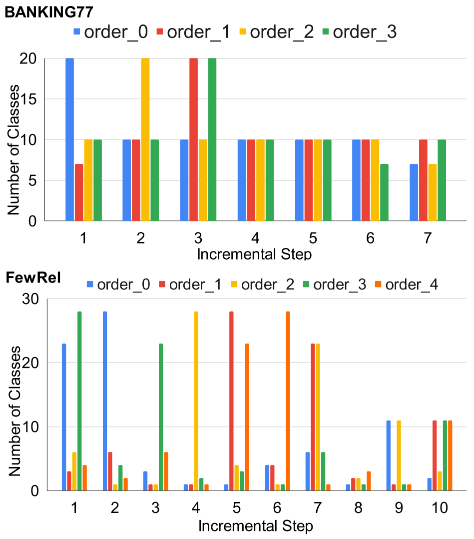

Figure 6: Different shuffled versions of *BANKING77* and *FewRel* dataset.

A.2 Training Details

For all the experiments reported in this paper we employ the GPT-2 PLM. To ensure a fair comparison across baselines we use GPT-2 as a common backbone for all baseline models. Training for all experiments is run for a fixed number of eight epochs. During training, the batch size was constrained to lie within the range $[8-32]$ and the maximum utterance length was fixed to 200 words. We used the Adam (Kingma and Ba, 2014) optimizer (with default values) for all the models and the learning rate was set to 5e-5. In all variants of PAGeR, we use top-k sampling (Holtzman et al., 2020) with $k = 20$ and $\lambda_1 = 1, \lambda_2 = 0.25, \lambda_3 = 0.25$. While synthesizing samples for contrastive learning, four negative samples were created for each positive sample. The distillation loss was optimized with a temperature value of 2. Baselines *EWC*, *A-GEM*, *ER*, *DER* are derived from the *DER*[1] code repository. Code for PAGeR experiments is derived from LAMOL and “Hugging Face” (Wolf et al., 2020). All the experiments were run on Titan P100, V100 and A100 GPUs. For exemplar replay based approaches, $\mathcal{M}$ is defined as the percentage of total training samples that can be stored for replay. $\mathcal{M}$ is uniformly distributed across existing intents. Upon arrival of new intents, $\mathcal{M}$ is uniformly redistributed across the total intents, both

---

[1] https://github.com/aimagelab/mammoth

old and new. In *PAGeR*, instead of real samples, we only store the corresponding concept words. For a fair comparison, we calculate the number of tokens that can be stored in the same amount of memory $\mathcal{M}$ and we generate one pseudo-labelled utterance corresponding to each entry in $\mathcal{M}$. We run every approach four times with shuffled versions of $\mathcal{D}$, i.e., set of intents introduced at $\mathcal{T}^{th}$ incremental step can be introduced at 1^{st} incremental step in another run. Please refer to A.3 for further details about memory management over incremental steps for different datasets.

A.3 Memory ($\mathcal{M}$)

To alleviate catastrophic forgetting, $\mathcal{M}$ contains labelled utterances corresponding to old intents Y_{all}^{i} while training the model at $i+1^{th}$ incremental step. The size of $\mathcal{M}$ is defined in terms of the percentage of whole labelled training utterances which can be stored in it. For *PAGeR*, we define the memory in terms of number of tokens where the number of tokens are obtained by tokenizing the labelled utterances present in the memory at a given incremental step. Instead of storing labelled utterances in *PAGeR*, we only store corresponding *Concepts* which take less memory in terms of tokens. So in *PAGeR* we can store more number of *Concepts* in the same amount of memory as shown in Table 7.

And after $i+1^{th}$ incremental step, $\mathcal{M}$ is equally divided among the intents seen so far, i.e., Y_{all}^{i+1} and excess existing labelled utterances corresponding to old intents Y_{all}^{i} are removed randomly.

		Intent Detection				**TC**
$\mathcal{M}$	**Approach**	**C150^B**	**C150^I**	**B77**	**H64**	**S20**
10%	Baselines	1500	1040	1000	900	1600
	PAGeR	6574	4025	3673	2480	4042
5%	Baselines	750	520	500	450	800
	PAGeR	2964	1751	1892	1238	2041
1%	Baselines	150	104	100	90	160
	PAGeR	512	516	232	121	401

Table 7: No. of *Labelled Utterances*/*Concepts* stored in $\mathcal{M}$.

A.4 Results

A.4.1 MSR Vs PAGeR

Liu et al. (2021b) (MSR) shows the experiments in lifelong intent detection with a fixed memory of 200 only. We performed same experiment with *PAGeR* and compiled the average accuracy at the last incremental step in table 8.

Dataset	**MSR**	**PAGeR**
CLINC150 (C150^B)	78.00	**92.16**
HWU64	52.14	**82.38**
SNIPS	93.57	**94.27**

Table 8: PAGeR experiments with fixed memory size (200)

A.4.2 Catastrophic forgetting over incremental steps

We evaluate all baselines, PAGeR-Base and *PAGeR* on four shuffled versions of a dataset and report *Average Accuracy* along with the Standard Deviation as shown in Table 9. We observed that *PAGeR* gets similar results on different shuffled versions of a dataset.

It's also evident from Fig. 7, forgetting is less in case of *PAGeR* as compared to other baselines as number of intents increases over incremental steps.

Abstract

Extractive text summarisation aims to select salient sentences from a document to form a short yet informative summary. While learning-based methods have achieved promising results, they have several limitations, such as dependence on expensive training and lack of interpretability. Therefore, in this paper, we propose a novel non-learning-based method by for the first time formulating text summarisation as an Optimal Transport (OT) problem, namely Optimal Transport Extractive Summariser (OTExtSum). Optimal sentence extraction is conceptualised as obtaining an optimal summary that minimises the transportation cost to a given document regarding their semantic distributions. Such a cost is defined by the Wasserstein distance and used to measure the summary's semantic coverage of the original document. Comprehensive experiments on four challenging and widely used datasets - MultiNews, PubMed, BillSum, and CNN/DM demonstrate that our proposed method outperforms the state-of-the-art non-learning-based methods and several recent learning-based methods in terms of the ROUGE metric. [1]

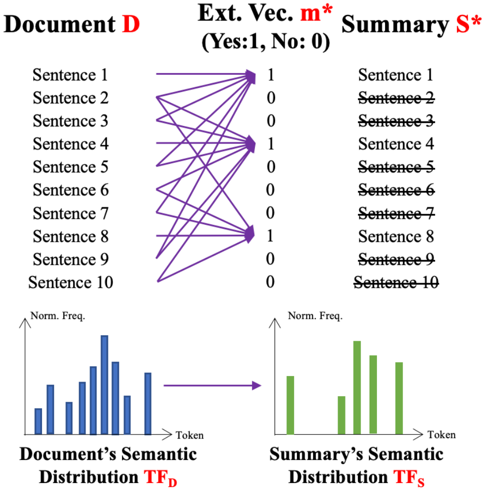

Figure 1: Illustration of Optimal Transport Extractive Summariser (OTExtSum): the formulation of extractive summarisation as an optimal transport (OT) problem. Optimal sentence extraction is conceptualised as obtaining the optimal extraction vector $\mathbf{m}^*$, which achieves an OT plan from a document $\mathbf{D}$ to its optimal summary $\mathbf{S}^*$ that has the minimum transportation cost. Such a cost is defined as the Wasserstein distance between the document's semantic distribution $\mathrm{TF}_\mathbf{D}$ and the summary's semantic distribution $\mathrm{TF}_\mathbf{S}$ and is used to measure the summary's semantic coverage.

1 Introduction

Text summarisation aims to condense a given document into a short and succinct summary that best covers the semantics of the document with the least redundancy. It helps users quickly browse and understand long documents by focusing on their most important sections (Mani, 2001; Nenkova and McKeown, 2011). A common practice for text summarisation is extractive summarisation which aims to select the salient sentences of a given document to form its summary. Extractive summarisation ensures the production of grammatically and factually correct summaries, though the output summaries could be inflexible. Since abstractive summaries are highly prone to contain contents that are unfaithful and nonfactual to the original document (Maynez et al., 2020), extractive summaries are more practical for real-world scenarios, especially for the domains requiring formal writing such as legal, science, and journalism documents.

Existing methods (Yao et al., 2017) often first score the importance of individual sentences of a given document and then combine the top-ranked ones to form a summary. However, the sentences with high importance scores may not well represent the document from a global perspective, which results in a sub-optimal summary. Recently, learning-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1128 - 1141
July 10-15, 2022

based methods, especially those based on supervised and unsupervised deep learning techniques (Narayan et al., 2018; Zheng and Lapata, 2019; Zhang et al., 2019; Narayan et al., 2020; Xu et al., 2020; Zhong et al., 2020; Padmakumar and He, 2021) can significantly improve summarisation performance. However, training deep learning models is computationally expensive, and it can be difficult to apply those models learned from a particular domain to other domains with different distributions. Moreover, deep learning methods generally lack interpretability for the summarisation process.

Motivated by these issues, we propose a novel non-learning based extractive summarisation method, namely Optimal Transport Extractive Summariser (OTExtSum). As illustrated in Figure 1, we formulate extractive summarisation based on the optimal transport (OT) theory (Peyré et al., 2019). A candidate summary can be evaluated by an OT plan regarding the optimal cost to transport between the semantic distributions of the summary and its original document. Then a Wasserstein distance can be obtained with this optimal plan to measure the discrepancy between the two distributions. To this end, it can be expected that a summary of high quality minimizes this Wasserstein distance. Moreover, a common assumption in the formulations of the OT problem is that the source and target distributions are fixed. In OTExtSum problem formulation, we relax this assumption by adding an extraction vector $\mathbf{m}^*$ to indicate which document sentences would be extracted to form the summary's semantic distribution, thus making the target distribution variable.

The semantic distributions of a given document and its candidate summary can be formulated in line with the frequency of their tokens. Inspired by Word Mover's Distance (Kusner et al., 2015), summarisation can be conceptualized as moving the "semantics" of a given document to its summary, and the ideal summary is obtained at the minimal transportation cost. This ensures the highest semantic coverage of the given document and the least redundancy in the summary without explicitly modelling conventional criteria such as relevance and redundancy. Thus, under the OT plan, the Wasserstein distance indicates the candidate summary's semantic coverage of the given document.

We design two optimisation strategies to approximate the extraction vector $\mathbf{m}^*$, namely beam search strategy (Tillmann and Ney, 2003), which iteratively evaluates the semantic coverage scores of a set of candidate summaries to obtain the optimal extraction, and binary integer programming strategy, which approximates the optimal extraction given the constraints of the Wasserstein distance and extraction budget. As a non-learning based method, OTExtSum does not require any training and is applicable to different document domains. Furthermore, it provides explainable results in terms of the semantic coverage of the summary.

There have been some studies on OT in NLP, such as document distance (Kusner et al., 2015; Yurochkin et al., 2019), text generation (Chen et al., 2018), text matching (Swanson et al., 2020), and machine translation (Xu et al., 2021). These methods generally focus on deriving similarities between words, sentences, and documents. On the contrary, we for the first time formulate text summarisation as an OT problem that optimally transports the semantic distributions between two texts (e.g., source document and summary candidate).

Overall, the key contributions of this paper are:

- We propose a non-learning based extractive summarisation method - OTExtSum by treating the text summarisation task as an optimal transport problem for the first time.
- We design two optimisation strategies for OTExtSum: beam search strategy and binary integer programming strategy.
- We present an interpretable visualisation of the semantic coverage of a generated summary by visualising the transport plan between summary tokens and document tokens.
- Comprehensive experimental results on four widely used datasets, including CNN/DM, MultiNews, BillSum and PubMed, demonstrate that OTExtSum outperforms the state-of-the-art non-learning based methods.

2 Related Work

Generally, text summarisation methods can be categorized as extractive, abstractive, and hybrid ones. While abstractive and hybrid summarisation methods (Lebanoff et al., 2019; Zhang et al., 2020) aim to mimic human beings in summarisation by paraphrasing a given document, extractive summarisation generally produces more factual summaries. In this section, we review existing extractive summarisation methods in two categories: non-learning based and learning-based methods.

2.1 Non-learning based Methods

Most of the non-learning based methods conceptualise text summarisation as a sentence ranking task. Each sentence in a given document is scored in terms of various sentence importance criteria, which measure how well the sentence could represent the document. The top-ranked sentences are combined to form a summary. These methods often heavily rely on handcrafted features in regards to linguistic knowledge by focusing on local and/or global contexts.

Local Context based Methods. Local context-based methods rank a sentence based on the features obtained from the sentence itself. Sentence features such as frequency-based and topic-based were studied. Frequency-based features (Edmundson, 1969; Hovy and Lin, 1998) assume that the occurrence of high-frequency terms in a sentence is associated with their importance. Topic-based features (Kupiec et al., 1995; Nobata and Sekine, 2004; Lin and Hovy, 2000) assume that the density of a set of topic terms is highly correlated to the topic of a document.

Global Context based Methods. As local context features could overlook the correlations between sentences and lead to redundant summaries involving similar sentences, global context-based methods rank individual sentences from the perspective of the entire document. Discourse-based methods (Marcu, 1999) construct a document's rhetorical structure and extract the sentences on the longest chain of the semantic structure, i.e. the main topic. Centroid-based methods (Radev et al., 2000) cluster the sentences of a document through similarity measures and rank the sentences based on their distances to the cluster centroids. TextRank (Mihalcea and Tarau, 2004), as a graph-based method, is the state-of-the-art non-learning based method. A graph among document sentences is first formed by connecting sentences using sentence similarity scores, then the sentence connectivity can be used to score the importance of a sentence. Nonetheless, the nature of these sentence based scoring methods could miss summary-level or document-level patterns.

2.2 Learning-based Methods

Instead of utilising handcrafted features, due to the great success of deep learning in many natural language processing tasks, recent studies on extractive summarisation aim to learn sentence features from the corpus in a data-driven manner.

Supervised Methods. Most of these methods follow the sentence ranking conceptualisation, and an encoder-decoder scheme is generally adopted (Nallapati et al., 2017; Zhang et al., 2019; Narayan et al., 2020; Xu et al., 2020). An encoder formulates document or sentence representations, and a decoder predicts a sequence of sentence importance scores with the supervision of ground-truth sentence labels.

Reinforcement Learning based Methods. Reinforcement learning (RL) can be utilised for extractive summarisation by directly optimising the ROUGE metric, which is used as the training reward. The RL based summarisation task can be treated as a sentence ranking problem similar to the aforementioned methods (Narayan et al., 2018) or as a contextual-bandit problem (Luo et al., 2019) .

Unsupervised Methods Various unsupervised methods have also been proposed to leverage pre-trained language models to compute sentence similarities and select important sentences. Some methods (Zheng and Lapata, 2019) use these similarities to construct a sentence graph and select sentences based on their centrality. Some methods (Padmakumar and He, 2021) use these to score relevance and redundancy of sentences as selection criteria.

Although these learning-based methods have significantly improved summarisation performance, computationally expensive training costs are inevitable, and it is challenging to generalise the trained models to documents from other domains that have distributions different from the training dataset. In addition, it is difficult to explain the correspondence and the coverage between a summary and a source document using these deep models. Therefore, to address these limitations, we revisit the non-learning based approach and propose a novel summarisation method by exploring the optimal transport theory for the first time.

3 Methodology

As shown in Figure 1, OTExtSum utilizes a text OT approximation to obtain the optimal extraction vector $\mathbf{m}^* = [m_1, ..., m_n]^T$, where $m_i \in \{0, 1\}$ denotes whether the i-th sentence is to be extracted (denoted by 1) or not (denoted by 0). The optimal extraction vector $\mathbf{m}^*$ achieves an OT plan from the semantic distribution of the document to that of its optimal candidate summary which has the minimum total transportation cost.

The OT approximation consists of four components: 1) a tokeniser & embedding procedure that formulates token level representations and a semantic distribution estimation that computes the frequency of each token within a summary or a document ; 2) a transportation cost matrix that measures the cost using one token to represent another based on their Euclidean distances; 3) an OT solver that approximates Wasserstein distance and semantic coverage of the candidate summaries; and 4) an optimisation strategy that obtains the optimal extraction vector by choosing the summary with the minimum Wasserstein distance, and thus with the highest semantic coverage of the source document.

3.1 Optimal Transport

Consider a transportation problem that transports goods from a collection of suppliers $\mathbf{D} = \{d_i | i = 1, ..., N\}$ to a collection of customers $\mathbf{S} = \{s_j | j = 1, ..., N\}$, where d_i and s_j indicate the supply quantity of the i-th supplier and the order quantity of the j-th customer, respectively. Note that, in this study, we consider the number of suppliers to be the same as the customers. By defining t_{ij} as the quantity transported from the i-th supplier to the j-th customer, a transport plan $\mathbf{T} = \{t_{ij}\} \in \mathbf{R}^{N \times N}$ can be obtained. Given a cost matrix $\mathbf{C} = \{c_{ij}\} \in \mathbf{R}^{N \times N}$, where c_{ij} is the cost to deliver a unit of goods from the i-th supplier to the j-th supplier, the cost of the transport plan $\mathbf{T}$ can be calculated. Particularly, an OT plan $\mathbf{T}^* = \{t^*_{i,j}\} \in \mathbf{R}^{N \times N}$ in pursuit of minimising the transportation cost can be obtained by solving the following optimisation problem:

$$\begin{aligned}
\mathbf{T}^* &= \underset{\mathbf{T}}{\text{argmin}} \sum_{i,j=1}^{N} t_{ij} c_{ij}, \\
\text{s.t.} & \sum_{j=1}^{N} t_{ij} = d_i, \quad \forall i \in \{1, ..., N\}, \\
& \sum_{i=1}^{N} t_{ij} = s_j, \quad \forall j \in \{1, ..., N\}, \\
& t_{ij} \geq 0, \quad \forall i, j \in \{1, ..., N\},
\end{aligned} \tag{1}$$

where the first two constraints indicate the quantity requirements for both suppliers and customers and the last constraint proves a non-negative order quantity. Mathematically, this OT problem is to find a joint distribution $\mathbf{T}$ with respect to a cost $\mathbf{C}$, of which the marginal distribution is $\mathbf{D}$ and $\mathbf{S}$. In particular, Wasserstein distance can be defined as:

$$d_W(\mathbf{D}, \mathbf{S}|\mathbf{C}) = \sum_{i,j} t^*_{i,j} c_{i,j}. \tag{2}$$

It can be viewed as the distance between the two probability distributions $\mathbf{D}$ and $\mathbf{S}$, if they are normalized, in line with the cost $\mathbf{C}$.

3.2 Semantic Distribution

In the context of text summarisation, denote $\mathbf{D} = \{\mathbf{s}_1, ..., \mathbf{s}_n\}$ to represent a document, where $\mathbf{s}_i$ denotes the i-th sentence contained in the document. The sentence $\mathbf{s}_i$ has a semantic distribution $\text{TF}_i \in \mathbb{R}^N$ computed by the normalised bag-of-tokens with removal of stop-words:

$$\begin{aligned}
\text{TF}_i &= [TF_{i1}, ..., TF_{iN}]^T, \\
TF_{ij} &= \frac{d_j}{\sum_{k=1}^{N} d_k},
\end{aligned} \tag{3}$$

where d_j indicates the count of the j-th token in a vocabulary of size N.

A document $\mathbf{D}$ has a semantic distribution $\text{TF}_{\mathbf{D}}$:

$$\text{TF}_{\mathbf{D}} = \frac{\text{TF}_1 + \ldots + \text{TF}_n}{n}. \tag{4}$$

For a summary $\mathbf{S} \subset \mathbf{D}$ with its corresponding extraction vector $\mathbf{m}$, of which the i-th element m_i is an indicator ($m_i = 1$ if $\mathbf{s}_i \in \mathbf{S}$, $m_i = 0$ otherwise), it has a semantic distribution $\text{TF}_{\mathbf{S}}$:

$$\text{TF}_{\mathbf{S}} = \frac{m_1 \times \text{TF}_1 + ... + m_n \times \text{TF}_n}{m_1 + ... + m_n}. \tag{5}$$

In our proposed method, a normalization step is introduced to approximate the semantic distributions of $\mathbf{D}$ and $\mathbf{S}$ with term frequency. Note that after the normalization $\text{TF}_{\mathbf{D}}$ and $\text{TF}_{\mathbf{S}}$ have an equal total good quantities of 1 and can be *completely transported from one to the other*. In addition, $\text{TF}_{\mathbf{D}}$ and $\text{TF}_{\mathbf{S}}$ satisfy the property of discrete probability distributions, of which the sum should be 1.

3.3 Transport Cost between Tokens

We define the unit transportation cost between two tokens by measuring their semantic similarity. Intuitively, the more semantically dissimilar a pair of tokens are, the higher the "transport cost" of transporting one token to another. Given a pre-trained tokeniser and token embedding model with N tokens, define $\mathbf{v}_i$ to represent the feature embedding of the i-th token. The transport cost from the i-th token to the j-th token c_{ij} in $\mathbf{C}$ can be written as:

$$c_{ij} = \|\mathbf{v}_i - \mathbf{v}_j\|_2 , \tag{6}$$

which is based on the Euclidean distance. [1]

3.4 Semantic Coverage of Candidate Summaries

Intuitively, a good summary $\mathbf{S}$ is supposed to be close to the document $\mathbf{D}$ in terms of their semantic distributions. OTExtSum utilizes the Wasserstein distance to measure the distance between the two associated semantic distributions $\mathrm{TF}_{\mathbf{D}}$ and $\mathrm{TF}_{\mathbf{S}}$ with the OT cost. The computation of the Wasserstein distance has time complexity of $O(p^3\log(p))$ (Altschuler et al., 2017), where p denotes the number of unique words in the document.

In detail, it can be obtained with Eq. (2) as $d_W(\mathrm{TF}_{\mathbf{D}}, \mathrm{TF}_{\mathbf{S}}|\mathbf{C})$ with a pre-defined cost matrix $\mathbf{C}$. Then a semantic coverage score of the summary $\mathbf{S}$ in respect to the document $\mathbf{D}$ can be further defined based on the Wasserstein distance:

$$g(\mathbf{D}, \mathbf{S}) = 1 - d_W(\mathrm{TF}_{\mathbf{D}}, \mathrm{TF}_{\mathbf{S}}|\mathbf{C}). \tag{7}$$

Therefore, OTExtSum aims to search for an extraction vector $\mathbf{m}$, of which the corresponding summary $\mathbf{S}$ minimises the Wasserstein distance, i.e. maximising the semantic coverage score for the given document $\mathbf{D}$ by solving OT problems.

3.5 Optimisation Strategy

The remaining problem for OTExtSum is to search for the optimal extraction vector $\mathbf{m}^*$ which achieves the minimum total transportation cost from the semantic distribution of the document $\mathrm{TF}_{\mathbf{D}}$ to that of the optimal summary $\mathrm{TF}_{\mathbf{S}}$, given a budget B which is the number of sentences can be extracted to create a summary:

$$\begin{aligned} \mathbf{m}^* = \operatorname*{argmin}_{\mathbf{m}} \; & d_W(\mathrm{TF}_{\mathbf{D}}, \mathrm{TF}_{\mathbf{S}}|\mathbf{C}), \\ \text{s.t. } & m_1 + ... + m_n \leq B. \end{aligned} \tag{8}$$

In search of optimal extraction vector $\mathbf{m}^*$, we design two optimisation strategies, namely beam search strategy to achieve better coverage approximation, and binary integer programming strategy to achieve better computational efficiency.

Algorithm 1: Optimisation of OTExtSum with Beam Search Strategy

```
Input  : $\mathbf{D}$ the document, $B$ the budget of the number of extracted sentences,
         $K$ the beam width.
Output : $\mathbf{S}^*$ the optimal extractive summary.
Compute the cost matrix $\mathbf{C}$, and the document's semantic distribution $\mathrm{TF}_{\mathbf{D}}$;
Initialise $\mathbf{m} = \mathbf{0}$, i.e. the candidate summary set $\mathbb{S} = \varnothing$;
while # of sentences in candidate summary $\leq B$ ; do //  Beam search
    for $k = 1, ..., |\mathbb{S}|$ do
        Generate the successor set $\mathbb{S}_b^k$ for $\mathbf{S}^k \in \mathbb{S}$;
    end
    $\mathbb{S} \leftarrow \bigcup_k \mathbb{S}_b^k$;
    for $k = 1, ..., |\mathbb{S}|$ do
        Compute the semantic distribution $TF_{\mathbf{S}^k}$ of $\mathbf{S}^k \in \mathbb{S}$;
        Compute the Wasserstein distance $d_W(TF_{\mathbf{D}}, TF_{\mathbf{S}^k}|\mathbf{C})$ and the
          semantic coverage $g(TF_{\mathbf{D}}, TF_{\mathbf{S}^k}|\mathbf{C}))$;
    end
    Keep the top $K$ candidate summaries with the highest $g(\mathrm{TF}_{\mathbf{D}}, \mathrm{TF}_{\mathbf{S}^k}|\mathbf{C}))$ and
      prune the rest in $\mathbb{S}$;
end
$\mathbf{S}^* = \operatorname*{argmax}_{\mathbf{S}^k \in \mathbb{S}} g(\mathrm{TF}_{\mathbf{D}}, \mathrm{TF}_{\mathbf{S}^k}|\mathbf{C}))$;
```

3.5.1 Beam Search Strategy

The Beam Search (BS) strategy with the beam width K maintains the candidate summary set $\mathbb{S}$ and searches for the optimal extraction vector $\mathbf{m}^*$, thus the optimal extractive summary $\mathbf{S}^*$. Algorithm 1 presents the steps to obtain the optimal summary with OTExtSum using the BS strategy. The time complexity is $O(BKn(p^3\log(p)))$.

Initially, we have $\mathbf{m} = \mathbf{0}$, where none of the sentences are extracted. Then, each sentence in the document $\mathbf{D}$ is selected as a candidate summary, which derives a set of candidate extraction vectors corresponding to a set of candidate summaries, and its semantic coverage score can be evaluated. The top K candidate summaries in terms of the semantic coverage are kept in the set $\mathbb{S}$ and the rest are pruned. During the b-th iteration of the beam search, by appending each possible sentence

---

[1] We investigated the effect of different distance measurements. As discussed in Section 4.3, cost matrix based on the Euclidean distance and the cosine distance yield similar ROUGE scores.

to an existing candidate summary $\mathbf{S}^k \in \mathbb{S}$, where the sentence is not in $\mathbf{S}^k$, a set of new candidate summaries $\mathbb{S}_b^k$ can be obtained. Then $\mathbb{S}$ is updated by combining all these sets of new candidate summaries in regards to k:

$$\mathbb{S} \leftarrow \bigcup_k \mathbb{S}_b^k. \tag{9}$$

At the end of beam search, a set of final K summary candidates within the budget B is obtained.

Among the K final candidates from the beam search, OTExtSum obtains the optimal extraction vector and thus the optimal summary by choosing the candidate with the highest semantic coverage of the document $\mathbf{D}$.

Algorithm 2: Optimisation of OTExtSum with Binary Integer Programming Strategy

```
Input  : $\mathbf{D}$ the document, $B$ the budget of
         the number of extracted sentences,
         $T$ the number of iterations.
Output : $\mathbf{S}^*$ the optimal extractive summary.
Compute the cost matrix $\mathbf{C}$, Compute
  document's semantic distribution $\text{TF}_\mathbf{D}$;
Initialise $\mathbf{w} \in \mathbb{R}^n$;
for iteration $t \in [1, ..., T]$ do
    Convert $\mathbf{w}$ to probability value $\mathbf{pr}$ with
      Sigmoid function;
    Convert $\mathbf{pr}$ to $\mathbf{b} = [b_i, .., b_n]$ by hard
      sampling from the Gumbel-Softmax
      distribution;
    Construct summary's semantic
      distribution $TF_\mathbf{S}$;
    Compute the Wasserstein distance
      $d_W(TF_\mathbf{D}, TF_\mathbf{S}|\mathbf{C})$;
    Compute the $L_1$ regularisation of $\mathbf{b}$;
    Compute loss by weighted sum of the
      Wasserstein distance and the squared
      difference of $B$ and $\mathbf{b}$;
    Compute gradients and update $\mathbf{w}$;
end
Compute $\mathbf{m}^*$ by soft sampling Sigmoid($\mathbf{w}$)
  from the Gumbel-Softmax distribution;
Obtain $\mathbf{S}^*$ by extracting top-$B$ sentences
  with the highest $m_i$ values for $i = 1, ..., n$;
```

3.5.2 Binary Integer Programming Strategy

Some prior works showed that integer linear programming is an efficient solution to summarisation problem (McDonald, 2007; Gillick and Favre, 2009).The Binary Integer Programming (BIP) strategy therefore is utilised to search for the optimal extraction vector $\mathbf{m}^*$ with T iterations. Based on the extraction vector, we obtain the optimal extractive summary $\mathbf{S}^*$. Algorithm 2 presents the optimisation steps to obtain the optimal summary with OTExtSum using the BIP strategy. The time complexity is $O(T(p^3 \log(p)))$.

As $\mathbf{m}^*$ is a multi-hot vector and is not differentiable, to make the backpropagation work, we optimise a proxy continuous vector $\mathbf{w} \in \mathbb{R}^n$, which is differentiable. Then we hard sample from the Gumbel-Softmax distribution (Maddison et al., 2016) to discretise and compute a multi-hot vector $\mathbf{b}$ during the iterations, and soft sample to compute $\mathbf{m}^*$ at the end.

The BIP strategy optimises the following loss function w.r.t. $\mathbf{w}$, which is a weighted sum of the Wasserstein distance $d_W(\text{TF}_\mathbf{D}, \text{TF}_\mathbf{S})$ and the L_1 regularisation of $\mathbf{b}$ [2]:

$$d_W(\text{TF}_\mathbf{D}, \text{TF}_\mathbf{S}|\mathbf{C}) + \alpha|B - \sum_{i=1}^{n} b_i|, \tag{10}$$

where α denotes the weight of L_1 regularisation.

4 Experimental Results and Discussions

4.1 Datasets

To validate the effectiveness of the proposed OTExtSum on the documents with various writing styles and its ability to achieve improved summarisation performance, we perform experiments on four widely used challenging datasets collected from different domains.

Dataset	**Multi-News**	**BillSum**	**PubMed**	**CNN/DM**
Domain	News	Law	Science	News
#Sent./Doc.	80	46	102	33
B	9	7	6	3
Test Set Size	5,622	3,269	6,658	11,490

Table 1: Overview of the datasets. #Sent./Doc. denotes the average number of sentences in the documents, B denotes the budget of number of extracted sentences.

CNN/DailyMail (CNN/DM) (Hermann et al., 2015) is the standard single-document datasets with manually-written summaries. *Multi-News* (Fabbri et al., 2019) is a multi-document dataset which summarises multiple news articles. We concatenate the multiple articles as a single input. *BillSum*

---

[2] We choose L_1 regularisation for sparsity (Ng, 2004).

Table 2: Comparisons between our OTExtSum and the state-of-the-art methods across different categories. The highest scores are **bold**, and the second highest ones are underlined.

(Kornilova and Eidelman, 2019) is a dataset for law document summarization, which contains long state bill documents. *PubMed* (Cohan et al., 2018) is a scientific article dataset that uses the abstract section as the ground-truth summary and the long body section as the document. Table 1 shows an overview of the four datasets. The dataset details are in Appendix A.

While *CNN/DM* contains shorter documents and summaries, the other three datasets are more challenging because they have more extended documents and summaries, thus have a higher chance to extract sentences containing redundant contents or having limited relevance to the document.

4.2 Implementation Details

In terms of the pre-trained token embedding model, we compare the static embedding model Word2Vec and the contextual embedding models BERT and GPT2. The details of hyperparameter settings and software used are in Appendix B and C.

Our OTExtSum is compared against LEAD (See et al., 2017), ORACLE (Nallapati et al., 2017), the state-of-the-art non-learning based methods and the recent unsupervised learning-based methods. LEAD and ORACLE are standard baselines in the summarisation task. LEAD baseline extracts the first several sentences of a document as a summary. ORACLE baseline greedily extracts the sentences that maximise the ROUGE-L score based on the reference summary. We compare with the results of strong non-learning-based methods, including LSA (Gong and Liu, 2001), TextRank (Mihalcea and Tarau, 2004), and LexRank (Erkan and Radev, 2004). Their results on MultiNews, BillSum, PubMed, and CNN/DM are from (Fabbri et al., 2019), (Kornilova and Eidelman, 2019), (Cohan et al., 2018), and (Padmakumar and He, 2021) respectively. For an informative reference, we report recent unsupervised learning-based methods, including PacSum (Zheng and Lapata, 2019), which its released model was trained on the news domain, and PMI (Padmakumar and He, 2021), of which the released models were trained on the news and science domains. Their results on CNN/DM are from (Padmakumar and He, 2021). Their results on Multi-News, BillSum, and PubMed are evaluated on the datasets with the corresponding released models from the same domains. And we include the results of the state-of-the-art supervised learning-based methods with extractive approach MatchSum from (Zhong et al., 2020), and those with abstractive approach PEGASUS from (Zhang et al., 2020).

4.3 Quantitative Analysis

The commonly used ROUGE metric (Lin, 2004) is also adopted for our quantitative analysis. It evaluates the content consistency between the generated summary and the reference summary. In detail, ROUGE-n scores measure the number of overlapping n-grams between the generated summary and the reference summary. A ROUGE-L score considers the longest common subsequence between the generated summary and the reference summary.

Performance Overview. The experimental results of OTExtSum on the four datasets are listed in Table 2 in terms of ROUGE-1, ROUGE-2 and ROUGE-L F-scores. We observed that the BS strategy could generally achieve better optimisation results than the BIP strategy. It is in line with our design understanding that beam search can better reach the global optimum. Whereas, the two strategies achieve similar results in CNN/DM, which could be because CNN/DM has fewer document sentences and lower budget, thus fewer possible solutions and easier to find the optimum.

OTExtSum outperforms the state-of-the-art non-learning based methods and is comparable to the learning-based methods. Note that the state-of-the-art methods usually optimise at the sentence level, whilst OTExtSum is based on the summary level OT evaluation, by which the quality of the resulting summaries is improved.

We observed that OTExtSum obtains significantly better ROUGE scores than the baseline methods on Multi-News, BillSum and PubMed, while the improvement is not that significant on CNN/DM . When the summary is more extended, such as these three more challenging datasets, the summary sentences are more likely to have redundant content. That is, even summary-level optimisation is more difficult to achieve, our OTExtSum demonstrates higher improvements.

OTExtSum is a non-learning based method, and training is not required. Unlike learning-based methods, it is not limited by the training data domain and can be used for different domains. Experimental results demonstrate generalisation ability of OTExtSum over news, law, and science domains.

Effects of Token Embeddings Models. OTExtSum is dependent on a pre-trained token embedding method. Specifically, the token embedding model affects the cost matrix C and the tokenisation, thus the frequency vector, of the document. We examine how different token embedding models would affect the performance of OTExtSum by comparing static embedding model Word2Vec, and contextual embedding models BERT and GPT2.

The results on most of the datasets indicate that a more advanced contextual embedding model such as BERT and GPT2 is more effective than a static embedding model Word2Vec. It is in line with the intuitive understanding that a more representative model with adequate training samples often approximates better token embeddings and representation. Despite that, the performance of OTExtSum with Word2Vec is surprisingly competitive.

Effects on Stop-words. We investigate the impact of stop-words on the performance of OTExtSum. As shown in Table 3 in Appendix E, the effect varies slightly across the datasets, and may not much influence the ROUGE scores. It could be because text summarisation does not generally depend on stop-words. A side benefit of removing the stop-words is reducing the vocabulary size and thus the computation time of OT.

Effects on Distance Measurement. We examine how the distance measurement of the cost matrix would impact the performance of OTExtSum. As shown in Table 3 in Appendix E, cost matrix based on the cosine distance and the Euclidean distance usually yield similar ROUGE scores.

4.4 Interpretable Visualisation

OTExtSum is able to provide an interpretable visualisation of the summarisation procedure. Figure 2 in Appendix D illustrates the transport plan heatmap, which indicates the transportation of semantic contents between tokens in the document and its resulting summary. The higher the intensity, the more the semantic content of a particular document token is covered by a summary token.

4.5 Qualitative Analysis

Figure 3 , 4 , 5, and 6 in Appendix F compare the summaries produced by OTExtSum and TextRank. TextRank extracted sentences that are salient on their own yet redundant when combined to form a summary. In comparison, OTExtSum is able to compose summaries that have higher semantic coverage and less redundant content.

5 Conclusion

In this paper, we have presented OTExtSum, the first optimal transport-based optimisation method for extractive text summarisation. It aims to identify an optimal subset of sentences for producing a summary that achieves high semantic coverage of the document by minimising the Wasserstein distance between the semantic distributions of the document and the summary. It helps obtain a summary from a global perspective and provides an interpretable visualisation of extraction results. In addition, OTExtSum does not require computationally expensive training. The comprehensive experiments demonstrate the effectiveness of OTExtSum, which is generalisable over various document domains. In our future work, we will explore other OT solvers for extractive summarisation.

A Dataset Details

We followed (Zhong et al., 2020) to set B for CNN/DM, PubMed and Multi-News, and used the average number of sentences in the summaries to set B for BillSum since this is a common practice in the literatures (Narayan et al., 2018). These datasets were obtained from a source, namely HuggingFace Datasets [3].

Since OTExtSum does not require training, for a fair comparison, all experimental results are reported on the test splits of the four datasets only.

B Hyperparameter Details

For the hyperparameter settings of the BIP strategy, the number of iteration T was set to 200, α was set to 1, and it used the SGD optimiser (Sutskever et al., 2013) with learning rate 0.1. For the BS strategy, the beam width K was set to 5 [4].

C Software and Hardware Used

We obtained the pre-trained Word2vec (Google News 300 dimension) from GENSIM [5], and the contextual embedding models BERT (base version) and GPT2 from HuggingFace [6]. To compute the Wasserstein distances, we adopted GENSIM, the POT [7] and GeomLoss (Feydy et al., 2019) libraries. List of stop-words was from NLTK library [8]. Our experiments were run on a GeForce GTX 1080 GPU card. We obtain our ROUGE scores by using the pyrouge package [9].

D Example of Interpretable Visualisation

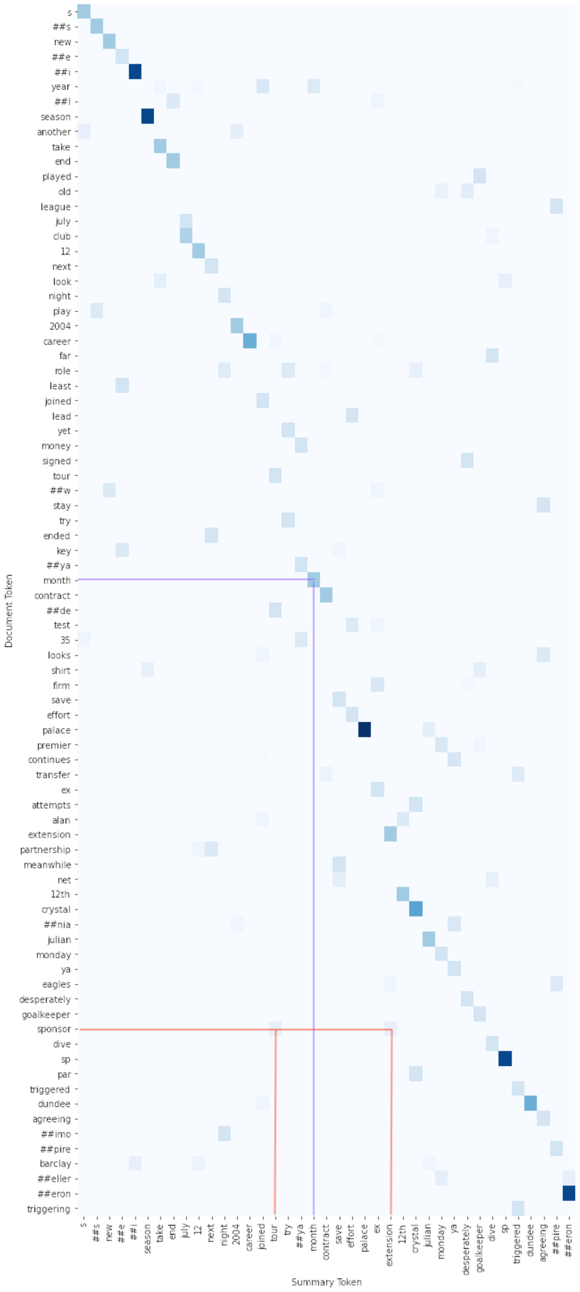

Figure 2: Interpretable visualisation of the OT plan from a source document to a resulting summary on the CNN/DM dataset. The higher the intensity, the more the semantic content of a particular document token is covered by a summary token. Purple line highlights the transportation from the document to the summary of semantic content of token "month", which appears in both the document and the summary. Red line highlights how the semantic content of token "sponsor", which appears in the document only but not the summary, are transported to token "tour" and "extension", which are semantically closer and have lower transport cost, and thus achieve a minimum transportation cost in the OT plan.

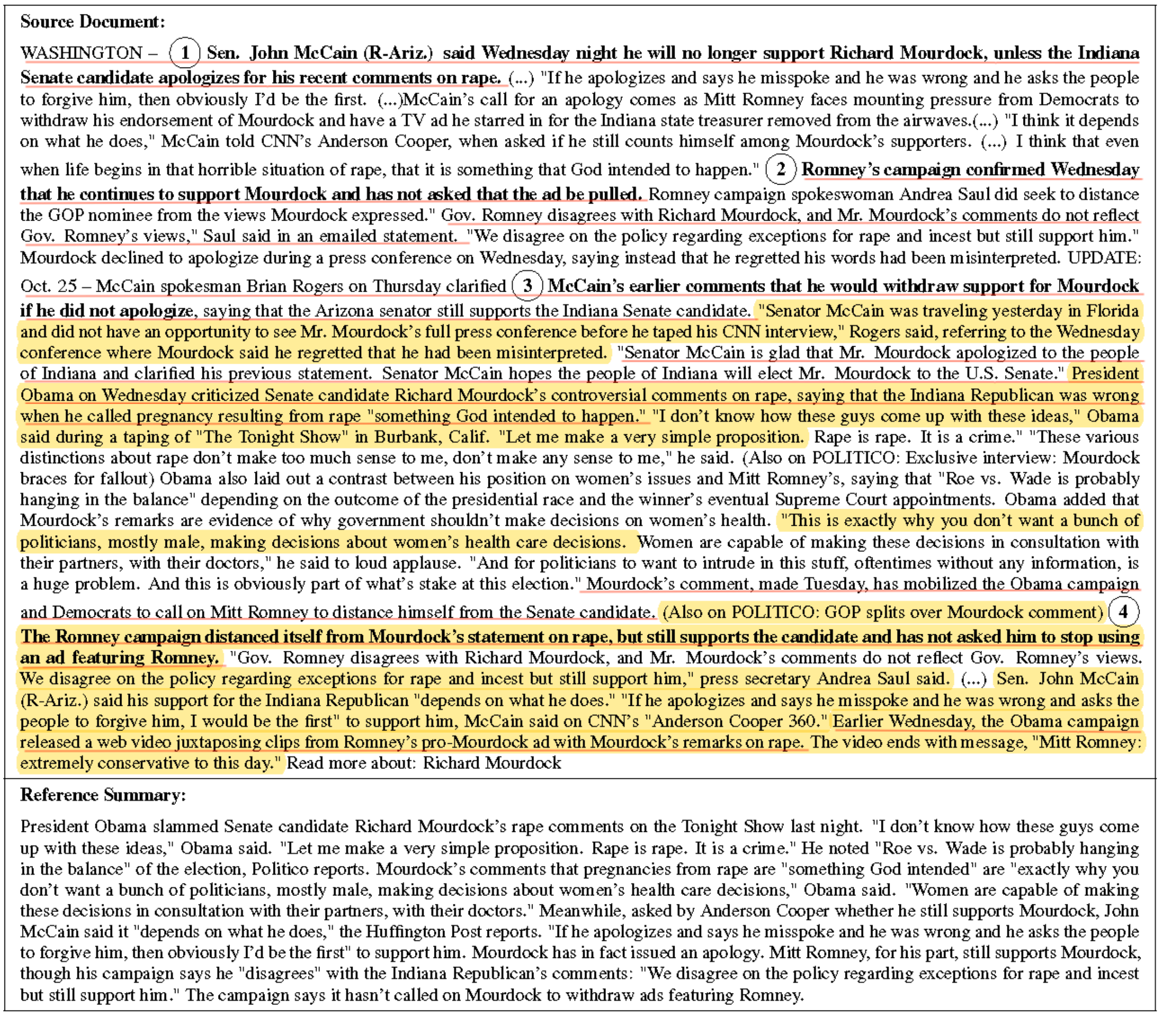
F Generation Samples

Below are the generation samples of OTExtSum and TextRank. In general, OTExtSum based summary contains less redundant content and provides higher semantic coverage with the same number of extracted sentences.



Source Document:

WASHINGTON – ① **Sen. John McCain (R-Ariz.) said Wednesday night he will no longer support Richard Mourdock, unless the Indiana Senate candidate apologizes for his recent comments on rape.** (...) "If he apologizes and says he misspoke and he was wrong and he asks the people to forgive him, then obviously I'd be the first. (...)McCain's call for an apology comes as Mitt Romney faces mounting pressure from Democrats to withdraw his endorsement of Mourdock and have a TV ad he starred in for the Indiana state treasurer removed from the airwaves.(...) "I think it depends on what he does," McCain told CNN's Anderson Cooper, when asked if he still counts himself among Mourdock's supporters. (...) I think that even when life begins in that horrible situation of rape, that it is something that God intended to happen." ② **Romney's campaign confirmed Wednesday that he continues to support Mourdock and has not asked that the ad be pulled.** Romney campaign spokeswoman Andrea Saul did seek to distance the GOP nominee from the views Mourdock expressed." Gov. Romney disagrees with Richard Mourdock, and Mr. Mourdock's comments do not reflect Gov. Romney's views," Saul said in an emailed statement. "We disagree on the policy regarding exceptions for rape and incest but still support him." Mourdock declined to apologize during a press conference on Wednesday, saying instead that he regretted his words had been misinterpreted. UPDATE: Oct. 25 – McCain spokesman Brian Rogers on Thursday clarified ③ **McCain's earlier comments that he would withdraw support for Mourdock if he did not apologize**, saying that the Arizona senator still supports the Indiana Senate candidate. "Senator McCain was traveling yesterday in Florida and did not have an opportunity to see Mr. Mourdock's full press conference before he taped his CNN interview," Rogers said, referring to the Wednesday conference where Mourdock said he regretted that he had been misinterpreted. "Senator McCain is glad that Mr. Mourdock apologized to the people of Indiana and clarified his previous statement. Senator McCain hopes the people of Indiana will elect Mr. Mourdock to the U.S. Senate." President Obama on Wednesday criticized Senate candidate Richard Mourdock's controversial comments on rape, saying that the Indiana Republican was wrong when he called pregnancy resulting from rape "something God intended to happen." "I don't know how these guys come up with these ideas," Obama said during a taping of "The Tonight Show" in Burbank, Calif. "Let me make a very simple proposition. Rape is rape. It is a crime." "These various distinctions about rape don't make too much sense to me, don't make any sense to me," he said. (Also on POLITICO: Exclusive interview: Mourdock braces for fallout) Obama also laid out a contrast between his position on women's issues and Mitt Romney's, saying that "Roe vs. Wade is probably hanging in the balance" depending on the outcome of the presidential race and the winner's eventual Supreme Court appointments. Obama added that Mourdock's remarks are evidence of why government shouldn't make decisions on women's health. "This is exactly why you don't want a bunch of politicians, mostly male, making decisions about women's health care decisions. Women are capable of making these decisions in consultation with their partners, with their doctors," he said to loud applause. "And for politicians to want to intrude in this stuff, oftentimes without any information, is a huge problem. And this is obviously part of what's stake at this election." Mourdock's comment, made Tuesday, has mobilized the Obama campaign and Democrats to call on Mitt Romney to distance himself from the Senate candidate. (Also on POLITICO: GOP splits over Mourdock comment) ④ **The Romney campaign distanced itself from Mourdock's statement on rape, but still supports the candidate and has not asked him to stop using an ad featuring Romney.** "Gov. Romney disagrees with Richard Mourdock, and Mr. Mourdock's comments do not reflect Gov. Romney's views. We disagree on the policy regarding exceptions for rape and incest but still support him," press secretary Andrea Saul said. (...) Sen. John McCain (R-Ariz.) said his support for the Indiana Republican "depends on what he does." "If he apologizes and says he misspoke and he was wrong and asks the people to forgive him, I would be the first" to support him, McCain said on CNN's "Anderson Cooper 360." Earlier Wednesday, the Obama campaign released a web video juxtaposing clips from Romney's pro-Mourdock ad with Mourdock's remarks on rape. The video ends with message, "Mitt Romney: extremely conservative to this day." Read more about: Richard Mourdock

Reference Summary:

President Obama slammed Senate candidate Richard Mourdock's rape comments on the Tonight Show last night. "I don't know how these guys come up with these ideas," Obama said. "Let me make a very simple proposition. Rape is rape. It is a crime." He noted "Roe vs. Wade is probably hanging in the balance" of the election, Politico reports. Mourdock's comments that pregnancies from rape are "something God intended" are "exactly why you don't want a bunch of politicians, mostly male, making decisions about women's health care decisions," Obama said. "Women are capable of making these decisions in consultation with their partners, with their doctors." Meanwhile, asked by Anderson Cooper whether he still supports Mourdock, John McCain said it "depends on what he does," the Huffington Post reports. "If he apologizes and says he misspoke and he was wrong and he asks the people to forgive him, then obviously I'd be the first" to support him. Mourdock has in fact issued an apology. Mitt Romney, for his part, still supports Mourdock, though his campaign says he "disagrees" with the Indiana Republican's comments: "We disagree on the policy regarding exceptions for rape and incest but still support him." The campaign says it hasn't called on Mourdock to withdraw ads featuring Romney.

Figure 3: A sample summary comparison on the **Multi-News** dataset. OTExtSum based summary sentences are highlighted in yellow colour. TextRank based summary sentences are underlined in red colour. TextRank extracted redundant contents, specifically the part ① is duplicated with the part ③, and the part ② is duplicated with the part ④. The summary generated by OTExtSum has ROUGE-1 F-Score of 65.21 and Semantic Coverage Score of 0.93, while the summary generated by TextRank has ROUGE-1 F-Score of 44.87 and Semantic Coverage Score of 0.89. Semantic Coverage Score of the ground-truth summary is 0.89.

Abstract

Softmax is the de facto standard for normalizing logits in modern neural networks for language processing. However, by producing a dense probability distribution each token in the vocabulary has a nonzero chance of being selected at each generation step, leading to a variety of reported problems in text generation. α-entmax of Peters et al. (2019) solves this problem, but is unfortunately slower than softmax.

In this paper, we propose an alternative to α-entmax, which keeps its virtuous characteristics, but is as fast as optimized softmax and achieves on par or better performance in machine translation task.

1 Introduction

Sparseness of vector representations is a desirable trait in neural network models for natural language processing (NLP): words (subwords) are discrete objects by their nature, and, accordingly, are encoded by one-hot embeddings at the input and output of neural networks. However, to predict a categorical response in neural models, softmax is most often used, which produces a *dense* probability distribution, i.e. every category (word/subword) receives a non-zero probability.

Recent studies suggest that it is this output density that poses problems when the trained NLP model is used for inference. For example, in the case of text generation, unconstrained sampling from a trained language model results in poor quality of the resulting text (Holtzman et al., 2020). In neural machine translation (NMT), exact decoding from a trained model often results in empty text (Stahlberg and Byrne, 2019).[1] To get around these problems, constrained decoding techniques have been proposed, most of which artificially impose sparsity on softmax prediction. For example, Fan et al. (2018) propose to sample from the top-k probable words, and Holtzman et al. (2020) propose to sample from the most probable words, which comprise the cumulative probability p. While these methods are effective, they are ad-hoc solutions that lead to a mismatch between how the model is trained and how it is used at inference.

In this regard, the works on sparse alternatives to softmax stand apart since they allow us to make inference from the model in the same way than it was trained. Some of the most successful and elegant solutions are sparsemax (Martins and Astudillo, 2016) and its generalization α-entmax (Peters et al., 2019). When coupled with suitable losses, these transformations are not inferior to softmax, and sometimes even surpass it as measured with final performance metrics on a number of tasks. A problem with these transformations however is that they are significantly slower than softmax when the number of categories (vocabulary size) is tens of thousands, as in the case of text generation. This is because α-entmax transformation—in its original formulation—requires sorting over the logits.[2]

In this work, we ask the question: *is it possible to obtain a sparse output like that of α-entmax, but without its degradation in computational speed?* Our answer is affirmative—we propose a sparse output transformation that

- is on par or superior to softmax and α-entmax in the NMT tasks,
- works as fast as softmax during training and at inference,
- gives the same training dynamics as α-entmax (in training steps).

The most surprising thing is that such a transformation is simply a shifted ReLU raised to power $\frac{1}{\alpha-1}$, which we call **α-ReLU**.

---

[1] The authors called this phenomenon the *cat got your tongue* problem.

[2] We also compare against an approximate version which only performs sorting on the highest values of the logits.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1142 - 1158
July 10-15, 2022

The rest of the paper is organised as follows. In Sect. 2 we motivate the choice of α-ReLU as the output transformation, and also select an appropriate loss function. In Sect. 3 we experimentally confirm our claims about performance and output speed of α-ReLU in the NMT task. Sect. 4 is devoted to a comparative analysis of α-ReLU and α-entmax in terms of sparsity, ability to solve the empty translation problem, and training dynamics.

2 α-ReLU at Output

Our departure point is the α-entmax transformation of Peters et al. (2019) which can be defined for $\mathbf{z} \in \mathbb{R}^d$ as

$$\alpha\text{-entmax}_i(\mathbf{z}) = [(\alpha-1)z_i - \tau(\mathbf{z})]_+^{\frac{1}{\alpha-1}}, \qquad (1)$$

where $[x]_+ := \max\{x, 0\}$, and $\tau : \mathbb{R}^d \to \mathbb{R}$ is the (unique) function that satisfies $\sum_j [(\alpha-1)z_j - \tau(\mathbf{z})]_+^{\frac{1}{\alpha-1}} = 1$ for any $\mathbf{z}$. It is this threshold τ that makes the computation of α-entmax slow, because one needs to sort the components of $\mathbf{z}$ to find τ (Peters et al., 2019, Alg. 2).

As we can see, the threshold τ is only needed to ensure that $\alpha\text{-entmax}(\mathbf{z})$ is a *probability* distribution. We loosen this constraint, and only require *non-negative* weights, which is sufficient for most uses. Consider then a transformation

$$\alpha\text{-ReLU}_i(\mathbf{z}) := [(\alpha-1)z_i - \tau]_+^{\frac{1}{\alpha-1}}, \qquad (2)$$

where τ is a *constant* that does not depend on $\mathbf{z}$. In order to force $\alpha\text{-ReLU}(\mathbf{z})$—applied to the logits $\mathbf{z}$—to converge to the one-hot vector $\mathbf{e}_y$ of the gold label y we need to adjust the corresponding loss. This can easily be done by feeding the logits $\mathbf{z}$ and the output $\alpha\text{-ReLU}(\mathbf{z})$ into the following loss, which we call **α-ReLU loss**.

$$\ell(\mathbf{z}, y) = (\alpha\text{-ReLU}(\mathbf{z}) - \mathbf{e}_y)^\top \left(\mathbf{z} - \tfrac{\tau}{\alpha-1}\mathbf{1}\right) + \mathrm{H}_\alpha[\alpha\text{-ReLU}(\mathbf{z})], \qquad (3)$$

where $\mathrm{H}_\alpha[\mathbf{p}] := \frac{1}{\alpha(\alpha-1)}\left(1 - \sum_j p_j^\alpha\right)$, $\alpha \neq 1$, is the Tsallis α-entropy (Tsallis, 1988), and $\mathbf{1} := (1, \dots, 1) \in \mathbb{R}^d$ is a vector of ones. The rationale for coupling α-ReLU with the loss (3) is the following

Lemma 1. *For any $\tau \in \mathbb{R}$, the gradient of the α-ReLU loss (3) is given by*

$$\nabla_{\mathbf{z}} \ell(\mathbf{z}, y) = \alpha\text{-ReLU}(\mathbf{z}) - \mathbf{e}_y.$$

Proof. The proof is in Appendix B.1. □

By Lemma 1, gradient-based minimization of ℓ indeed forces $\alpha\text{-ReLU}(\mathbf{z}) \to \mathbf{e}_y$. Notice that this is similar to what happens when the softmax normalization is coupled with the cross-entropy loss or when α-entmax is coupled with the entmax loss. In both cases differentiating the loss with respect to logits gives $\mathbf{p} - \mathbf{e}_y$, where $\mathbf{p}$ is either $\mathrm{softmax}(\mathbf{z})$ or $\alpha\text{-entmax}(\mathbf{z})$ (Martins and Astudillo, 2016; Peters et al., 2019).

Remark. Recall that α-entmax is a generalization of sparsemax. For example, 2-entmax is essentially sparsemax, and for $\alpha \in (1, 2)$ we get a smoothed version of sparsemax. Similarly, α-ReLU is a kind of generalization of ReLU. So, the standard ReLU is 2-ReLU (with $\tau = 0$), and for $\alpha \in (1, 2)$ we get a smoothed ReLU (see Fig. 1).

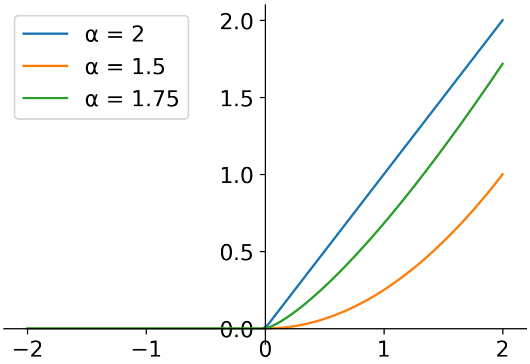

Figure 1: The graph of $\alpha\text{-ReLU}(x)$ for several $\alpha \in (1, 2]$, with $\tau = 0$. 2-ReLU is a standard $\mathrm{ReLU}(x) := [x]_+$.

3 Experiments

In theory, nothing prevents α-ReLU from learning what α-entmax is learning. However, in practice we can have a different picture, because training is conditioned by many factors—the size of the dataset, the architecture of the neural network, the optimization algorithm, etc. In this section, we compare α-ReLU empirically with α-entmax (as well as with sparsemax and softmax), assuming all other factors are fixed. The goal of these experiments is to evaluate the consequences of using α-ReLU as drop-in replacement for α-entmax.

We test α-ReLU at output in a neural machine translation task (Sutskever et al., 2014), which is essentially a conditional text generation task. Compared to open-ended text generation, there is a

Output Transform	Loss	IWSLT De→En	WMT En→De	WMT En→Ru
softmax	cross-entropy	35.3	**28.7**	22.4

Table 1: NMT results: comparison of softmax, sparsemax, 1.5-Entmax and the proposed 1.5-ReLU as the output transformations in the Transformer NMT model. Reported is detokenized test BLEU.

clearer metric of the quality of the generated text—the BLEU score (Papineni et al., 2002). As in open-ended text generation, at each prediction step, the NMT system needs to make a choice from all words (subwords) of the vocabulary, the size of which can reach several tens of thousands. Therefore, the sparsity of the output distribution becomes critical in such setups, since it can explicitly prevent the occurrence of most of the words that are inappropriate in the context.

3.1 Setup

Data. We conduct experiments on three datasets of varied sizes:

- IWSLT'14 De→En (Cettolo et al.), 172K training examples,
- WMT'14 En→De (Bojar et al., 2014), 4.5M training examples,
- WMT'13 En→Ru (Bojar et al., 2013), 1.3M tranining examples.[3]

We preprocess all datasets using the byte pair encoding algorithm (Sennrich et al., 2016) with 10K merge operations on IWSLT, 40K merge operations on WMT En→De, and 60K merge operations on WMT En→Ru. We report detokenized case-sensitive BLEU with SacreBLEU (Post, 2018).[4]

Hyperparameters α and τ. In all experiments we set $\alpha = 1.5$, because this value was recommended by Peters et al. (2019); Peters and Martins (2021) as the middle ground between $\alpha = 1$ (softmax) and $\alpha = 2$ (sparsemax).

The value for τ is chosen as follows: we run the first batch through a non-trained neural network, which has 1.5-entmax at the output, in the forward direction and determine the average τ value across the batch. This value is then used to train the 1.5-ReLU network. Our preliminary experiments have shown that 1.5-ReLU convergence is sensitive to the τ value, and that having output close to the probability distribution early in the learning phase works well with the rest of hyperparameters which are set to their default values.

Training. We trained the Transformer Base (Vaswani et al., 2017) using the OpenNMT-py 2.0 toolkit (Klein et al., 2017). Optimization details are in Appendix A.

3.2 Results

The results are given in Table 1. Reported are test BLEU scores for best checkpoints which are selected based on validation BLEU. We observe that the 1.5-ReLU performs on par with 1.5-entmax or better, while sparsemax is inferior to all others.

Training Time. Fig. 2&3 show the training dynamics in training steps and in wall time on WMT'14 En→De. Despite the closeness of performance in intermediate steps and at the end of training, we see that on the larger datasets 1.5-entmax is slower in wall time than softmax and 1.5-ReLU.

To speed up the learning process, Peters et al. (2019) recommended limiting the number of sorted logits in the α-entmax to the k largest logits. We tried this using $k = 100$, which is the default value in the author's implementation of α-entmax.[5] The resulting training dynamics are shown as dashed curves in Fig. 2&3. As we can see, partial sorting indeed speeds up the learning process, and at the same time does not harm the quality of the translation compared to α-entmax with full sorting. But in the end, learning is still slower than in the case

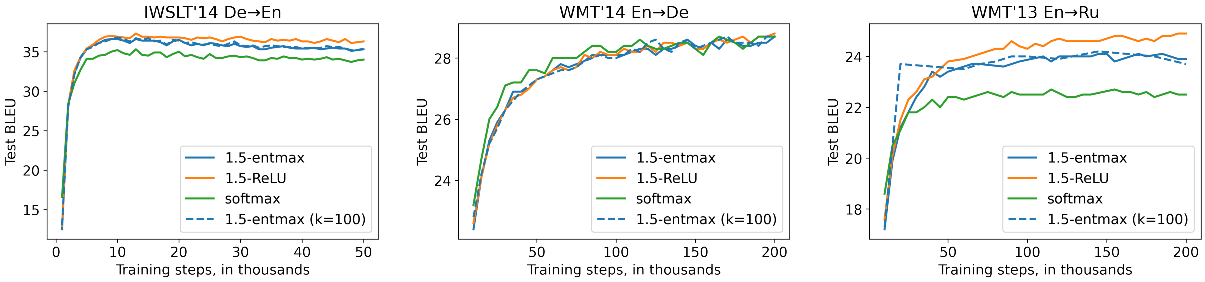

Figure 2: Training dynamics in training steps.

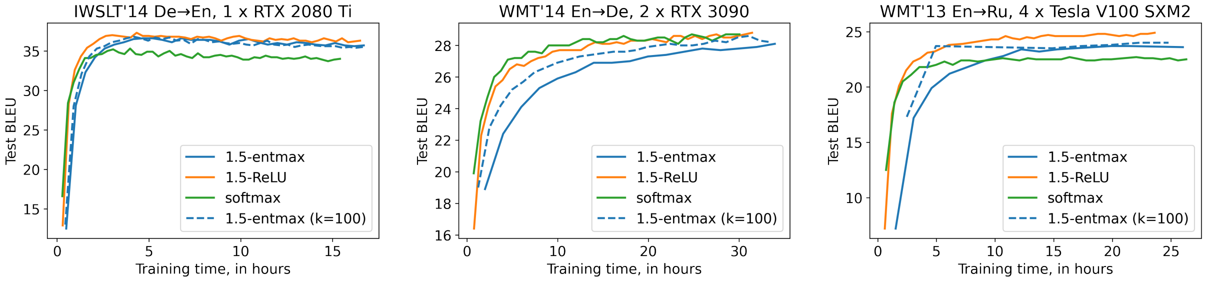

Figure 3: Training dynamics in absolute time. *1.5-entmax (k=100)* is a variant of 1.5-entmax in which sorting is performed only for the largest $k = 100$ logits.

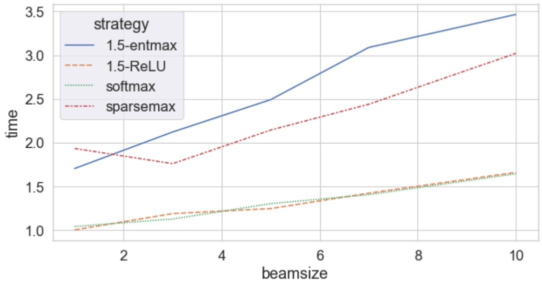

Figure 4: Normalized inference for WMT En→Ru with different beam sizes.

of 1.5-ReLU. Of course, one can try to select such k that the speed of calculating the 1.5-entmax will be as close as possible to the speed of 1.5-ReLU without losing quality, but this requires additional efforts on the part of the user, and this must be done for each case separately. Also note that both 1.5-entmaxes (with full and partial sorting) cannot learn the English-Russian data set as well as 1.5-ReLU.

In this regard, 1.5-ReLU does not require additional fine-tuning, converges as fast as softmax in absolute time and performs on par or better. Thus 1.5-ReLU combines all three desired properties: computation speed, task performance, and sparsity of output.

Inference Time. We measured inference time of translating the WMT En→Ru test data with the different strategies and with different beam sizes. The results—normalized by the smallest value—are shown in Fig. 4. As can be seen the relative difference seems independent of the beam size: softmax is almost twice faster than 1.5-entmax (with full sorting over the logits). Even though the softmax version is optimized through the softmax CUDA kernel, it performs equivalent to the 1.5-ReLU model in terms of computation speed.

4 Analysis

4.1 Empty Translations

We remind the reader that the *cat got your tongue* problem (Stahlberg and Byrne, 2019) is one of the main motivations for using sparse transformations when generating text. As Peters and Martins (2021) have shown, 1.5-entmax successfully tackles this problem by significantly lowering the proportion of cases where an empty string is more likely than the beam search hypothesis. For 1.5-ReLU, we also calculated this proportion, and compared it with the proportions for softmax and sparsemax (Table 2). As we see, 1.5-ReLU also successfully tackles the *cat got your tongue* problem.

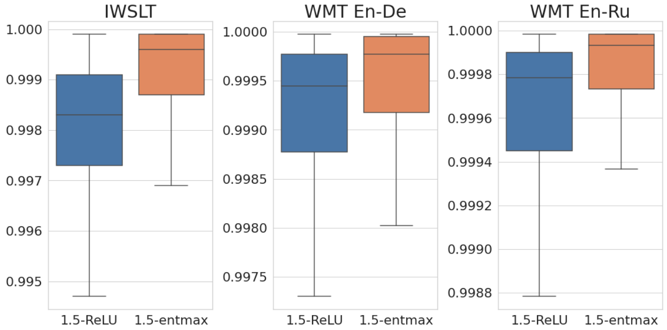

Figure 5: Sparsity as proportion of zero components after applying 1.5-ReLU and 1.5-entmax, test sets.

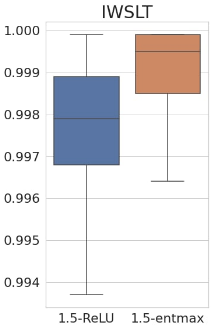

Figure 6: Sparsity on training set.

Output Transform	IWSLT De→En	WMT En→De	WMT En→Ru
softmax	7.5%	29.8%	31.7%
sparsemax	0%	0.03%	0%
1.5-entmax	0%	0.2%	0%
1.5-ReLU	0%	0.3%	0.1%

Table 2: Percentage of development set examples for which the model assigns higher probability to the empty string than to the beam-decoded hypothesis.

4.2 Sparsity

To compare the sparsity of 1.5-ReLU and 1.5-entmax we depict in Fig. 5 the distributions of the number of zero components after applying these transformations (recall that for softmax all components are always nonzero). Since we constructed the α-ReLU in such way that it mimics the α-entmax (at least in the early stages of training), we expected that these two transformations would have similar properties, including sparsity. However, this is not the case: as we can see, the 1.5-ReLU is significantly less sparse than the 1.5-entmax. It is noteworthy that lower sparsity in this case correlates with a better performance in the translation task (see Table 1).

A possible explanation for the difference in sparsity levels could be that α-ReLU, in contrast to α-entmax, behaves significantly differently on the test set than on the training set. However, this is not the case: for example, comparing the sparsity on the IWSLT training set (Fig. 6), we see that the distributions of non-zero components are almost the same as on the test set for 1.5-ReLU and 1.5-entmax.

Note that the sparsity of α-ReLU and α-entmax is approximately the same at the beginning of training due to how we initialize τ in 1.5-ReLU (making it as close as possible to 1.5-entmax's τ in the untrained model, Sec. 3.1). However, during training, α-ReLU's τ remains *fixed*, and the model can only adapt the logits themselves so that $\alpha\text{-ReLU}(\mathbf{z})$ converges to the corresponding one-hot vector. At the same time, in $\alpha\text{-entmax}$, $\tau(\mathbf{z})$ adapts *together* with logits $\mathbf{z}$. We hypothesize that during training, the entmax's $\tau(\mathbf{z})$ gradually increases which entails greater sparsity by the end of the training. However, the logits themselves also change during training, so the increase in τ may not be the cause of greater sparsity. To find out, we track the dynamics of mean logit norm $\|\mathbf{z}\|$ and mean τ during training for both 1.5-entmax and 1.5-ReLU (Fig. 7). As we can see, the logit sizes grow in both cases.

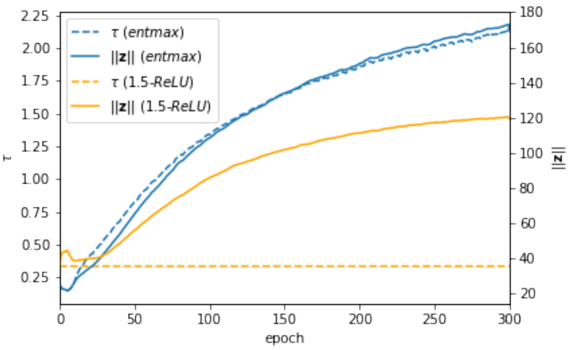

Figure 7: Evolution of the mean $\tau(\mathbf{z})$ and $\|\mathbf{z}\|$ during training for 1.5-entmax and 1.5-ReLU models on IWSLT'14 En→De.

At the same time, the 1.5-entmax's $\tau(\mathbf{z})$ increases following the logit size, while the 1.5-ReLU's τ remains constant. From this we conclude that the sparsity of 1.5-entmax is inevitably less than the sparsity of 1.5-ReLU.

4.3 Impact of τ

The selection of τ was described in Section 3.1. However, the question arises: does the described approach lead to the choice of the *optimal* τ? To find out, we trained the α-ReLU models for $\tau \in \{0, 0.1, 0.2, ..., 0.9, 1, 2, 5, 10\}$ on the IWSLT data. Note that all of these τ's have led to almost the same result at the end of the training (as predicted by Lemma 1). In Fig. 8, we present the dynamics of early training only for $\tau \in \{0, 0.1, 0.2, 0.3, 5, 10\}$, since the curves for $\tau \in \{0.4, ..., 0.9, 1, 2\}$ practically coincided with the optimal curve corresponding to $\tau = 0.3$. Note that our τ selection method gave a value of 0.33, thus we have no evidence against the adequacy of our method.

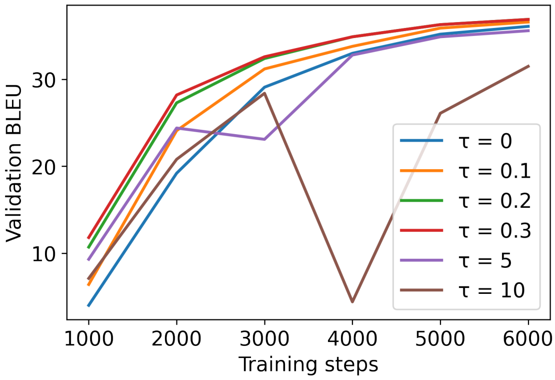

Figure 8: Impact of τ on training dynamics, IWSLT'14 En→De.

4.4 Estimation of τ without data

On closer inspection, we noticed that the pre-entmax logits in the *untrained* Transformer model are distributed according to the normal law, regardless of what data is supplied to the input, Shapiro-Wilk test, p-value > 0.15. This allows us, using asymptotic theory, to estimate τ as

$$\hat{\tau} = \sqrt{\frac{d_{\text{model}}}{2(d_{\text{model}} + d_{\text{vocab}})}} \cdot \Phi^{-1}(1 - p^*), \quad (4)$$

where d_{model} is the size of hidden representations, d_{vocab} is the vocabulary size for a target language, $\Phi^{-1}(\cdot)$ is the probit function and p^* is the solution of a non-linear equation that involves functions related to the standard normal distribution (see Appendix B.2 for details). Table 3 compares the $\tilde{\tau}$ calculated by running data through an untrained model with the estimate $\hat{\tau}$ obtained from (4). As we can see, $\hat{\tau}$ practically coincides with $\tilde{\tau}$ with an accuracy of two decimal places. Unfortunately, the formula (4) is not universal: it is only true for the Transformer architecture.

	IWSLT'14 De→En	WMT'14 En→De	WMT'13 En→Ru
d_{model}	512	512	512
d_{vocab}	10,000	40,000	60,000
p^*	.0184	.0171	.0169
$\tilde{\tau}$	.33	.17	.14
$\hat{\tau}$	.33	.17	.14

Table 3: Estimating threshold of 1.5-entmax: $\tilde{\tau}$ is a value obtained by running a data through an untrained model; $\hat{\tau}$ is an estimate based on asymptotic theory, i.e. without running the data through the model.

4.5 Self-normalization

The attentive reader may have noticed that the output of α-ReLU is not normalized, i.e. the components of $\alpha\text{-ReLU}(\mathbf{z})$ do not have to sum up to 1. Accordingly, the question arises: how correct is it to compare translation scores at different steps of the beam-search decoding if the conditional probabilities are not normalized? However, the comparison is possible if the $\alpha\text{-ReLU}(\mathbf{z})$ components add up to approximately the same number, i.e. if the model is self-normalizing. To check this, we ran the trained α-ReLU model on the IWSLT and WMT'14 test sets, and looked at the distribution of $\sum_i \alpha\text{-ReLU}_i(\mathbf{z})$ at each decoding step. The results are shown in Fig. 9. As we can see, the sum of the $\alpha\text{-ReLU}(\mathbf{z})$ components concentrates well around its mean ≈ 1.24 (IWSLT) and 1.09 (WMT'14), which might indicate that the model indeed has a self-normalization property.

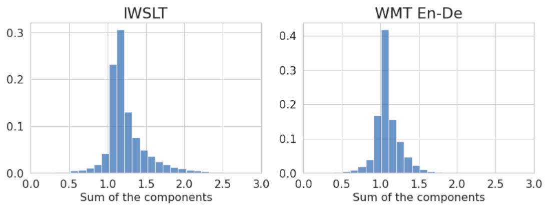

Figure 9: Distribution of the sum of $\alpha\text{-ReLU}(\mathbf{z})$ components across the IWSLT'14 and WMT'14 test sets: α-ReLU self-normalizes.

4.6 Training Dynamics

As we noted in Sect. 3.2, the training dynamics are similar in all three cases (softmax, 1.5-

entmax, 1.5-ReLU) when time is measured in training steps. Here we attempt to explain this phenomenon through the recently proposed Neural Tangent Kernel (NTK) approach of Jacot et al. (2018). Roughly speaking, the NTK theory suggests that a sufficiently wide neural network trains like a kernel regression. We use this theory to show (in Appendix B.3) that in all three cases the logits $\mathbf{z}(x, t)$ for a training instance x at a training step t evolve (approximately) according to the same differential equation

$$\frac{d\mathbf{z}}{dt} = -\mathbb{E}_{(x',y')}[\mathbf{K}_\sigma(x, x') \cdot (\sigma(\mathbf{z}') - \mathbf{e}_{y'})], \quad (5)$$

where expectation is over training examples (x', y'), $\sigma(\cdot)$ is one of the transformations considered (softmax, α-entmax, or α-ReLU), and $\mathbf{K}_\sigma(x, x') \in \mathbb{R}^{d \times d}$ is a positive semi-definite matrix that depends on σ. The Equation (5) is a non-linear matrix differential equation which in general cannot be solved analytically. However, it has an equilibrium point $\mathbf{z}(x, t)$ such that $\mathbb{E}_{(x',y')}[\mathbf{K}_\sigma(x, x') \cdot (\sigma(\mathbf{z}') - \mathbf{e}_{y'})] = \mathbf{0}$, thus its solution converges to this point as $t \to \infty$. This similarity in the evolution of $\sigma(\mathbf{z})$ implies the similarity in the evolution of the perfomance metric—such as BLEU—across all three transformations.

4.7 Human Evaluation

Although the BLEU metric (Papineni et al., 2002) has stood the test of time, it is still an automated assessment of translation quality. To double-check the reliability of the results from Table 1, we decided to manually evaluate the translations from the WMT'13 En→Ru test split. To do this, we followed the human evaluation setup from (Berard et al., 2019). We formed two random samples of 135 instances each and gave them to two annotators. 45 instances were shared across two samples in order to calculate inter-annotator agreement. Each instance consists of an original sentence in English and 4 candidate translations into Russian (reference, softmax, entmax, α-ReLU). The annotators were to rate each translation on a 4-point scale. For annotation instructions, see Appendix C.

The order of candidate translations was shuffled for each instance, so the annotators did not know which sentence is from which model. Nevertheless, the annotator always had a good chance of guessing which translation was the reference one, due to the large difference in quality between human and machine translation.

Model	Avg. Score	Std. Dev.
Reference	3.9	0.30
Softmax	3.3	0.75
1.5-entmax	3.2	0.74
1.5-ReLU	3.3	0.74

Table 4: Results of Human Evaluation across 270 random examples (with repetitions) from WMT'13 En→Ru test split. Scores are on a 4-point scale.

The results of human evaluation are shown in Table 4. Cohen's $\kappa = 0.56$, indicating moderate agreement between annotators. As we can see, all three models give approximately the same translation quality, and all three are significantly inferior to the reference translation. This is generally consistent with the results of 1.5-ReLU and 1.5-entmax in Table 1, but at the same time casts doubt on the softmax lag behind 1.5-ReLU and 1.5-entmax as the BLEU metric suggests.

In Appendix D we give a few examples where 1.5-ReLU translates better than 1.5-entmax and vice versa.

5 Related Work

Sparse seq2seq models. Our proposed α-ReLU transformation is based on the α-entmax transformation of Peters et al. (2019), which in turn is a generalization of the sparsemax transformation (Martins and Astudillo, 2016). In our work, we study sparseness at the output of a neural network. Nevertheless, there are a number of works aimed at sparsification within a neural network. For example, Malaviya et al. (2018); Peters et al. (2019); Correia et al. (2019) show that sparsemax and α-entmax can replace softmax in the attention mechanism with some success. A recent work of Zhang et al. (2021) attempted to replace softmax with a component-wise ReLU in the attention mechanism. Unfortunately, in its pure form, this replacement leads to the inability of the model to learn at all, since its loss function does not decrease during optimization. The authors solve this problem by adding a normalizing layer on top of the attention layer.

These and other works (Zhang et al., 2019) state that sparsity in the weights of attention produces more interpretable patterns. However, Meister et al. (2021) questioned this claim and were unable to find clear evidence to support it. Therefore, in this work, we focused on the application of α-ReLU to the output of the transformer model, and not to the mechanism of attention, but at the same time we do not deny the possibility of studying the latter.

Self-normalization. Self-normalizing training aims to bypass the need of normalization during inference time. This is done by tweaking the learning mechanism so that the sum of all predictions sums (approximately) to a constant value. Theoretical work on why this works is poorly understood (Andreas et al., 2015) but early work in neural machine translation has shown its empirical value. Vaswani et al. (2013) achieves that by using noise-contrastive estimation (the neural model is used to re-rank the output of a hierarchical phrase-based machine translation system). Noise-contrastive estimation is also the standard training mechanism for word2vec (more popular than the alternative hierarchical softmax), which also eschews any expensive normalization. Differently, Devlin et al. (2014) changes the training loss to include a factor that encourages the normalizing factor to be 1. At inference time, this is just assumed and decoding time is reported to achieve a 15x speed-up.

6 Limitations and Risks

We believe that the main limitations of our work are as follows:

- α-ReLU's output is still not a probability distribution, as required by the classical formulation of a probabilistic classification model.
- τ evaluation requires either running the data through an untrained model with α-entmax at the output, or deriving a formula similar to (4) for each individual architecture.
- Our approach only works for the case when α-ReLU is used at the output of the model, but it is not clear how to use it as an alternative to softmax/α-entmax in the attention layer.

The last mentioned limitation leads to the potential risk of inability to learn if α-ReLU is misused in the intermediate layers of the neural network such as attention layers. The experiments of Zhang et al. (2021) using vanilla ReLU (2-ReLU with $\tau = 0$ in our notation) instead of softmax to produce attention weights lead to a divergence of the loss function of the Transformer model. This translates into a waste of energy, especially when training large models on large datasets. Therefore, we believe that in the future, a preliminary mathematical analysis and/or experiments with small models on small datasets should be carried out as to why the unnormalized distribution of attention weights leads to the inability of the model to learn.

7 Conclusion

It seems that the sparsity of the output is natural for (sub)word prediction models. Nevertheless, sparsity does not have to come with slowdown of computations, as our work shows. The proposed transformation, α-ReLU, gives a sparse output, shows competitive performance, and is as fast as softmax. The reduced dependency on the vocabulary size seems particularly important in translation, where neural models are moving more and more towards multi-lingual ones, which in general have a much higher vocabulary size in order to accommodate enough tokens for all languages.

A natural extension of this work will be the evaluation of α-ReLU in the problem of open-ended text generation, as well as a replacement for softmax in the attention layers of Transformer models.

Our standalone implementation of α-ReLU in PyTorch is available at `https://github.com/MaxatTezekbayev/alpha-relu`.

A Optimization

IWSLT'14 De→En

- Architecture: Transformer, embedding size 512, 6 layers, 8 heads, hidden size 1024, shared vocabulary.
- Batch size: 4096 tokens (with gradient accumulation for 8 steps).
- Optimizer: *ADAM*, $\beta_1 = 0.9$, $\beta_2 = 0.998$, noam decay, learning rate 2.0, 4000 warmup steps.
- Dropout: 0.3
- No label smoothing.

WMT'14 En→De

- Architecture: Transformer, embedding size 512, 6 layers, 8 heads, hidden size 2048, shared vocabulary of 40K tokens, shared embeddings and decoder embeddings.
- Batch size: 4096 tokens (with gradient accumulation for 4 steps).
- Optimizer: *ADAM*, $\beta_1 = 0.9$, $\beta_2 = 0.998$, noam decay, learning rate 2.0, 8000 warmup steps, average decay 0.0005.
- Dropout: 0.1.
- Attention dropout: 0.1.
- No label smoothing.

WMT'13 En→Ru Same as in WMT'14 En→De, except that Dropout is 0.3.

A.1 GPU Power Consumption

Dataset	IWSLT'14 En→De	WMT'14 De→En	WMT'13 En→Ru
GPU(s)	1 × RTX 2080 Ti	2 × RTX 3090	4 × Tesla V100 SXM2
Power consumption, W	250	2×320	4×300
		Training time, hours	
softmax	15.41	30.06	28.43
sparsemax	24.43	73.33	58.82
1.5-entmax	26.11	79.89	61.20
1.5-ReLU	16.50	31.44	24.21
TOTAL hours	82.44	214.72	172.67
TOTAL kW-hours	20.61	137.42	207.20
GRAND TOTAL kW-hours		**365.23**	

Table 5: Power consumed by GPUs for training.

We do not report CO_2 consumption, as experiments were run in different countries, making aggregate statistics difficult to compute. The largest experiment (on WMT'13), were run in France, which benefits from a very low CO_2 emission intensity in its electrical mix.

B Proofs

Notation. We let $\mathbb{R}$ denote the real numbers. Bold-faced lowercase letters ($\mathbf{x}$) denote vectors in Euclidean space, bold-faced uppercase letters ($\mathbf{A}$) denote matrices, plain-faced lowercase letters (x) denote scalars, $\|\cdot\|$ denotes the Euclidean norm: $\|\mathbf{x}\| := \sqrt{\mathbf{x}^\top \mathbf{x}}$. The gradient of $f : \mathbb{R}^d \to \mathbb{R}$ is denoted by ∇f. The Jacobian of $\mathbf{z} \mapsto g(\mathbf{z})$ is denoted by $\mathbf{J}_g(\mathbf{z})$. Also, we denote $\operatorname{ReLU}(x) := [x]_+ := \max\{x, 0\}$, $[d] := \{1, \ldots, d\}$, $\Delta^{d-1} := \{\mathbf{p} \in \mathbb{R}^d \mid \sum_i p_i = 1,\, p_i \geq 0\}$, $\mathbf{e}_y := (0, \ldots, 0, 1, 0, \ldots, 0)$ where 1 is at y^{th} position.

B.1 Proof of Lemma 1.

First, let us calculate the Jacobian of the mapping $\mathbf{z} \mapsto \alpha\text{-ReLU}(\mathbf{z})$. Recall that

$$\alpha\text{-ReLU}_i(\mathbf{z}) := [(\alpha-1)z_i - \tau]_+^{\frac{1}{\alpha-1}}.$$

Therefore, the partial derivatives are given by

$$\begin{aligned}
\frac{\partial[\alpha\text{-ReLU}_i(\mathbf{z})]}{\partial z_i} &= \frac{1}{\alpha-1} \cdot [(\alpha-1)z_i - \tau]_+^{\frac{1}{\alpha-1}-1} \cdot (\alpha-1) = [(\alpha-1)z_i - \tau]_+^{\frac{2-\alpha}{\alpha-1}} \\
&= [\alpha\text{-ReLU}_i(\mathbf{z})]^{2-\alpha}, \\
\frac{\partial[\alpha\text{-ReLU}_i(\mathbf{z})]}{\partial z_j} &= 0. \qquad i \neq j
\end{aligned}$$

Thus, the Jacobian can be written concisely as

$$\mathbf{J}_{\alpha\text{-ReLU}}(\mathbf{z}) = \operatorname{diag}\{[\alpha\text{-ReLU}(\mathbf{z})]^{2-\alpha}\}, \tag{6}$$

where raising to power is done component-wise (i.e. $\mathbf{x}^\beta = [x_1^\beta, \dots, x_d^\beta]$), and $\operatorname{diag}[\mathbf{x}]$ is a diagonal matrix with $\mathbf{x}$ on its diagonal.

Recall the definition of the Tsallis α-entropy:

$$\mathrm{H}_\alpha[\mathbf{p}] := \frac{1}{\alpha(\alpha-1)}\left(1 - \sum_j p_j^\alpha\right).$$

Its gradient w.r.t. $\mathbf{p}$ is

$$\nabla_{\mathbf{p}} \mathrm{H}_\alpha[\mathbf{p}] = -\frac{1}{\alpha-1}\mathbf{p}^{\alpha-1},$$

Combining this with (6), and using the chain rule, we have

$$\begin{aligned}
\nabla_{\mathbf{z}} \mathrm{H}_\alpha[\alpha\text{-ReLU}(\mathbf{z})] &= [\mathbf{J}_{\alpha\text{-ReLU}}(\mathbf{z})]^\top \cdot \left(-\frac{1}{\alpha-1}[\alpha\text{-ReLU}(\mathbf{z})]^{\alpha-1}\right) \\
&= \left[\operatorname{diag}\{[\alpha\text{-ReLU}(\mathbf{z})]^{2-\alpha}\}\right]^\top \cdot \left(-\frac{1}{\alpha-1}[\alpha\text{-ReLU}(\mathbf{z})]^{\alpha-1}\right) \\
&= -\frac{1}{\alpha-1}[\alpha\text{-ReLU}(\mathbf{z})]^{2-\alpha} \odot [\alpha\text{-ReLU}(\mathbf{z})]^{\alpha-1} \\
&= -\frac{1}{\alpha-1}\, \alpha\text{-ReLU}(\mathbf{z}),
\end{aligned} \tag{7}$$

where $\odot$ is the Hadamard product (element-wise multiplication), and we used $\operatorname{diag}[\mathbf{x}] \cdot \mathbf{y} = \mathbf{x} \odot \mathbf{y}$. Taking into account (7), the gradient of the α-ReLU loss (3) w.r.t. $\mathbf{z}$ is

$$\begin{aligned}
\nabla_{\mathbf{z}} \ell(\mathbf{z}, y) &= \nabla_{\mathbf{z}} \left[(\alpha\text{-ReLU}(\mathbf{z}) - \mathbf{e}_y)^\top \left(\mathbf{z} - \frac{\tau}{\alpha-1}\mathbf{1}\right)\right] + \nabla_{\mathbf{z}} \mathrm{H}_\alpha[\alpha\text{-ReLU}(\mathbf{z})] \\
&= (\alpha\text{-ReLU}(\mathbf{z}) - \mathbf{e}_y) + \mathbf{J}_{\alpha\text{-ReLU}(\mathbf{z})}^\top \left(\mathbf{z} - \frac{\tau}{\alpha-1}\mathbf{1}\right) - \frac{1}{\alpha-1}\, \alpha\text{-ReLU}(\mathbf{z}) \\
&= (\alpha\text{-ReLU}(\mathbf{z}) - \mathbf{e}_y) + \frac{1}{\alpha-1}\left[\operatorname{diag}\{[\alpha\text{-ReLU}(\mathbf{z})]^{2-\alpha}\}\right]^\top [(\alpha-1)\mathbf{z} - \tau\mathbf{1}] - \frac{1}{\alpha-1}\, \alpha\text{-ReLU}(\mathbf{z}) \\
&= (\alpha\text{-ReLU}(\mathbf{z}) - \mathbf{e}_y) + \frac{1}{\alpha-1} \underbrace{[(\alpha-1)\mathbf{z} - \tau\mathbf{1}]_+^{\frac{2-\alpha}{\alpha-1}} \odot [(\alpha-1)\mathbf{z} - \tau\mathbf{1}]}_{\alpha\text{-ReLU}(\mathbf{z})} - \frac{1}{\alpha-1}\, \alpha\text{-ReLU}(\mathbf{z}) \\
&= \alpha\text{-ReLU}(\mathbf{z}) - \mathbf{e}_y,
\end{aligned}$$

where in the fourth line we used $[\mathbf{x}]_+^\beta \odot \mathbf{x} = [\mathbf{x}]_+^\beta \odot [\mathbf{x}]_+ = [\mathbf{x}]_+^{\beta+1}$. This concludes the proof.

B.2 Approximation of τ for 1.5-entmax

We derive the formula (4) in two steps: first in Lemma 2, we approximate $\tau(\mathbf{z})$ of 1.5-entmax when $\mathbf{z}$ is an arbitrary random sample from the normal distribution with zero mean and variance σ^2; next in Lemma 3, we compute σ^2 for the case when $\mathbf{z}$ is the pre-softmax vector of logits in the Transformer model.

Lemma 2. *Let $z_1, \ldots, z_d$ be independent and identically distributed random variables from the normal distribution $\mathcal{N}(0, \sigma^2)$. Then the thresholding function of* $1.5\text{-entmax}(\mathbf{z})$ *can be approximated as*

$$\tau(\mathbf{z}) \approx \frac{\sigma}{2}\Phi^{-1}(1 - p^*),$$

where $\Phi^{-1}(\cdot)$ is a probit function, and p^* is the solution of

$$\Phi^{-1}(1-p) = m(p) - \sqrt{\frac{4}{\sigma^2} \cdot \frac{\epsilon}{p} - s(p)}$$

with

$$m(p) := \frac{1}{p-\epsilon}\left[\phi(\Phi^{-1}(x)\right]_{x=\epsilon}^{x=p} \tag{8}$$

$$s(p) := \frac{1}{p-\epsilon}\left[-\phi(\Phi^{-1}(x)) \cdot \Phi^{-1}(x) + x\right]_{x=\epsilon}^{x=p} - [m(p)]^2 \tag{9}$$

$$\phi(t) := \frac{1}{\sqrt{2\pi}}e^{-\frac{t^2}{2}}$$

$$\epsilon := \frac{1}{d}$$

Proof. Let $z_{(1)} \geq \ldots \geq z_{(d)}$ be a sorting of $z_1, \ldots, z_d$ in descending order. Peters et al. (2019) showed that

$$\tau(\mathbf{z}) = \frac{M(k)}{2} - \sqrt{\frac{1}{k} - \frac{S(k)}{4}}, \tag{10}$$

where $k \in [d]$ is any index that satisfies

$$\frac{z_{(k)}}{2} \geq \frac{M(k)}{2} - \sqrt{\frac{1}{k} - \frac{S(k)}{4}} \geq \frac{z_{(k+1)}}{2} \quad \Leftrightarrow \quad z_{(k)} \geq M(k) - \sqrt{\frac{4}{k} - S(k)} \geq z_{(k+1)} \tag{11}$$

with

$$M(k) := \frac{1}{k}\sum_{i=1}^{k} z_{(i)}, \qquad S(k) := \frac{1}{k}\sum_{i=1}^{k} z_{(i)}^2 - [M(k)]^2.$$

Approximating $z_{(i)}$ by its asymptotic mean $\sigma\Phi^{-1}\left(1 - \frac{i}{d}\right)$ (Arnold et al., 2008), and denoting $\epsilon := \frac{1}{d}$, $p := \frac{k}{d}$, we have

$$M(k) \approx \frac{1}{k}\sum_{i=1}^{k}\sigma\Phi^{-1}\left(1 - \frac{i}{d}\right) \approx \frac{\sigma}{p-\epsilon}\int_{\epsilon}^{p}\Phi^{-1}(1-x)dx = \frac{\sigma}{p-\epsilon}\int_{\epsilon}^{p} -\Phi^{-1}(x)dx$$
$$= \frac{\sigma}{p-\epsilon}\left[\phi(\Phi^{-1}(x))\right]_{x=\epsilon}^{x=p} = \sigma m(p),$$

where we approximated the average of finitely many numbers $\{\Phi^{-1}(1-i/d)\}_{i=1}^{k}$ by the mean value of the function $\Phi^{-1}(1-x)$, and then we used the fact that $-\phi(\Phi^{-1}(x))$ is an antiderivative for the probit function $\Phi^{-1}(x)$; and $m(p)$ is defined by (8).

Similarly, for the second empirical moment, we have

$$\frac{1}{k}\sum_{i=1}^{k} z_i^2 \approx \frac{1}{k}\sum_{i=1}^{k}\left[\sigma\Phi^{-1}\left(1 - \frac{i}{d}\right)\right]^2 \approx \frac{\sigma^2}{p-\epsilon}\int_{\epsilon}^{p}[\Phi^{-1}(1-x)]^2dx = \frac{\sigma^2}{p-\epsilon}\int_{\epsilon}^{p}[\Phi^{-1}(x)]^2dx$$
$$= \frac{\sigma^2}{p-\epsilon}\left[-\phi(\Phi^{-1}(x)) \cdot \Phi^{-1}(x) + x\right]_{x=\epsilon}^{x=p},$$

and thus

$$S(k) \approx \frac{\sigma^2}{p-\epsilon}\left[-\phi(\Phi^{-1}(x))\cdot\Phi^{-1}(x)+x\right]_{x=\epsilon}^{x=p} - [m(p)]^2 = \sigma^2 s(p),$$

where $s(p)$ is defined by (9). Hence, finding $k \in [d]$ that satisfies (11) is (approximately) equivalent to finding $p \in (0,1)$ that satisfies

$$\sigma\Phi^{-1}(1-p) = \sigma m(p) - \sqrt{4\cdot\frac{\epsilon}{p} - \sigma^2 s(p)} \quad \Leftrightarrow \quad \Phi^{-1}(1-p) = m(p) - \sqrt{\frac{4}{\sigma^2}\cdot\frac{\epsilon}{p} - s(p)}. \tag{12}$$

Let p^* be the solution of (12). Then, taking into account (10), we have

$$\tau(\mathbf{z}) \approx \frac{\sigma m(p^*)}{2} - \sqrt{\frac{\epsilon}{p^*} - \frac{\sigma^2 s(p^*)}{4}} = \frac{\sigma}{2}\left(m(p^*) - \sqrt{\frac{4}{\sigma^2}\cdot\frac{\epsilon}{p^*} - s(p^*)}\right) = \frac{\sigma}{2}\Phi^{-1}(1-p^*),$$

which concludes the proof. □

Lemma 3. *Let* $\mathbf{z} = \mathbf{W}\mathbf{x}$ *be a pre-softmax vector of logits in the OpenNMT-py (Klein et al., 2017) implementation of the Transformer model (Vaswani et al., 2017). Then for any input, in a non-trained model the logits* $z_1, \ldots, z_d$ *are distributed according to the normal distribution* $\mathcal{N}\left(0, \frac{2\cdot d_{model}}{d_{model}+d_{vocab}}\right)$*, where* d_{model} *is the size of hidden representations, and* d_{vocab} *is the vocabulary size for a target language.*

Proof. The default Transformer configuration in OpenNMT-py implies that the elements w_{ij} of $\mathbf{W}$ are initialized from a uniform distribution $\mathcal{U}[-a,a]$, where $a = \sqrt{\frac{6}{d_{\text{model}}+d_{\text{vocab}}}}$, thus

$$\mathbb{E}[w_{ij}] = 0, \qquad \mathrm{Var}[w_{ij}] = \frac{(2a)^2}{12} = \frac{a^2}{3} = \frac{2}{d_{\text{model}}+d_{\text{vocab}}} \tag{13}$$

Since $\mathbf{x}$ is the result of a layer normalization (Ba et al., 2016), we have

$$\frac{1}{d_{\text{model}}}\sum_{j=1}^{d_{\text{model}}} x_j = 0, \qquad \frac{1}{d_{\text{model}}}\sum_{j=1}^{d_{\text{model}}} x_j^2 = 1 \tag{14}$$

Therefore, from (13) and (14), we have

$$\mathbb{E}[z_i] = \mathbb{E}\left[\sum_{j=1}^{d_{\text{model}}} w_{ij}x_j\right] = \sum_{j=1}^{d_{\text{model}}} \mathbb{E}[w_{ij}]\cdot x_j = 0,$$

$$\mathrm{Var}[z_i] = \mathrm{Var}\left[\sum_{j=1}^{d_{\text{model}}} w_{ij}x_j\right] = \frac{2}{d_{\text{model}}+d_{\text{vocab}}}\sum_{j=1}^{d_{\text{model}}} x_j^2 = \frac{2\cdot d_{\text{model}}}{d_{\text{model}}+d_{\text{vocab}}}.$$

Being a sum of independent random variables, by the Central Limit Theorem, each z_i tends to normal distribution with the mean and variance above. □

B.3 Derivation of the Equation (5)

We provide derivation for the case of α-ReLU. Extension to α-entmax and softmax is done analogously. Let $\mathbf{x} \in \mathbb{R}^{n_0}$ be the input vector. We define a feedforward neural network with $L-1$ hidden layers recursively:

$$\begin{aligned}
\mathbf{h}^{(0)} &= \mathbf{x} \\
\mathbf{z}^{(k)} &= \frac{1}{\sqrt{n_{k-1}}}\mathbf{W}^{(k-1)}\mathbf{h}^{(k-1)}, \\
\mathbf{h}^{(k)} &= \sigma(\mathbf{z}^{(k)}), \quad k = 1, \ldots, L-1
\end{aligned}$$

where $\mathbf{W}^{(k-1)} \in \mathbb{R}^{n_k \times n_{k-1}}$ is the weight matrix in the k^{th} hidden layer, and $\sigma(\cdot)$ is a nonlinear activation function applied element-wise. We consider the case of a multi-label classification, i.e. the output layer is a vector

$$\mathbf{z} := \mathbf{z}^{(L)} \in \mathbb{R}^d,$$

which is fed into the α-ReLU loss:

$$\ell(\mathbf{z}, y) = (\alpha\text{-ReLU}(\mathbf{z}) - \mathbf{e}_y)^\top \left(\mathbf{z} - \frac{\tau}{\alpha - 1}\mathbf{1}\right) + \mathrm{H}_\alpha[\alpha\text{-ReLU}(\mathbf{z})], \tag{15}$$

where $\mathrm{H}_\alpha[\mathbf{p}] := \frac{1}{\alpha(\alpha-1)} \sum_j (p_j - p_j^\alpha)$, $\alpha \neq 1$, is the Tsallis α-entropy (Tsallis, 1988). Given a training sample $S := \{(x, y)\}$ learning is performed by minimizing the training error

$$\mathcal{L} := \mathbb{E}_{(x,y)\sim S}[\ell(\mathbf{z}(x), y)] \tag{16}$$

with respect to the network parameters $\boldsymbol{\theta} := \operatorname{vec}\left(\{\mathbf{W}^{(k-1)}\}_{k\in[L-1]}\right)$.

Lemma 4. *Let the training error (16) be minimized by gradient descent with infinitesimally small learning rate. Let $\mathbf{z}(x,t) \in \mathbb{R}^d$ be the network output on any training instance x at time t, and y be the desired output. Then, as the widths of hidden layers $n_k \to \infty$, $\forall k \in [L-1]$, the output $\mathbf{z}(x,t)$ follows the following evolution*

$$\frac{d\mathbf{z}}{dt} = - \mathop{\mathbb{E}}_{(x',y')\sim S}[\mathbf{K}(x,x') \cdot (\alpha\text{-ReLU}(\mathbf{z}') - \mathbf{e}_{y'})], \tag{17}$$

where $\mathbf{K}(x,x') \in \mathbb{R}^{d\times d}$ is a positive semidefinite matrix, and $\mathbf{z}' := \mathbf{z}(x',t)$.

Proof. From (16) and Lemma 1 we have

$$\nabla_{\mathbf{z}} \mathcal{L} = \nabla_{\mathbf{z}} \mathbb{E}_{(x',y')\sim S}[\ell(\mathbf{z}', y)] = \nabla_{\mathbf{z}} \ell(\mathbf{z}, y) = \alpha\text{-ReLU}(\mathbf{z}) - \mathbf{e}_y, \tag{18}$$

where we denoted $\mathbf{z} := \mathbf{z}(x,t)$ and $\mathbf{z}' := \mathbf{z}(x',t)$ for shorthand. Now, consider the gradient descent update

$$\boldsymbol{\theta}_{t+\eta} = \boldsymbol{\theta}_t - \eta \nabla_{\boldsymbol{\theta}} \mathcal{L} \quad \Leftrightarrow \quad \frac{\boldsymbol{\theta}_{t+\eta} - \boldsymbol{\theta}_t}{\eta} = -\nabla_{\boldsymbol{\theta}} \mathcal{L}, \tag{19}$$

where η is the learning rate. Taking the limit in (19) as $\eta \to 0$, we have:

$$\frac{d\boldsymbol{\theta}}{dt} = -\nabla_{\boldsymbol{\theta}} \mathcal{L} = -\mathbb{E}_{(x',y')\sim S}[\mathbf{J}_{\mathbf{z}'}^\top(\boldsymbol{\theta}) \cdot \nabla_{\mathbf{z}'} \mathcal{L}],$$

where the last equality is due to the chain rule. Combining this with (18), we get

$$\frac{d\boldsymbol{\theta}}{dt} = -\mathbb{E}_{(x',y')\sim S}[\mathbf{J}_{\mathbf{z}'}^\top(\boldsymbol{\theta}) \cdot (\alpha\text{-ReLU}(\mathbf{z}') - \mathbf{e}_{y'})] \tag{20}$$

Applying the chain rule again, and using (20), we have

$$\frac{d\mathbf{z}}{dt} = \mathbf{J}_{\mathbf{z}}(\boldsymbol{\theta}) \cdot \frac{d\boldsymbol{\theta}}{dt} = -\mathbb{E}_{(x',y')\sim S}[\underbrace{\mathbf{J}_{\mathbf{z}}(\boldsymbol{\theta})\mathbf{J}_{\mathbf{z}'}^\top(\boldsymbol{\theta})}_{\mathbf{K}(x,x';\boldsymbol{\theta})} \cdot (\alpha\text{-ReLU}(\mathbf{z}') - \mathbf{e}_{y'})].$$

The quantity $\mathbf{K}(x,x';\boldsymbol{\theta})$ was named the *Neural Tangent Kernel* by Jacot et al. (2018). They also showed (see their Theorem 1) that

$$\mathbf{K}(x,x';\boldsymbol{\theta}) \to \mathbf{K}(x,x') \quad \text{as} \quad n_1, \ldots, n_{L-1} \to \infty,$$

where $\mathbf{K}(x,x') \in \mathbf{R}^{d\times d}$ is the deterministic kernel that does not depend on $\boldsymbol{\theta}$. This concludes the proof. □

C Instructions for Human Annotators

You are shown a reference sentence and several candidate translations. Please indicate, for each, on a 4-point scale, how much of the meaning is represented in the translation, ignoring the language quality.

Imagine you are a forgiving reader, ignoring any error that does not prevent you from getting the meaning of the text. So please ignore language oddities, typographic errors and the like. (This is difficult but key to us!)

The scale of *meaning preservation* is: 4 = Everything / 3 = Most / 2 = Little / 1 = None

As we are interested in comparing system's output, you can refine your judgement using + or −, e.g. 3+.

When you do not know, simply leave empty.

For instance, given the reference sentence

“This restaurant is beautiful and the staff is very friendly”,

valid judgements for different translations are provided in Table 6.

Score	Sentence
4	“This restaurant is beautiful and the staff is very friendly.”
4	“This restaurant is beautiful and the staff is very friendly..”
4	“Beautiful restaurant, staff is very friendly.”
4−	“This restaurant is beautiful and the staff is friendly.”
4−	“Beautiful restaurant, staff is friendly.”
2+	“Friendly staff”
2	“This is a restaurant.”
1	“Hello guys!”
1	“Bad restaurant”
1−	“Bad restaurant, bad staff”

Table 6: Evaluation example

We insist that evaluating by meaning differs from a natural intuitive evaluation. Provided the meaning is not impacted, we want to ignore the language quality, the punctuation, the casing.

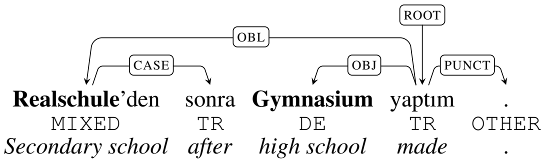
Abstract

Code-switching dependency parsing stands as a challenging task due to both the scarcity of necessary resources and the structural difficulties embedded in code-switched languages. In this study, we introduce novel sequence labeling models to be used as auxiliary tasks for dependency parsing of code-switched text in a semi-supervised scheme. We show that using auxiliary tasks enhances the performance of an LSTM-based dependency parsing model and leads to better results compared to an XLM-R-based model with significantly less computational and space complexity. As the first study that focuses on multiple code-switching language pairs for dependency parsing, we acquire state-of-the-art scores on all of the studied languages. Our best models outperform the previous work by 7.4 LAS points on average.

1 Introduction

Code-switching (CS) is the producing of utterances by combining phrases and word forms from multiple languages. This is a phenomenon observed frequently in utterances of bilingual speakers (Auer and Wei, 2007). Figure 1 shows an example to this type of utterance formation. Although much work has been done on the syntactic parsing of monolingual languages, CS language pairs are quite understudied in this regard. There have been only a few studies on CS dependency parsing (Bhat et al., 2017; Partanen et al., 2018b; Braggaar and van der Goot, 2021), each focusing only on a single CS language pair. Although CS dependency parsing also benefited from the recent rise of multilingual and cross-lingual natural language processing (NLP) models as shown by van der Goot et al. (2021), these models, which are usually trained on monolingual corpora, are insufficient on CS parsing. The poor performance on CS language pairs is not only due to the lack or scarcity of the training data but also because of the shortage on resources required by deep neural models such as pretrained embeddings, language models, or even raw data. In addition, each language composing a CS language pair inherits its own structural difficulties which contributes a good deal to the problem.



'After secondary school I went to high school.'

Figure 1: Dependency tree of a code-switched sentence from the Turkish-German SAGT Treebank. Language ID of each token is located below the token. `TR` stands for *Turkish*, `DE` for *German*, `MIXED` for tokens with intra-word code-switching, `OTHER` is for punctuation. German tokens and token parts are shown in bold.

Recently, a small number of CS treebanks were manually annotated within Universal Dependencies (UD) (Nivre et al., 2016). Even though these treebanks have little to no training data, their existence provides an opportunity to study dependency parsing also on CS language pairs.

In such low-resource scenarios, utilizing raw data can be helpful in boosting the performance. A common method to benefit from raw data is self-training (McClosky et al., 2006), a semi-supervised approach where a small number of labeled data is used to train a model that is later used to predict labels for unlabeled data. This pseudo-labeled data is then combined with the initial data to re-train the model. This method is usually found successful in low-resource scenarios (Rybak and Wróblewska, 2018; Yu et al., 2020), although error propagation is a known problem when pseudo-labels are noisy.

With very restricted resources, we hypothesize that CS dependency parsing can also benefit from unlabeled data. Based on this hypothesis, we form our *first research question*: is using pseudo-labeled data directly beneficial for CS dependency pars-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1159 - 1171
July 10-15, 2022

ing or can we find better ways of integrating the knowledge from pseudo-labeled data?

Starting from this question, we follow a deep contextualized self-training approach (Rotman and Reichart, 2019) and integrate semi-supervised auxiliary tasks to the parsing architecture to enhance CS dependency parsing. Our method enhances a widely-used BiLSTM-based parser (Dozat and Manning, 2017) by training parsing-related auxiliary sequence labeling tasks on automatically labeled data and combining these trained auxiliary task models with the base parser through a gating mechanism. We introduce new sequence labeling tasks that are shown to be beneficial in improving the parsing performance. Seeing the success of our semi-supervised enhancement method on the BiLSTM-based parser, we form our *second research question*: can we reach even better parsing scores if we combine this enhancement method with XLM-R (Conneau et al., 2020), a state-of-the-art (SOTA) transformer-based language model that shows superior performance on many NLP tasks? Our experimental results demonstrate notable success of our proposed models over the previous state-of-the-art on these treebanks. Our contributions are as follows:

- We employ a semi-supervised learning approach based on auxiliary tasks for CS dependency parsing. We present the first study with a focus on parsing all CS UD treebanks and achieve SOTA results on all of them.
- We introduce novel sequence labeling tasks including a CS-specific one, that capture syntactic information better and hence improve dependency parsing.
- We adapt this method to the powerful XLM-R model and elaborate the effectiveness of this approach when combined with XLM-R-based word representation for dependency parsing. We demonstrate that the mighty transformer model remains inadequate for the case of low-resource CS parsing.

2 Related Work

Code-switching dependency parsing is a newly-studied research area. The first CS UD treebank was created by Bhat et al. (2017) which included only a test set of Hindi-English sentences. In the absence of CS training data, the test set was split to monolingual fragments and existing Hindi and English monolingual treebanks in UD were used to parse these fragments. Bhat et al. (2018) extended this dataset with a CS training set. They trained a BiLSTM architecture on this additional training data by also integrating syntactic knowledge extracted from monolingual treebanks.

Partanen et al. (2018b) laid the first foundations of a Komi-Russian UD treebank with 25 CS sentences. They adopted a multilingual parsing approach (Lim and Poibeau, 2017) and used Russian and Komi monolingual training data with bilingual Komi-Russian word embeddings. Later, this treebank expanded into the Komi-Zyrian IKDP treebank (Partanen et al., 2018a).

Çetinoğlu and Çöltekin (2019) created a Turkish-German UD treebank from a Turkish-German spoken corpus. Seddah et al. (2020) introduced the Maghrebi Arabic-French treebank and performed parsing experiments on the treebank using UDPipe (Straka and Straková, 2017). This treebank is yet to be included in the UD. A Frisian-Dutch UD treebank which includes only test data was introduced by Braggaar and van der Goot (2021). The authors performed data selection from eight related monolingual treebanks using Latent Dirichlet Allocation (Blei et al., 2003) to create a training set. Their experiments performed using a deep biaffine parser (van der Goot et al., 2021) demonstrated no significant performance difference between training the parser on the selected training set and only on a Dutch monolingual treebank.

Lately, multilingual and cross-lingual parsing studies have begun to include CS treebanks in their experimental setups. van der Goot et al. (2021) presented a multi-task learning tool that utilizes multilingual BERT (Devlin et al., 2019) to perform several NLP tasks, including dependency parsing. Evaluation was done on all available UD treebanks which include CS UD treebanks mentioned above. The model was fine-tuned on training set of each treebank, which is also the case for Hindi-English and Turkish-German CS treebanks. For Frisian-Dutch and Komi-Russian CS treebanks with no training data, they used Dutch Alpino and Russian SynTagRus treebanks, respectively. Müller-Eberstein et al. (2021) applied a sentence level genre-based data selection from UD treebanks in a cross-lingual setup. They trained a multilingual BERT-based biaffine parser (van der Goot et al., 2021) for 12 low-resource UD treebanks including Hindi-English and Turkish-German CS treebanks.

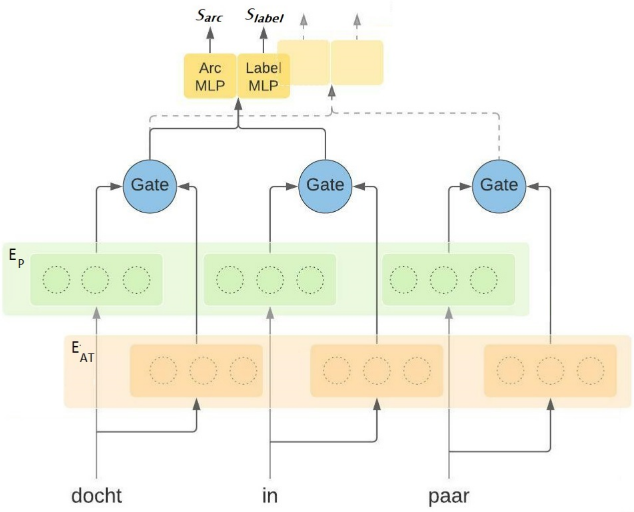


Figure 2: The parser architecture with semi-supervised auxiliary task enhancement. E_p is the parser encoder, E_{AT} is the sequence labeler encoder trained on one of the auxiliary tasks. For a given token pair, the model calculates a weighted average of each token's hidden representation from E_P and E_{AT}. The resulting vectors are given to two multi-layer perceptrons (MLP) to produce an arc score S_{arc} and a label score S_{label} for the given token pair. The input tokens are taken from the Frisian-Dutch Fame Treebank.

Our study on CS dependency parsing differs from the previous work in the sense that none of the previous work utilized raw CS data to improve parsing in a semi-supervised scheme.

3 Methodology

3.1 Base Parsing Model

Our base parser is a neural graph-based parser by Dozat and Manning (2017) that uses two biaffine classifiers, one to predict the head of a given token and the other to predict the resulting arc's label. For input representation, the model uses BiLSTM modules to compute learned word embeddings and add them to their corresponding pretrained word embeddings that are later concatenated with corresponding part-of-speech (POS) embeddings. To ensure a well-formed tree at test time, the maximum spanning tree (MST) algorithm is used.

3.2 Semi-supervised Enhancement through Auxiliary Sequence Labeling Tasks

We follow Rotman and Reichart (2019) to exploit unlabeled data for CS dependency parsing. Rather than directly using pseudo-labeled data as an additional source in training, the main idea is to extract and utilize parsing-related knowledge from automatically parsed data. This is achieved by training contextualized embedding models on a number of auxiliary sequence labeling tasks derived from the raw data parsed by the base parser and then combining encoders of these trained models with that of the base parser through a gating procedure (Sato et al., 2017) as described in Section 3.3. Figure 2 depicts this enhanced parser. The combined model is then re-trained on the gold labeled data.

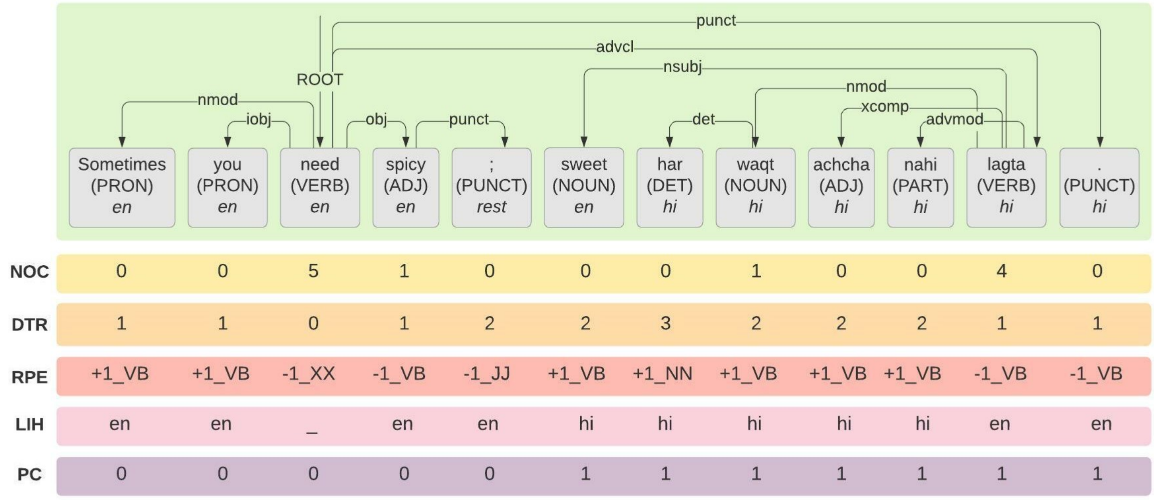
For their experimental setup, Rotman and Reichart (2019) consider three token-level sequence labeling schemes to extract the structural information encoded in the parsed sentences. These are:

(i) Number of Children (NOC) The task is to predict the number of children each token has in a dependency tree.

(ii) Distance to the Root (DTR) Each token is tagged with its minimum distance to the root token of the dependency tree.

(iii) Relative POS-based Encoding (RPE) Each token in a sentence is tagged with its head's POS tag in a simplified form and its distance from the head. The distance calculation considers only the intermediate tokens that share the same POS tag with its head.

Although these three auxiliary tasks offer a comprehensive scheme in terms of extracting parsing-related knowledge from automatically parsed data, we search ways of channeling the embedded knowledge in parsed trees more thoroughly to the trained word embedding layers of the parser. We come up with three additional sequence labeling tasks:



NOC	0	0	5	1	0	0	0	1	0	0	4	0
DTR	1	1	0	1	2	2	3	2	2	2	1	1
RPE	+1_VB	+1_VB	-1_XX	-1_VB	-1_JJ	+1_VB	+1_NN	+1_VB	+1_VB	+1_VB	-1_VB	-1_VB
LIH	en	en	_	en	en	hi	hi	hi	hi	hi	en	en
PC	0	0	0	0	0	1	1	1	1	1	1	1

Figure 3: The dependency tree of an example sentence from Hindi-English HIENCS Treebank. Each node in the tree is tagged with the five auxiliary task schemes depicted in Section 3.2. Tags for the case of the SMH scheme are not shown for this example since the HIENCS Treebank does not include morphology.

(iv) Language ID of Head (LIH) We start with CS-specific features of parsed trees. The most prominent of them is the language ID (LID) features of the tokens in CS treebanks. Considering the positive impact of LIDs in various other NLP tasks (Jamatia et al., 2015; Aguilar and Solorio, 2020; Özateş and Çetinoğlu, 2021), we design a simple auxiliary sequence labeling task that makes use of LIDs. Unlike previous work using token LIDs, LIH tags each token with the LID of its head. This way, information about the language of tokens with which each token tends to relate in terms of dependencies is conveyed to the learning model.

(v) Simplified Morphology of Head (SMH) Morphological features are found to be beneficial in parsing morphologically-rich languages (Dehouck and Denis, 2018). This was our motivation to create a new auxiliary task based on morphology. In the SMH scheme, each token is assigned its head's morphological features. To reduce the number of labels, we use only a subset of the morphological features set, selected by considering the inclusiveness and the prevalence of the features across the data.[1] The main idea of SMH is to provide morphological clues to the parser while also giving information about the structure of the tree.

A similar approach is also tried by Sandhan et al. (2021). They define a sequential task to predict the full set of morphological features for a given token. In our preliminary experiments, we observed that using the full set of morphological features does not improve the accuracy. In CS treebanks the unique number of features is increased due to the combination of language-specific feature sets of the language pair, making the task more complex. To reduce the complexity, we design SMH as utilizing only a subset of the morphological features of (not the token itself, but) the head of the token.

(vi) Punctuation Count (PC) Lastly, we design the PC task that only needs root tokens unlike all other tasks that need parsed trees to function. PC is also not dependent on morphological, POS, or LID tags as SMH, RPE, and LIH tasks.

PC simply tags each token with the number of punctuations between that token and the root token in the sentence. We observe a connection between the position of punctuation and phrase boundaries in a sentence which goes in line with previous studies (Li et al., 2010; Spitkovsky et al., 2011). PC roughly groups tokens into phrases that usually constitute sub-trees in a dependency tree.

Figure 3 shows the outputs of these tasks on the dependency tree of an example CS sentence.

3.3 The Gating Procedure

To create the final parser, the trained auxiliary task models are combined with the base parser through a gating mechanism (Sato et al., 2017) which learns to scale between the encoders of the auxiliary sequence labelers and that of the parser (see Fig. 2).

---

[1] The selected UD features are *Aspect, Case, Foreign, Mood, NumType, Person,* and *VerbForm.*

Formally, the combined representation can be formulated as:

$$b^t = \sigma(W^{gate}(e^{parser} \oplus e^{labeler}) + w^{gate})$$
$$g^t = b^t \cdot e^{parser} + (1 - b^t) \cdot e^{labeler}$$

where e^{parser} and $e^{labeler}$ are the outputs of the parser and sequence labeler encoders, respectively. $\oplus$ denotes concatenation. W^{gate} and w^{gate} are the learned parameters of the gating procedure and σ is the sigmoid function. The final combined vector g^t is then given to the biaffine classifiers.

3.4 Transformer-based Adaptation of the Model

Our base parser as described in Dozat and Manning (2017) has some shortcomings in the choice of the input representation, especially when the target language has very little or no training data and there is no accompanying pretrained word embeddings to represent the input. This is also the case with CS language pairs. In that situation, utilizing the expressive power of transformers can be a good solution. Pretrained on huge amounts of raw data in different languages, multilingual transformer-based language models have proven remarkably effective (Devlin et al., 2019; Sanh et al., 2019; Liu et al., 2019). One such model is XLM-R (Conneau et al., 2020). Pretrained on text data in 100 languages, XLM-R shows SOTA performance in many languages including low-resource ones.

To the best of our knowledge, such a deep contextualized semi-supervised scheme has not been incorporated with XLM-R before. So, we re-implement the auxiliary task modules and the combined parsing approach for an XLM-R-based encoding module. For this purpose we follow the XLM-R-based parsing architecture of Grünewald et al. (2021) which has the same biaffine parsing model described in Dozat and Manning (2017). Our aim is to observe how extracting parsing-related knowledge from semi-supervised auxiliary tasks affects a multilingual transformer model.

4 Experiments

4.1 Data

We perform experiments on all CS treebanks[2] in Universal Dependencies (v2.8).[3] These are Komi-Zyrian IKDP (Kpv-Ru), Hindi-English HIENCS (Hi-En), Frisian-Dutch Fame (Fy-Nl), and Turkish-German SAGT (Tr-De) treebanks. All except Hi-En are based on spoken CS data. Hi-En is constructed from bilingual tweets. Table 1 states basic statistics and related resources for each treebank.

4.2 Training Setup

Due to lack of training data in some CS treebanks, we have two types of experimental setup. We train the parser models on *in-domain* data for Hi-En and Tr-De. In these experiments we use each treebank's own training set. However, Kpv-Ru and Fy-Nl consist of a test set only. Hence, training of the latter two treebanks are on *out-of-domain* data. For Kpv-Ru which includes Komi-Russian code-switching, we train the models on Komi-Zyrian Lattice UD Treebank (Partanen et al., 2018a) of monolingual Komi data. The first 562 sentences in Komi-Zyrian Lattice are used for training, the remaining 100 are used for development. For Fy-Nl, our training data is the Dutch Alpino UD Treebank (Van der Beek et al., 2002). We chose Dutch Alpino over the other Dutch UD treebank (LassySmall) as Alpino is found more effective in parsing Fy-Nl (Braggaar and van der Goot, 2021).

4.2.1 Unlabeled Data

Komi-Russian Komi Social Media Corpus[4] is part of a social media corpora project for minority Uralic languages (Arkhangelskiy, 2019). The data is crawled from *vkontakte*, a social media service mostly popular in Russia. Collected texts are automatically separated to monolingual segments of *Komi, Russian*, or *Unknown* via a dictionary-based method. For our purposes, we extract 3,862 CS sentences from the corpus by joining consecutive segments that alternate between *Komi* and *Russian*.

Hindi-English We employ the datasets in the LinCE CS benchmark[5] (Aguilar et al., 2020) for this language pair. The benchmark provides three different corpora with gold LID and POS labels for Hindi-English (Mave et al., 2018; Singh et al., 2018a,b). We combine these three corpora to use them as unlabeled data. The resulting data consists of 10,989 sentences.

---

[2] There is also the Maghrebi Arabic-French Treebank (Seddah et al., 2020) but its annotations are not yet compatible with the UD scheme and it is not included in the UD repository.

[3] `https://lindat.mff.cuni.cz/repository/xmlui/handle/11234/1-3687`. All UD treebanks used in this paper are licensed with CC BY-SA 4.0.

[4] Available for research purposes. We obtained the corpus by contacting Timofey Arkhangelskiy at `http://komi-zyrian.web-corpora.net/index_en.html`

[5] The datasets are publicly available for research purposes.

	Kpv-Ru (Komi-Russian)	Hi-En (Hindi-English)	Fy-Nl (Frisian-Dutch)	Tr-De (Turkish-German)
Train	–	1,448	–	578
Dev	–	225	150	801
Test	214	225	250	805
CMI	16.97	36.08	17.80	28.78
Morphology	yes	no	no	yes
Monolingual treebanks	both	both	only Dutch	both
Unlabeled CS data	Komi Social Media	LinCE	FAME!	TuGeBiC
XLM-R	only Russian	both	both	both
FastText	only Russian	both	both	both

Table 1: Some statistics and related resources for the CS treebanks. Fy-Nl is provided as a single test set of 400 utterances. As in Braggaar and van der Goot (2021), we split it into a development set (first 150 utterances) and a test set (remaining 250 utterances). CMI is the code-mixing index (Das and Gambäck, 2014) that shows how frequent code-switching happens in the text.

Frisian-Dutch We extract CS sentences from the FAME! Corpus[6] (Yılmaz et al., 2016) which contains radio broadcasts in Frisian-Dutch. From this corpus, which is also the source of the Fy-Nl treebank, we select 2,170 sentences that include at least one CS point and are not already in the treebank.

Turkish-German TuGeBiC[7] (Treffers-Daller and Çetinoğlu, 2022) is a set of transciptions, collected from interviews with Turkish-German bilinguals in the 90s (Treffers-Daller, 2020). It contains 16,950 sentences. We use the whole corpus, and only remove the speaker IDs and metadata from the files.

4.2.2 Sequence Labeler Training

Training auxiliary models on sequence labeling tasks is done on automatically parsed version of the corresponding unlabeled data for each treebank. Some of the sequence labeling tasks need specific labels on unlabeled data to function. These are POS tags for RPE, LID labels for LIH, and morphological annotation for SMH. In training of these tasks, we use gold labels when available (POS tags for Hi-En; LIDs for Kpv-Ru, Hi-En, and Fy-Nl) and train taggers in the absence of gold labels (POS tags for Kpv-Ru, Fy-Nl, and Tr-De; LIDs for Tr-De; morphological features for Kpv-Ru and Tr-De).

4.3 Baselines

As our baseline, we use Ma et al. (2018)'s re-implementation of the biaffine parser by Dozat and Manning (2017). We call this model `Base`$_{\texttt{LSTM}}$ as it uses BiLSTMs for contextualized word vectors.

As a second baseline, we implement the traditional self-training approach (McClosky et al., 2006) in which the parser is first trained only on gold labeled data. Then, labels of unlabeled data are predicted by the trained parser. Finally the parser is re-trained on the combination of gold labeled data and pseudo-labeled data. We name this approach as `Self-training`.

For our experiments with XLM-R, we use Grünewald et al. (2021)'s implementation of the biaffine parser with XLM-R-based input representation. Input word embeddings are calculated as a weighted sum of all intermediate outputs of the transformer layers. Coefficients of the weighted sum are learned during the training phase. Apart from its multilingual transformer-based contextualized word representation model, it has the same biaffine parsing model in Dozat and Manning (2017). We call this version `Base`$_{\texttt{XLMR}}$.

Hyper-parameters of both parser models and sequence labelers can be found in Appendix A.1.

4.4 Semi-supervised Enhancement Models

We provide the list of enhancement models built on top of `Base`$_{\texttt{LSTM}}$ and `Base`$_{\texttt{XLMR}}$ where parser is combined with a sequence labeler trained on:

- `+NOC`: *Number of Children*,
- `+DTR`: *Distance to the Root*,
- `+RPE`: *Relative POS Encoding*,
- `+LIH`: *Language ID of Head*,
- `+SMH`: *Simplified Morphology of Head*,[8]
- `+PC`: *Punctuation Count*.[9]

---

[6] Available via a license agreement. `https://www.ru.nl/clst/tools-demos/datasets/`

[7] Available at `https://github.com/ozlemcek/TuGeBiC`

[8] Note that only Kpv-Ru and Tr-De treebanks have morphological annotation. Hence, `+SMH` is applied only to them.

[9] The `+PC` model is not applied to Fy-Nl since the treebank does not have punctuation.

Additionally, we perform experiments by ensembling more than one auxiliary task model with the base parser. We experiment with two configurations. First, we integrate *Number of Children*, *Distance to the Root*, and *Relative POS Encoding* models together (`+NOC,+DTR,+RPE`). This is also the ensemble configuration in Rotman and Reichart (2019). Since we have additional three tasks, we also make the combination of three best performing models for each treebank and name this ensemble version as `+Best Combination`.[10] For combining encoders of more than one auxiliary task model with the parser encoder, we use Rotman and Reichart (2019)'s extension to the gating mechanism of Sato et al. (2017).

We perform three runs for each model and report the average scores. We measure the performance of all models using the CoNLL 2018 Shared Task evaluation script[11] and report the unlabeled and labeled attachment scores (UAS and LAS, respectively).

5 Results and Discussion

Table 2 shows the performance of all LSTM-based models and of the previous works on the test set of each treebank in terms of attachment scores. Significance testing is performed using the approximate randomization test (Noreen, 1989) on the model outputs with the number of shuffles set to 5,000.

Comparison to Baselines On all treebanks, the auxiliary task enhancement methods improve the scores when compared to $\texttt{Base}_{\texttt{LSTM}}$ by 4.94 points in UAS and 3.86 points in LAS on average. The best performing enhancement model differs across treebanks. We observe the same pattern for the traditional self-training method. `Self-training` fails to surpass the proposed approach on any of the treebanks. Its parsing performance even falls below that of $\texttt{Base}_{\texttt{LSTM}}$ on Kpv-Ru and Tr-De. It shows the highest improvement with respect to $\texttt{Base}_{\texttt{LSTM}}$ on Fy-Nl. Yet, the best one of the auxiliary task enhancement methods significantly outperforms `Self-training` on each treebank.

New Individual Tasks The `+LIH` model which employs LIDs performs best on Kpv-Ru, and second best on Hi-En. Its performance on Tr-De and Fy-Nl is comparable with the other models. It is also in the `Best Combination` ensemble for all treebanks. This indicates the importance of language IDs in CS dependency parsing.

The `+SMH` model which is only applied to Kpv-Ru and Tr-De is the best performing one on Tr-De. However, all other tasks outperform `+SMH` on Kpv-Ru. This might be due to the quality difference in morphological taggers trained on these treebanks. The morphological tagger we trained on the CS training set of Tr-De has an accuracy of 82% on its test set. However, to train a tagger for Kpv-Ru we used monolingual Komi data only. Accuracy of this tagger on Kpv-Ru test set is 66%. It seems the Kpv-Ru parser suffers from error propagation.

The simplest enhancement model `+PC` performs comparable to others, even outperforming `+NOC` and `+DTR` on Kpv-Ru and Tr-De. Since it only needs the root position in the sentence to perform, this model can be an alternative to other models when gold/predicted POS or morphological tags are hard to acquire. It can also be preferred when the error propagated to the auxiliary tasks from the base parser through predicted trees is high, damaging accuracy of the tasks that rely on these parses.

Individual Tasks vs Ensembles Ensembling multiple tasks improves UAS and LAS on Hi-En and Fy-Nl and LAS on Tr-De when compared with the best performing single task. The `+Best Combination` ensemble works better on Fy-Nl and Tr-De than the `+NOC,+DTR,+RPE` ensemble proposed by Rotman and Reichart (2019). Looking at the overall results, we observe that including `+RPE` and `+LIH` together has a favorable effect on improving CS parsing performance.

Who Benefits Most and Least? Fy-Nl is the most benefited treebank from the proposed model. The best performing enhancement model `+Best Combination` on Fy-Nl achieves almost 10/7 points increase in UAS/LAS when compared with $\texttt{Base}_{\texttt{LSTM}}$. The least benefited treebank is Kpv-Ru with 2.5/1.1 points increase in UAS/LAS. Having similar amount of unlabeled data and no CS training data, these treebanks differ in their training data amounts. The Dutch Alpino Treebank used to train Fy-Nl models has 13,603 sentences whereas the Komi-Zyrian Lattice Treebank for Kpv-Ru models includes 662 sentences. So, automatic parsing of unlabeled data of Kpv-Ru by a model trained on 662 sentences can be much noisier than that of Fy-Nl. In Appendix A.2, we show that the performance ranking of the systems does not change by the amount of gold training data.

---

[10] Due to high memory consumption of XLM-R-based models, this ensemble technique cannot be applied to our XLM-R-based parsing architecture.

Table 3: Performance of XLM-R-based parser and our XLM-R adaptation of auxiliary task enhancement models. The best scores for each dataset are underlined and bold. Scores marked with $*$ significantly outperform `Base`$_{\text{XLMR}}$.

Comparison to Previous Work The best enhancement model always achieves better scores than previous state-of-the-art on each treebank. In this respect, the biggest improvement is observed on Kpv-Ru with more than 24 points increase in LAS. In addition, it should be noted that model architectures are not quite comparable as some of the previous work use a lot more resources than our models. For instance, Müller-Eberstein et al. (2021) perform data selection on whole UD datasets for training and utilize multilingual BERT.

Proposed Method and XLM-R Attachment scores of `Base`$_{\text{XLMR}}$ and our XLM-R adaptation of auxiliary task enhancement models are given in Table 3. Our first observation is the limited performance of `Base`$_{\text{XLMR}}$ in parsing CS treebanks. We see that the enhancement models do not have the same impact on `Base`$_{\text{XLMR}}$ as they have on `Base`$_{\text{LSTM}}$. The only significant performance increase is on Fy-Nl where the best performing enhancement model `+NOC` outperforms `Base`$_{\text{XLMR}}$ by almost 2/1.5 points in UAS/LAS. For Kpv-Ru, the only model that surpasses the baseline is `+RPE`. The difference is found statistically significant only in UAS. For Hi-En, all enhancement models except `+NOC` perform better than `Base`$_{\text{XLMR}}$. Yet, the only significant improvement is achieved by `+DTR` in UAS. None of the enhancement models surpass `Base`$_{\text{XLMR}}$ on Tr-De but the difference between the scores is not found to be significant. Another remarkable observation is our models built on top of `Base`$_{\text{LSTM}}$ outperforming all XLM-R-based models with the exception of Tr-De. This answers our second research question: XLM-R is not always the best option. For powerful models like XLM-R, multilinguality can harm the performance when the target language is unknown to the model. Our results suggest that in such cases it is better to employ simpler models that are tailored for the exact task.

Comparison of the Proposed Approach with Baselines in terms of Computational Resources Table 4 provides time and memory usage of $\texttt{Base}_{\texttt{LSTM}}$, $\texttt{Base}_{\texttt{XLMR}}$, and our proposed best model for each treebank. Labeled attachment scores (LAS) acquired by these models on each treebank are also given.

	Kpv-Ru	Hi-En	Fy-Nl	Tr-De
Training time				
$\texttt{Base}_{\texttt{LSTM}}$	**0h9m**	**0h15m**	**0h45m**	**0h20m**
Our best model	0h25m	0h40m	2h30m	0h55m
$\texttt{Base}_{\texttt{XLMR}}$	3h40m	3h15m	11h0m	1h30m
Memory usage (GB)				
$\texttt{Base}_{\texttt{LSTM}}$	**3.6**	**3.6**	**3.8**	**3.5**
Our best model	4.5	7.6	7.3	7.4
$\texttt{Base}_{\texttt{XLMR}}$	9.9	7.9	9.6	8.4
LAS				
$\texttt{Base}_{\texttt{LSTM}}$	45.10	71.29	49.56	57.88
Our best model	**47.13**	**74.09**	**56.39**	61.65
$\texttt{Base}_{\texttt{XLMR}}$	43.12	71.54	50.27	**66.30**

Table 4: Comparison of baselines and the proposed approach according to training time, memory usage during training, and LAS. Our best model on Kpv-Ru is the `+LIH` model. For all other treebanks, our best model is an ensemble that combines three task models.

From the table, we observe that there is a trade-off between performance and resource consumption for the three models. The training time of the $\texttt{Base}_{\texttt{LSTM}}$ model is the shortest. Yet, our best model improves the performance significantly at the expense of a slight increase in training time. $\texttt{Base}_{\texttt{XLMR}}$ has the longest training time by a large margin.

In terms of memory usage, there is a similar pattern to that of training time. $\texttt{Base}_{\texttt{LSTM}}$ needs approximately 50% less memory than our best model, yet there is on average 3.86 points gap between LAS of the two models. $\texttt{Base}_{\texttt{XLMR}}$ is again the least preferable model here due to its highest memory consumption and low performance on parsing the treebanks with the exception of Tr-De. Only for Tr-De it outperforms the other two models and can be the model of choice for the parsing of Tr-De data.

Considering the long training time and high resource consumption of the XLM-R-based parser and the success of our LSTM-based enhancement models, we suggest LSTM-based auxiliary task enhancement for low-resource dependency parsing of CS data.

6 Conclusion

In this paper, we focus on CS dependency parsing. We present a semi-supervised auxiliary task enhancement to a graph-based neural parser and create novel sequence labeling tasks that are shown as useful in improving the parser's success. Experimental results show that our enhancement technique achieves SOTA performance on all CS UD treebanks and helps better utilization of unlabeled data for CS dependency parsing. We combine our enhancement models with XLM-R to see their performance on a multilingual transformer-based model. Results demonstrate that the powerful XLM-R shows limited performance and fails to surpass our semi-supervised auxiliary task enhancement models. Our implementation of the proposed sequence labeling tasks and the XLM-R-based enhancement are publicly available for research purposes at `https://github.com/sb-b/ss-cs-depparser`.

This work is funded by DFG via project CE 326/1-1 "Computational Structural Analysis of German-Turkish Code-Switching (SAGT)". The numerical calculations reported in this paper were performed at the computing servers of IMS at University of Stuttgart and at TUBITAK ULAKBIM (TRUBA resources). GEBIP Award of the Turkish Academy of Sciences (to A.Ö.) is gratefully acknowledged. We thank the anonymous reviewers for their valuable comments and feedbacks.

Ethical Considerations

The UD datasets we use in this study are all from published works and licensed with CC BY-SA 4.0. All the used unlabeled corpora also have accompanying papers and were made publicly available by their providers. To utilize TuGeBiC in our experiments, we removed speaker IDs that were already anonymized.

Code-switching is very understudied computationally and by employing datasets from multiple language pairs, including minority languages, we minimize the potential risk of exposure. Our study asks foundational research questions on code-switching datasets. Our experiments show that even within our datasets results vary, hence we believe the paper avoids possible overgeneralizations.

XLM-R-based models employed in this study have higher memory consumption than the LSTM-based models (see Table 4). They also require longer training time which means higher energy consumption. To reduce this negative side-effect, we avoid performing the same experiment many times and repeated each experiment only three times. Moreover, we chose not to utilize XLM-R-large model with 550M parameters but instead used XLM-R-base model with 270M parameters to reduce the training time and memory consumption. All the experiments with XLM-R models in this study were run on a single NVIDIA RTX A6000 GPU.

A Appendix

A.1 Model Configuration and Hyper-parameters

We provide the configuration and hyper-parameters of the parser and sequence labeler models presented in Section 4.3.

$\texttt{Base}_{\texttt{LSTM}}$ We use Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.002, batch size of 16, and all dropout probabilities are set to 0.33 for the parser and the sequence labeler models. We train the parser for 150 epochs and sequence labeling tasks for 100 epochs.

We use 300-dimensional FastText embeddings (Grave et al., 2018) as pretrained word vectors. Since these embeddings are monolingual, we choose Russian FastText embeddings for Kpv-Ru, Hindi embeddings for Hi-En, Dutch embeddings for Fy-Nl, and Turkish embeddings for Tr-De treebanks. The model also uses 100-dimensional character embeddings and POS tag embeddings which are randomly initialized. The 3-layer BiLSTM modules of the parser and the sequence labeler have hidden layer size of 512 on each side. The decoder of the parser includes an arc MLP of size 512

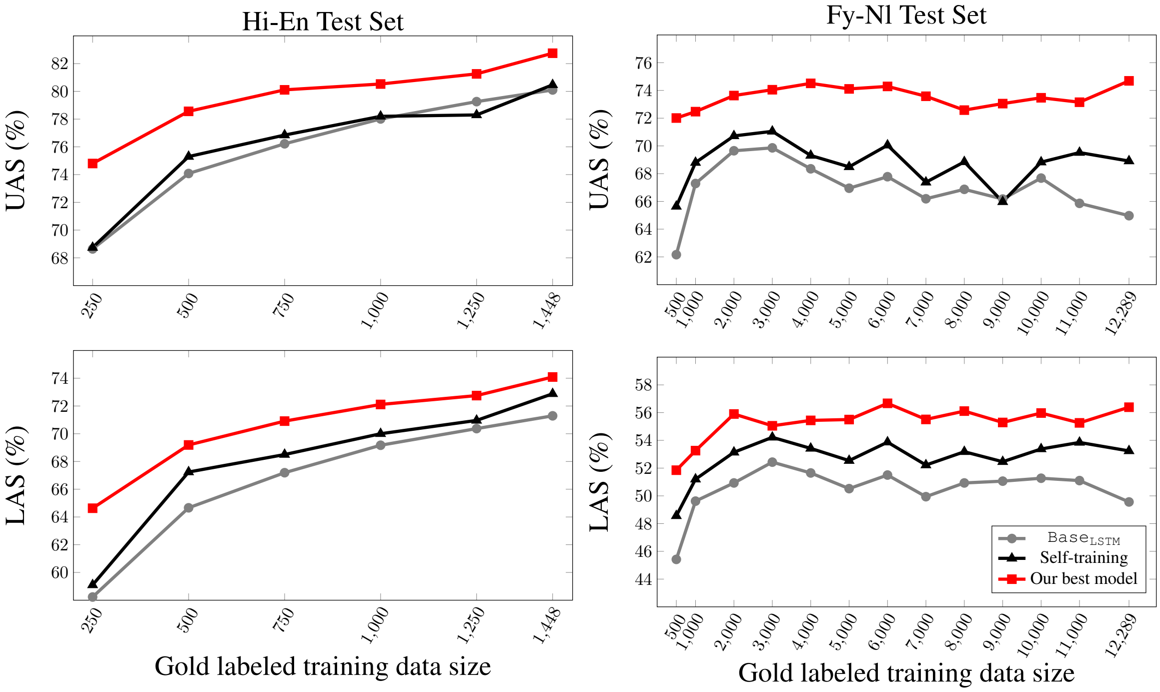

Figure 4: Comparison of `Base`$_{\text{LSTM}}$, `Self-training`, and our best model for Hi-En and Fy-Nl in terms of attachment scores.

and a label MLP of size 128. The decoder of the sequence labeler consists of two fully connected layers with size 128 and 64, respectively.

`Base`$_{\text{XLMR}}$ Due to computational efficiency, we choose the 768-dimensional XLM-R base language model as the word representation module of the `Base`$_{\text{XLMR}}$ architecture. For the parser, the arc MLP of the biaffine classifier has the same size with XLM-R model and the label MLP has the size of 256. Dropout for the classifier is set to 0.33. For the sequence labeler, we use a single-layer feed-forward neural network to extract logit vectors. We use AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of 0.00004 and set batch size to 16. The number of epochs for the parser is 300 with an early stop of 50 epochs. For the sequence labeler, we train the models for 100 epochs with an early stop of 15 epochs.

A.2 Effect of Gold Labeled Data on the Parsing Performance

In our main experiments the gold training data size differs among the four datasets. While the gold labeled data used for training of Kpv-Ru and Tr-De includes approximately 500 sentences, Hi-En has 1,448 gold labeled training CS data and for Fy-Nl we used the training set of the Dutch Alpino UD Treebank which consists of 12,289 gold labeled Dutch sentences. In order to observe how the amount of gold labeled training data affects the models' performance, we did a set of experiments on each of Hi-En and Fy-Nl datasets by incrementally increasing the size of labeled training data from 500 to the original training data size as used in the main experiments. Figure 4 shows results of these experiments.

We observe that our best model on these datasets (`+NOC,+DTR,+RPE` for Hi-En and `+NOC,+RPE,+LIH` for Fy-Nl) always surpasses `Self-training` and `Base`$_{\text{LSTM}}$ regardless of the available gold training data. Increasing the labeled training data has always a positive effect on the performance of all models for Hi-En but causes fluctuations in the performance for the case of Fy-Nl. The reason for this difference might be that the training data of Hi-En is in-domain and includes CS sentences, while the training data we use for Fy-Nl is out-of-domain and includes monolingual Dutch sentences.

Dangling-Aware Entity Alignment with Mixed High-Order Proximities

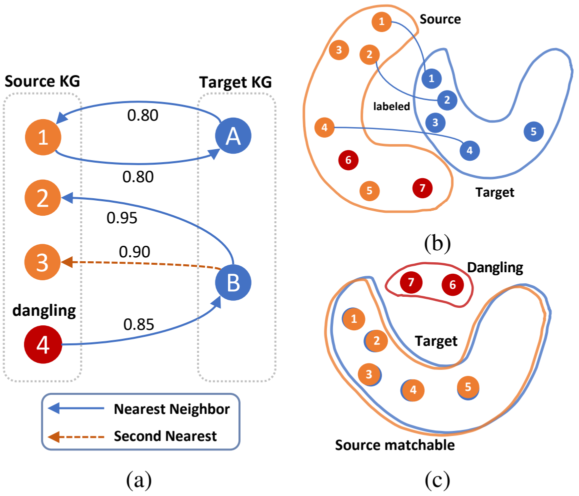
Abstract

We study dangling-aware entity alignment in knowledge graphs (KGs), which is an underexplored but important problem. As different KGs are naturally constructed by different sets of entities, a KG commonly contains some dangling entities that cannot find counterparts in other KGs. Therefore, dangling-aware entity alignment is more realistic than the conventional entity alignment where prior studies simply ignore dangling entities. We propose a framework using mixed high-order proximities on dangling-aware entity alignment. Our framework utilizes both the local high-order proximity in a nearest neighbor subgraph and the global high-order proximity in an embedding space for both dangling detection and entity alignment. Extensive experiments with two evaluation settings shows that our framework more precisely detects dangling entities, and better aligns matchable entities. Further investigations demonstrate that our framework can mitigate the hubness problem on dangling-aware entity alignment.

1 Introduction

Knowledge graphs (KGs) have become the backbone of many intelligent applications (Ji et al., 2021). In spite of their importance, many KGs are independently created without considering the interrelated and interchangeable nature of individually created knowledge (Chen et al., 2020). To allow complementary knowledge to be automatically combined and migrated across individual KGs, entity alignment seeks to identify equivalent entities in distinct KGs (Sun et al., 2020a). Recent literature has focused on learning embedding representations of multiple KGs where identical entities are aligned based on their embedding similarity (Chen et al., 2017; Cao et al., 2019; Fey et al., 2020; Sun et al., 2020a; Liu et al., 2021).



(a) (b) (c)

Figure 1: Toy examples for mixed high-order proximities. (a) Nearest neighbor (NN) subgraph where entities connect to NNs in the other KG using embedding similarities. 4 and its nearest neighbor B have 0.85 similarity. B prefers 2 and 3 with higher similarities. 1 and A are mutual nearest neighbors. (b) Labeled alignments and dangling entities. (c) Aligning matchable source and target distributions rather than only labeled alignments.

Aside from the surge of research effort on entity alignment (Zeng et al., 2021), an unresolved but important challenge that existing methods face is the *dangling entity* problem. Dangling entities are those unique entities in a KG that cannot find counterparts in another KG. Considering that individually created KGs are unlikely to share the same set of entities, identifying dangling entities is undoubtedly an indispensable step of any practical solution to entity alignment. However, nearly all prior studies have neglected dangling entities and assume there must be one-to-one entity mapping from the source KG to the target one (Sun et al., 2020c). This assumption prevents prior methods from practically supporting the alignment between KGs in real-world scenarios. To fill the gap, Sun et al. (2021) formally define a more practical problem setting where a model needs to both determine whether each given source entity is a matchable one, as well as retrieve counterparts for the predicted matchable entities.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1172 - 1184
July 10-15, 2022 ©2022 Association for Computational Linguistics

Although some preliminary attempts have been made to implement dangling-aware entity alignment (Sun et al., 2021), the attempted methods still suffer from a major drawback, i.e., they only consider the first-order proximity (namely, pairwise cosine similarity) between source and target entities. However, to effectively discover dangling entities as outliers in the embedding representation, we argue that *high-order proximity measures* should also be involved. Fig. 1a shows the intuition of using the high-order proximity for dangling entity detection. Despite a fairly high cosine similarity, the source entity 4 is not the nearest neighbor of target entity B, indicating that 4 is likely to be dangling. In contrast, 1 and A are mutual nearest neighbors even with a relatively low similarity, indicating that 1 is more likely to be matchable. Hence, in addition to the first-order proximity from source to target, the *local high-order proximity* (e.g., the second-order proximity[1] in the nearest neighbor subgraph) is also useful for detecting dangling entities. In alignment learning, the previous works neglect global information since they merely optimize the entity-level alignment loss on labeled alignments without considering entity embedding distributions as shown in Fig. 1b. In Fig. 1c, we show that a desirable dangling-aware model should align the *global* distributions of matchable source and target entities (i.e., *global high-order proximity* in an embedding distribution space), such that dangling entities in both KGs could appear as dissimilar outliers in both distributions.

Motivated by the above intuition, we propose a dangling-aware entity alignment framework based on *mixed high-order proximities* (MHP). MHP considers both local and global high-order proximities to foster both dangling entity detection and matchable entity alignment. We introduce the optimization of global high-order proximity measure as finding the Optimal Transport between matchable source entities and target entities. Through this optimization process, to facilitate dangling detection, MHP also encourages a large distance between the dangling entity distribution and matchable entity distribution. Additionally, to leverage the local high-order proximity, we propose a dangling entity classifier which takes into account the second-order proximity in the nearest neighbor subgraph. Furthermore, with the similar principle of local high-order proximity, we adopt an NCA (Neighborhood Component Analysis) loss (Goldberger et al., 2004; Liu et al., 2021) for alignment learning to mitigate the hubness problem[2] (Radovanovic et al., 2010), which is severe in dangling-aware entity alignment as observed in our experiments.

Our main technical contributions to the studied problem are two-fold. First, the local high-order proximity (i.e., the second-order proximity in the nearest neighbor subgraph) is modeled to facilitate both dangling detection and alignment learning. Second, we design the use of the global high-order proximity to align the distributions of matchable entities, therefore precisely separating the representations of dangling entities and matchable ones. In addition, the techniques are model-agnostic and can be incorporated with various alignment methods (e.g., MTransE (Chen et al., 2017) or AliNet (Sun et al., 2020a)) and dangling detection methods (e.g., the marginal or background ranking (Sun et al., 2021)). Extensive experiments on DBP2.0 demonstrate its effectiveness and adaptiveness.

2 Preliminary

In this section, we provide the problem definition of dangling-aware entity alignment and briefly introduce previous methods for this problem.

2.1 Problem definition

A KG is defined as $\mathcal{G} = (\mathcal{E}, \mathcal{R}, \mathcal{T})$, where $\mathcal{E}$ denotes a set of entities; $\mathcal{R}$ denotes a set of relations, and $\mathcal{T} \subset \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ is a set of triples. Following the convention (Chen et al., 2017), we consider entity alignment between a source KG $\mathcal{G}_s = (\mathcal{E}_s, \mathcal{R}_s, \mathcal{T}_s)$ and a target KG $\mathcal{G}_t = (\mathcal{E}_t, \mathcal{R}_t, \mathcal{T}_t)$. Our study focuses on a more practical and challenging setting with dangling entities (Sun et al., 2021). In this setting, the training data contain a set of seed entity alignment $\mathcal{A} = \{(x_s, x_t) \in \mathcal{E}_s \times \mathcal{E}_t \| x_s \equiv x_t\}$ and a set of source dangling entities $\mathcal{D} \subset \mathcal{E}_s$ that has no counterparts in target KG. After training, the model is required to first identify dangling entities and then find alignment for predicted matchable entities. This definition breaks the one-to-one assumption used in previous studies on the conventional setting (Sun et al., 2020c) and causes their methods to not be directly usable in our setting.

---

[1] The second-order proximity of a source entity s is defined as aggregated cosine similarities between the nearest targets of s and the nearest sources of these nearest targets.

[2] The hubness problem is where some target entities dominantly appear as the nearest neighbors of many source entities.

2.2 Dangling-aware entity alignment

To the best of our knowledge, there is only one previous work (Sun et al., 2021) which has been attempted for dangling-aware entity alignment along with the proposing of this important problem. This work also incorporates an embedding-based entity alignment technique (i.e., MTransE (Chen et al., 2017) and AliNet (Sun et al., 2020a)) as the backbone, which learns alignment of KG embeddings based on the seed entity pairs. Taking MTransE as an example, for each pair $(x_s, x_t) \in \mathcal{A}$, MTransE uses the learned embedding $\mathbf{x}_s$ and $\mathbf{x}_t$ to optimize a linear transformation matrix $\mathbf{M}$ by minimizing $||\mathbf{M}\mathbf{x}_s - \mathbf{x}_t||$. To detect dangling entities in the embedding space, a margin ranking (MR) loss and a background ranking (BR) loss are experimented with, both encouraging dangling entities to be isolated from others in the embedding space. MR sets a distance margin λ to separate the dangling entity x and its nearest neighbors by minimizing $\max(0, \lambda - \|\mathbf{M}\mathbf{x} - \mathbf{x}_{\text{nn}}\|)$. In like manner, BR treats dangling entities as the background of embedding space and learns to separate dangling entities and randomly-sampled other entities.

3 Methodology

In this section, we introduce the techniques in our framework which captures both local and global high-order proximities to collaboratively tackle dangling detection and entity alignment.

3.1 Global high-order proximity

To leverage the global high-order proximity in an embedding space, in MHP, we introduce a method based on Optimal Transport (OT) for globally aligning the distributions of matchable source and target entities. In addition, to facilitate dangling entity detection, the OT model encourages a large distribution distance between source- and target-KG dangling entities. Intuitively, this strategy treats dangling entities as dissimilar parts of two embedding distributions, therefore tending to put dangling entities as outliers in the embedding space.

Optimal transport. Let $\mathbf{s}$ and $\mathbf{t}$ be the distribution of transformed source-space embeddings $\mathbf{M}\mathbf{x}_s$ and target space embeddings $\mathbf{x}_t$, respectively.[3] Intuitively, $\mathbf{s}$ should be similar with $\mathbf{t}$ if they represent matchable entities. Meanwhile, to make dangling entities distinguishable, the distribution of transformed dangling entity vectors $\mathbf{M}\mathbf{x}_d$ should be different from $\mathbf{t}$. The discrepancy between $\mathbf{s}$ and $\mathbf{t}$ can be represented as a Wasserstein distance which is one type of OT distance (Peyré et al., 2019):

$$\mathcal{D}_c(\mathbf{s}, \mathbf{t}) = \inf_{\gamma \in \Pi(\mathbf{s}, \mathbf{t})} \mathbb{E}_{(\mathbf{x}, \mathbf{y}) \sim \gamma}[c(\mathbf{x}, \mathbf{y})], \quad (1)$$

where $\Pi(\mathbf{s}, \mathbf{t})$ is the set of all possible joint distributions $\gamma(\mathbf{s}, \mathbf{t})$ and $c(\mathbf{x}, \mathbf{y})$ denotes the cost function describing the distance between $\mathbf{x}$ and $\mathbf{y}$. Then the Wasserstein distance $\mathcal{D}_c(\mathbf{s}, \mathbf{t})$ denotes the cost of the optimal transport plan.

However, the infimum to calculate $\mathcal{D}_c(\mathbf{s}, \mathbf{t})$ is highly intractable (Arjovsky et al., 2017). To handle this, the Kantorovich-Rubinstein duality points out that Eq. (1) can be transformed to:

$$\mathcal{L}_{ot}(\mathbf{s}, \mathbf{t}) = \frac{1}{K} \sup_{\|f\|_L \leq K} \mathbb{E}_{x \sim \mathbf{t}}[f(x)] - \mathbb{E}_{x \sim \mathbf{s}}[f(x)], \quad (2)$$

where the supremum is over all possible K-Lipschitz functions f. As Arjovsky et al. (2017) point out that optimizing Wasserstein GAN (WGAN) can be used to solve this optimal transport problem, we utilize WGAN in our study. Specifically, we adopt a MLP to approximate the function f (called as critic D) since neural networks are universal approximators (Hornik et al., 1989). The objective of the critic is defined as follows:

$$\max_D \mathbb{E}_{y \sim \mathbf{t}} [f_D(y)] - \mathbb{E}_{x \sim \mathbf{s}} [f_D(\mathbf{M}x)]. \quad (3)$$

Thus, the critic D aims to distinguish transformed source embeddings from target embeddings. In contrast, the transformation matrix $\mathbf{M}$ tries to minimize the distance between the two sets of embeddings. The objective to optimize $\mathbf{M}$ is defined as:

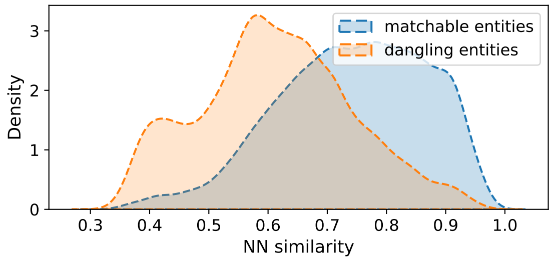
$$\begin{aligned} &\min_{\mathbf{M}} \mathbb{E}_{y \sim \mathbf{t}} [f_D(y)] - \mathbb{E}_{x \sim \mathbf{s}} [f_D(\mathbf{M}x)] \\ &= \min_{\mathbf{M}} -\mathbb{E}_{x \sim \mathbf{s}} [f_D(\mathbf{M}x)]. \end{aligned} \quad (4)$$

Therefore, conducting entity alignment with the consideration of whole embedding distributions is converted to the problem of optimizing a WGAN.

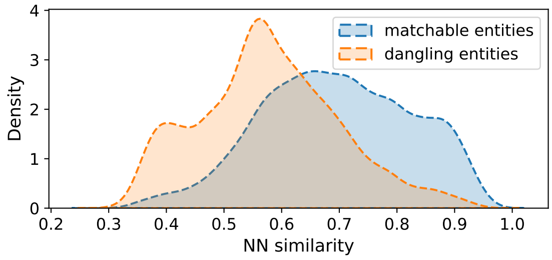
So far, only the distribution of matchable source entity embeddings and that of target entity embeddings are considered, whereas the distribution of dangling entity embeddings is neglected. Therefore, to tailor the optimization problem for dangling entities, we adopt an additional objective for the

---

[3] Without loss of generality, we use a matrix M to transform embeddings from source KG to target KG.



(a) Proximity distribution of nearest entities.



(b) Proximity distribution of the second nearest entities.

Figure 2: Second-order proximity distributions.

transformation matrix $\mathbf{M}$:

$$\begin{aligned} &\max_{\mathbf{M}} \mathbb{E}_{y\sim\mathbf{t}}\left[f_D(y)\right] - \mathbb{E}_{x\sim\mathbf{d}}\left[f_D\left(\mathbf{M}x\right)\right] \\ &= \min_{\mathbf{M}} \mathbb{E}_{x\sim\mathbf{d}}\left[f_D\left(\mathbf{M}x\right)\right], \end{aligned} \tag{5}$$

where $\mathbf{d}$ denotes the distribution of dangling entity embeddings. Hence, the transformation matrix $\mathbf{M}$ is enforced to maximize the difference between the distribution of transformed dangling embeddings and that of target entity embeddings, which can make dangling entities more distinguishable.

3.2 Local high-order proximity

In addition to the global proximity measure, MHP also captures local high-order proximity measures in the nearest neighbor subgraph. In contrast, the previous work (Sun et al., 2021) merely uses the first-order proximity between an individual source entity s and its nearest target entity to decide whether s should be dangling. However, apart from the first-order proximity, the second-order proximity measure could be informative as well for detecting dangling entities.

Furthermore, we verify the above hypothesis empirically using the previous work. From the nearest target entity t of a given source entity, we obtain the cosine similarities between t and its top 2 nearest source entities as the second-order proximity measures, and plot the proximity distributions in Fig. 2a and 2b for the first and second nearest entities, respectively. Fig. 2a shows that the second-order proximity between matchable entities and their nearest neighbors appear as a very different distribution in comparison to that of the proximity between dangling entities and their nearest neighbors. Fig. 2b demonstrates a similar observation for the proximity distributions of the second nearest entities. Therefore, the second-order proximities are informative and should be used for distinguishing dangling entities, meanwhile combining proximity measures that consider multiple neighboring entities is more useful than a single similarity measure on only the nearest entity.

To this end, we design a dangling entity classifier using both first-order and second-order proximity measures as the input. From the perspective of a given source entity s, we conduct nearest neighbor search to obtain top k nearest target entities $\{t_1, ..., t_k\}$ and their proximity score vector $\mathbf{d}_1 = [d_{st_1}, ..., d_{st_k}] \in \mathbb{R}^{1\times k}$. The proximity d_{st} is measured by the cosine similarity between transformed source embedding $\mathbf{M}\mathbf{x}_s$ and target entity embedding $\mathbf{x}_t$:

$$d_{st_1} = \left\langle \frac{\mathbf{M}\mathbf{x}_s}{\|\mathbf{M}\mathbf{x}_s\|_2}, \frac{\mathbf{x}_t}{\|\mathbf{x}_t\|_2} \right\rangle \tag{6}$$

After getting the first-order proximity vector $\mathbf{d}_1$ between the source and target, through the reverse direction (target KG to source KG), we can further obtain the second-order proximity vector. Specifically, we retrieve top m nearest source entities $\{s_1, ..., s_m\}$ of each target entity t in $\{t_1, ..., t_k\}$. Accordingly, through the target entity t, the second-order proximity measures with regard to the m retrieved source entities are obtained as the vector $\mathbf{d}_t = [d_{s_1t}, ..., d_{s_mt}] \in \mathbb{R}^{1\times m}$. Subsequently, we can collect $\{\mathbf{d}_{t_1} ... \mathbf{d}_{t_k}\}$ and concatenate them as the whole second-order proximity vector $\mathbf{d}_2 = [\mathbf{d}_{t_1}||...||\mathbf{d}_{t_k}] \in \mathbb{R}^{1\times km}$.

To utilize both second-order and first-order information, the whole proximity distribution vector is constructed as $\mathbf{d} = [\mathbf{d_1}||\mathbf{d_2}] \in \mathbb{R}^{1\times(k+1)m}$. In this way, we use the distribution as profile of the neighborhood of a source entity s, then we adopt a simple feed-forward neural network (FNN) binary classifier to determine whether s is dangling. The probability of s being a dangling entity can be calculated as $p(y = 1|s) = \text{sigmoid}(\text{FNN}(\mathbf{d}))$. Define $\mathcal{D}$ and $\mathcal{A}$ to be the training set of dangling entities and that of matchable entities, respectively.

We minimize the binary cross-entropy loss:

$$\mathcal{L}_s = -\frac{1}{|\mathcal{D} \cup \mathcal{A}|} \sum_{s \in \mathcal{D} \cup \mathcal{A}} (y_s \log(p(y=1|s)) + (1-y_s)\log(1-p(y=1|s))) \tag{7}$$

NCA loss. With the similar principle of local high-order proximity, MHP adopts an additional Neighbor Component Analysis (NCA) loss (Liu et al., 2021) to mitigate the hubness problem. The hubness problem can be more severe in dangling-aware entity alignment as dangling entities might be aligned to some certain hubs if they are not detected as dangling. The NCA loss measures importance of samples and punishes hard negative pairs based on the proximities. Given the set of seed entity alignments $\{(x_s, x_t) \in \mathcal{E}_s \times \mathcal{E}_t\}$, let $\mathbf{S}$ be the cosine similarity matrix between source and target entity embeddings $\mathbf{E}_1$ and $\mathbf{E}_2$. The NCA loss can be defined as follows:

$$\mathcal{L}_{NCA} = \frac{1}{N}\sum_{i=1}^{N}\Big(\frac{1}{\alpha}\log(1+\sum_{m\neq i} e^{\alpha \mathbf{S}_{im}}) + \frac{1}{\alpha}\log(1+\sum_{n\neq i} e^{\alpha \mathbf{S}_{ni}}) - \log(1+\beta e^{\mathbf{S}_{ii}})\Big), \tag{8}$$

where $\mathbf{S}_{ii}$ denotes the proximity of the i-th positive pair (i.e., the i-th source entity and the i-th target entity); α, β are temperature hyper-parameters; and N is the number of positive pairs in the mini-batch.

3.3 Learning and inference

Note that our techniques are used to improve existing first-order methods. MHP optimizes the entity alignment component and the dangling detection component alternately. For entity alignment, besides an entity-level loss (e.g., MTransE), we first train WGAN for optimal transport and then optimize the NCA loss $\mathcal{L}_{NCA}$. For dangling detection, besides a first-order objective (e.g., a marginal ranking loss) used in Sun et al. (2021), we train our dangling classifier for detection. In the inference phase, for each source entity, the dangling entity classifier provides a probability score and uses a probability threshold to decide whether an entity is dangling, where the threshold is set as the average probability. After this dangling detection process, the predicted dangling entities are excluded from being aligned. Then, in the alignment process, MHP conducts nearest neighbor search to find the alignment in the target KG embedding space for each of the rest matchable source entities.

4 Experiments

In this section, we report our experiments to show the effectiveness of MHP. We describe the evaluation settings in Sec. 4.1, and present the results in two alignment settings separately in Sec. 4.2 and 4.3. We conduct an ablation study and demonstrate that MHP can mitigate the hubness problem in Sec. 4.4, followed by a case study to show the importance of local high-order proximity in Sec. 4.5.

4.1 Experimental settings

We use two evaluation settings as suggested by Sun et al. (2021). The first one is *consolidated evaluation* which requires a model to first detect and remove dangling entities, and then conduct alignment search for the rest of entities. The performance of dangling entity detection is also evaluated in this setting. Besides, a simplified *relaxed evaluation setting* seeks to test the performance of alignment alone without involving dangling source entities in the test set. In this setting, the effect of dangling detection on entity alignment can be evaluated.

Evaluation protocol. For the *relaxed setting*, the counterpart list is selected by the Nearest Neighbor (NN) search in the embedding space for each source entity. To assess the ranking list, we use mean reciprocal rank (MRR), Hits@1 and Hits@10 (hereinafter H@1 and H@10) as metrics. Higher values indicate better performance.

For the *consolidated setting*, we evaluate the performance of both dangling entity detection and entity alignment using precision, recall, and F1 score, following Sun et al. (2021).[4] In this setting, only the source entities that are correctly predicted as matchable are sent to the NN search and the nearest counterpart is evaluated. Particularly, incorrect dangling detection (i.e., a matchable entity is wrongly predicated as dangling or a dangling entity is predicted as matchable) will propagate an error case to the alignment process. We refer to this practical entity alignment as *two-step entity alignment*.

Dataset. We use the cross-lingual dangling-aware entity alignment dataset DBP2.0 (Sun et al., 2021), which is constructed using multilingual DBpedia (Lehmann et al., 2015). There are three language pairs (ZH-EN, JA-EN, FR-EN) in DBP2.0 and two alignment directions are considered for each pair. We follow its data splits where 30% dangling

---

[4] Note that H@1, H@10 and MRR are not applicable to this entity alignment in the consolidated setting.

entities are for training, 20% for validation, and 50% for test. The dataset statistics are reported in Appx. A.

Baselines. To the best of our knowledge, the framework with a dangling detection module proposed in Sun et al. (2021) is the only study on dangling-aware entity alignment. It includes three dangling detection techniques: (i) NN classification, (ii) marginal ranking (MR), and (iii) background ranking (BR). As the NN classification performs much worse than others, we choose MR and BR as baselines. For a fair comparison with (Sun et al., 2021), we use the same base alignment model MTransE (Chen et al., 2017). The results using AliNet (Sun et al., 2020b) [5] as a base are presented in Appx. D. Note that our methods are model-agnostic and can be incorporated with any detection and alignment methods. The entity alignment models that consider side information are left for future work.

Model configuration. In MHP, aside from our proposed components as described in Sec. 3, we have a base alignment module (e.g., MTransE) and a base dangling entity loss (e.g., MR) as in Sun et al. (2021). For KG embeddings and model weights, we use Xavier initialization (Glorot and Bengio, 2010) and optimize them using Adam optimizer (Kingma and Ba, 2014). The number of hidden units in the dangling entity classifier is 128. The number of nearest targets k and nearest sources m are set as 5. The learning rate is set to 0.001 for all components except WGAN where the learning rate is 5e-5 for three objectives. To terminate training, early stopping is used based on the F1 score of two-step entity alignment on validation set. The computational environment and other configuration details are reported in Appx. B and C.

4.2 Consolidated evaluation

Dangling entity detection. According to the results in Tab. 1, no matter which base dangling detection loss we adopt, MHP consistently achieves better F1 scores compared with the corresponding baseline by Sun et al. (2021) without our proposed techniques. In terms of the recall, MHP also outperforms baselines with a large margin, which indicates that our framework has a better coverage to find more dangling entities. With better recalls, MHP has the same level or slightly worse precision compared with baselines. But our higher recall and F1 scores in dangling detection imply that more predicted matchable source entities would enter two-step entity alignment, which can improve the final alignment performance. Comparing MHP + MR and MHP + BR, we can see that the MR variant is generally better than the BR variant. This is because MR considers the similarity between a source and its nearest neighbor, which can benefit the learning of local high-order proximity in MHP. In summary, MHP demonstrates superior effectiveness for detecting dangling entities.

Two-step entity alignment. The results of two-step alignment are shown in Tab. 2. In general, MHP again consistently offers better F1 scores than baseline methods. The relative improvement ranges from 11% to 32%. The improvement can be partly attributed to the more accurate dangling entity detection performance, and thus less error is propagated to the alignment process. In contrast, baselines may try to align many dangling entities, which leads to lower performance on two-step alignment. As MHP with MR outperforms MHP + BR in dangling detection, MHP + MR also achieves better performance in two-step alignment. This indicates that dangling entity detection is of importance on the dangling-aware entity alignment problem since it has strong effects on the performance of two-step alignment.

4.3 Relaxed evaluation

Tab. 3 shows the results of relaxed evaluation. This setting only considers matchable source entities in the test phase to investigate how our framework affects the alignment learning of these entities.

Generally, MHP offers better performance than baselines on all language pairs in terms of all metrics. This indicates that dangling awareness captured by MHP further helps with a more precise alignment. The improvement can also be partly attributed to the alleviated hubness problem by the NCA loss which we investigate more in Sec. 4.4. Comparing two variants of MHP, we can see that MHP + MR usually outperforms the BR variants on most language pairs except for FR-EN. The reason could be that FR-EN has more entities and only with sufficient data BR can effectively separate dangling entities from randomly sampled target entities, while MR is not sensitive to data volume.

---

[5] AliNet performs worse than MTransE on dangling-aware entity alignment as found by Sun et al. (2021).

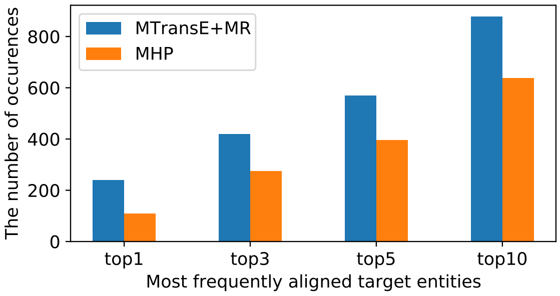

Figure 3: The number of total occurrences of most frequently aligned target entities on ZH-EN.

4.4 Ablation study

To investigate the effectiveness of each module in MHP, we conduct an ablation study on the consolidated setting and show the results in Tab. 4. Compared with the full version MHP, removing any component causes the degraded performance. Specifically, by removing the dangling classifier, the F1 score of dangling detection drops 0.055, which also leads to a large performance drop on two-step alignment. This indicates that the local high-order proximity is useful for dangling detection. Removing OT decreases the F1 scores on both detection and two-step alignment, showing the effectiveness of globally aligning distributions. Lastly, leaving the NCA loss out makes the F1 score of two-step alignment decrease 0.02 compared with MHP, because using the NCA loss reduces the extent of hubness, as discussed below.

Hubness problem. To examine whether the NCA loss reduces the hubness problem, we list a set of most frequently aligned (target) entities, and observe how frequently they appear as the nearest neighbor of other entities in the embedding space. We compare MHP with the MTransE + MR variant used by Sun et al. (2021). As shown in Fig. 3, the most frequently aligned target entity (i.e., top 1) appears over 200 times as the nearest neighbor using the baseline, whereas it only appears around 100 times using MHP. A similar phenomenon is also observed for the top 3, top 5, and top 10 frequently aligned target entities. This indicates that the hubness problem is mitigated by using NCA.

4.5 Case study

To further investigate the superiority of MHP, we provide a case study on ZH-EN comparing MHP with the previous method. Fig. 4 shows that, the previous method predicts some dangling source entities as matchable based on their high cosine similarities (i.e., > 0.7) to their nearest target entities. Each dangling entity and its corresponding nearest target entity are different but share similar meanings (e.g., are both war events in ancient China or locations). However, the nearest targets prefer other source entities with higher similarities. Using this second-order proximity information, MHP correctly detects these dangling entities with high probability scores (i.e., > 0.9).

Additionally, Tab. 5 demonstrates more dangling entities which are not correctly detected by the previous method (Sun et al., 2021). Most of the dangling entities are aligned to some similar counterparts sharing the same attribute. For example, the dangling entity and its nearest target entity are both colleges, theoretical physicists, or political parties. However, from the view of the nearest target entity, it prefers other nearest neighbors on source KG. Such second-order proximity information cannot be captured by the previous method, which causes those dangling entities not able to be detected. In contrast, MHP can successfully detect those dangling entities with high probabilities. This shows the effectiveness of MHP and the informativeness of the second-order proximity.

5 Related Work

Entity alignment. Embedding-based entity alignment methods seek to find identical entities between KGs in their embedding spaces. Such a method encodes each KG into an embedding space and capture entity alignment by learning a linear mapping between embedding spaces (Chen et al., 2017) or directly infer the embedding proximity in a shared space (Sun et al., 2017). Existing studies mainly fall into two lines of improving the embedding representations. The first line exploits better graph encoders to improve embedding learning (Sun et al., 2018; Wang et al., 2018; Cao et al., 2019; Sun et al., 2020a,b; Fey et al., 2020). The second group considers the side information of entities (Chen et al., 2018b; Trisedya et al., 2019; Zhang et al., 2019; Xu et al., 2019b; Wang et al., 2020; Tang et al., 2020; Wu et al., 2019; Yang et al., 2019; Liu et al., 2020, 2021). Interested readers can refer to the recent surveys (Sun et al., 2020c; Zeng et al., 2021). Note that prior methods nearly all assume one-to-one perfect match exists between two KGs, without considering dangling entities.

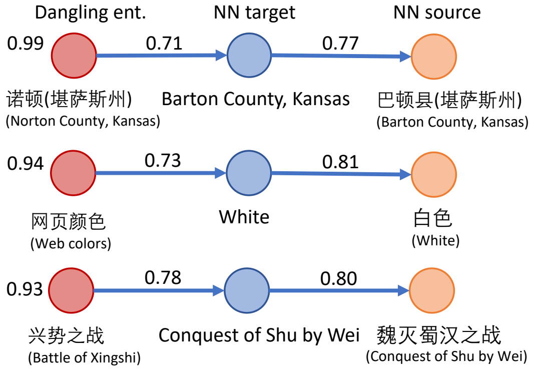

Figure 4: Case study on ZH-EN where some dangling entities wrongly predicted as matchable by the previous first-order method can be correctly predicted as dangling with high probabilities via MHP. Arrows point from an entity to its NN in the other KG. The scores above arrows denote cosine similarities and those beside dangling ent. are probabilities of dangling by MHP.

Recently, Sun et al. (2021) have proposed a new problem setting, i.e., danging-aware entity alignment, which is more practical as dangling entities naturally exist in real-world KGs. This problem setting requests a model to both detect dangling entities and align matchable ones. As the pioneering work, Sun et al. (2021) propose three baseline methods (i.e., marginal ranking, background ranking, and nearest neighbor classification) based on the nearest neighbor of source entities. Thus, these methods only rely on the first-order proximity, which is the major difference with MHP.

Optimal transport. Optimal transport (OT) aims to find the plan with minimal transportation cost for changing one distribution to another distribution, which naturally provides a way to align two distributions. Arjovsky et al. (2017) use the Wasserstein distances to recast the learning of generative adversarial network (GAN) as a transportation problem. OT has been widely used in other applications like text generation (Chen et al., 2018a) and graph

Table 5: Some dangling source entities wrongly predicted as matchable by the previous method, while MHP predicts them as dangling with high probabilities. Cls. Prob. denotes the probabilities of dangling generated by MHP. The fourth column denotes the cosine similarity between the dangling entity and its nearest target. The nearest source is the nearest neighbor of the nearest target on the source KG. The last column denotes the cosine cosine similarity between the nearest target and its nearest source.

matching (Xu et al., 2019a). Pei et al. (2019) formalize entity alignment as OT in the conventional setting, which however only considers one-to-one alignment between matchable entities. We instead leverage OT to identify dissimilar parts of embedding distributions to detect dangling entities, meanwhile using OT only as one of the three high-order measures for alignment.

6 Conclusion

In this paper, we propose a framework, MHP, with mixed high-order proximities for dangling-aware entity alignment. MHP captures the local high-order proximity via a dangling classifier based on both the first- and second-order proximities. Additionally, we propose a Optimal Transport based method considering the global high-order proximity to facilitate both dangling detection and entity alignment. Comprehensive experiments on two alignment settings show the effectiveness of utilizing mixed high-order proximities. Furthermore, our extensive ablation study demonstrates the effectiveness of each technique.

Appendices

A Dataset Statistics

We present the dataset statistics of DBP2.0 (Sun et al., 2021) in Tab. 6. DBP2.0 contains three cross-lingual settings for dangling-aware entity alignment, i.e., Chinese-English (ZH-EN), Japanese-English (JA-EN) and French-English (FR-EN). Please note that FR-EN is much larger than ZH-EN and JA-EN, and our methods are scalable to such a large dataset.

Datasets		# Entities	# Danglings	# Rel.	# Triples	# Align.
ZH-EN	ZH	84,996	51,813	3,706	286,067	33,183
	EN	118,996	85,813	3,402	586,868	
JA-EN	JA	100,860	61,090	3,243	347,204	39,770
	EN	139,304	99,534	3,396	668,341	
FR-EN	FR	221,327	97,375	2,841	802,678	123,952
	EN	278,411	154,459	4,598	1,287,231	

Table 6: Dataset statistics of DBP2.0

B Computational Environment

We run experiments on a Linux machine with a single GeForce RTX 2080 Ti GPU with 11 GB GPU memory and a Intel(R) Xeon(R) Gold 6240 CPU @ 2.60GHz. The operating system of our machine is Ubuntu 18.04.2 LTS. The major software packages used are as follows: TensorFlow 1.12; CUDA 10.1; Python 3.6; NumPy 1.18.1; SciPy 1.4.1. Our source code is available in the attachment for reproducible experiments.

C Hyperparameter Settings

To ensure a fair comparison, we follow the hyperparameter settings of the base alignment model (i.e., MTransE and AliNet) and the base dangling detection loss (i.e., MR and BR) reported in the previous work (Sun et al., 2021). For our proposed methods, in WGAN, we use a two-layer FNN with 500 hidden units for the critic. As suggested by Arjovsky et al. (2017), we adopt weight clipping to ensure K-Lipschitz for WGAN and train the critic more than the generator (i.e., the transformation matrix). Besides the hyperparameter stated in Section 4.1, we tune other hyperparameters within a search space as follows:

- The number of nearest targets k: {5, 10, 15}
- The number of nearest sources m: {5, 10, 15}
- Batch size: {4096, 8192, 10240, 20480}

D More on Experiments

As shown in Sun et al. (2021), AliNet (Sun et al., 2020b) performs much worse than MTransE (Chen et al., 2017) in dangling-aware entity alignment. Dangling entity detection would also suffer as a result of the poor alignment performance. However, in this section, we still present the results of MHP with AliNet as the base alignment model to demonstrate that MHP is model-agnostic and has a good robustness.

Consolidated evaluation. Tab. 7 shows that, using AliNet as the base model, MHP still outperforms baselines in terms of F1 scores on dangling detection. We can see that baselines sometimes achieve better precision with the sacrifice of recall, which leads to unsatisfactory F1 scores. Comparing our two variants MHP + MR and MHP + BR, there is no one consistently achieving better performance than the other one. We report the performance of

Table 9: Entity alignment results in the relaxed setting on DBP2.0. The base alignment model is AliNet.

two-step entity alignment on Tab. 8. In general, MHP offers better performance on two-step alignment compared with baselines that do not consider high-order proximities. We observe that when we choose AliNet as the base model, the improvement over the baselines is less than the improvement when using MTransE as the base model. The reason could be that AliNet generally performs worse than MTransE, even only with MR or BR. For example, combining Tab. 1 and 7, MTransE+MR can achieve 0.740 F1 score, while AliNet+MR only obtains 0.627 F1 score. The observation is also pointed out by Sun et al. (2021). The inherent inferiority of AliNet in dangling-aware entity alignment can hinder our new proposed techniques. Therefore, we suggest to use MTransE as the base alignment model for dangling-aware entity alignment. Future work could investigate other advanced alignment models on this setting.

Relaxed evaluation. Tab. 9 demonstrates the results of entity alignment in the relaxed setting. We observe that AliNet without any dangling detection technique performs the worst. By applying dangling detection techniques, the alignment performance increases, indicating that learning to detect dangling entities can indirectly help alignment. MHP with two different base dangling losses (i.e., MR and BR) generally outperforms the corresponding baselines without our proposed techniques. For our two variants, MHP + MR slightly outperforms MHP + BR variants in most cases.

E Computational Cost

Note that, similar with the MR loss (Sun et al., 2021), MHP also relies on nearest neighbor search (NNS) for training. Therefore, MHP can reuse the results of NNS obtained by MR during the training phase, and cause negligible additional overhead. On ZH-EN, MHP averagely spends around 60 seconds training an epoch. When the efficiency is of importance in some real-time applications, we can adopt the large-scale efficient similarity search library faiss (Johnson et al., 2021) which uses GPUs for fast NNS. Additionally, we could also maintain a cache unit to store the results of NNS and only lazily update the results every ten or twenty epochs during training.

F Limitations

We notice that many prior studies on conventional entity alignment consider the side information of entities (e.g., names, descriptions and attributes) (Chen et al., 2018b; Trisedya et al., 2019; Zhang et al., 2019; Xu et al., 2019b; Wang et al., 2020; Wu et al., 2020). However, on dangling-aware entity alignment, the pioneer work (Sun et al., 2021) proposes a framework that only considers the structure information of entities since most KGs are built around relation triples. Thus, for a fair comparison, we follow their setting and do not utilize side information of entities. Future work could investigate how to effectively incorporate side information for dangling-aware entity alignment in the proper way and with a fair evaluation.

DecBERT: Enhancing the Language Understanding of BERT with Causal Attention Masks

Abstract

Since 2017, the Transformer-based models play critical roles in various downstream Natural Language Processing tasks. However, a common limitation of the attention mechanism utilized in Transformer Encoder is that it cannot automatically capture the information of word order, so explicit position embeddings are generally required to be fed into the target model. In contrast, Transformer Decoder with the causal attention masks is naturally sensitive to the word order. In this work, we focus on improving the position encoding ability of BERT with the causal attention masks. Furthermore, we propose a new pre-trained language model *DecBERT* and evaluate it on the GLUE benchmark. Experimental results show that (1) the causal attention mask is effective for BERT on the language understanding tasks; (2) our *DecBERT* model without position embeddings achieve comparable performance on the GLUE benchmark; and (3) our modification accelerates the pre-training process and *DecBERT w/ PE* achieves better overall performance than the baseline systems when pre-training with the same amount of computational resources.

1 Introduction

In recent years, Transformer model proposed by Vaswani et al. (2017) has supplanted the widely-used LSTM (Hochreiter and Schmidhuber, 1997) as an indispensable component of many NLP systems. There are two branches of model variant: Transformer Encoder and Transformer Decoder. The Encoder-based Language Models, e.g., BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and DeBERTa (He et al., 2020), have achieved great success on many natural language understanding benchmarks (e.g. GLUE (Wang et al., 2019b) and SuperGLUE (Wang et al., 2019a)). The Decoder-based Language Models such as GPT-family (Radford and Narasimhan, 2018; Radford et al., 2019; Brown et al., 2020) have shown superior performances on natural language generation. All of them utilize the Multi-Head Self-Attention (MHA) mechanism (Vaswani et al., 2017). Since MHA is designed as an order-invariant mechanism (Lee et al., 2019), Transformer Encoder without the help of position embeddings should share the same intuitions with the bag-of-word model. On the other hand, in Transformer Decoder, the causal attention masks make the MHA different from that of the Transformer Encoder. Specifically, Tsai et al. (2019) have proved that MHA with such attention masks is not permutation equivalent, indicating that Transformer Decoder is sensitive to word order.

It is noticed that several studies focus on enriching the position information of BERT to improve the performance of natural language understanding (Dai et al., 2019; Dufter et al., 2020; He et al., 2020; Wu et al., 2021a; Ke et al., 2021), e.g., introducing extra learnable parameters to trace the word order. Previous analysis also indicate that the lower layers of BERT tend to capture rich surface-level language structural information such as position information (Jawahar et al., 2019). In this paper, to improve the language understanding of BERT, we propose to enrich the position information in the lower hidden layers instead of introducing extra learnable positional parameters.

To this end, we firstly design analysis experiments to examine the effectiveness of causal attention masks in terms of capturing position information. Then we propose a new pre-trained language model *DecBERT* by adding the causal attention masks into the lower layers of BERT (e.g., the first two layers) to enhance the position encoding ability. In this way, our proposed model is naturally sensitive to word order. Then we pre-train our *DecBERT* as a masked language model, following the same objective as BERT. To verify whether our modification can help BERT trace word order, we also make a comparison with a variant of our *DecBERT* that

---

[*] equal contribution

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1185 - 1197
July 10-15, 2022

excludes any position embeddings. The experimental results show that *DecBERT w/o PE* has 77 times (4.59 vs. 353.97) lower valid PPL score than BERT w/o PE and achieves comparable performance with BERT w/ PE on downstream tasks, corroborating the effectiveness of our modification. Furthermore, *DecBERT w/ PE* achieves better performances than BERT on most downstream tasks when pre-training with the same amount of time and computational resources. By analyzing the pre-training process, we find that our modification can also accelerate pre-training.

The contributions of this work are summarised as follows:

- We propose a novel pre-train model *DecBERT* utilizing the causal attention masks to enhance language understanding of BERT.
- We show that *DecBERT w/o PE* has comparable performance with BERT w/ PE, indicating that the causal attention masks are effective for modeling word order.
- When pre-training with the same amount of time and computational resources, *DecBERT w/ PE* achieves lower validation PPL and better overall performance on GLUE than BERT.

2 Background: Transformer

Transformer is a neural network model proposed by Vaswani et al. (2017), which relies on the multi-head self-attention (MHA) mechanism.

Input Layer. Due to the order-invariance of MHA (Lee et al., 2019), a token embedding is added with a position embedding as the input of Transformer Encoder or Decoder:

$$h_i = TE(x_i) + PE(i), \tag{1}$$

where x_i is a token at the i^{th} position. TE is a token embedding matrix and PE is a position embedding matrix. In the paper of Vaswani et al. (2017), they use a fixed sinusoidal PE:

$$\begin{aligned} PE[i, 2j] &= \sin(i/10000^{2j/d_m}), \\ PE[i, 2j+1] &= \cos(i/10000^{2j/d_m}), \end{aligned} \tag{2}$$

where j is the dimension and d_m is the model size. In the later work, Devlin et al. (2019) choose to use a learnable PE matrix.

Multi-head Self-attention (MHA). MHA takes a sequence of vectors $h = [h_1, h_2, ..., h_n]$ as input. Then they are transformed into three different vectors, query (Q), key (K) and value (V), by three linear transformations and passed to the multi-head self-attention (MHA). The computation process of a single head is:

$$Attention(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V, \tag{3}$$

where d_k is the dimension of a single head. MHA repeats the same process for h heads. The outputs of all heads are concatenated together and passed through a linear projection W^O again:

$$\begin{aligned} &H_i = Attention(Q_i, K_i, V_i), \\ &MHA(Q, K, V) = concat(H_1, ..., H_h)W^O. \end{aligned} \tag{4}$$

Transformer Encoder and Decoder. An Encoder layer consists of multi-head attention following with a feed-forward network (FFN). The outputs of MHA and FFN are passed through a LayerNorm (Ba et al., 2016) with residual connections (He et al., 2016). Then we stack multi-layer to form a Transformer Encoder. The difference between Decoder and Encoder is that Decoder uses the causal attention masks to mask the attention values of the subsequent tokens so that Decoder can only decode tokens relying on the tokens in the past.[1]

3 Methodology

In this section, we first analyze the relationship between Transformer Decoder and position embeddings (section 3.1). Based on this analysis, we inject the causal attention masks into BERT to create our new pre-trained language models, *DecBERT* (section 3.2).

3.1 Transformer Decoder and Position Embeddings

Previous studies (Tsai et al., 2019) indicate that Transformer Decoder with causal attention masks is sensitive to word order. We wonder whether Transformer Decoder can perform well without position embeddings. We assume that if Transformer Decoder without any position

---

[1] We do not consider the Encoder-Decoder Seq2seq structure with cross attention here. Encoder and Decoder are used independently.

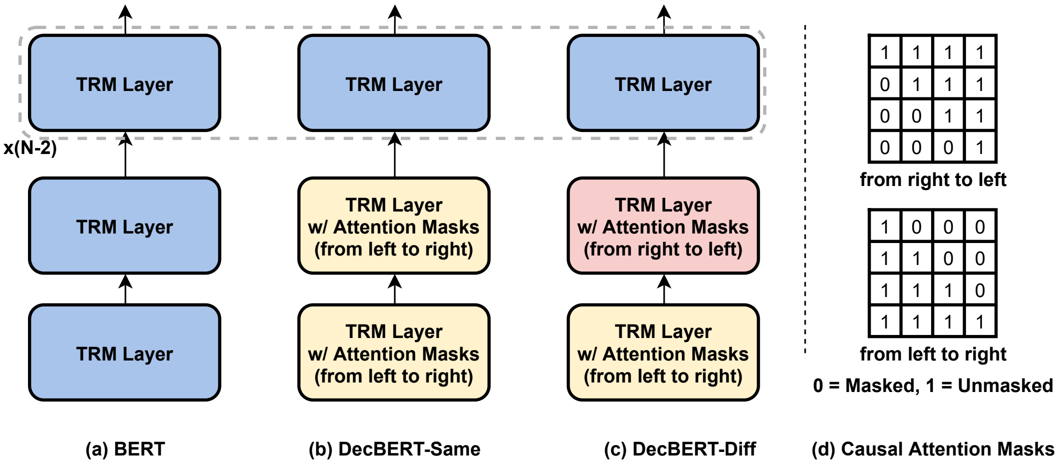

Figure 1: Model structures of BERT and DecBERT. TRM refers to the Transformer layer.

embeddings still retains comparable performance with its counterpart with position embeddings, it will corroborate that the causal attention masks are helpful for Transformer to encode word order. To this end, we design a straightforward experiment of causal language modeling respectively on English and Chinese data as followed.

Basic Model. Our basic model is an 8-layer Transformer Decoder with 768 embedding size, 3072 feedforward layer hidden size, 12 attention heads and GELU activation function (Hendrycks and Gimpel, 2020), which is a smaller version of GPT and has 95M trainable parameters for English model and 77.5M for Chinese model.[2] We find that if we use a standard 12-layer GPT, the number of trainable parameters will be higher than the number of tokens in the WikiText-103 dataset. This has a risk to cause over-fitting, so we choose to use an 8-layer model.

Data and Training. We resort to two publicly available wikipedia datasets. The first one is the English WikiText-103 (Merity et al., 2017). We train and evaluate our language models on the standard splits of the WikiText-103, which contains 1.8M sentences for training and 3.76k sentences for evaluation. The second one is the Chinese Wikipedia which contains about 9.28M sentences. We randomly select 34k sentences for evaluation and 9.25M for training. We use Fairseq (Ott et al., 2019) to pre-process all the data into the binary files. All the English data is tokenized by SentencePiece tokenizer (Kudo and Richardson, 2018), which is the same as RoBERTa. All Chinese data is tokenized by character.

Transformer Decoder	w/o *PE*	w/ *PE*
WikiText-103	23.52	23.37
Chinese Wiki	12.96	12.75

Table 1: Transformer Decoders perplexity (PPL) on WikiText-103 and Chinese Wikipedia validation sets. *PE* refers to the learnable position embeddings.

All models are trained with Fairseq. The training objective is the Causal Language Modeling objective. We use a batch size of 128 and train for 100k steps, optimized by Adam (Kingma and Ba, 2015). We also use the polynomial learning rate decay with 10k warmup steps. All models use the same hyper-parameters. We list the details in the Appendix. We use two NVIDIA A100 40GB GPUs to train each model. For the WikiText-103, it costs about 10 hours per model. For the Chinese Wikipedia, it costs about 8.5 hours per model.

Results and Discussion. Table 1 presents the perplexity (PPL) scores of Transformer Decoders with or without position embeddings on WikiText-103 and Chinese Wikipedia validation sets. Transformer Decoder w/o PE achieves comparable performance with its counterpart with learnable PE, which is only about 0.2 higher. This result reveals that the additional performance gain brought by position embeddings is small. Only relying on its causal attention masks, Transformer Decoder still can perform well. Combing our experiment and the previous studies (Tsai et al., 2019; Irie et al., 2019),

---

[2] The Chinese vocabulary size is smaller than English, so the Chinese model has fewer parameters.

the causal attention masks can make Transformer sensitive to word order.

3.2 Our DecBERT Model

In section 3.1, we conclude that Transformer with the causal attention masks is naturally sensitive to word order. Since the position information is inevitable for BERT, we propose to enhance existing BERT model based on causal attention masks.

In this paper, we intend to add the causal attention masks into all or some hidden layers of BERT. In this way, the specific layers with such masks are sensitive to word order by design, which can enhance the position encodings ability of BERT. Such framework can further result in better language understanding performances, e.g., in pre-trained language modeling, casual attention masks were added on all 12 layers of GPT (Radford and Narasimhan, 2018). However, comparing with BERT (Devlin et al., 2019), we observe that GPT lags behind BERT on almost all downstream tasks.[3] This is because self-attention mechanism with such masks only consider one-side information flow, it cannot process the input sentence comprehensively and has a high risk of language information loss. Therefore, we can conjecture that it is not effective to use the causal attention masks in all hidden layers. There is a strong need to maintain a balance between the gain of position encoding ability and the loss of language information.

In order to determine which layer(s) should add casual attention masks, we refer to the BERTology work (Jawahar et al., 2019) that conduct comprehensive experiments to analyze and interpret the information captured by each layer of BERT. The experimental results indicate that the lower layers of BERT capture rich language structure information. The position information is also a common structure information, so that we propose to add the causal attention masks into the lower layers (e.g., the first two layers[4]) to improve the position encoding ability of BERT. We denote our model as **DecBERT**. There are two versions of our model, **DecBERT-Same** and **DecBERT-Diff**. All of them are 12-layer base size models.

- **DecBERT-Same**: This model has a similar structure as BERT (see Figure 1(a)), but we use the causal attention masks to convert the first two Encoder layers into two Decoder layers with the same direction (from left to right). So the 12-layer model has 10 Encoder layers and 2 Decoder layers, which is shown in Figure 1(b). In this way, the first two layers are naturally sensitive to word order;
- **DecBERT-Diff**: This model is designed to enhance **DecBERT-Same** to gain more language information from different encoding directions. This model has a same structure as **DecBERT-Same**, except the second Decoder layer that has the opposite direction (from right to left). Figure 1(c) illustrates the model structure.

One would think that **DecBERT** is similar to Transformer with RNN layer (Neishi and Yoshinaga, 2019). Note that **DecBERT** is quite different from it, because **DecBERT** has similar structure as **BERT** and both of them require the same amount of computational time, which is much faster than that of Transformer with RNN.

4 Experiments and Results

4.1 Experimental Setup

Our experiments can be separated into two parts, small-scale pre-training scenario and large-scale pre-training scenario. Since the small-scale pre-training consumes much less time and fewer computational resources, we intend to answer several research questions in this part:

- Can DecBERT **without** any position embeddings still understand language well?
- Can DecBERT **with** position embeddings outperform BERT?
- Is using different directional causal attention masks more helpful than using the same directional?
- Why can DecBERT benefit from the causal attention masks, how do such masks affect the pre-training process?

For the large-scale pre-training scenario, we intend to examine whether the performance gap between our *DecBERT* and BERT will be diminished after scaling up the pre-training data size and time. Such settings can present a more comprehensive

---

[3] Although GPT and BERT are pre-trained with different objectives, the comparison is reasonable due to the same downstream tasks.

[4] We conducted massive experiments by adding the masks in the first, first-two, or first-three layer(s), and the first-two layers achieve the best performance.

view of whether our modification can benefit the pre-trained language models.

For a fair comparison, we re-implement BERT and pre-train it with the same settings as *DecBERT* in the small-scale and large-scale pre-training. We denote it as *BERT-reImp*.

Small-scale Pre-training Scenario. The pre-training data is the widely-used English Wikipedia Corpus. We randomly select 158.4M sentences for training and 50k sentences for validation. The pre-training objective is the Masked Language Modeling objective. We use a batch size of 256 and pre-train for 200k steps, optimized by Adam. All models use the same hyper-parameters. We list the details in the Appendix. We use four NVIDIA A100 40GB GPUs to pre-train each model, costing about 34.5 hours per model.

Large-scale Pre-training Scenario. Limited by time and computational resources, it is impossible for us to pre-train all models in the small-scale pre-training scenario from scratch in this setting. Thus, we decide to pre-train the best model in the small-scale scenario and the baseline model *BERT-reImp w/ PE* in this part. We use a large amount of pre-training data (around 160GiB[5]). The batch size is set to 4096 and the pre-training steps are 300k. We pre-train each model with 8 NVIDIA A100 40GB GPUs, costing about 15 days per model. The hyper-parameters details can be also seen in the Appendix.

Fine-tuning. To evaluate the language understanding ability of our models, we fine-tune them with 8 tasks of GLUE benchmark (Wang et al., 2019b), including SST-2 (Socher et al., 2013), QNLI (Rajpurkar et al., 2016), MNLI (Williams et al., 2018), QQP,[6] MRPC (Dolan and Brockett, 2005), CoLA (Warstadt et al., 2019), RTE[7] and STS-B (Cer et al., 2017). All fine-tuning hyper-parameters details are listed in the Appendix.

4.2 Small-scale Pre-training

Table 2 presents the pre-training perplexity scores of all systems on the validation set. Table 3 shows the performance of different systems on the GLUE benchmark. One can notice that our proposed models achieve lower valid PPL scores and higher overall scores on the downstream tasks.

Models	w/ *PE*	Valid PPL
Baseline		
BERT-reImp	False	353.97
BERT-reImp	True	4.28
Ours (w/o position embeddings)		
DecBERT-Same	False	4.59
DecBERT-Diff	False	4.59
Ours (w/ position embeddings)		
DecBERT-Same	True	4.12
DecBERT-Diff	True	**4.07**

Table 2: The validation set perplexity of all models in small-scale pre-training scenario. (w/ *PE* = with learnable position embeddings)

Can DecBERT without any position embeddings still understand language well? Since the self-attention of Transformer Encoder is order-invariant, the extra position information is inevitable for it to model language. Otherwise, it just becomes a bag-of-word model. From Table 2, we can find that the valid PPL score of *BERT-reImp w/o PE* is up to 353.97, which is about 82 times higher than its counterpart with position embeddings (4.28), revealing that this bag-of-word model cannot model language well. However, one can notice that *DecBERT* does not have such phenomenon. The valid PPL score of *DecBERT w/o PE* is only about 0.5 higher than *DecBERT w/ PE*. Compared with *BERT-reImp w/o PE*, the causal attention masks can decrease the PPL score by a large margin (from 353.97 to 4.59). After fine-tuning on downstream tasks, Table 2 indicates that *DecBERT-Same/Diff w/o PE* retains the same level performance as *BERT-reImp w/ PE*. These results reveal that *DecBERT* still can understand language well without the help of position embeddings, which is in line with our experimental results in section 3.1.

Can DecBERT with position embeddings outperform BERT? Table 2 shows that both *DecBERT-Same* and *DecBERT-Diff* have lower validation PPL scores than *BERT-reImp* (w/ PE). After fine-tuning on the downstream tasks, Table 3 reveals that they also have better performance on most tasks. These results confirm our belief that

our models can benefit from the causal attention masks. Such masks enhance the position encoding ability of BERT, leading to better language understanding ability.

Is using different directional causal attention masks helpful? The only difference between *DecBERT-Same* and *DecBERT-Diff* is that we adopt a different directional causal attention mask in the second layer. Table 2 shows that *DecBERT-Diff w/ PE* achieves the lowest validation PPL score (4.07). After fine-tuning on the downstream tasks, it also has the best overall score. These results confirm our belief that *DecBERT* can benefit from using different directional attention masks. Though the first two layers of *DecBERT-Diff* only consider one-side information flow, the model can learn to process different directional information in the first two layers. This design maintains a better balance between the gain of position encoding ability and the loss of language information.

Why can DecBERT benefit from the causal attention masks? The experimental results in the previous part indicate that the causal attention masks can increase the model's position encoding ability. Then such ability leads to better language understanding ability. However, the relation between these two abilities remains unclear. We analyze the pre-training process of our models to give a possible explanation.

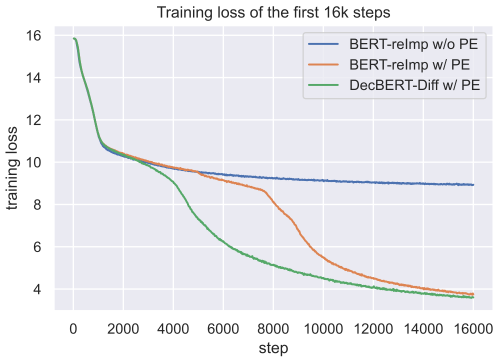

Figure 2: The pre-training loss of the first 16k steps. (Small-scale pre-training)

Our models' pre-training loss curves are presented in Figure 2 and 3. Since the randomly initialized Multi-head Self-Attention of BERT is a "balance" structure without any inductive bias, the model needs to learn suitable position embeddings to trace the word order during pre-training. In Figure 2, one can notice that the pre-training process of *BERT-reImp w/ PE* can be divided into four stages: (1) starting stage (0-1000 steps), (2) plateau

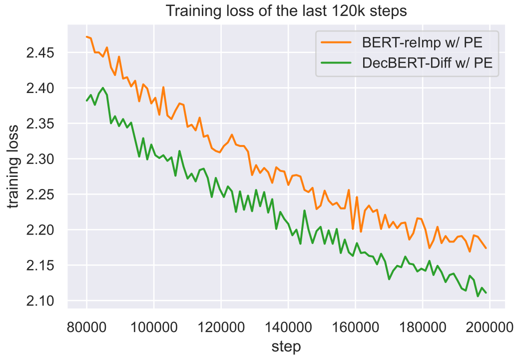

Figure 3: The pre-training loss of the last 120k steps. (Small-scale pre-training)

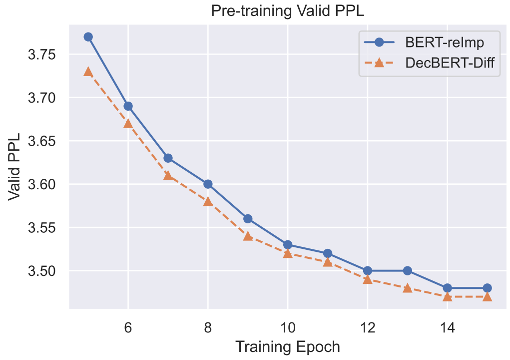

Figure 4: The PPL scores on validation set from epoch 5 to epoch 15 of our models. (Large-scale pre-training)

stage (1000-8000 steps), (3) "diving" stage (8000-10000 steps) and (4) convergence stage (10000-final steps). In the starting and plateau stages, *BERT-reImp w/ PE* has almost the same training loss as its counterpart without PE, which indicates that it is still a bag-of-word model and does not know how to make use of the position information. In the "diving" stage, the training loss of *BERT-reImp w/ PE* decreases rapidly, while *BERT-reImp w/o PE* starts to converge. This reveals that the word order information becomes more useful for models to understand language in such stage. In the convergence stage, the training loss decreases slowly to the end of the whole pre-training process.

So, how do the causal attention masks affect the pre-training process? The first two layers of *DecBERT* can break the "balance" of the multi-head self-attention by design. The position bias from the attention masks makes the first two layers sensitive to word order information. In Figure 2, one can notice that the plateau stage of *DecBERT* is shortened (from around 7000 to 3000 steps). This reveals that *DecBERT* does not need to spend as much time as BERT to learn to make use of the position information. It can escape from the bag-of-words sub-optimal point faster. Though the gap between *BERT-reImp w/ PE* and *DecBERT-Diff w/ PE* become smaller in the convergence stage, Figure 3 indicates that *DecBERT-Diff w/ PE* still has lower training loss in the whole pre-training process.

4.3 Large-scale Pre-training

In the large-scale pre-training scenario, we intend to verify whether our modification still achieves better performance. From Figure 4 and Table 4, one can find that the experimental results are similar to the small-scale pre-training scenario. For the validation PPL, *DecBERT-Diff* achieves lower scores than *BERT-reImp* in the whole pre-training process. Especially, at the 13^{th} epoch (265k steps), the valid PPL score of *DecBERT-Diff* is 3.48, which is the same as *BERT-reImp* at the 15^{th} epoch (300k steps). This suggests that the pre-training process of *DecBERT-Diff* is about 2 epochs faster than *BERT-reImp*. Combing our previous analysis, one advantage of our modification is that it can accelerate the pre-training process. Comparing the downstream tasks, one can also notice that the performance gap between *DecBERT-Diff* and *BERT-reImp* even becomes larger. The average score is 1.2 points higher.

All results in this part indicate that our modification is effective not only in the small-scale pre-training, but also in the large-scale pre-training. It can accelerate the pre-training process. When pre-training with the same amount of computational resources, our modification can achieve better performance on masked language modeling and downstream tasks.

4.4 Discussion

The analysis and experimental results detailed in the previous sections point out an interesting finding that the pre-training process of BERT can be divided into different stages. A similar phenomenon also can be found in the work of Kovaleva et al. (2021). In their work, they find that both scaling factors and biases of the Layer Normalization begin to diverge from their initialization values quickly in the "diving" stage. Especially, one/two specific neurons of the biases have larger and larger absolute values. Luo et al. (2021) indicates that such neurons are highly related to the positional informa-

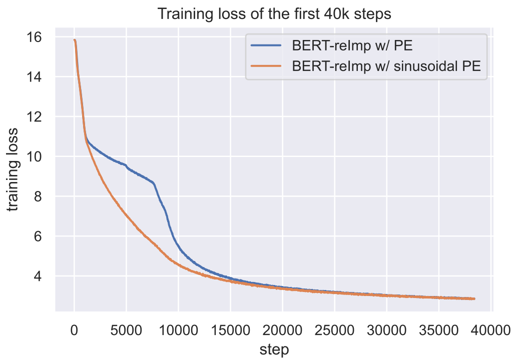

Figure 5: The pre-training loss of the first 40k steps. (Extra small-scale pre-training)

tion. These complement our possible explanation that in the plateau stage, the model needs to learn suitable position embeddings. Then in the "diving" stage, the model learns to adopt such embeddings to better model language. Our *DecBERT* models indicate that breaking the "balance" by design can help BERT better capture the position information, which leads to better performance.

One would wonder how about the fixed sinusoidal position embeddings. With such embeddings, BERT does not need to learn suitable position embeddings during pre-training. Based on our previous analysis, the plateau stage is possible to disappear. To examine whether such position embeddings are better, we conduct an extra small-scale pre-training experiment. The pre-training loss curve is in Figure 5, revealing that the plateau stage indeed disappears. This is in line with our previous results. However, in the convergence stage, we find that BERT with the sinusoidal PE has higher pre-training loss than using the learnable PE. This indicates that the learnable position embeddings are more suitable for BERT.

5 Related Work

The previous works (Vaswani et al., 2017; Shaw et al., 2018; Huang et al., 2019; Dai et al., 2019; Child et al., 2019) indicate that the self-attention mechanism of Transformer Encoder is permutation equivalent, so it needs to use the position embedding. Tsai et al. (2019) have proved that Decoder's self-attention is not permutation equivalent, indicating that Decoder is not a bag-of-word model as Encoder, but they do not conduct further analysis on Decoder's position encoding ability. Apart from the analysis, Irie et al. (2019) train the Transformer Language Models with speech dataset. They find that models without position embeddings have lower perplexity scores. Schlag et al. (2021a) introduce a new Linear Transformer Language Model with fast weight memories (Schmidhuber, 1992; Schlag et al., 2021b), which has lower perplexity without position encodings on the WikiText-103 dataset.

Furthermore, an explosion of work focuses on proposing a better method to add the position information into the pre-trained language model. Dufter et al. (2021) give a comprehensive introduction of different position encodings methods of Transformer. They divide position encodings into three approaches. One line of such work is to add position embeddings to the input before it is fed to the actual Transformer model (Vaswani et al., 2017; Shaw et al., 2018; Devlin et al., 2019; Kitaev et al., 2020; Liu et al., 2020; Press et al., 2020; Wang et al., 2020). The second line of work directly modify the attention matrix (Dai et al., 2019; Dufter et al., 2020; He et al., 2020; Wu et al., 2021a; Ke et al., 2021; Su et al., 2021). The last one combine the first two approaches together. However, all of them focus on introducing an extra set of parameters to trace the word order. Our work chooses to make use of the causal attention masks.

Most similar to our modification in Section 3.2, Im and Cho (2017) propose a self-attention based model which achieve better performance on SNLI task (Bowman et al., 2015) without the help of explicit position encodings. However, their models are different from the standard Transformer and use extra local attention masks to control the information flow. With the popularity of the Transformer model in the Computer Vision field, some works propose different methods to make Vision Transformer know word order implicitly (Chu et al., 2021; Yuan et al., 2021; Wu et al., 2021b), but all of them modify the models with convolution neural network (Lecun et al., 1998).

6 Conclusion

In this work, we introduce a new pre-trained model, called **DecBERT**, adopting the causal attention masks to enhance the language understanding of BERT. We conduct a series of experiments to verify the effectiveness of our models. Experimental results indicate that our proposed models achieve better performance than BERT on most downstream tasks when pre-training with the same amount of data and computational resources. Moreover, our analysis also indicates that our models can accelerate the pre-training process.

B The details of the large-scale pre-training corpus

The first part is the same as BERT. We use the English wikipedia dump (about 17 GiB) and the bookcorpus (Zhu et al., 2015) (about 4 GiB). The second part is based on the Pile dataset (Gao et al., 2020), which is a large datasets with 800 GiB diverse text data. We randomly extract 64 GiB data from the Pile-cc block, 35 GiB data from the OpenWebText2 block and 43 GiB data from the Books3 block. The overall size of all data is about 163 GiB.

Abstract

Active learning (AL) is a prominent technique for reducing the annotation effort required for training machine learning models. Deep learning offers a solution for several essential obstacles to deploying AL in practice but introduces many others. One of such problems is the excessive computational resources required to train an acquisition model and estimate its uncertainty on instances in the unlabeled pool. We propose two techniques that tackle this issue for text classification and tagging tasks, offering a substantial reduction of AL iteration duration and the computational overhead introduced by deep acquisition models in AL. We also demonstrate that our algorithm that leverages pseudo-labeling and distilled models overcomes one of the essential obstacles revealed previously in the literature. Namely, it was shown that due to differences between an acquisition model used to select instances during AL and a successor model trained on the labeled data, the benefits of AL can diminish. We show that our algorithm, despite using a smaller and faster acquisition model, is capable of training a more expressive successor model with higher performance.[1]

1 Introduction

Active learning (AL) (Cohn et al., 1996) is an approach for reducing the amount of dataset annotation required for achieving the desired level of machine learning model performance. This is especially important in domains where obtaining labeled instances is expensive or wide crowdsourcing is unavailable. For example, annotation of clinical and biomedical texts usually requires the help of physicians or biomedical researchers. The time of such highly qualified experts is extremely valuable and should be spent wisely. Straightforward annotation of datasets can be very redundant, wasting the time of annotators on unimportant instances. AL alleviates this problem by asking human experts to label only the most informative instances selected according to the information acquired from a machine learning model. The algorithm for selection of such instances is called a *query strategy*, and a model used to estimate the informativeness of yet unlabeled instances is called an *acquisition model*.

AL starts from a small *seeding set* of labeled instances, which are used to train an initial acquisition model. A query strategy ranks unlabeled instances in a large pool according to a criterion that measures their informativeness based on the acquisition model output. One of the most widely adopted criteria is the uncertainty of the acquisition model on instances in question (Lewis and Gale, 1994). Eventually, top selected instances are presented to annotators, and this active annotation process iteratively continues.

After labels are collected, we would like to train a model for a final application. In the same vein as (Lowell et al., 2019), we call it a *successor model*. AL can help reduce the amount of annotation required to achieve a reasonable quality of the successor text processing model by multiple times (Settles and Craven, 2008; Settles, 2009).

Recently, deep learning has given us a tool for solving one of the essential problems of AL. When we start annotating, we have to build an acquisition model almost without insights from the data that could help us to do feature engineering or to introduce inductive bias. Deep learning does not require feature engineering and transfer learning with deep pre-trained models like ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), and followers such as ELECTRA (Clark et al., 2020) provide near state-of-the-art performance on a variety of tasks without any modifications to their architectures. However, deep learning introduces another problem related

to computational performance. Since AL annotation typically is an interactive process, we have to train acquisition models and perform inference on a huge unlabeled pool of instances very quickly. This imposes constraints on the acquisition model size and entails another issue.

Ideally, the architectures of acquisition and successor models should be the same. Lowell et al. (2019) demonstrate that when the acquisition model is different from the successor model, the performance of the latter one can degrade compared to the performance of the model trained on the same amount of annotation obtained without AL. The performance drop in the case of acquisition-successor mismatch (ASM) raises the question of whether AL is a practical technique at all since the usage of different models on the annotated dataset is a common practice. The problem is complicated by a contradiction between the fact that the acquisition model is required to be as lightweight as possible to mitigate computational overhead and the successor model should be as expressive as possible because we apparently care about the quality of our final application.

In this work, we propose a simple algorithm based on pseudo-labeling and demonstrate that it is able to alleviate the ASM problem. Moreover, we show that it is possible to substitute a resource-intensive acquisition model with a smaller one (e.g., take DistilBERT instead of BERT) but train a more powerful successor model of an arbitrary type (e.g., ELECTRA) without loss of quality. This helps to accelerate the execution of AL iterations and reduce computational overhead.

We also find that the most time-consuming part of an AL iteration with uncertainty-based query strategies can be the inference on the unlabeled pool of instances, while a set of the most certain instances usually does not change substantially from iteration to iteration. Therefore, the straightforward approach to instance acquisition wastes much time on instances shown to be unimportant in previous iterations. We leverage this finding and propose an algorithm that subsamples instances in the unlabeled pool depending on their uncertainty scores obtained on previous AL iterations. This helps to speed up the AL iterations further, especially when the unlabeled pool is large. A series of experiments on text classification and tagging benchmarks widely used in recent works on AL demonstrate the efficiency of the proposed algorithms.

The contributions of the paper are the following:

- We propose a novel algorithm denoted as **P**seudo-**L**abeling for **A**cquisition **S**uccessor **M**ismatch (PLASM) that allows the use of computationally cheap models during the acquisition of instances in AL, while it does not introduce constraints on the type of the successor model and effectively alleviates the ASM problem. It helps to reduce the hardware requirements and the duration of AL iterations.
- We propose a novel algorithm denoted as **U**nlabeled **P**ool **S**ubsampling (UPS) that helps to reduce the time required for calculating informativeness of instances in AL based on the fact that the set of instances that model is certain about does not change substantially. This helps to further speed up the AL iteration.

2 Related Work

Deep learning, to a large extent, has freed data scientists from doing feature engineering, which has been one of the essential obstacles to annotation with AL. This advantage has sparked a series of works on deep active learning (DAL) in natural language processing (NLP).

Shen et al. (2017) conduct one of the first investigations on DAL in sequence tagging tasks. They propose an efficient way of quantifying the uncertainty of sentences, namely maximal normalized log probability (MNLP), by averaging log probabilities of their tokens. They also address the problem of excessive duration of a neural network training step during an AL iteration by interleaving online learning with training from scratch. In our work, we take MNLP as a query strategy for experiments on sequence tagging tasks since it has demonstrated a good trade-off between quality and computational performance. We consider that online learning can potentially be used as a complement to our algorithms. Since the most time-consuming part of an AL iteration can be model inference instead of training, in this work, we also pay attention to the acceleration of the inference step.

Several recent publications investigate deep pre-trained models based on the Transformer architecture (Vaswani et al., 2017), ELMo (Peters et al., 2018), and ULMFiT (Howard and Ruder, 2018) in AL on NLP tasks (Prabhu et al., 2019; Ein-Dor et al., 2020; Yuan et al., 2020; Shelmanov et al., 2021). We continue this line of works by relying on pre-trained Transformers since this architecture has been shown promising for AL in NLP due to its good qualitative and computational performance.

A few works have experimented with Bayesian query strategies for AL. Shen et al. (2017), Siddhant and Lipton (2018), Ein-Dor et al. (2020), and Shelmanov et al. (2021) leverage Monte Carlo dropout (Gal and Ghahramani, 2016) for quantifying uncertainty of models. Siddhant and Lipton (2018) also apply the Bayes by backprop algorithm (Blundell et al., 2015) for performing variational inference of a Bayesian neural network. This approach demonstrates the best improvements upon the baseline but introduces large computational overhead both for training and uncertainty estimation of a model, as well as the memory overhead for storing parameters of a Bayesian neural network. The query strategies based on Monte Carlo dropout do not affect the model training procedure and do not change the memory footprint. However, they also suffer from slow uncertainty estimation due to the necessity of making multiple stochastic predictions, while their empirical evaluations with Transformers in recent works (Ein-Dor et al., 2020; Shelmanov et al., 2021) do not demonstrate big advantages. Therefore, we do not use Bayesian query strategies in our experiments and adhere to the classical uncertainty-based query strategies.

Recently proposed alternatives to uncertainty-based query strategies leverage reinforcement learning and imitation learning (Fang et al., 2017; Liu et al., 2018; Vu et al., 2019; Brantley et al., 2020). This series of works aims at constructing trainable policy-based query strategies. However, this requires an excessive amount of computation while the transferability of learned policies across domains and tasks is underresearched.

Finally, Lowell et al. (2019) question the usefulness of AL techniques in general. They demonstrate that due to the ASM problem, AL can be even detrimental to the performance of the successor. This finding is also revealed for classical machine learning models by Baldridge and Osborne (2004), Tomanek and Morik (2011), Hu et al. (2016) and supported by experiments with Transformers in (Shelmanov et al., 2021). Our work directly addresses the question raised by Lowell et al. (2019) and suggests a simple solution to the ASM problem. Moreover, we combine it with the method proposed by Shelmanov et al. (2021), who suggest using distilled models for instance acquisition and their teacher models as successors.

3 Background

This section describes models and AL query strategies used in this work.

3.1 Query Strategies

We conduct experiments with four basic AL query strategies. We note that despite their simplicity, these strategies are usually on par with more elaborated counterparts (Ein-Dor et al., 2020; Shelmanov et al., 2021; Margatina et al., 2021).

Random sampling is used for both text classification and sequence tagging experiments. Applying this strategy means that we do not use AL at all and just emulate that an annotator labels a randomly sampled piece of a dataset.

Least Confident (LC) is used for text classification experiments. This strategy sorts texts in the ascending order of their maximum class probabilities given by a machine learning model. Let y be a predicted class of an instance x, then LC_{cls} is:

$$\mathrm{LC}_{\mathrm{cls}} = 1 - \max_{y} \mathbb{P}\left(y|x\right).$$

Maximum Normalized Log-Probability (MNLP) is proposed by Shen et al. (2017) to mitigate the drawback of the standard LC when it is applied to sequence tagging tasks. Let y_i be a tag of a token i, let x_j be a token j in an input sequence of length n. The MNLP score can be formulated as follows:

$$\mathrm{MNLP}_{\mathrm{ner}} = -\max_{y_1,\ldots,y_n} \frac{1}{n}\sum_{i=1}^{n} \log \mathbb{P}\left[y_i|\{y_j\}\backslash y_i,\{\mathbf{x}_j\}\right].$$

This modified version of LC works slightly better for sequence tagging tasks (Shen et al., 2017), and is adopted in many other works on DAL (Siddhant and Lipton, 2018; Erdmann et al., 2019; Shelmanov et al., 2021).

Mahalanobis Distance (MD) between a test instance and the closest class-conditional Gaussian distribution is suggested by Lee et al. (2018) for detection of out-of-distribution instances and adversarial attacks. MD is a strong baseline for uncertainty estimation of NLP model predictions (Podolskiy et al., 2021) and is also a backbone for other subsequent techniques (Zhou et al., 2021). We use it as an informativeness score in AL since previous work shows that MD captures epistemic uncertainty well (Podolskiy et al., 2021).

$$\mathrm{MD}_{\mathrm{cls}} = \min_{c \in C} (h_i - \mu_c)^T \Sigma^{-1} (h_i - \mu_c), \quad (1)$$

where h_i is a hidden representation of a i-th instance, μ_c is a centroid of class c, and Σ is a covariance matrix for hidden representations of training instances.

3.2 Models

We use the standard models based on the Transformer architecture (Vaswani et al., 2017): BERT, RoBERTa (Liu et al., 2019), ELECTRA, and XLNet (Yang et al., 2019). For supplementary experiments, we also employ two classical neural models: a CNN-BiLSTM-CRF sequence tagging model (Ma and Hovy, 2016) and a CNN-based text classification model (Le et al., 2018).

Besides full-fledged Transformers, we leverage their three smaller distilled versions: DistilBERT (Sanh et al., 2019), DistilRoBERTa, and a custom DistilELECTRA trained by ourselves. The distillation procedure aims at creating a smaller-size model (*student*) while keeping the behavior of the original model (*teacher*) by minimizing the distillation loss over the student predictions and soft target probabilities of the teacher (Hinton et al., 2015): $L_{distil} = -\sum_{i,c} t_{ic} \cdot \log(s_{ic})$, where t_{ic} and s_{ic} are probabilities estimated by the teacher and the student correspondingly for each instance i and class c. Typically, distillation loss is supplemented with additional techniques that help to align a student with a teacher (Sanh et al., 2019).

Distilled models are usually much more compact than their teachers. For example, DistilBERT reduces the memory footprint by 40% compared to the original BERT-base. It achieves the 60% speedup, sacrificing only 3% of its qualitative performance (Sanh et al., 2019). Since the qualitative performance during acquisition is not essential, we would like to use such lightweight models for instance acquisition to reduce AL iteration duration and the requirements for the computational power of the hardware.

4 Proposed Methods

This section outlines two proposed algorithms that help to reduce the computational cost of AL.

4.1 Pseudo-labeling for Acquisition-Successor Mismatch

We propose a simple algorithm for constructing a successor model of an arbitrary type using AL: *Pseudo-Labeling for Acquisition-Successor Mismatch (PLASM)*. The algorithm is designed for reducing the amount of computation required for instance acquisition during AL with uncertainty-based query strategies.

PLASM leverages the finding of Shelmanov et al. (2021) that the successor model can be trained on instances labeled during AL without a penalty to the quality if its distilled version was used for instance acquisition. However, this idea alone does not resolve the question, how we can train new models of arbitrary type on datasets collected via AL (Lowell et al., 2019).

The algorithm consists of the following steps:

1. Consider we have a resource-intensive pretrained teacher model (e.g. BERT). We construct a lightweight distilled version of this model (e.g. DistilBERT) using unlabeled data.
2. We apply a distilled model to perform acquisition during AL for collecting the gold labels.
3. The collected labels are used for fine-tuning a resource-intensive teacher model of a higher quality than the distilled acquisition model.
4. The teacher model is used for pseudo-labeling of the whole unlabeled pool of instances.
5. The automatically acquired annotations are filtered to reduce noise introduced by mistakes of the pseudo-labeling model. In the main experiments, we use TracIn – a strong and practical method for mislabelled data identification (Pruthi et al., 2020). In the ablation study, we also test a simpler solution: filtering instances with high uncertainty of the pseudo-labeling model predictions. The fraction of the filtered out instances in both cases is determined from the evaluation score of the pseudo-labeling model on a held-out subset of the training corpus (100%-score).
6. Finally, we train a successor model of an arbitrary type on the dataset that contains automatically labeled instances and instances with gold labels obtained from human experts.

If the teacher model is expressive enough, it will generate reasonable pseudo labels, which can be filtered and reused by another model of a different type and architecture. This additional annotation helps to mitigate the performance drop due to ASM and to keep the benefits of AL even when the successor model is more expressive than the model used for pseudo-labeling. Meanwhile, PLASM helps to reduce the duration of AL iterations similarly to the approach of Shelmanov et al. (2021), and it does not introduce any additional computational overhead during the annotation process since training the teacher model and pseudo-labeling are performed after the AL annotation is completed.

4.2 Unlabeled Pool Subsampling

If the unlabeled pool of instances is large, which is a common situation, and a deep neural network is used as an acquisition model, the most time-consuming step of the AL cycle is the generation of predictions for unlabeled instances, which is necessary for uncertainty-based query strategies (refer to Table 2). We note that uncertainty estimates of the most certain instances in the unlabeled pool do not alter substantially across multiple AL iterations (Table 1). This means that AL wastes much time and resources on these unimportant instances. We claim that it is possible to recalculate uncertainty scores on the current iteration only for the top instances of the unlabeled pool, which were the most uncertain on previous iterations, while not sacrificing the benefits of AL.

We propose an unlabeled pool subsampling (UPS) algorithm, in which uncertainty estimates only for a fraction of instances are updated. On the current iteration, we suggest always selecting a fraction of the most uncertain instances on previous iterations equal to $\gamma \in [0, 1]$ and sample a small portion of instances with a probability that depends on their rank in a list sorted by their uncertainty. Formally, this can be written as follows. Let u be the last recalculated uncertainty score of an instance on one of the previous iterations. We order the instances according to this value: $u_0 \leq u_1 \leq \dots \leq u_i \leq \dots \leq u_M$ and denote a normalized rank of an instance as $r_i = \frac{i}{M}$. Let $T > 0$ be a "temperature" hyperparameter. Then the probability of keeping an instance i for recalculation of uncertainty on the current iteration is:

$$\mathbb{P}(i) \propto \exp\left(-\frac{max(0, r_i - \gamma)}{T}\right).$$

Sampling certain instances with a non-negative probability instead of just ignoring them gives a chance of overcoming a situation when an informative instance is occasionally assigned a high certainty score and is never selected ever since. This method is inspired by subsampling techniques used in gradient boosting algorithms for selecting a training subset for decision trees (Ke et al., 2017; Ibragimov and Gusev, 2019).

On initial AL iterations, an acquisition model is trained on an extremely small amount of data, which leads to unreliable uncertainty estimates. To mitigate this problem, we suggest keeping the standard approach to performing instance acquisition on several first iterations and switching to the optimized process later during AL. We also note that interleaving the optimized selection with the standard approach, in which we recalculate the uncertainty for the whole unlabeled pool of instances, can help to keep the high performance of AL.

5 Experiments

5.1 Experimental Setup

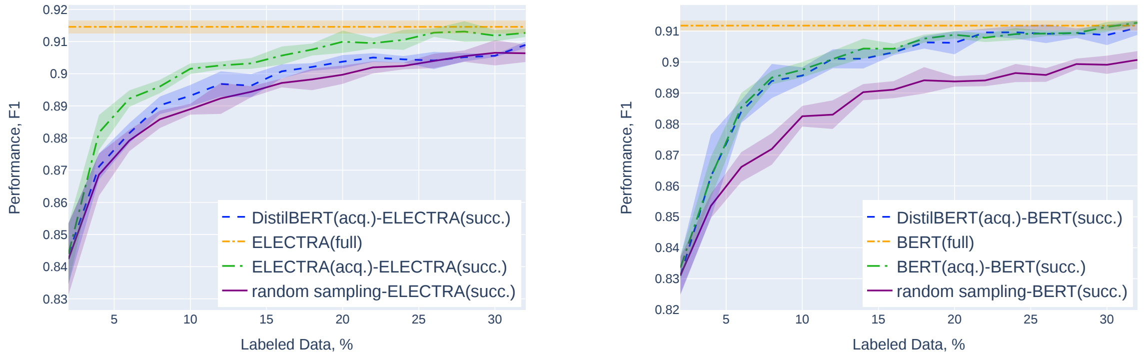
We follow the common schema of AL experiments adopted in many previous works (Settles and Craven, 2008; Shen et al., 2017; Siddhant and Lipton, 2018; Shelmanov et al., 2021). We emulate the AL annotation cycle starting with a small random sample of the dataset used as a seed for the construction of the initial acquisition model. On each iteration, we pick a fraction of top instances from the unlabeled pool sorted using the query strategy and, instead of demonstrating them to annotators, automatically label them according to the gold standard. These instances are removed from the unlabeled pool and added to the training dataset for the next iterations. On each iteration, we train the successor model on the data acquired so far and evaluate it on the whole available test set. Acquisition and successor models are always trained from scratch. We run several iterations of emulation to build a chart, which demonstrates the performance of the successor depending on the amount of "labor" invested into the annotation process. To report standard deviations of scores, we repeat the whole experiment five times with different random seeds. In most experiments, we use LC or MNLP query strategies for classification and sequence tagging correspondingly. Results with MD are presented only in Figure 11 in Appendix B.

For classification, accuracy is used as the evaluation metric. For sequence tagging, we use the strict span-based F1-score (Sang and Meulder, 2003).

5.1.1 Datasets

We experiment with widely-used datasets for the evaluation of AL methods on text classification and sequence tagging tasks.

For text classification, we use the English AG News topic classification dataset (Zhang et al.,



a) ELECTRA is a successor model.

b) BERT is a successor model.

Figure 1: AL experiments on CoNLL-2003, in which a successor model does not match an acquisition model (DistilBERT).

2015) and the binary sentiment classification IMDb dataset (Maas et al., 2011). We randomly select 1% of instances of the training set as a seed to train the initial acquisition model and select 1% of instances for "annotation" on each AL iteration.

For sequence tagging, we use English CoNLL-2003 (Sang and Meulder, 2003) and English OntoNotes 5.0 (Pradhan et al., 2013). We randomly sample instances with a total number of tokens equal to 2% of all tokens from the training set as a seed. On each AL iteration, we select instances from the unlabeled pool until a total number of tokens equals 2% of all training tokens.

The corpora statistics are presented in Table 3 in Appendix A.

5.1.2 Model Choice, Training Details, and Hyperparameter Selection

We conduct experiments with pre-trained Transformers used in several previous works on AL. The exact checkpoints and parameter numbers are presented in Table 5 in Appendix A. Section A.1 contains the distillation details of the custom DistilELECTRA model.

We keep a single pre-selected set of hyperparameters for all AL iterations. Tables 4, 6, 7 in Appendix A describe the hyperparameter setup. Hyperparameter tuning on each AL iteration is very time-consuming. This is an important research problem but out of the scope of the current work.

5.2 Results and Discussion

5.2.1 Acquisition-Successor Mismatch

First of all, we illustrate the ASM problem on the selected datasets with various acquisition-successor pairs (Figure 1a and Figures 5a, 6a, 7a, 8a, 9a in Appendix B). The presented results correspond to the findings of Lowell et al. (2019) and Shelmanov et al. (2021). In each experiment, we see a significant reduction in the performance of successor models when for acquisition, a distilled model from a different family is used. The performance drop is especially notable when we compare results of ELECTRA(acq.)-ELECTRA(succ.) to results of DistilBERT(acq.)-ELECTRA(succ.) on the CoNLL-2003 dataset in Figure 1a and to results of DistilRoBERTa(acq.)-ELECTRA(succ.) on AG News in Figure 8a in Appendix B. Moreover, Figure 10 in Appendix B shows that even if use full-fledged BERT for acquisition and ELECTRA as a successor (and vice versa), a similar performance drop is also present.

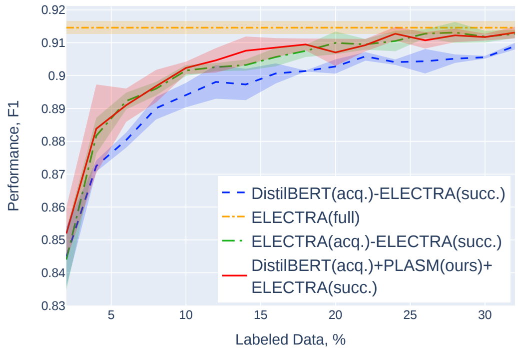


Figure 2: The performance of PLASM (BERT is a pseudo-labeling model) on CoNLL-2003 compared with the standard approach to AL.

The ASM problem appears to be even more severe with the modern uncertainty estimation technique based on MD. Figure 11 in Appendix B shows the results of experiments with MD and DistilBERT(acq.)-ELECTRA(succ.) on the AG

	DistilBERT	BERT	DistilELECTRA	ELECTRA	DistilRoBERTa	RoBERTa
DistilBERT	1.00	0.47	0.41	0.33	0.35	0.27
BERT	0.47	1.00	0.32	0.30	0.31	0.27
DistilELECTRA	0.41	0.32	1.00	0.46	0.32	0.28
ELECTRA	0.33	0.30	0.46	1.00	0.28	0.24
DistilRoBERTa	0.35	0.31	0.32	0.28	1.00	0.33
RoBERTa	0.27	0.27	0.28	0.24	0.33	1.00

Figure 3: Uncertainty correlation matrix of various Transformers on the AG News dataset. The correlations were obtained by training a model on the 1% of the training data and calculating the LC score for the rest 99% of instances.

News dataset. On most iterations, the performance drop for MD is even bigger than the drop for LC shown in Figure 6a.

In the next series of experiments, we demonstrate on both text classification and tagging tasks that when an acquisition model is a distilled version of the full-fledged successor model, the ASM problem is substantially alleviated (Figure 1b, and Figures 5b, 6b, 7b, 8b, 9b in Appendix B). Previously, this effect was also revealed by Shelmanov et al. (2021) for tagging. As we can see in Figure 1b, when DistilBERT is used as an acquisition model, the successor model based on BERT does not experience a performance drop. A similar effect with other model pairs can be noted for sequence tagging on OntoNotes and for text classification on AG News and IMDb.

Figure 3 shows the correlation between the output probabilities of various Transformer-based models fine-tuned on 1% of the AG News dataset. As we can see, for each model, the other most similar model is its student / teacher (except for DistilRoBERTa, which has a slightly larger correlation with DistilBERT). This explains the absence of the ASM problem for such model pairs. Since, after fine-tuning, the distilled version of a model produces similar uncertainty estimates, it will strive to query similar instances during AL.

Although we can mitigate the ASM problem for such model pairs as DistilBERT-BERT, it is still a serious constraint for applying AL. Obviously, such an approach is not feasible if for the final application, one would like to train a completely different model (e.g. XLNet). In the next section, we show that the proposed method based on pseudo-labeling helps to overcome this limitation and resolve the ASM problem in a more general case.

5.2.2 Pseudo-labeling for Acquisition-Successor Mismatch

Figure 2, and Figures 12, 13, 14 in Appendix C present the performance of PLASM on considered datasets for various combinations of acquisition, successor, and pseudo-labeling Transformer models in comparison with the case when acquisition and successor models are the same and with the case of ASM. On the AG News dataset (Figure 12), we investigate the effect of PLASM for three different successors: ELECTRA, RoBERTa, XLNet and for three different distilled acquisition models: DistilBERT, DistilRoBERTa, and our custom DistilELECTRA model. In all experiments, PLASM substantially alleviates the ASM problem yielding higher results compared to directly fine-tuning on data acquired with a different acquisition model.

Usually, PLASM yields a similar or slightly better results than the case when the same model is used both for acquisition and as a successor. PLASM might be superior than this case when a pseudo-labeling model is better suited to the dataset than a successor model. For example, in Figure 12d, PLASM shows better results on early AL iterations than ELECTRA(acq.)-ELECTRA(succ.) due to the fact that RoBERTa used for pseudo-labeling has generally higher performance on AG News than ELECTRA when fine-tuned on the same amount of labeled data. However, we argue that PLASM also effectively helps to deal with the ASM problem when the successor model is more expressive than the pseudo-labeling model. This is the case of the experiment on CoNLL-2003 (Figure 2), where PLASM completely mitigates the ASM problem, while ELECTRA successor shows generally better results than BERT used for pseudo-labeling.

Figures 15 and 16 in Appendix C show that PLASM also mitigates the performance drop due to ASM between a DistilBERT acquisition model and classical CNN-BiLSTM-CRF or CNN successor models. In this case, PLASM gives a very big boost to performance compared to the case when the same classical model is used both for acquisition and as a successor. This happens because the BERT-based pseudo-labeling model is better suited for fine-tuning on small data than the classical models and produces good automatically labeled instances that are reused by successors.

Figure 17a presents the results of the first ablation study, in which, for pseudo-labeling, we leverage the same distilled model used for acquisition instead of a more expressive teacher. In particular, DistilBERT performs acquisition and pseudo-labeling instead of BERT, while ELECTRA is a successor. The performance drop in this case compared to PLASM demonstrates that using an expressive model (e.g. BERT) for pseudo-labeling is necessary for achieving high scores at the beginning of annotation. Figure 17b presents the results of the second ablation study, in which we use DistilBERT for acquisition and ELECTRA for pseudo-labeling and as a successor. This study demonstrates that pseudo-labeling on its own cannot alleviate the ASM completely. It is better to use an expressive pseudo-labeling model that also matches the lightweight acquisition model (e.g. distilled model for acquisition, its teacher – for labeling), as it is proposed in PLASM.

The ablation study of the methods for filtering erroneous instances in the pseudo-labeling step is conducted on the AG News dataset in Figures 18a,b in Appendix C. Applying each of the methods gives substantial improvements over the PLASM without the filtering step, while TracIn is slightly better than thresholding uncertainty of pseudo-labeling model predictions. We note that for XLNet as a successor, PLASM without filtering alleviates the ASM problem, but does not approach the performance of the case when XLNet is used as an acquisition model.

Table 2 and Table 8 in Appendix D summarize the time required for conducting AL iterations with different acquisition functions on the AG News and CoNLL-2003 datasets. As we can see, since PLASM uses DistilBERT for acquisition, our method reduces the iteration time by more than 30% compared to the standard approach, in which ELECTRA is used for acquisition. Thereby, empirical results show that PLASM offers two benefits: (1) it helps to alleviate the ASM problem in AL; (2) it reduces the time of an AL iteration and required computational resources for training and running acquisition models. These benefits substantially increase the practicality of using AL in interactive annotation tools.

5.2.3 Unlabeled Pool Subsampling

Table 2 compares the duration of AL iterations on the AG News dataset, including the duration of the acquisition model training step and the duration of inference on instances from the unlabeled pool. We can see that the inference step is very time-consuming, especially on early iterations, and takes more than half of the time required for performing an AL iteration. Therefore, we claim that in such cases, it is more important to accelerate the inference step rather than the training step as it was done in previous work (Shen et al., 2017).

Top-k% / Curr. AL iter.	1	2	6
10%	0.503	0.649	0.924
20%	0.789	0.883	0.992
30%	0.915	0.947	0.995
40%	0.958	0.976	1.000
50%	0.980	0.991	1.000

Table 1: A fraction of instances that would be standardly selected on the current AL iteration, contained in top-k% uncertain instances according to the acquisition model on the previous iteration (AG News corpus).

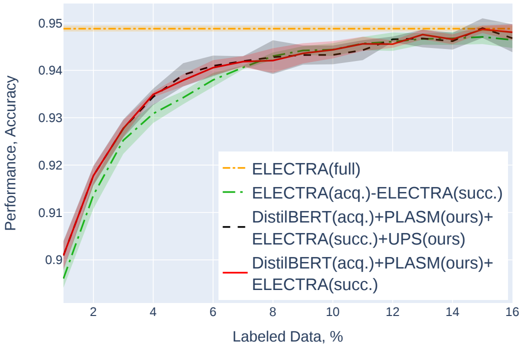

Figure 4: The performance of UPS with PLASM (BERT is a pseudo-labeling model) on AG News compared with baselines ($\gamma = 0.1$, $T = 0.01$).

To justify our approach to accelerating the inference step, we show that many unlabeled instances have similar uncertainty estimates across different AL iterations. Table 1 presents the fraction of instances, which would be standardly queried on the current iteration if we selected them from the whole unlabeled pool that are contained in k-% of most uncertain instances, according to the acquisition model built on the previous AL iteration. For example, we observe that 50% of the most uncertain instances according to the model trained on the first iteration contain more than 99% of instances from the "standard query" on the second iteration, and 30% contains almost 95% of instances from the "standard query". Later iterations have even a better trade-off. Thereby, it is reasonable to avoid spending computational resources on instances that were most certain in previous iterations.

Table 2: Duration of training and inference steps of AL iterations in seconds on AG News. Hardware configuration: 2 Intel Xeon Platinum 8168, 2.7 GHz, 24 cores CPU; NVIDIA Tesla v100 GPU, 32 Gb of VRAM.

If we exclude a big part of the unlabeled pool from consideration during acquisition, the benefits of AL can potentially deteriorate. Results of experiments presented in Figure 4 and Figures 19, 20 in Appendix D show that the proposed UPS algorithm does not lead to the performance drop compared to the standard approach, in which we consider the whole unlabeled pool for instance selection. Meanwhile, the results of the ablation study in Figure 21 in Appendix D demonstrate that the baseline, which randomly subsamples the unlabeled dataset, has a performance drop compared to UPS. In another ablation study, we set $T = 0$, which means that UPS just takes a fraction of the most uncertain instances (Figure 22). On some iterations, this results in a slight reduction of performance.

From Table 2, we can see that UPS accelerates the query process up to 10 times. The corresponding results for CoNLL-2003 are presented in Table 8 in Appendix D. Overall, applying both PLASM and UPS algorithms on AG News reduces the duration of AL iterations by more than 60% compared with the standard approach. We can also tune the hyperparameters γ and T to reduce duration further in exchange for slightly worse scores.

6 Conclusion

We investigated several obstacles to deploying AL in practice and proposed two algorithms that help to overcome them. In particular, we considered the acquisition-successor mismatch problem revealed by Lowell et al. (2019), as well as the problem related to the excessive duration of AL iterations with uncertainty-based query strategies and deep learning models. We demonstrate that the proposed PLASM algorithm helps to deal with both of these issues: it removes the constraint on the type of the successor model trained on the data labeled with AL and allows the use of lightweight acquisition models that have good training and inference performance, as well as a small memory footprint. The unlabeled pool subsampling algorithm helps to substantially decrease the inference time during AL without a loss in the quality of successor models. Together the PLASM and UPS algorithms help reduce the duration of an AL iteration by more than 60%. We consider that the conducted empirical investigations and the proposed methods will help to increase the practicality of using deep AL in interactive annotation tools.

We note that applying PLASM requires some conditions to be met. Particularly, when a pseudo-labeling model is of considerably lower performance than a successor model, and filtering is not strict enough, training a successor directly on labeled instances acquired during AL with a different acquisition model may result in higher performance. Consequently, despite the pseudo-labeling model may be less expressive compared to the successor model, it should not be too "weak". In practice, we suggest comparing results obtained by the models trained with pseudo-labeling and without on a hold-out set and selecting the best model.

There are still many issues that hinder the application of AL techniques. We consider that one of the most important obstacles is the necessity of hyperparameter optimization of deep learning models that can take a prohibitively long time to keep the annotation process interactive. We are looking forward to addressing this problem in future work.

A Dataset Statistics and Model Hyperparameters

Table 3: Dataset statistics. We provide a number of sentences/tokens for the training and test sets. k stands for a size of seeding datasets (% of the training dataset) and a size of sets of instances selected for "annotation" on each iteration. C is a number of classes/entity types.

Dataset	Train	Test	k	C
CoNLL-2003	15K/203.6K	3.7K/46.4K	2%	4(5)
OntoNotes 5.0	59.9K/1088.5K	8.3K/152.7K	2%	18
AG News	120K/4541.7K	7.6K/286.7K	1%	4
IMDb	25K/5844.7K	25K/5713.2K	1%	2

Table 4: Hyperparameter values of Transformers. "Sequence tagging" incorporates CoNLL-2003 & OntoNotes datasets, while "Classification" combines AG-News & IMDB. The hyperparameters are chosen according to evaluation scores on the validation datasets when models are trained using the whole available training data on CoNLL-2003 for sequence tagging & AG-News for classification.

Hparam	Sequence tagging	Classification
Number of epochs	15	5
Batch size	16	16
Min. number of training steps	1000	1000
Max. sequence length	-	256
Optimizer	AdamW	AdamW
Learning rate	5e-5	2e-5
Weight decay	0.01	0.01
Gradient clipping	1.	1.
Scheduler	STLR	STLR
% warm-up steps	10	10

A.1 Distillation Details for the Custom DistilELECTRA Model

The DistilELECTRA model is distilled from the ELECTRA-base model. It has the same architecture, but half as many layers initialized by taking from the teacher one layer out of two. Distillation is performed on the AG News dataset using a linear combination $L = L_{ce} + L_{mlm} + L_{cos} + L_{mse}$ of the following loss functions as a training objective: $L_{ce} = \sum_i t_i \cdot log(s_i)$ is a distillation loss of the student's probabilities s_i over the soft target probabilities of the teacher t_i; L_{mlm} is the student's self-supervised masked language modeling loss; L_{cos} is the cosine embedding loss that aligns the directions of the student's and teacher's hidden state vectors; L_{mse} is a mean squared error between student's and corresponding teacher's hidden states vectors. DistilELECTRA is trained with the following hyperparameters: 50 epochs, batch size 5, 50 gradient accumulation steps, AdamW optimizer with a learning rate $5e-4$, epsilon $1e-6$.

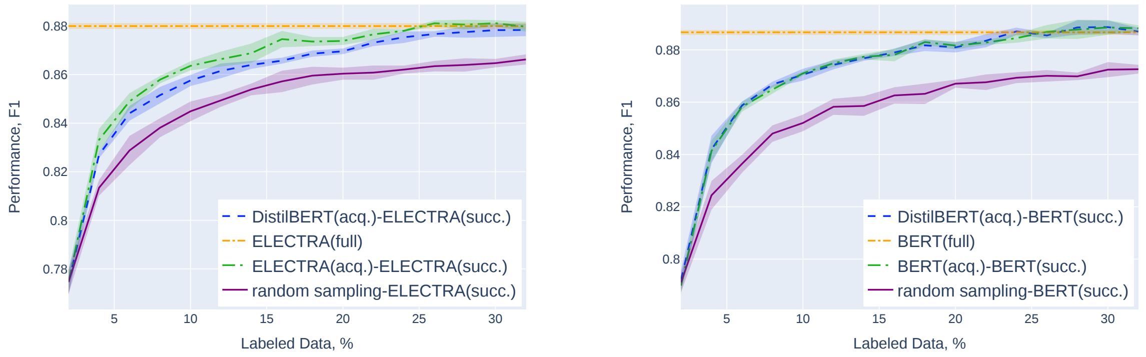
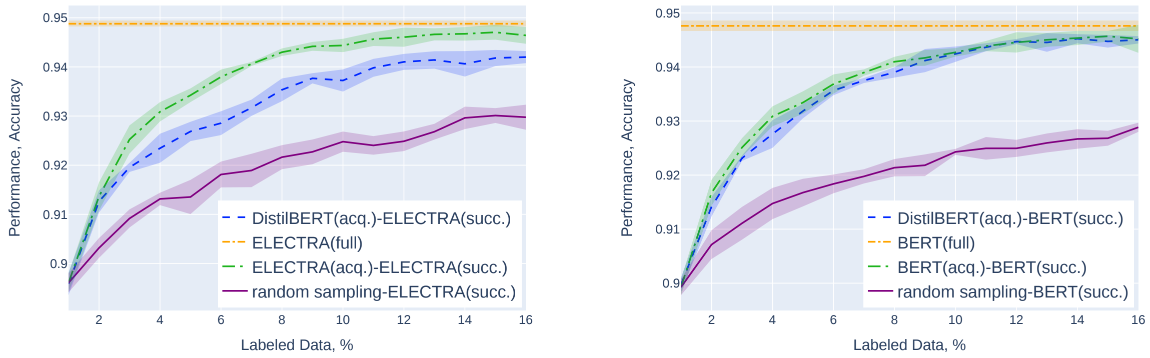
B Additional Experimental Results with Acquisition-successor Mismatch



a) ELECTRA is a successor model.

b) BERT is a successor model.

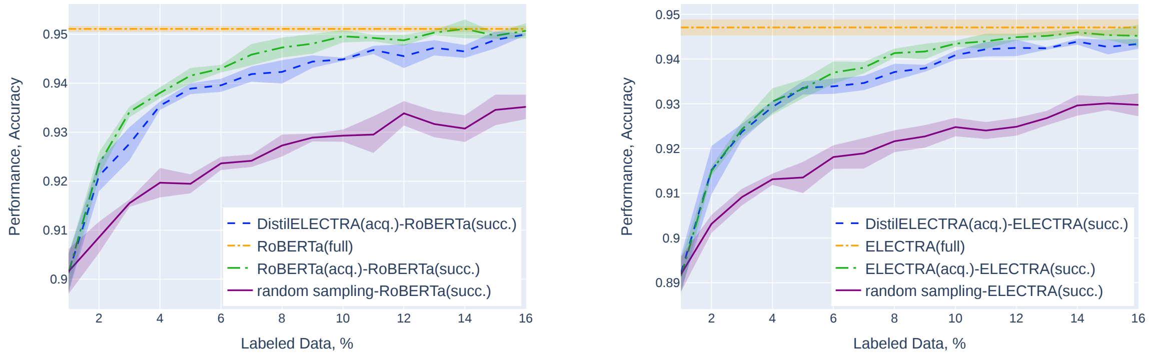
Figure 5: AL experiments on OntoNotes, in which a successor model does not match an acquisition model (DistilBERT).



a) ELECTRA is a successor model.

b) BERT is a successor model.

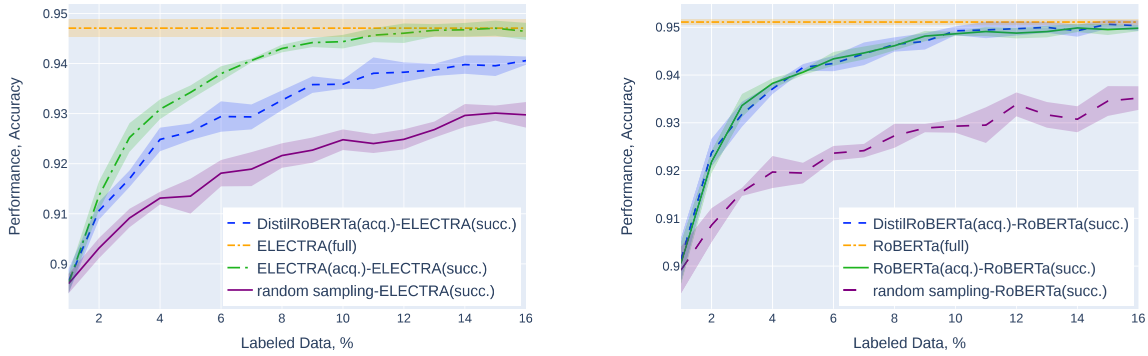
Figure 6: AL experiments on AG News, in which a successor model does not match an acquisition model (DistilBERT).



a) RoBERTa is a successor model.

b) ELECTRA is a successor model.

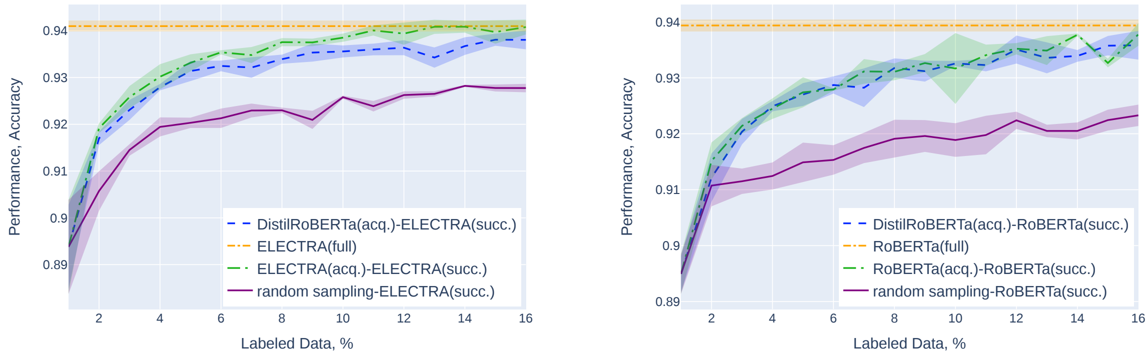
Figure 7: AL experiments on AG News, in which a successor model does not match an acquisition model (DistilELECTRA).



a) ELECTRA is a successor model.

b) RoBERTa is a successor model.

Figure 8: AL experiments on AG News, in which a successor model does not match an acquisition model (DistilRoBERTa).



a) ELECTRA is a successor model.

b) RoBERTa is a successor model.

Figure 9: AL experiments on IMDb, in which a successor model does not match an acquisition model (DistilRoBERTa).

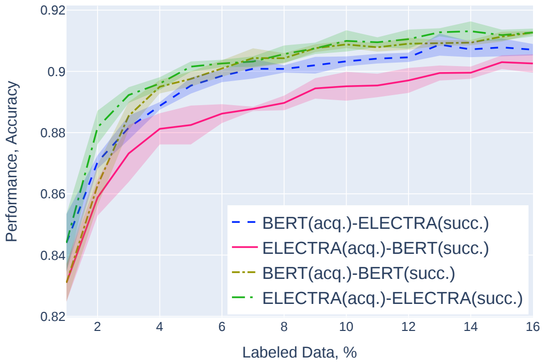


Figure 10: AL experiments on CoNLL-2003, in which a successor model does not match an acquisition model. This experiment demonstrates that models with similar expressiveness and size (BERT and ELECTRA) cannot be used interchangeably for acquisition in AL.

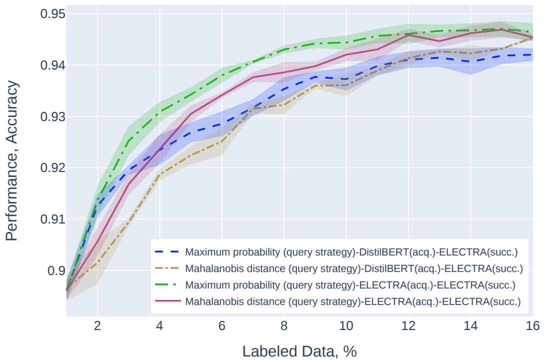

Figure 11: AL experiments on AG News with Mahalanobis distance used as an uncertainty measure in a query strategy. This experiment demonstrates that the acquisition-successor mismatch problem also persists for this modern uncertainty estimation technique.

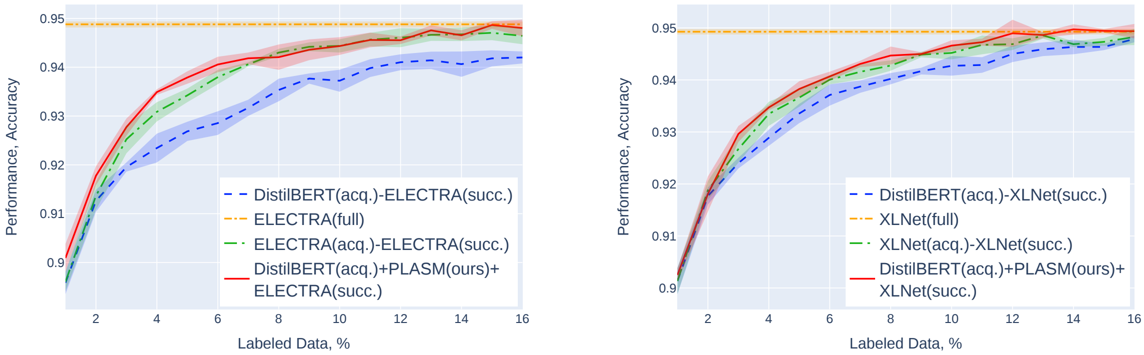
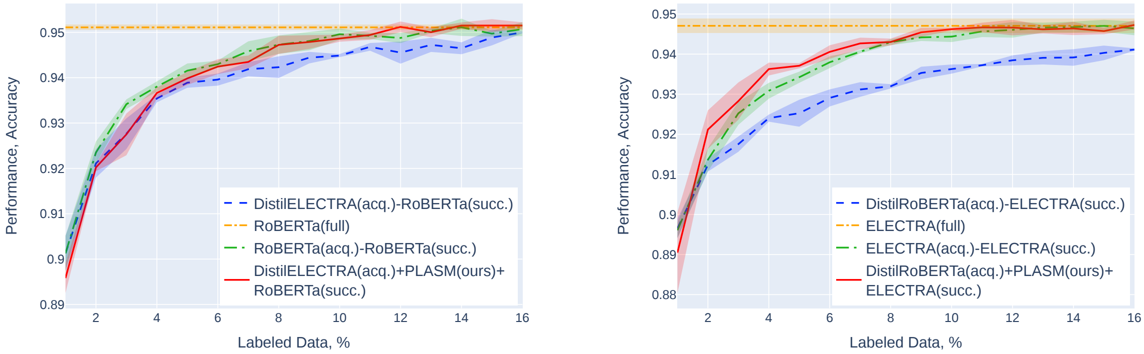
C Additional Experimental Results with PLASM



a) DistilBERT is an acquisition model, BERT is a pseudo-labeling model, ELECTRA is a successor model.

b) DistilBERT is an acquisition model, BERT is a pseudo-labeling model, XLNet is a successor model.



c) DistilELECTRA is an acquisition model, ELECTRA is a pseudo-labeling model, RoBERTa is a successor model.

d) DistilRoBERTa as an acquisition model, RoBERTa as a pseudo-labeling model, ELECTRA is a successor model.

Figure 12: The performance of PLASM compared with the standard approach to AL on AG News with various acquisition – pseudo-labeling model pairs and successor models.

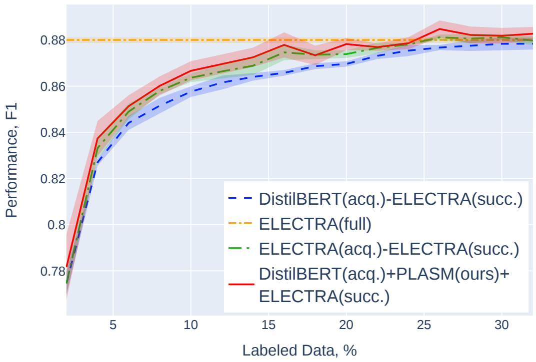


Figure 13: The performance of PLASM (BERT is a pseudo-labeling model) compared with the standard approach to AL on OntoNotes.

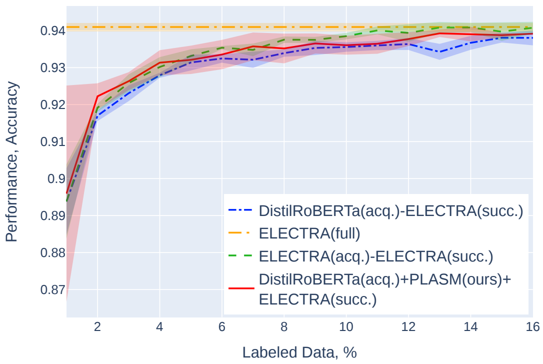

Figure 14: The performance of PLASM (RoBERTa is a pseudo-labeling model) compared with the standard approach to AL on IMDb.

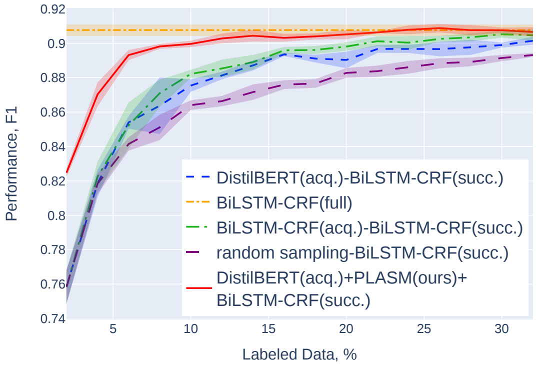

Figure 15: Experiments with PLASM and standard approaches on CoNLL-2003, in which CNN-BiLSTM-CRF is used as a successor model. We can see that due to using PLASM and the expressiveness of the pseudo-labeling model (BERT), the successor achieves substantial improvements over the baseline.

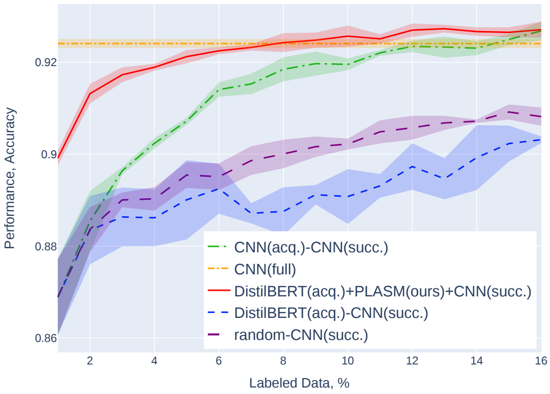

Figure 16: Experiments with PLASM and standard approaches on AGNews, in which simple CNN is used as a successor model. We can see that due to using PLASM and the expressiveness of the pseudo-labeling model (BERT), the successor achieves substantial improvements over the baseline. We also note that using AL with DistilBERT as an acquisition model results in worse performance than using the baseline random sampling; this corresponds to findings of (Lowell et al., 2019).

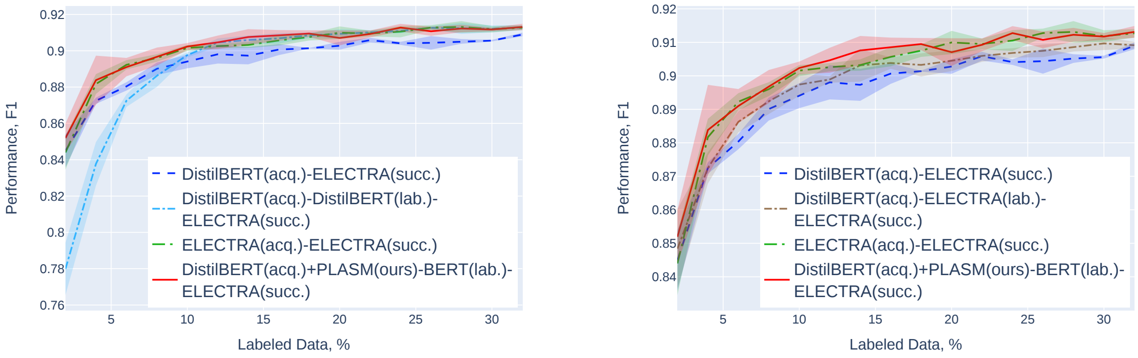
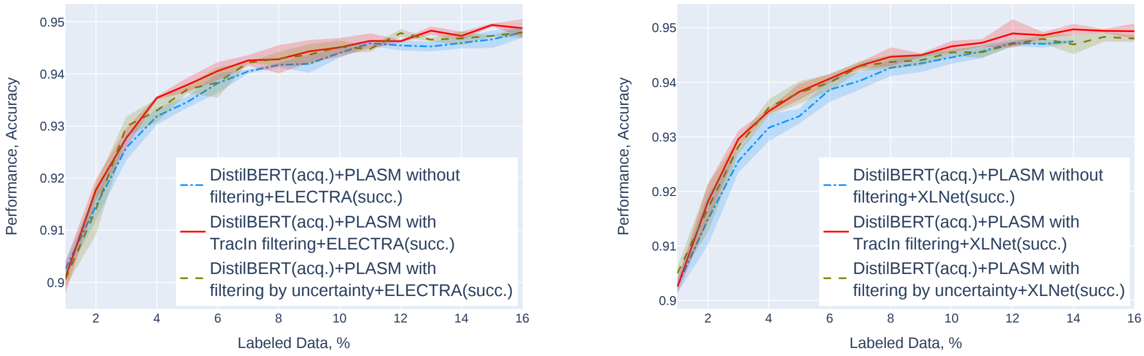


a) DistilBERT for pseudo-labeling.

b) ELECTRA for pseudo-labeling.

Figure 17: Ablation studies of PLASM on the CoNLL-2003 dataset, in which an inappropriate model is used for pseudo-labeling.

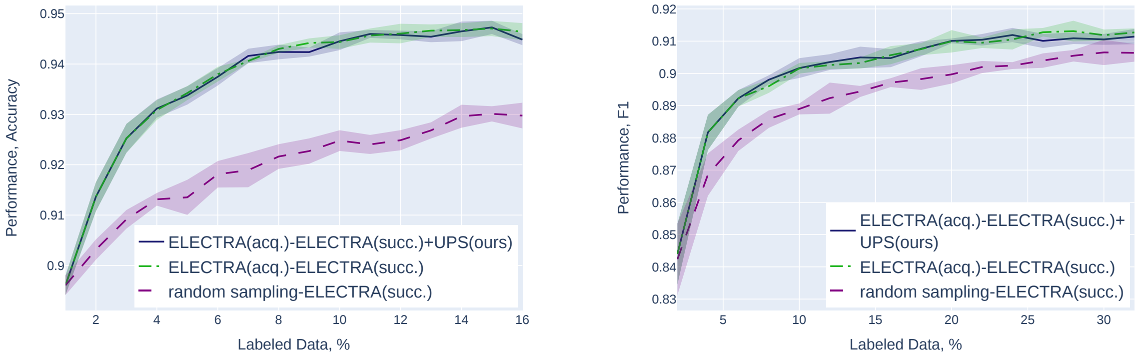


a) ELECTRA as a successor.

b) XLNet as a successor.

Figure 18: Ablation studies of filtering methods in PLASM on the AG News dataset.

D Additional Experimental Results with UPS



a) AG News dataset.

b) CoNLL-2003 dataset.

Figure 19: The performance of UPS compared with the standard approach to AL on AG News and CoNLL-2003 datasets with ELECTRA as a successor model ($\gamma = 0.1$, $T = 0.01$).

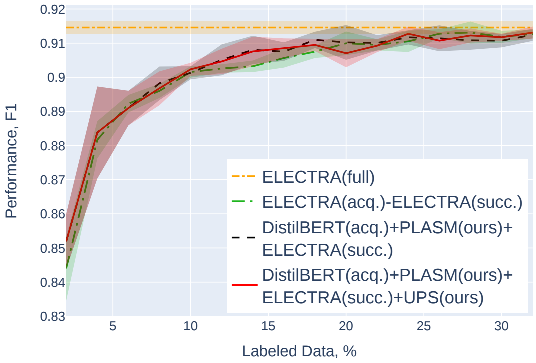


Figure 20: The performance of UPS in conjunction with PLASM (BERT is a pseudo-labeling model) on CoNLL-2003 compared with baselines ($\gamma = 0.1$, $T = 0.01$).

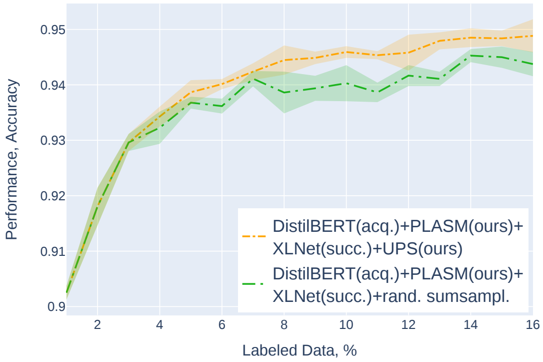

Figure 21: The comparison of UPS with a random-subsampling baseline on the AG News dataset ($\gamma = 0.1$, $T = 0.01$). A pseudo-labeling model in PLASM is BERT.

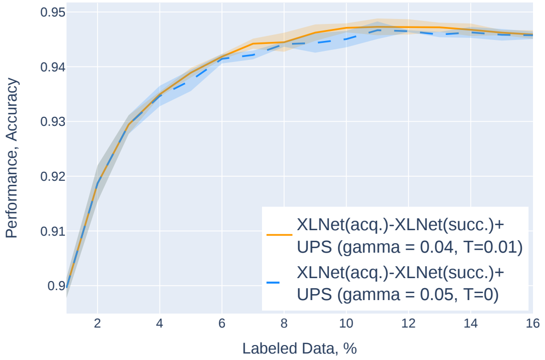

Figure 22: Ablation study for the parameter T in the UPS algorithm. We see that when sampling a total of 5% of the dataset to select for the query, using a non-zero value for the parameter T gives an increase in performance compared to a case when only 5% most uncertain samples are considered for query (i.e. $T = 0$).

Abstract

In spoken question answering, the systems are designed to answer questions from contiguous text spans within the related speech transcripts. However, the most natural way that human seek or test their knowledge is via human conversations. Therefore, we propose a new **S**poken **C**onversational **Q**uestion **A**nswering task (SCQA), aiming at enabling the systems to model complex dialogue flows given the speech documents. In this task, our main objective is to build the system to deal with conversational questions based on the audio recordings, and to explore the plausibility of providing more cues from different modalities with systems in information gathering. To this end, instead of directly adopting automatically generated speech transcripts with highly noisy data, we propose a novel unified data distillation approach, DDNET, which effectively ingests cross-modal information to achieve fine-grained representations of the speech and language modalities. Moreover, we propose a simple and novel mechanism, termed Dual Attention, by encouraging better alignments between audio and text to ease the process of knowledge transfer. To evaluate the capacity of SCQA systems in a dialogue-style interaction, we assemble a **Spoken Co**nversational **Q**uestion **A**nswering (Spoken-CoQA) dataset with more than 40k question-answer pairs from 4k conversations. The performance of the existing state-of-the-art methods significantly degrade on our dataset, hence demonstrating the necessity of cross-modal information integration. Our experimental results demonstrate that our proposed method achieves superior performance in spoken conversational question answering tasks.

1 Introduction

Conversational question answering (CQA) has been studied extensively over the past few years within the natural language processing (NLP) communities (Zhu et al., 2018; Liu et al., 2019; Yang et al., 2019). Different from traditional question answering (QA) tasks, CQA aims to enable models to learn the representation of the context paragraph and multi-turn dialogues. Existing CQA methods (Huang et al., 2018a; Devlin et al., 2018; Xu et al., 2019; Gong et al., 2020) have achieved superior performances on several benchmark datasets, such as QuAC (Choi et al., 2018) and CoQA (Elgohary et al., 2018).

Current CQA research mainly focuses on leveraging written text sources in which the answer can be extracted from a large document collection. However, humans communicate with each other via spontaneous speech (*e.g.*, meetings, lectures, online conversations), which convey rich information. Consider our multimodal experience, fine-grained representations of both audio recordings and text documents are considered to be of paramount importance. Thus, we learn to draw useful relations between modalities (speech and language), which enables us to form fine-grained multimodal representations for end-to-end speech-and-language learning problems in many real-world applications, such as voice assistant and chat robot.

In this paper, we propose a novel and challenging spoken conversational question answering task - SCQA. An overview pipeline of this task is shown in Figure 1. Collecting such a SCQA dataset is a non-trivial task, as in contrast to current CQA tasks, we build our SCQA with two main goals as follows: (1) SCQA is a multi-turn conversational spoken question answering task, which is more challenging than *only* text-based task; (2) existing CQA methods rely on a single modality (text) as the context source. However, plainly leveraging uni-modality information is naturally undesirable for end-to-end speech-and-language learning problems since the useful connections between speech and text are elusive. Thus, employing data from

Table 1: An example from Spoken-CoQA. We can observe large misalignment between the manual transcripts and the corresponding ASR transcripts. Note that the misalignment is in **bold** font and the example is the extreme case. For more dataset information, please see Section 5 and Appendix Section "More Information about Spoken-CoQA".

the context of another modality (speech) can allow us to form fine-grained multimodal representations for the downstream speech-and-language tasks; and (3) considering the speech features are based on regions and are not corresponding to the actual words, this indicates that the semantic inconsistencies between the two domains can be considered as the *semantic gap*, which requires to be resolved by the downstream systems themselves.

In order to provide a strong baseline for this challenging multi-modal spoken conversational question answering task, we first present a novel knowledge distillation (KD) method for the proposed SCQA task. Our intuition is that speech utterances and text contents share the dual nature property, and we can take advantage of this property to learn the correspondences between these two forms. Specifically, we enroll multi-modal knowledge into the *teacher* model, and then guide the *student* (*only* trained on noisy speech documents) to boost network performance. Moreover, considering that the semantics of the speech features and the textual representations are usually inconsistent, we introduce a novel mechanism, termed Dual Attention, to encourage fine-grained alignments between audio and text to close the cross-modal semantic gap between speech and language. One example of cross-modal gap is shown in Table 1. The experimental results show that our proposed DDNET achieves remarkable performance gains in the SCQA task. To the best of our knowledge, we are the first work in spoken conversational question answering task.

Our main contributions are as follows:

- We propose Spoken Conversational Question Answering task (SCQA), and comprise Spoken-CoQA dataset for machine comprehension of spoken question-answering style conversations. To the best of our knowledge, our Spoken-CoQA is the first spoken conversational question answering dataset.
- We develop a novel end-to-end method based

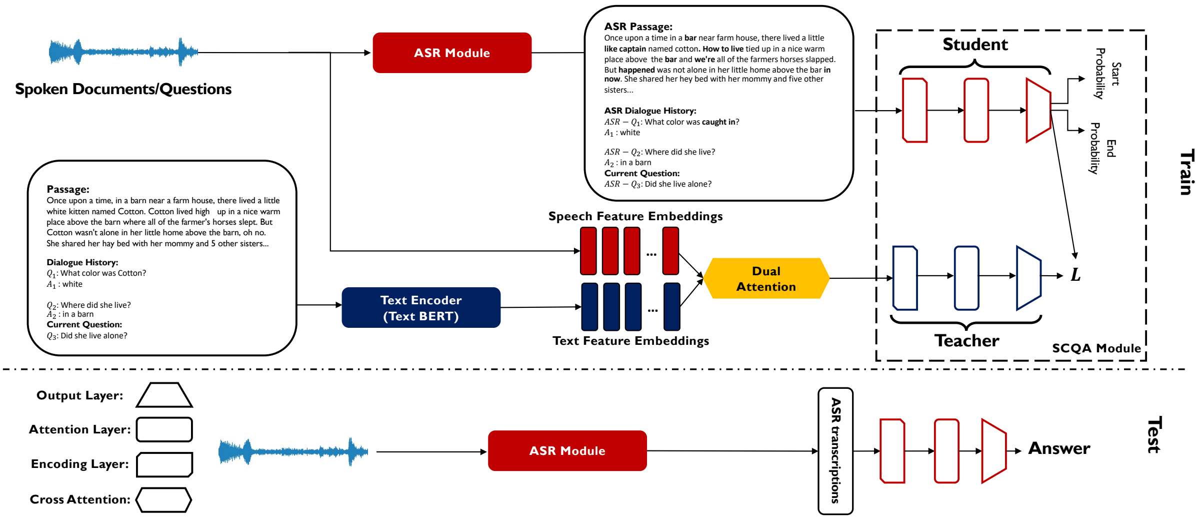

Figure 2: An illustration of the architecture of DDNet. In training stage, we adopt the teacher-student paradigm to enable the student model (only trained on speech documents) to achieve good performance. As for test, we only use student model for inference.

on data distillation to learn both from speech and language domain. Specifically, we use the model trained on clear texts as well as recordings to guide the model trained on noisy speech transcriptions. Moreover, we propose a novel Dual Attention mechanism to align the speech features and textual representations in each domain.

- We demonstrate that, by applying our proposed DDNet on several previous baselines, we can obtain considerable performance gains on our proposed Spoken-CoQA dataset.

2 Related Work

Text Question Answering. In recent years, the natural language processing research community has devoted substantial efforts to text question answering tasks (Huang et al., 2018a; Zhu et al., 2018; Xu et al., 2019; Zhang et al., 2020; Gong et al., 2020; Chen et al., 2020, 2021a). Within the growing body of work on machine reading comprehension, an important sub-task of text question answering, two signature attributes have emerged: the availability of large benchmark datasets (Choi et al., 2018; Elgohary et al., 2018; Reddy et al., 2019) and pre-trained language models (Devlin et al., 2018; Liu et al., 2019; Lan et al., 2020). However, these existing works typically focus on modeling the complicated context dependency in text form. In contrast, we focus on enabling the machine to build the capability of language recognition and dialogue modeling in both speech and text domains.

Spoken Question Answering. In parallel to the recent works in natural language processing (Huang et al., 2018a; Zhu et al., 2018), these trends have also been pronounced in the speech field (Chen et al., 2018; Haghani et al., 2018; Lugosch et al., 2019; Palogiannidi et al., 2020; You et al., 2021a,b,c,d, 2020a; Chen et al., 2021b; Xu et al., 2021; Su et al., 2020, 2021), where spoken question answering (SQA), an extended form of QA, has explored the prospect of machine comprehension in spoken form. Previous work on SQA typically includes two separate modules: automatic speech recognition (ASR) and text question answering. It involves transferring spoken content to ASR transcriptions, and then employs NLP techniques to handle speech tasks.

Existing methods (Tseng et al., 2016; Serdyuk et al., 2018; Su and Fung, 2020) focus on optimizing each module in a two-stage manner, where errors in the ASR module would result in severe performance loss. Lee et al. (2019) proved that utilizing clean texts can help model trained on the ASR transcriptions to boost the performance via domain adaptation. Chuang et al. (2019) cascaded the BERT-based models as a unified model, and then trained it in a joint manner of audio and text. However, the existing SQA methods aimed at solving a single question given the related passage, without building and maintaining the connections of different questions in the human conversations. In addition, we compare our Spoken-CoQA with existing SQA datasets (See Table 2). Unlike existing SQA datasets, Spoken-CoQA is a multi-turn con-

Dataset	Conversational	Spoken	Answer Type
TOEFL (Tseng et al., 2016)	×	√	Multi-choice
S-SQuAD (Li et al., 2018)	×	√	Spans
ODSQA (Lee et al., 2018)	×	√	Spans
S-CoQA	√	√	Free-form

Table 2: Comparison of Spoken-CoQA with existing spoken question answering datasets. S-SQuAD and S-CoQA denote Spoken-SQuAD and Spoken-CoQA, respectively.

versational SQA dataset, which is more challenging than single-turn benchmarks.

Knowledge Distillation. Hinton et al. (2015) introduced the idea of Knowledge Distillation (KD) in a *teacher-student* scenario. In other words, we can distill the knowledge from one model (massive or *teacher* model) to another (small or *student* model). Previous work has shown that KD can significantly boost prediction accuracy in natural language processing and speech processing (Kim and Rush, 2016; Hu et al., 2018; Huang et al., 2018b; Hahn and Choi, 2019; Liu et al., 2021b,a; Cheng et al., 2016b; Cheng and You, 2016; Cheng et al., 2016a; You et al., 2020b, 2021e, 2022b,a, 2018, 2019a,b; Lyu et al., 2018, 2019; Guha et al., 2020; Yang et al., 2020; Ma et al., 2021a,b), while adopting KD-based methods for SQA tasks has been less explored. In this work, our goal is to handle the SCQA tasks. More importantly, we focus the core nature property in speech and text: Can spoken conversational dialogues further assist the model to boost the performance? Finally, we incorporate the knowledge distillation framework to distill reliable dialogue flow from the spoken contexts, and utilize the learned predictions to guide the *student* model to train well on the noisy input data.

3 Task Definition

In this section, we propose the novel SCQA task and collect a Spoken-CoQA (S-CoQA) dataset, which uses the spoken form of multi-turn dialogues and spoken documents to answer questions in multi-turn conversations.

Given a spoken document D^s, we use D^t to denote the clean original text and D^a to denote the ASR transcribed document. We also have $Q^a_{1:L}$=$\{q^a_1, q^a_2, ..., q^a_L\}$, which is a collection of L-turn ASR transcribed spoken questions $Q^s_{1:L}$, as well as $A^t_{1:L}$= $\{a^t_1, a^t_2, ..., a^t_L\}$ which are the corresponding answers to the questions in clean texts. The objective of SCQA task is then to generate the answer a^t_L for question q^a_L, given document D^a, multi-turn history questions $Q^a_{1:L-1}$=$\{q^a_1, q^a_2, ..., q^a_{L-1}\}$, and reference answers $A^t_{1:L-1}$= $\{a^t_1, a^t_2, ..., a^t_{L-1}\}$. In other words, our task in the testing phase can be formulated as

$$\{D^s, Q^s_{1:L}\} \xrightarrow{\text{ASR}} \{q^a_L, D^a, Q^a_{1:L-1}, a^t_{1:L-1}\} \rightarrow a^t_L \tag{1}$$

Please note that in order to improve the performance, in the training phase, we make use of auxiliary information which are the clean texts of document D^t and dialogue questions Q^t=$\{q^t_1, q^t_2, \dots, q^t_L\}$, to guide the training of student model. As a result, the training process could be formulated as below:

$$\left.\begin{array}{r}\text{student: } \{D^s, Q^s_{1:L}\} \xrightarrow{\text{ASR}} \{q^a_L, D^a, Q^a_{1:L-1}, a^t_{1:L-1}\} \\ \text{teacher: } \{D^t, Q^t_{1:L}\}\end{array}\right\} \rightarrow a^t_L$$

However, in the inference stage, these additional information of D^t and $Q^t_{1:L}$ are not needed.

4 DDNet

In this section, we propose DDNET to deal with the SCQA task, which is illustrated in Figure 2. We first describe the embedding generation process for both audio and text data. Next, we propose *Dual Attention* to fuse the speech and textual modalities. After that, we present the major components of the DDNET module. Finally we describe a simple yet effective distillation strategy in the proposed DDNET to learn enriched representations in the speech-text domain comprehensively.

4.1 Embedding

Given spoken words $S = \{s_1, s_2, ..., s_m\}$ and corresponding clean text words $T = \{t_1, t_2, ..., t_n\}$, we utilize Speech-BERT and Text-BERT to generate speech feature embedding $\mathbf{E}_s$=$\{\mathbf{E}_{s1}, \mathbf{E}_{s2}, ..., \mathbf{E}_{sm}\}$ and context word embedding $\mathbf{E}_t$=$\{\mathbf{E}_{t1}, \mathbf{E}_{t2}, ..., \mathbf{E}_{tn}\}$[1], respectively. Concretely, for speech input, we first use vq-wav2vec (Baevski et al., 2019) to transfer speech signals into a series of tokens, which is the standard tokenization procedure in speech related tasks. Next, use Speech-BERT (Chuang et al., 2019), a variant of BERT-based models retrained on our Spoken-CoQA dataset, to process the speech sequences for training. The text contents are embbed into a sequence of vectors via our text encoder - Text-BERT, with the same architecture of BERT-base (Devlin et al., 2018).

---

[1] In our implement, the padding strategy is used to keep m and n to be the same as the max sequence length.

4.2 Dual Attention

Dual Attention (DA) is proposed to optimize the alignment between speech and language domains by capturing useful information from the two domains. In particular, we first use cross attention to align speech and text representations in the initial stage. After that, we utilize contextualized attention to further align the cross-modal representations in the contextualized word-level. Finally, we employ the self-attention mechanism to form fine-grained audio-text representations.

Cross Attention. Inspired by ViLBERT (Lu et al., 2019), we apply the co-attention transformer layer, a variant of Self-Attention (Vaswani et al., 2017), as the Cross Attention module for the fusing of speech and text embeddings. The Cross Attention is implemented by the standard Attention module involving Multi-Head Attention (MHA) and Feed-Forward Network (FFN) (Vaswani et al., 2017) as below:

$$\begin{aligned}\text{Attention}(Q, K, V) &= \text{FFN}(\text{MHA}(Q, K, V))\\ \text{CrossAttention}(F_1, F_2) &= \text{Attention}(F_1, F_2, F_2)\end{aligned} \tag{2}$$

where Q, K, V denote query, key, and value matrices, and F_1, F_2 denote features from difference modalities, respectively. The co-attention module then use the Cross Attention function to compute the cross attention-pooled features, by querying one modality using the query vector of another modality.

$$\begin{aligned}\hat{\mathbf{E}}_s^{\text{cross}} &= \text{CrossAttention}(\mathbf{E}_s, \mathbf{E}_t)\\ &= \text{Attention}(\mathbf{E}_s, \mathbf{E}_t, \mathbf{E}_t),\\ \hat{\mathbf{E}}_t^{\text{cross}} &= \text{CrossAttention}(\mathbf{E}_t, \mathbf{E}_s)\\ &= \text{Attention}(\mathbf{E}_t, \mathbf{E}_s, \mathbf{E}_s),\end{aligned} \tag{3}$$

where $\hat{\mathbf{E}}_s^{\text{cross}} \in \mathbb{R}^{n \times d}$, $\hat{\mathbf{E}}_t^{\text{cross}} \in \mathbb{R}^{n \times d}$ and d is the dimension of feature vectors.

Contextualized Attention (CA). After obtaining *speech-aware* representation $\hat{\mathbf{E}}_s^{\text{cross}}$ and *text-aware* representation $\hat{\mathbf{E}}_t^{\text{cross}}$, our next goal is to construct more robust contextualized cross-modal representations by integrating features from both modalities. The features with fused modalities are computed as follows:

$$\mathbf{H}_{\text{CA}} = \text{ReLU}(\hat{\mathbf{E}}_s^{\text{cross}} W_1^T)\text{ReLU}(\hat{\mathbf{E}}_x^{\text{cross}} W_1^T) W_2^T, \tag{4}$$

where $W_1, W_2 \in \mathbb{R}^{n \times d}$ are trainable weights.

Self-Attention. To build a robust SCQA system, special attention needs to be paid on the sequential order of the dialogue, since the changes in utterances order may cause severely low-quality and in-coherent corpora. As a result, to capture the long-range dependencies such as co-references for the downstream speech-and-language tasks, similar to (Li et al., 2016; Zhu et al., 2018), we introduce a self-attention layer to obtain the final Dual Attention (DA) representations.

$$\begin{aligned}\mathbf{E}_{\text{DA}} &= \text{SelfAttention}(\mathbf{H}_{\text{CA}})\\ &= \text{Attention}(\mathbf{H}_{\text{CA}}, \mathbf{H}_{\text{CA}}, \mathbf{H}_{\text{CA}}).\end{aligned} \tag{5}$$

4.3 Key Components

The framework of our SCQA module is similar to recent works (Zhu et al., 2018; Huang et al., 2017), which is divided into three key components: Encoding Layer, Attention Layer and Output Layer.

Encoding Layer. Then documents and conversations (questions and answers) are first converted into the corresponding feature embeddings (i.e., character embeddings, word embeddings, and contextual embedding). The output contextual embeddings are then concatenated by the aligned cross-modal embedding $\mathbf{E}_{\text{DA}}$ to form the encoded input features:

$$\mathbf{E}_{enc} = [\mathbf{E}_t; \mathbf{E}_{\text{DA}}]. \tag{6}$$

Attention Layer. We compute the attention on the context representations of the documents and questions, and extensively exploit correlations between them. Note that we adopt the default attention layers in four baseline models.

Output Layer. After obtaining attention-pooled representations, the Output Layer computes the probability distributions of the start and end index within the entire documents and predicts an answer to current question:

$$\begin{aligned}\mathcal{L} = &-\mathtt{log}\mathcal{P}(\text{st} = a_{L,\text{st}}|\mathbf{X})\\ &-\mathtt{log}\mathcal{P}(\text{ed} = a_{L,\text{ed}}|\mathbf{X})\end{aligned} \tag{7}$$

where $\mathbf{X}$ denotes the input document D and Q^L, and “st”, “ed” denote the start and end positions.

4.4 Knowledge Distillation

In previous speech-language models, the only guidance is the standard training objective to measure the difference between the prediction and the reference answer. However, for noisy ASR transcriptions, such criteria may not be suitable enough. To overcome such problem, we distill the knowledge

Domain	Passages	QA-Pairs	Passage Length	Avg.Turns
Children	357	3.5k	212	9.8
Literature	898	8.7k	275	9.7
Mid./High School	878	9.5k	308	10.8
News	967	9.5k	271	9.8
Wikipedia	864	8.9k	249	10.3
Overall	3964	40.1k	270	10.1

Table 3: Statistical analysis on Spoken-CoQA.

from our *teacher* model, and use them to guide the *student* model to learn contextual features in our SCQA task. Concretely, we set the model trained on the speech document and the clean text corpus as the *teacher* model and trained on the ASR transcripts as the *student* model, respectively. Thus, the *student* trained on low-quality data learns to absorb the knowledge that the *teacher* has discovered. Given the z_S and z_T as the prediction vectors by the *student* and *teacher* models, the objective is defined as:

$$\mathcal{L}_{\text{SCQA}}=\sum_{x\in\mathcal{X}}(\alpha\tau^2\text{KL}(p_\tau(z_S),p_\tau(z_T))+(1-\alpha)\mathcal{L}), \tag{8}$$

where $\text{KL}(\cdot)$ denotes the Kullback-Leibler divergence. $p_\tau(\cdot)$ is the softmax function with temperature τ, and α is a balancing factor.

5 Experiments and Results

In this section, we first describe the collection and filtering process of our proposed Spoken-CoQA dataset in detail. Next, we introduce several state-of-the-art language models as our baselines, and then evaluate the robustness of these models on our proposed Spoken-CoQA dataset. Finally, we provide a thorough analysis of different components of our method. Note that we use the default settings in all evaluated methods.

Data Collection. We detail the procedures to build Spoken-CoQA as follows. First, we select the conversational question-answering dataset CoQA (Reddy et al., 2019)[2] as our basis data since it is one of the largest public CQA datasets. CoQA contains around 8k stories (documents) and over 120k questions with answers. The average dialogue length of CoQA is about 15 turns, and the answers areis in free-form texts. In CoQA, the training set and the development set contain 7,199 and 500 conversations over the given stories, respectively. Therefore, we use the CoQA training set as our reference text of the training set and the CoQA development set as the test set in Spoken-CoQA.

Next, we employ the Google text-to-speech system to transform the questions and documents in CoQA into the spoken form, and adopt CMU Sphinx to transcribe the processed spoken contents into ASR transcriptions. In doing so, we collect more than 40G audio data, and the data duration is around 300 hours. The ASR transcription has a kappa score of 0.738 and Word Error Rates (WER) of 15.9%, which can be considered sufficiently good since it is below the accuracy threshold of 30% WER (Gaur et al., 2016). For the test set, we invite 5 human native English speakers to read the sentences of the documents and questions. The sentences of one single document are assigned to a single speaker to keep consistency, while the questions in one example may have different speakers. All speech files are sampled at 16kHz, following the common approach in the speech community. We provide an example of our Spoken-CoQA dataset in Table 1 and Fig. 5.

Data Filtering In our SCQA task, the model predicts the start and end positions of answers in the ASR transcriptions. As a result, during data construction, it is necessary for us to perform data filtering by eliminating question-answer pairs if the answer spans to questions do not exist in the noisy ASR transcriptions. We follow the conventional settings in (Lee et al., 2018)[3]. In our approach, an ASR question will be removed if the ground-truth answers do not exist in ASR passages. However, when coreference resolution and inference occurs, the contextual questions related to the previous ones are required to be discarded too. For the case of coreference resolution, we change the corresponding coreference. For the case of coreference inference, if the question has strong dependence on the previous one that has already been discarded, it will also be removed. After data filtering, we get a total number of our Spoken-CoQA dataset, we collect 4k conversations in the training set, and 380 conversations in the test set in our Spoken-CoQA dataset, respectively. Our dataset includes 5 domains, and we show the domain distributions in Table 3.

Baselines. For SCQA tasks, our DDNet is able to utilize a variety of backbone networks for SCQA

---

[2] Considering that the test set of CoQA (Reddy et al., 2019) idoes not publicly availablesh the test set, we follow the widely used setting in the spoken question answering task (Li et al., 2018), where we divide Spoken-CoQA dataset into train and test set.

[3] We compare different Speech APIs, *e.g.*, Google and CMU. Considering the quality of generated speech transcripts, we choose Google TTS for TTS and CMU Sphinx for ASR.

	CoQA				S-CoQA			
	CoQA dev		S-CoQA test		CoQA dev		S-CoQA test	
Methods	EM	F1	EM	F1	EM	F1	EM	F1
FlowQA (Huang et al., 2018a)	66.8	75.1	44.1	56.8	40.9	51.6	22.1	34.7
SDNet (Zhu et al., 2018)	68.1	76.9	39.5	51.2	40.1	52.5	41.5	53.1

ALBERT-base (Lan et al., 2020)	71.4	80.6	42.6	54.8	42.7	56.0	41.4	55.2
Average	68.5	77.6	42	54.4	41.5	54.0	36.4	49.3

Table 4: Comparison of four baselines (FlowQA, SDNet, BERT, ALBERT). Note that we denote Spoken-CoQA test set as S-CoQA test for brevity.

tasks. We choose several state-of-the-art language models (FlowQA (Huang et al., 2018a), SDNet (Zhu et al., 2018), BERT-base (Devlin et al., 2018), ALBERT (Lan et al., 2020)) as our backbone network baselines. We also compare our proposed DDNET with several state-of-the-art SQA methods (Lee et al., 2018; Serdyuk et al., 2018; Lee et al., 2019; Kuo et al., 2020). To use the *teacher-student* architecture in our models, we first train baselines on the CoQA training set as *teacher* and then evaluate the performances of testing baselines on CoQA dev set and Spoken-CoQA dev set. Finally, we train the baselines on the Spoken-CoQA training set as *student* and evaluate the baselines on the CoQA dev set and Spoken-CoQA test set. We provide quantitative results in Table 4.

Experiment Settings. We use the official BERT (Devlin et al., 2018) and ALBERT (Lan et al., 2020) as our textual embedding modules. We use BERT-base (Devlin et al., 2018) and ALBERT-base (Lan et al., 2020), which both include 12 transformer encoders, and the hidden size of each word vector is 768. BERT and ALBERT both utilize BPE as the tokenizer, but FlowQA and SDNet use SpaCy (Honnibal and Montani, 2017) for tokenization. Under the circumstance when tokens in spaCy (Honnibal and Montani, 2017) correspond to more than one BPE sub-tokens, we average the BERT embeddings of these BPE sub-tokens as the final embeddings for each token. For fair comparisons, we use standard implementations and hyper-parameters of four baselines for training. The balancing factor α is set to 0.9, and the temperature τ is set to 2. We train all models on 4 24GB RTX GPUs, with a batch size of 8 on each GPU. For evaluation, we use three metrics: Exact Match (EM), F_1 score and Audio Overlapping Score (AOS) (Li et al., 2018) to compare the model performance comprehensively. Please note that the metric numbers of baseline may be different from that in the CoQA leader board as we use our own implementations, Note that, we only utilize the *student* network for inference.

Results. We compare several *teacher-student* pairs on CoQA and Spoken-CoQA dataset and the quantitative results are shown in Table 4. We can observe that the average F1 scores is 77.6% when training on CoQA (text document) and testing on CoQA dev set. However, when training the models on Spoken-CoQA (ASR transcriptions) and testing on Spoken-CoQA test set, the average F1 scores drops significantly to 49.3%. For FlowQA, the performance even drops by 40.4 pts in terms of F1 score. This corroborates the importance of mitigating ASR errors.

Table 5 compares our approach DDNET to all the previous results. As shown in the table, our distillation models achieve strong performance, and incorporating DA mechanism further improves the results considerably. Our DDNET using BERT-base models as backbone achieves similar or better results compared to all the state-of-the-art methods, and we observe that using a larger encoder ALBERT-base will give further bring large gains on performance.

As seen from Table 6, we find that our best model ALBERT-base *only* trained with KD achieve an absolute EM/F1 improvement of +1.7pts/+1.7pts, +2.5pts/+2.5pts, on CoQA and S-CoQA, respectively. This shows that cross-modal information is useful for the model, hence demonstrating that such information is able to build more robust contextualized cross-modal representations for the network performance improvements. As shown in Table 6, we also observe that our approach ALBERT-base *only* trained with DA outperforms the original method by an absolute EM/F1 of +1.4pts/+1.2pts, +1.8pts/+2.0pts, on CoQA and S-CoQA, respectively. This indicates that the fine-grained alignment between audio and text learned through DA during training benefits the downstream speech-and-language tasks. Overall, our results suggest that such a network notably improves prediction performance for spoken conversational question answering tasks. Such significant improvements demonstrate the effectiveness of DDNET.

Table 6: Comparison of our method. We set the model on text corpus as the *teacher* model, and the one on the ASR transcripts as the *student* model. DA and KD represent Dual Attention and knowledge distillation.

6 Ablation Study

We conduct ablation studies to show the effectiveness of several components in DDNet in this section and appendix.

Multi-Modality Fusion Mechanism. To study the effect of different modality fusion mechanisms, we introduce a novel fusion mechanism *Con Fusion*: first, we directly concatenate two output embedding from speech-BERT and text-BERT models, and then pass it to the encoding layer in the following SCQA module. In Table 8, we observe that Dual Attention mechanism outperform four baselines with *Con Fusion* in terms of EM and F1 scores. We further investigate the effect of uni-model input. Table 8 shows that *text-only* performs better than *speech-only*. One possible reason for this performance is that only using speech features can bring additional noise. Note that speech-only (text-only) means that we only feed the speech (text) embedding for speech-BERT (text-BERT) to the encoding layer in the SCQA module.

7 Conclusions

In this paper, we have presented SCQA, a new spoken conversational question answering task, for enabling human-machine communication. We make our effort to collect a challenging dataset - Spoken-CoQA, including multi-turn conversations and passages in both text and speech form. We show that the performance of existing state-of-the-art models significantly degrade on our collected dataset, hence demonstrating the necessity of exploiting cross-modal information in achieving strong results. We provide some initial solutions via knowledge distillation and the proposed dual attention mechanism, and have achieved some good results on Spoken-CoQA. Experimental results show that DDNET achieves substantial performance improvements in accuracy. In future, we will further investigate the different mechanisms of integrating speech and text content, and our method also opens up the possibility for downstream spoken language tasks.

Appendix

A Temperature τ

To study the effect of temperature τ, we conduct the additional experiments of four baselines with the standard choice of the temperature $\tau \in \{1, 2, 4, 6, 8, 10\}$. All models are trained on Spoken-CoQA dataset, and validated on the Spoken-CoQA test set. We present the results in Figure 4. When τ is set to 2, four baselines all achieve their best performance in term of F1 and EM metrics.

B Effects of Different Word Error Rates

We study how the network performances change when trained with different word error rates (WER) in Figure 3. Specifically, we first split Spoken-SQuAD and Spoken-CoQA into smaller groups with different WERs. Then we utilize Frame-level F1 score (Chuang et al., 2019) to validate the effectiveness of our proposed method on Spoken-CoQA. In Figure 3, we find that all evaluated networks for two tasks are remarkably similar: all evaluated models suffer larger degradation in performance at higher WER, and adopting knowledge distillation strategy is capable of alleviating such issues. Such phenomenon further demonstrates the importance of *knowledge distillation* in the case of high WER.

C Results on Human Recorded Speech

The results using BERT-base as the baseline are shown in Table 7. We train the model in the Spoken-CoQA training dataset and evaluate the model in both machine synthesized and human recorded speech. As shown in Table 7, the average EM/F1/AOS scores using BERT fell from 40.6/54.1/48.0 to 39.4/53.0/46.8, respectively. In addition, the similar trends can be observed on our proposed method. We hypothesise that the human recorded speech introduces additional noise during training, which leads to the performance degradation.

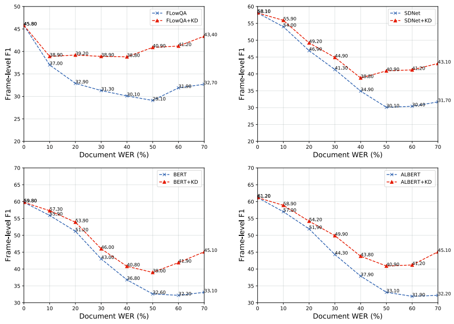

Figure 3: Comparison of different WER on Spoken-CoQA.

Table 7: Comparisons between human recorded speech and synthesized speech. We employ BERT as our base model.

Dataset	Method	EM	F1	AOS
Machine	BERT	40.6	54.1	48.0
	BERT+KD+DA	45.6	60.1	53.6
Human	BERT	39.4	53.0	46.8
	BERT+KD+DA	44.7	59.4	53.1

Table 8: Comparison of different fusion mechanisms in DDNET.

Models	CoQA dev EM	CoQA dev F1	S-CoQA test EM	S-CoQA test F1
FlowQA (Huang et al., 2018a)	40.9	51.6	22.1	34.7

D More Information about Spoken-CoQA

To perform qualitative analysis of speech features, we visualize the log-mel spectrogram features and the mel-frequency cepstral coefficients (MFCC) feature embedding learned by *DDNet* in Figure 5. We can observe how the spectrogram features respond to different sentence examples. In this example, we observe that given the text document (ASR-document), the conversation starts with the question Q_1 (ASR-Q_1), and then the system requires to answer Q_1 (ASR-Q_1) with A_1 based on a contiguous text span R_1. Compared to the existing benchmark datasets, ASR transcripts (both the document and questions) are much more difficult for the machine to comprehend questions, reason among the passages, and even predict the correct answer.

E More Comparisons on Spoken-SQuAD

To verify that our proposed DDNET is not biased towards specific settings, we conduct a series of experiments on Spoken-SQuAD (Li et al., 2018) by training the *teacher* model on textual documents, and the *student* model on the ASR transcripts. From the Table 5, compared with the performances on Spoken-CoQA, all baselines performances improve by a large margin, indicating our proposed dataset is a more challenging task for current models. We verify that, in the setting (KD+DA), the model consistently achieves significant performance boosts on all

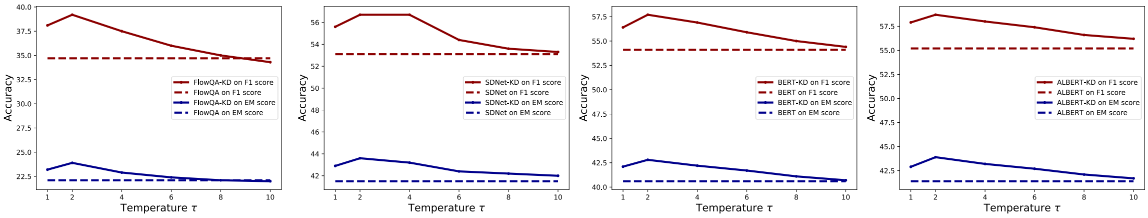

Figure 4: Ablation studies of temperature τ on DDNET performance (FlowQA, SDNet, BERT, ALBERT). Red and blue denote the results on Spoken-CoQA test set.

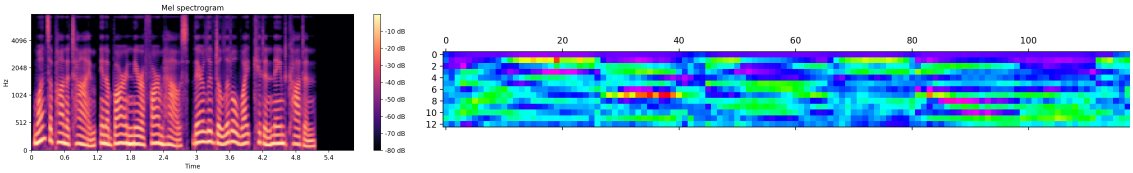
baselines. Specifically, for FlowQA, our method achieves 55.6%/68.8% (vs.51.9%/65.7%), and 52.8%/68.0% (vs.49.1%/63.9%) in terms of EM/F1 score over the text documents and ASR transcriptions, respectively. For SDNet, our method outperforms the baseline without distillation, achieving 60.1%/73.7% (vs.56.1%/70.5%) and 60.9%/75.7% (vs.57.8%/71.8%) in terms of EM/F1 score. As for two BERT-based models (BRET-large and ALBERT-large), our methods with KD consistently improve EM/F1 scores to 62.1%/74.6% (vs.58.3%/70.2%) and 63.3%/76.0% (vs.58.6%/71.1%); 62.6%/75.7% (vs.59.1%/71.9%) and 64.1%/77.1% (vs.59.4%/72.2%), respectively. These results confirm the importance of knowledge distillation strategy and dual attention mechanism.

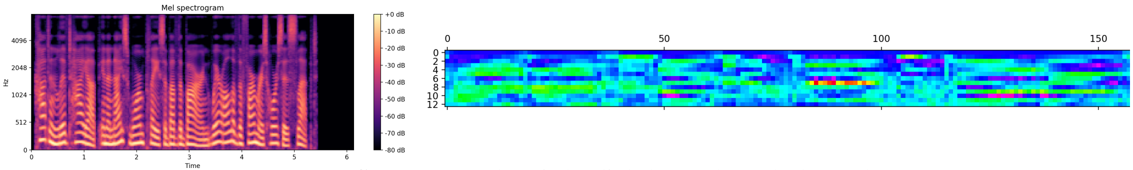
F Broader Impact

In this section, we acknowledge that our work will not bring potential risks to society considering the data is from open source with no private or sensitive information. We also discuss some limitations of our work. First, we admit that using Google TTS for TTS and CMU Sphinx for ASR may affect the distribution of errors compared with the human recorded speech. Second, we currently cover only English language but it would be interesting to see that contributions for other languages would follow. Finally, as our collection comes with reliable data, it should trigger future analysis works on analyzing spoken conversational question answering biases.

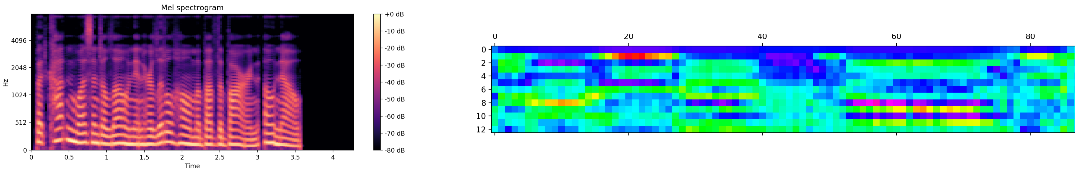
Once upon a time, in a barn near a farm house, there lived a little white kitten named Cotton.



Cotton lived high up in a nice warm place above the barn where all of the farmer's horses slept.



But Cotton wasn't alone in her little home above the barn, oh no.



She shared her hay bed with her mommy and 5 other sisters.

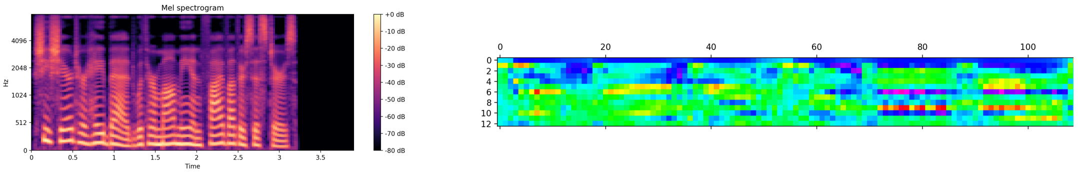


Figure 5: Examples of the log-mel spectrograms and the corresponding MFCC feature embedding. It can see that the log-mel spectrograms corresponds to different example sentences from the Spoken-CoQA dataset.

Retrieval-Augmented Multilingual Keyphrase Generation with Retriever-Generator Iterative Training*

Abstract

Keyphrase generation is the task of automatically predicting keyphrases given a piece of long text. Despite its recent flourishing, keyphrase generation on non-English languages haven't been vastly investigated. In this paper, we call attention to a new setting named multilingual keyphrase generation and we contribute two new datasets, EcommerceMKP and AcademicMKP, covering six languages. Technically, we propose a retrieval-augmented method for multilingual keyphrase generation to mitigate the data shortage problem in non-English languages. The retrieval-augmented model leverages keyphrase annotations in English datasets to facilitate generating keyphrases in low-resource languages. Given a non-English passage, a cross-lingual dense passage retrieval module finds relevant English passages. Then the associated English keyphrases serve as external knowledge for keyphrase generation in the current language. Moreover, we develop a retriever-generator iterative training algorithm to mine pseudo parallel passage pairs to strengthen the cross-lingual passage retriever. Comprehensive experiments and ablations show that the proposed approach outperforms all baselines.[1]

1 Introduction

Keyphrases are single or multi-word lexical units that best summarize a piece of text. As such, they are of great importance for indexing, categorizing, and mining in many information retrieval and natural language processing tasks (Jones and Staveley, 1999; Frank et al., 1999; Hulth and Megyesi, 2006; Dave et al., 2003). Keyphrase generation is the task of automatically predicting keyphrases given a piece of long text. Existing works on keyphrase generation mostly focus on English datasets (Gallina et al., 2019; Meng et al., 2017) while keyphrase generation for languages other than English is still under-explored. Since search engines usually provide services to customers using different languages, multilingual keyphrase generation becomes a significant problem while it is still unknown how well existing keyphrase generation approaches perform in non-English languages.

Nevertheless, there are two challenges we will face regarding multilingual keyphrase generation. First, to the best of our knowledge, there is no large-scale dataset publicly available for training and benchmarking multilingual keyphrase generation models. Building keyphrase datasets at a sufficient scale is difficult and costly. Second, compared with the existing datasets in English, which can contain millions of data examples and cover a wide diversity of topics, the data resources in non-English languages are inherently scarce. For example, in the domain of e-commerce, marketplaces using English have abundant customer queries to be used for keyphrase mining, while queries in some languages are relatively less than in English, which is probably because of a smaller size of user population or a shorter operation time.

We start tackling these challenges by contributing two new datasets for multilingual keyphrase, which cover six languages and two domains. The first dataset EcommerceMKP is collected from a real-world major e-commerce website. The product descriptions are used as the source text while the target keyphrases are collected from user search queries. This dataset contains a total of 73k data examples, covering four different languages (Spanish, German, Italian and French). The second multilingual keyphrase dataset AcademicMKP lies in the academic domain, in which titles and abstracts are used as the source text and the author-provided keyphrases are deemed targets. A total of 2,693 aca-

demic papers in Chinese and Korean are included in AcademicMKP.

To overcome the resource scarcity challenge in training multilingual models, we propose a retrieval-based method to leverage the keyphrase knowledge in large-scale English datasets. By investigating multilingual keyphrase data, we observe that data in different languages may talk about similar topics. Therefore, we conjecture that passage-keyphrases pairs in English can be of help as an external knowledge base for multilingual keyphrase generation. To be specific, given a passage in low-resource language `XX`, we propose to use a retrieval model to find multiple top-related passages in English. These retrieved English passages provide high-quality English keyphrases that can be used as hints for generating keyphrases in other languages. After that, the generator takes the code-mixed inputs, including the passage in language `XX` and retrieved English keyphrases, and predicts keyphrases in language `XX`.

In the cross-lingual retrieval training, parallel passage-keyphrases pairs between English and other languages are extremely limited. For example, in the e-commerce domain, only a small fraction of products have both English and non-English descriptions (being sold in multiple countries). Such a data scarcity issue weakens the ability of cross-lingual knowledge acquisition from high-resource English keyphrases as intermediary, and finally hinders the potential of the retrieval-augmented keyphrase generation. To mitigate the problem, we propose a retriever-generator iterative training (RGIT) algorithm to automatically mine pseudo training parallel pairs from unlabeled data. Concretely, the retriever can dynamically adjust in terms of the current variations of generation performance between the proposed retrieval-augmented generator and the base one without the aid of retrieved English keyphrases. Starting from insufficient seed parallel pairs, if the retrieved pseudo passage-keyphrases pairs in the current iteration can bring in higher generation results as the generator's feedback, those pseudo parallel data will be regarded as high quality and incorporated into the seed ones to further boost the retriever. Such cycle providing positive effects can be repeated until the increasing generation performance stopped.

We conduct extensive experiments on EcommerceMKP and AcademicMKP and demonstrate that large-scale English datasets do provide useful knowledge for multilingual keyphrase generation. The proposed retrieval-augmented method outperforms traditional extraction-based models, sequence-to-sequence neural models, and its variants. Moreover, the RGIT algorithm boosts the retrieval performance significantly by mining over 20k pseudo-parallel passage pairs. We also conduct detailed analyses to investigate the effectiveness of retriever-generator iterative training.

2 Related Work

Keyphrase Generation. The advance of neural language generation enables models to freely generate keyphrases according to the phrase importance and semantics, rather than extracting a list of sub-strings from the text (Witten et al., 1999a; Liu et al., 2011; Wang et al., 2016). Meng et al. (2017) propose the first keyphrase generation model CopyRNN, which not only generates words based on a vocabulary but also points to words in the source text — overcoming the barrier of predicting absent keyphrases. Following this idea, Chen et al. (2018); Zhao and Zhang (2019); Ahmad et al. (2021) leverage the attention mechanism to reduce duplication and improve coverage. Chen et al. (2019b); Ye and Wang (2018); Wang et al. (2019); Liang et al. (2021) propose to leverage extra structure information (e.g., title, topic) to guide the generation. Chan et al. (2019); Luo et al. (2021) propose a model using reinforcement learning, and Swaminathan et al. (2020) propose using GAN for KPG. Chen et al. (2020) introduce hierarchical decoding and exclusion mechanism to prevent models from generating duplicate phrases. Ye et al. (2021b) propose to dynamically align target phrases to eliminate the influence of order, as highlighted by Meng et al. (2021). Mu et al. (2020); Liu et al. (2020a); Park and Caragea (2020) use pre-trained language models for better representations of documents.

Retrieval Augmented Text Generation (RAG) recently shows great power in knowledge-intensive NLP tasks such as open-domain question answering, fact checking and entity linking (Lewis et al., 2020; Petroni et al., 2021; Guu et al., 2020). In RAG, a retriever (either sparse (Lee et al., 2019) or dense (Karpukhin et al., 2020)) searches for useful non-parametric knowledge from a knowledge base, then a generator combines the non-parametric retrieved knowledge with its parametric knowledge, learned during pre-training, for solving the task. Different from these tasks, keyphrase gen-

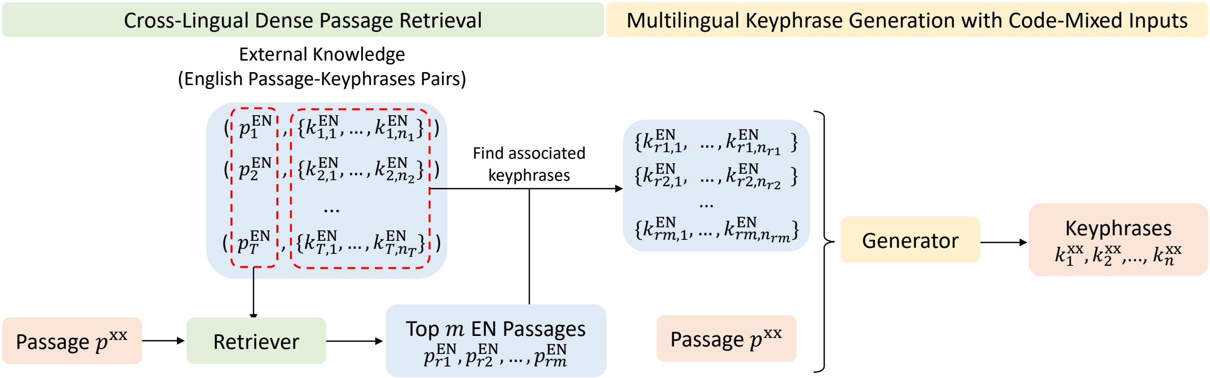

Figure 1: Overview of our Retrieval-Augmented Multilingual Keyphrase Generation (RAMKG) framework. p^{XX}, k_i^{XX} denote a passage and keyphrases in language `XX` (`XX` $\in$ { `DE`, `ES`, `FR`, `IT`, `KO`, `ZH` }). p^{EN}, k_i^{EN} denote relevant passages and keyphrases retrieved from the English dataset.

eration is not a knowledge-intensive task but we treat the English passage-keyphrase training data as our knowledge. Similar approaches have been investigated in neural machine translation (Gu et al., 2018; Cai et al., 2021), dialogue (Weston et al., 2018), and knowledge-base QA (Das et al., 2021). In keyphrase generation, Chen et al. (2019a); Ye et al. (2021a); Kim et al. (2021) retrieve similar documents from training data to produce more accurate keyphrases. However, their retrieval module is a non-parametric model and cannot be generalized in the multilingual setting due to the large vocabulary gap between languages.

3 Task Definition

In this paper, we aim to tackle the keyphrase generation task in a multilingual setting, which means one model of desire is capable of generating keyphrases in any language that it has been trained with. The benefits of having a single keyphrase generation model for multiple languages are threefold: (1) Collecting keyphrase annotation for individual language can be prohibitively expensive; (2) Training and deploying separate models for each language is laborious; (3) Joint training of multiple languages can alleviate the resource scarcity by utilizing rich monolingual data.

Formally, we define the multilingual keyphrase generation task as follows. Given a piece of text p^{XX} in language `XX`, our goal is to predict its corresponding keyphrases $k_1^{\mathrm{XX}}, k_2^{\mathrm{XX}}, ..., k_n^{\mathrm{XX}}$ in language `XX`, where n is the total number of target keyphrases for this text p^{XX}. In this study, `XX` can be German (`DE`), Spanish (`ES`), Italian (`IT`), French (`FR`), Korean (`KO`) or Chinese (`ZH`).

4 Model

Scarcity of resources is one of the topmost challenges for multilingual tasks, which is also the case for multilingual keyphrase generation. One may find it difficult to collect enough text data in languages other than English, much less the annotation of keyphrases in specific domains. To overcome this problem, we propose a retrieval-augmented approach to make use of the relatively rich resources in English. The motivation for our proposed retrieval-augmented approach comes from an observation from data: texts and keyphrases expressed in different languages usually share common topics or knowledge concepts. For example, in e-commerce websites, it is often the case that the same products are sold in different marketplaces/countries. Thus these products as well as their keyphrases, though exhibited in different languages, can share a high semantic similarity. In other words, given a text in language p^{AA}, if we could find a similar text in language p^{BB}, its associated keyphrases k^{BB} may serve as a good hint for the to-be-generated keyphrases k^{AA} in language `AA`. Since English has the most abundant text-keyphrases pairs in both e-commerce and academic papers domains, its resource can be treated as a non-parametric keyphrase knowledge base, which provides texts in English covering a wide range of topics and concepts, as well as the associated high-quality keyphrases.

As shown in Fig. 1, our framework consists of a retrieval step and a generation step:

1. *Retrieval Step*: given a source passage p^{XX} in language `XX`, the cross-lingual retriever first finds m semantically relevant English passages $p_1^{\mathrm{EN}}, p_2^{\mathrm{EN}}, ..., p_m^{\mathrm{EN}}$. Each retrieved En-

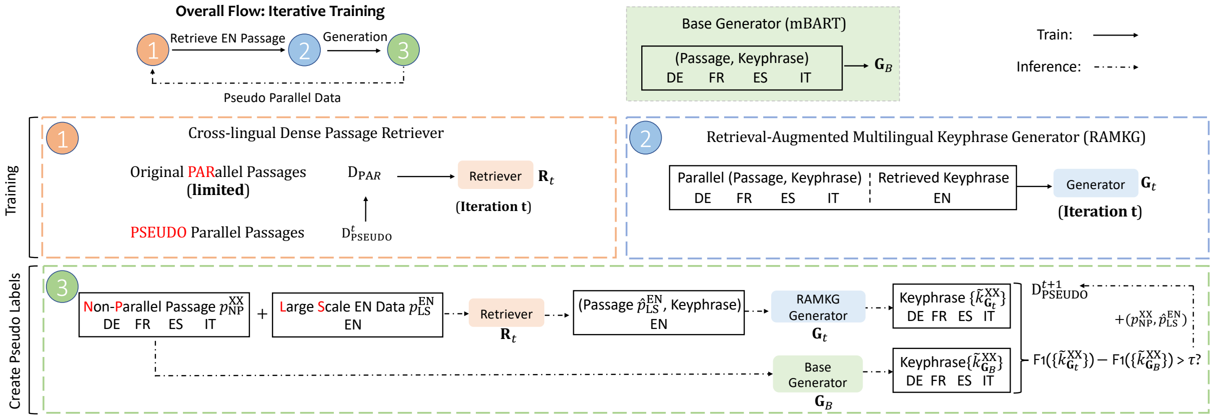

Figure 2: Retriever-Generator Iterative Training for Parallel Passage Mining

glish passage p_j^{EN} has its associated n_j English keyphrases $k_{j,1}^{\mathrm{EN}}$, $k_{j,2}^{\mathrm{EN}}$, ..., k_{j,n_j}^{EN}. These retrieved English keyphrases are taken as external knowledge for keyphrase generation in step 2.

2. *Generation Step*: taking the source text p^{XX} in language `XX` and all retrieved English keyphrases $\{k_{1,1}^{\mathrm{EN}}, ..., k_{1,n_1}^{\mathrm{EN}}\}$, ..., $\{k_{m,1}^{\mathrm{EN}}, ..., k_{m,n_m}^{\mathrm{EN}}\}$ as inputs, the generation module concatenates them as a sequence and generates keyphrases in target language `XX`.

4.1 Cross-Lingual Dense Passage Retrieval

The cross-lingual retriever includes a passage encoder $E_P(\cdot)$ and a query encoder $E_Q(\cdot)$. The passage encoder $E_P(\cdot)$ maps millions of English passages into d-dimensional vectors and builds indices for all English passages using FAISS (Johnson et al., 2021) offline. At inference time, the passage in language `XX` goes through the query encoder $E_Q(\cdot)$ and is converted into a d-dimensional vector. Then the cross-lingual retriever performs a KNN search to retrieve m English passages whose vectors are closest to the query vector measured by the dot product similarity: $\mathrm{sim}(p^{\mathrm{XX}}, p^{\mathrm{EN}_j}) = E_Q(p^{\mathrm{XX}})^\top E_P(p_j^{\mathrm{EN}})$.

Passage Encoder. Since naive lexical similarity can hardly handle text matching across languages, we resort to a BERT-based dense passage retriever (Karpukhin et al., 2020), expecting the contextualized semantic matching can retrieve similar passages accurately and robustly. In order to meet the demand of multilingual representation, we utilize multilingual pre-trained model mBERT (Devlin et al., 2019) to encode passages into 768-dimensional vectors.

Training. Since the output vectors of mBERT are not aligned across languages, we need extra alignment training to ensure that similar passages in different languages can be mapped into near regions in the high-dimensional space. Given a passage p_i^{XX} in language `XX`, we take its corresponding English passage $p_i^{\mathrm{EN}+}$ as the positive example and randomly select n negative passages $p_{i,1}^{\mathrm{EN}-}$, ..., $p_{i,n}^{\mathrm{EN}-}$ in the English corpus. The dense retriever is trained by optimizing the negative log likelihood loss of the positive English passage.

In the e-commerce domain, we select the positive passage according to product metadata. For a product sold in both `EN` and `XX` marketplaces, we regard its bilingual product descriptions $(p_i^{\mathrm{XX}}, p_i^{\mathrm{EN}+})$ as a parallel passage pair, i.e., positive training example. For the domain of academic paper, we notice that papers with parallel text is very rare. Therefore, we develop an automatic approach to mine parallel abstract pairs of English and the target language. Specifically, we adopt an off-the-shelf bi-text mining tool named Sentence Transformers (Reimers and Gurevych, 2019) to mine pseudo parallel pairs. Given two datasets in different languages, we encode passages using LaBSE (Feng et al., 2020), the current best method for learning language-agnostic sentence embeddings for 109 languages, and then parallel passages can be extracted through nearest-neighbor retrieval and filtered by setting a fixed threshold over a margin-based similarity score, as proposed in (Artetxe and Schwenk, 2019).

4.2 Multilingual Keyphrase Generation with Code-Mixed Inputs

Given the top m retrieved English passages p_1^{EN}, ..., p_m^{EN}, we find their associated keyphrases in the dataset: $\{k^{\text{EN}}_{1,1}, ..., k^{\text{EN}}_{1,n_1}\}, ..., \{k^{\text{EN}}_{m,1}, ..., k^{\text{EN}}_{m,n_m}\}$. We utilize mBART (Liu et al., 2020b), a multilingual denoising pre-trained sequence-to-sequence language model, to integrate information from multiple languages. Different from machine translation which maps a sentence a the source language to a target language, our multilingual keyphrase generation model takes code-mixed inputs – a combination of retrieved English keyphrases $\{k^{\text{EN}}_{1,1}, ..., k^{\text{EN}}_{1,n_1}\}, ..., \{k^{\text{EN}}_{m,1}, ..., k^{\text{EN}}_{m,n_m}\}$ from m retrieved English passages and the source passage $p^{\texttt{XX}}$ in the target language `XX`.

We concatenate retrieved English keyphrases with a delimiter token `[SEP]`, and add special tokens to separate different inputs: `[ENKPS]` for retrieved keyphrases and `[CTX]` for the source passage. Besides, we follow the fine-tuning setup of mBART by adding the language identifier `[XX]` (e.g. `[DE]` for German) at the end of the input sequence to denote the current input language: `[ENKPS]` $k^{\text{EN}}_{1,1}$ `[SEP]` ... `[SEP]` k^{EN}_{m,n_m} `[CTX]` $p^{\texttt{XX}}$ `[XX]`. The training target is a sequence of concatenated keyphrases $k^{\texttt{XX}}_1$, ..., $k^{\texttt{XX}}_n$, separated by a special token `[SEP]`. `[XX]`, the language identifier of the current language, is also added at the beginning of the target sequence to indicate the target language:

`[XX]` $k^{\texttt{XX}}_1$ `[SEP]` $k^{\texttt{XX}}_2$ `[SEP]` ... `[SEP]` $k^{\texttt{XX}}_n$.

4.3 Retriever-Generator Iterative Training

In spite of having utilized parallel passage pairs to align the multilingual representations of the retrieval module, it remains a concern because the parallel passage pairs between English and non-English languages account for only a small portion of the whole multilingual dataset. For example, in a popular e-commerce platform, only a small percentage of products (less than 10%) have both English and non-English descriptions. Without enough quality parallel pairs, the cross-lingual dense passage retriever may not work well to find relevant English passages. Consequently, associated English keyphrases may provide little help for multilingual keyphrase generation.

To make the multilingual keyphrase generation generalize better to any target languages or domains without reliance on numerous parallel passage pairs, we propose an iterative training method to mine parallel passages which requires only a small number of initial parallel pairs of bootstrap the process. Since our ultimate goal of the retriever model is to provide useful external knowledge for multilingual keyphrase generation, we mine parallel passage pairs (English and a non-English language) according to whether the retrieved English passage-keyphrases pairs could help the keyphrase generation for the target non-English language `XX`. For example, let p^{EN}_a and p^{EN}_b be two retrieved English passages for a passage $p^{\texttt{XX}}$ in target language, if the associated keyphrases of p^{EN}_a provide more useful information for generating the keyphrases of $p^{\texttt{XX}}$ than p^{EN}_b, then $(p^{\text{EN}}_a, p^{\texttt{XX}})$ would be considered as a better parallel passage pair. That said, we expect the mined pseudo parallel passage pairs to be of high quality according to the retrieval score, at the same time they can be directly helpful for training the generation module.

Algorithm 1 Parallel Passage Mining via Iterative Training

```
Input: (1) Parallel data $D_{\texttt{PAR}} = \{(p^{\text{EN}}_{\texttt{PAR}}, p^{\texttt{XX}}_{\texttt{PAR}}, k^{\text{EN}}_{\texttt{PAR}}, k^{\texttt{XX}}_{\texttt{PAR}})\}$, (2) Non-parallel data $D_{\text{NP}} = \{(p^{\texttt{XX}}_{\text{NP}}, k^{\texttt{XX}}_{\text{NP}})\}$, (3) Large-scale English corpus $D_{\texttt{LS}} = \{(p^{\text{EN}}_{\texttt{LS}}, k^{\text{EN}}_{\texttt{LS}})\}$.
Output: Pseudo parallel passage pairs $D_{\texttt{PSEUDO}}$

    $\mathbf{R}_t \leftarrow train(\{(p^{\text{EN}}_{\texttt{PAR}}, p^{\texttt{XX}}_{\texttt{PAR}})\} \in D^t_{\texttt{PSEUDO}} \cup D_{\texttt{PAR}})$
    ▷ 2. Train retrieval-augmented generator on $D_{\texttt{PAR}}$
    for each $(p^{\texttt{XX}}_{\texttt{PAR}}, k^{\texttt{XX}}_{\texttt{PAR}}) \in D_{\texttt{PAR}}$ do
        $\hat{p}^{\text{EN}}_{\texttt{LS}} \leftarrow \mathbf{R}_t(p^{\texttt{XX}}_{\texttt{PAR}}, D_{\texttt{LS}})$    // Retrieve EN passages
        $\{\hat{k}^{\text{EN}}_{\texttt{LS}}\} \leftarrow \hat{p}^{\text{EN}}_{\texttt{LS}}$    // Find associated EN keyphrases
    // Train retrieval-augmented generator with EN keyphrases
    $\mathbf{G}_t \leftarrow train(\{(p^{\texttt{XX}}_{\texttt{PAR}}, k^{\texttt{XX}}_{\texttt{PAR}})\} \in D_{\texttt{PAR}}, \{\hat{k}^{\text{EN}}_{\texttt{LS}}\})$
    ▷ 3. Create pseudo parallel passage pairs
    $D^{t+1}_{\texttt{PSEUDO}} \leftarrow \{\}$
    for each $p^{\texttt{XX}}_{\text{NP}} \in D_{\text{NP}}$ do
        $\hat{p}^{\text{EN}}_{\texttt{LS}} \leftarrow \mathbf{R}_t(p^{\texttt{XX}}_{\text{NP}}, D_{\texttt{LS}})$    // Retrieve EN passages
        $\{\hat{k}^{\text{EN}}_{\texttt{LS}}\} \leftarrow \hat{p}^{\text{EN}}_{\texttt{LS}}$    // Find associated EN keyphrases
        // Predict keyphrases w/o and w/ EN keyphrases
        $\{\tilde{k}^{\texttt{XX}}_{\text{NP},\mathbf{G}_B}\} \leftarrow \mathbf{G}_B(p^{\texttt{XX}}_{\text{NP}})$
        $\{\tilde{k}^{\texttt{XX}}_{\text{NP},\mathbf{G}_t}\} \leftarrow \mathbf{G}_t(p^{\texttt{XX}}_{\text{NP}}, \{\hat{k}^{\text{EN}}_{\texttt{LS}}\})$
        // If adding EN keyphrases leads to better keyphrase predictions, the retrieved EN passages are taken as positive examples
        if F1($\{\tilde{k}^{\texttt{XX}}_{\text{NP},\mathbf{G}_t}\}$) − F1($\{\tilde{k}^{\texttt{XX}}_{\text{NP},\mathbf{G}_B}\}$) $> \tau$ then
            $D^{t+1}_{\texttt{PSEUDO}} \leftarrow D^{t+1}_{\texttt{PSEUDO}} \cup \{(\hat{p}^{\text{EN}}_{\text{NP}}, p^{\texttt{XX}}_{\text{NP}})\}$
return $D^T_{\texttt{PSEUDO}}$
```

The proposed iterative training approach is sketched in Algo. 1 and Fig. 2. Given a Large-Scale keyphrase dataset in English $D_{\texttt{LS}} = \{(p^{\text{EN}}_{\texttt{LS}}, k^{\text{EN}}_{\texttt{LS}})\}$ and a smaller one $D_{\texttt{XX}} = \{(p^{\texttt{XX}}, k^{\texttt{XX}})\}$ in target language `XX`, we denote the set of annotated parallel examples (bilingual passages in English and other languages) as **PARallel split** $D_{\texttt{PAR}} = \{(p^{\text{EN}}_{\texttt{PAR}}, p^{\texttt{XX}}_{\texttt{PAR}}, k^{\text{EN}}_{\texttt{PAR}}, k^{\texttt{XX}}_{\texttt{PAR}})\}$, in which $\{(p^{\texttt{XX}}_{\texttt{PAR}}, k^{\texttt{XX}}_{\texttt{PAR}})\}$ comes from the `XX` dataset while $\{(p^{\text{EN}}_{\texttt{PAR}}, k^{\text{EN}}_{\texttt{PAR}})\}$ comes from the English dataset. The remaining data examples in the target dataset

Table 1: AcademicMKP & EcommerceMKP Dataset

$D_{\mathtt{XX}}$ have no annotated corresponding English examples in $D_{\mathtt{LS}}$ (the pairs may exist but are not known yet), and we name this set as the **Non-Parallel split** $D_{\mathtt{NP}} = \{(p^{\mathtt{XX}}_{\mathtt{NP}}, k^{\mathtt{XX}}_{\mathtt{NP}})\}$. We firstly fine-tune a mBART using only keyphrases data of target language $\{(p^{\mathtt{XX}}_{\mathtt{PAR}}, k^{\mathtt{XX}}_{\mathtt{PAR}})\}$ in $D_{\mathtt{PAR}}$ (Line 4). Then we start a loop to mine pseudo parallel passage pairs for refining the passage retriever. Each iteration is expected to bring in a higher quality of pseudo passage pairs, resulting in a better performance of retriever, with three steps:

1. We train a retriever $\mathbf{R}_t$ using existing available `EN-XX` passage pairs $\{(p^{\mathtt{EN}}_{\mathtt{PAR}}, p^{\mathtt{XX}}_{\mathtt{PAR}})\}$ from both parallel passage data $D_{\mathtt{PAR}}$ and most up-to-date pseudo passage data $D^{t}_{\mathtt{PSEUDO}}$ (Line 8).
2. We train a retrieval-augmented model $\mathbf{G}_t$ using multilingual passages $\{(p^{\mathtt{XX}}_{\mathtt{PAR}}, k^{\mathtt{XX}}_{\mathtt{PAR}})\}$ from the parallel data $D_{\mathtt{PAR}}$ and retrieved English keyphrases $\{\hat{k}^{\mathtt{EN}}_{\mathtt{LS}}\}$ from the English dataset $D_{\mathtt{LS}}$ (Line 14). To get the retrieved English keyphrases for each passage $p^{\mathtt{XX}}_{\mathtt{PAR}}$, we take the retriever $\mathbf{R}_t$ trained in step (1) to do a KNN search for passages $\hat{p}^{\mathtt{EN}}_{\mathtt{LS}}$ in `EN` $D_{\mathtt{LS}}$ and find their associated keyphrases $\{\hat{k}^{\mathtt{EN}}_{\mathtt{LS}}\}$ (Line 10-12).
3. For each passage $p^{\mathtt{XX}}_{\mathtt{NP}}$ in the non-aligned dataset $D_{\mathtt{NP}}$, we also retrieve English passages $\hat{p}^{\mathtt{EN}}_{\mathtt{LS}}$ and keyphrases $\{\hat{k}^{\mathtt{EN}}_{\mathtt{LS}}\}$ from $D_{\mathtt{LS}}$ (Line 18-19). Then the retrieved English passage $\hat{p}^{\mathtt{EN}}_{\mathtt{LS}}$ will be taken as the parallel text to $p^{\mathtt{XX}}_{\mathtt{NP}}$ if its associated keyphrases $\{\hat{k}^{\mathtt{EN}}_{\mathtt{LS}}\}$ provide *useful* information. The *usefulness* is measured by the keyphrase generation performance (F-score) between the retrieval-augmented generation model $\mathbf{G}_t$ and the base model $\mathbf{G}_0$ that does not use `EN` keyphrases (Line 21-25).

After T iterations, we train the retriever on the pseudo data $D^{T}_{\mathtt{PSEUDO}}$ and fine-tune it on the parallel data $D_{\mathtt{PAR}}$. Then we treat it as our final retriever and train the generation model in Sec. 4.2.

5 Datasets

EcommerceMKP Dataset is collected from a popular E-commerce shopping platform. There are four languages we consider for building EcommerceMKP: German (DE), French (FR), Spanish (ES) and Italian (IT). The title, product description, and bullet description provided by manufacturers are concatenated and treated as source input. The keyphrases of each product are selected from search queries under the following protocol. First, given a product, we only keep search queries that lead to purchases and treat them as effective queries. Then phrases are chunked from these effective queries using AutoPhrase (Shang et al., 2018) and further ranked by their frequency. Our assumption is: the more times a phrase appears in effective search queries of a product, the more important a phrase is. Finally a threshold is set to filter out unimportant phrases. Under this protocol, we receive 73k examples over four languages. The statistics are shown in Table 1.

We collect the passages and keyphrases under the same protocol for the English (EN) dataset and name it as EcommerceMKP-EN. In total the English dataset contains 3 million passage-keyphrases pairs. To obtain the parallel passage pairs for training the cross-lingual dense passage retriever, we pair the product descriptions in different languages according to the product identification information. We select a total of 1,247 parallel passages from EcommerceMKP training set which include 480 passages for `DE-EN`, 244 for `ES-EN`, 340 for `FR-EN`, and 183 for `IT-EN`. Besides, we keep 1,000 parallel passage pairs in the DEV set of EcommerceMKP to evaluate the performance of retrieval and bi-text mining.

AcademicMKP Dataset is collected from the academic domain. We take the title and abstract of each paper as the source text and author-provided keywords as the target output. All papers are sampled from Microsoft Academic Graph (Sinha et al., 2015), a web-scale academic entity graph that contains multiple types of scholarly entities and relationships: field of study, author, institution, abstract, venue, and keywords. We use Spacy (`https://spacy.io/`) to detect the language of abstracts and keyphrases, and choose two languages Chinese (ZH) and Korean (KO) to construct the AcademicMKP dataset. Since Microsoft Academic Graph (MAG) is automatically crawled and

Table 3: Results on AcademicMKP (mono: monolingual, multi: multilingual, Joint: EN Joint Train, Pretrain: EN Pretrain, RGIT: Iterative-training).

constructed, we find some of its data is extremely noisy. For example, keyphrases might be missing or contain incorrect information such as titles, author names, and publication venues. Some of the abstracts are incomplete. Therefore, we hire three annotators to manually examine the samples from MAG dataset. Data examples with incomplete abstracts are removed. We further manually verify the metadata of all examples and correct their keyphrase information if needed. Finally, 2,693 high-quality data examples of scientific papers in the computer science domain are collected to constitute AcademicMKP.

Besides the multilingual AcademicMKP dataset, we use KP20K (Meng et al., 2017) as the English data for retrieval-augmented generation. KP20K has 560k abstract-keyphrases pairs collected from various online digital libraries in computer science domain. The threshold is set as 1.03 for passage mining and we receive 841 parallel passage pairs from AcademicMKP training set, in which 433 `ZH-EN` passage pairs and 384 for `KO-EN`.

6 Experimental Setup

6.1 Evaluation Metrics

Keyphrase Generation. Let the ground truth keyphrases be $Y : k_1, k_2, ..., k_n$ and the predicted keyphrases be $\tilde{Y} : \tilde{k}_1, \tilde{k}_2, ..., \tilde{k}_M$, we compute the precision ($P@M$), recall ($R@M$) and F-score ($F_1@M$) between Y and $\tilde{Y}$ as $P@M = \frac{|Y \cap \tilde{Y}|}{|\tilde{Y}|}$, $R@M = \frac{|Y \cap \tilde{Y}|}{|Y|}$, $F_1@M = \frac{2 \times P \times R}{P+R}$, where $|Y|$ denotes the number of keyphrases in the gold set Y. We only consider exact match of two keyphrases (with some post-processing such as lowercase) for $|Y \cap \tilde{Y}|$. Then the average are computed for all languages in the test set.

Passage Retrieval. The quantity of retrieved English passages directly influences how much external knowledge could be utilized for keyphrase generation. Therefore, we evaluate the top-k recall (k=1,2,5,10,20) on the DEV set for evaluating retrieval performance.

6.2 Baselines and Ablations

We consider following baselines and ablations: **1) Unsupervised Statistical Keyphrase Extraction**: KP-Miner (El-Beltagy and Rafea, 2010), YAKE (Campos et al., 2020); **2) Unsupervised Graph-based Keyphrase Extraction**: TextRank (Mihalcea and Tarau, 2004), TopicalPageRank (Sterckx et al., 2015), PositionRank (Florescu and Caragea, 2017), MultipartiteRank (Boudin, 2018); **3) Supervised Feature-based Keyphrase Extraction**: KEA (Witten et al., 1999b); **4) Neural**

Supervised Keyphrase Generation: CopyRNN, Transformer; **5) mBART (monolingual)**: separately trained 6 mBART models on each language; **6) mBART (multilingual)**: a single mBART model on all languages; **7) mBART + EN Joint Train**: a mBART model jointly trained on the multilingual data and English data (KP20K (Meng et al., 2017) for AcademicMKP; EcommerceMKP-EN for EcommerceMKP). **8) mBART + EN Pretrain**: a mBART firstly pre-trained on the English data and then fine-tuned on the multilingual data. **9) RAMKG (Ours)**: The Retrieval-Augmented Multilingual Keyphrase Generation model (Sec. 4.1 & 4.2). **10) RAMKG + RGIT (Ours)**: RAMKG improved with retriever-generator iterative training (RGIT) (Sec. 4.3).

7 Results and Analyses

7.1 Main Results

Main results are shown in Table 2 & 3 for EcommerceMKP and AcademicMKP respectively, and we make the following observations:

- The unsupervised approaches, both statistical-based and graph-based, have robust results across all languages. PositionRank performs the best among all unsupervised approaches.
- The supervised approaches consistently outperform unsupervised approaches. The feature-based approach KEA receives a high recall by predicting more keyphrases while the CopyRNN receives a high precision. Different from the results on English keyphrase generation where Transformer and CopyRNN are comparable, the Transformer beats the CopyRNN by a large margin in the multilingual scenario.
- We observe that jointly training on all languages (mBART multilingual) receives better results than separately training on each language (mBART monolingual). This implies the ability of locating and summarizing key information is transferable across languages.
- Comparing different approaches using external large-scale English data, we find that our proposed RAMKG outperforms both "EN Joint Train" and "EN Pretrain". This is because the retrieval-augmented approach provides auxiliary knowledge information as part of the input to the generation module, while the other two variants have to "infuse" the knowledge learned from English data to model parameters. Moreover, "EN Joint Train" and "EN Pretrain" have no positive effect on AcademicMKP dataset (Table 3). Compared with multilingual and English data are from the same website, there is still a domain gap between papers (multilingual) in AcademicMKP and papers (English) in KP20K.

Recall @ Top K	1	2	5	10	20
RAMKG	26.4%	36.8%	50.1%	59.2%	67.3%
RAMKG + RGIT	45.8%	58.3%	72.4%	79.5%	85.2%

Table 4: Retrieval recall on EcommerceMKP DEV set.

Iteration	1	2	3	4	5	6
# Pseudo Passages	20,288	21,402	19,942	21,241	22,343	21,557
Label Accuracy %	28.0%	37.9%	40.5%	44.2%	45.1%	47.0%

Table 5: Number of pseudo parallel passages and their accuracy on EcommerceMKP DEV set in different iterations of parallel passages mining.

- The retriever-generator self-training (RAMKG + Iter) alleviates the data scarcity issue with the help of stronger retriever: since the retriever can find more relevant English keyphrases, it leads to a general improvement on keyphrase performance across languages.

7.2 Effect of Iterative Training

Retrieval Results We investigate the effect of retriever-generator iterative training by comparing the retrieval recall for models trained w/o and w/ the mined pseudo parallel passage pairs. Results on the DEV set of EcommerceMKP are shown in the Table 4. With additional mined pseudo parallel passage pairs, the retriever improves the Recall@5 from 50.1% to 72.4%. And therefore, the better retrieved English keyphrases lead to a better generation performance (44.50 vs. 45.73 in Table 2).

Quantity and Quality of Pseudo Parallel Passages We show the quantity and quality of mined pseudo parallel pairs in Table 5. After each iteration of passage mining, our algorithm can consistently find around 20k passage pairs from EcommerceMKP training set, which are nearly 20 times of the initial data. To assess the quality of mined passage pairs, we examine the label accuracy using the 1,000 parallel passage pairs from the DEV set of EcommerceMKP. Results in Table 5 show that while the passage mining finds a similar number of pseudo passage pairs, the labelling accuracy does increase from 28.0% to 47.0%. This is because the better pseudo parallel data improves the retriever, and the stronger retriever results in a better generator, which in turn leads to more relevant passages.

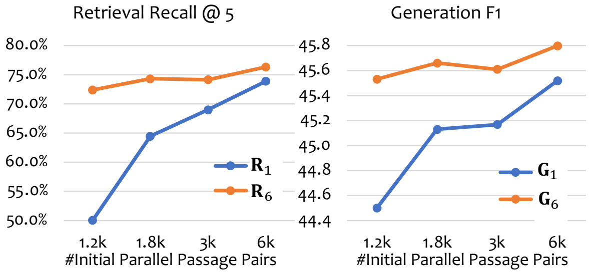

Figure 3: Performance of passage retrieval and keyphrase generation on EcommerceMKP, with different number of initial parallel data for iterative training.

Product Description (German): **Steiff** 113437 **Soft Cuddly Friends** Honey Teddybär, **grau**, 38 cm. Bereits der Name des **Soft Cuddly Friends** Honey Teddybär sagt es schon aus: der 38 cm große Freund mit seinem honigsüßen Lächeln begeistert alle Kinderherzen ...

(Translation in English): Steiff 113437 Soft Cuddly Friends Honey teddy bear, gray, 38 cm. The name of the Soft Cuddly Friends Honey Teddy bear already says it all: the 38 cm tall friend with his honey-sweet smile delights all children's hearts ...

Gold Keyphrases (German): *steiff kuscheltier*; *steiff teddy*; **soft cuddly friend**; **steiff**; *baer*; **grau**.

(Translation in English): steiff cuddly toy; steiff teddy; soft cuddly friend; steiff; bear; grey.

Retrieved English Keyphrases: steiff teddy bear; teddy bear; my first; grey; honey; sweetheart; steiff bear; pink; vintage; steiff stuffed animal; steiff; terry; soft; jimmy.

Predicted Keyphrases (German): *steiff kuscheltier*; *steiff teddy*; **soft cuddly friend**; **steiff**; *baer*; **grau**; *jimmy*.

(Translation in English): steiff cuddly toy; steiff teddy; soft cuddly friend; steiff; bear; grey; jimmy.

Figure 4: Case study on the EcommerceMKP dataset. The present keyphrases (keyphrases shown in the description) are in **bold** while absent keyphrases are in *italics*. Correct predictions are in green while wrong predictions are in red.

Initializing with Different Amount of Parallel Data To investigate the impact of initial parallel passage on the training, we conduct experiments by varying the number of parallel passage pairs on EcommerceMKP, from 1.2k (default setting) to 6k instances. We compare the single-round training (i.e., training with initial data) and iterative training after six rounds (in which round we generally obtain the best retrieval recall), on both passage retrieval ($\mathbf{R}_1$ & $\mathbf{R}_6$) and keyphrase generation ($\mathbf{G}_1$ & $\mathbf{G}_6$). Results are shown in Fig. 3. We observe that (1) the score of iterative training consistently increase when more annotated parallel data is available; (2) our iterative training demonstrates great robustness with limited parallel data (e.g. 1.2k pairs), while the benefit gradually diminishes while more parallel data becomes available.

7.3 Case Study

Fig. 4 exhibits an example of our model's prediction. Given a product description in German, the model retrieves several English keyphrases and generates keyphrases in German accurately (translations in English are also provided). Through this example, we find that the retrieved English keyphrases do provide certain useful information such as "steiff teddy bear", "grey" and "soft", while it also brings some noise such as "my first", "sweetheart" and "vintage". Although there is a wrong prediction "jimmy" caused by the retrieved English keyphrases, the improvement in results shows that the benefits of retrieved knowledge outweigh the noise it introduces. Moreover,the retrieved keyphrases are only regarded as a supplement to the original passage, and the generator can automatically focus on the informative parts from both inputs through self-attention. Our retrieval-augmented multilingual keyphrase generation can tolerate some noise from the retrieved English keyphrases and predict better keyphrases based on these external knowledge.

8 Conclusion

In this study, we investigate a novel task setting – multilingual keyphrase generation – and contribute two new multilingual keyphrase generation datasets covering multiple domains and languages. Furthermore, we propose a retrieval-augmented multilingual keyphrase generation framework with retriever-generator iterative training. Results show that the proposed approach outperforms a wide range of baselines.

A Appendix

A.1 Implementation Details

In the cross-lingual dense passage retriever, we use "bert-base-multilingual-cased" model (Wolf et al., 2020) to initialize the query and passage encoders and fine-tune it for 15 epochs with a batch size of 32. We share the parameters between the query encoder $E_Q(\cdot)$ and the passage encoder $E_P(\cdot)$ and map English and non-English passages into the same embedding space. Empirical results show the encoder with parameter sharing can perform slightly better. The positive examples are the corresponding English passages while we randomly sample 100 passages as negative examples in training. For the retrieval-augmented keyphrase generator, we fine-tune "mbart-large-cc25" (Wolf et al., 2020) for 10 epochs with Adam (Kingma and Ba, 2015) optimizer with a learning rate of 1e-4, a batch size of 8, a warm-up rate of 50 training steps. Similar to most Seq2Seq models, we train the mBART-based generation module by optimizing the negative log-likelihood loss of the ground-truth keyphrase sequence, and use beam search decoding with a beam size of 5 during inference. The number of retrieved keyphrases m for retrieval-augmented generation is a hyperparameter and is tuned on the development set. We use keyphrases from $m = 1$ English passages for AcademicMKP dataset and $m = 5$ for EcommerceMKP dataset. During inference, we set the maximum target sequence length as 128 and set the beam decoding size as 5. For parallel passage mining via iterative training, we continue the iterative process until the retrieval recall does not improve. The total number of iterations (T in Algo. 1) are 6 and 3 on EcommerceMKP and AcademicMKP respectively. The threshold τ in Line 23 for Algo. 1 is set as 5.

A.2 Variants of Retrieval Targets

There exists a misalignment between the retriever and the generator model. The retriever retrieves similar passages while the generator utilizes the associated keyphrases of these passages (not the retrieved passages) as external knowledge for generation. Therefore, a good retriever does not necessarily guarantee the good quality and usefulness of these keyphrases.

We tried two different retrieval targets which might close the misalignment. Given a non-English passage, we tried to either directly retrieve English keyphrases (RAMKG-P2K) or retrieve the concatenated sequences of passage-keyphrase pair (RAMKG-P2PK). We find that (1) RAMKG-P2K that directly retrieves keyphrases has poor retrieval performance. This is because it is hard to capture the similarity between non-English passages and English keyphrases; (2) RAMKG-P2PK has slightly worse results than only retrieval EN passages, which implies that additionally adding keyphrases in the retrieval targets does not bring any benefit.

Model	Retrieval Results			Generation Results		
	Recall@1	Recall@2	Recall@5	P	R	F1
P2P	26.00%	36.78%	50.05%	48.51	44.71	44.50
P2K	2.86%	4.70%	9.09%	46.91	43.13	42.95
P2PK	25.25%	35.45%	49.51%	48.50	44.39	44.34

Table 6: Results of RAMKG variants with different retrieval targets.

τ	0	5	10	15
Recall	62.28%	64.01%	63.67%	62.97%

Table 7: Influence of the threshold τ on the retriever-generator self-training algorithm.

Results are shown in Table 6. RAMKG (P2P) is our original model which retrieves English passages given a non-english passage. Results tell us that 1) directly retrieval of keyphrases have poor retrieval performance. This is because it is hard to capture the similarity between non-english passages and english keyphrases; 2) RAMKG (P2PK) has slightly worse results than the model , which implies that additionally adding keyphrases in the retrieval targets does not bring any benefit.

A.3 Discussion on Retriever-Generator Iterative training (RGIT) Algorithm

Difference between RGIT and Self-Training. Our approach shares some similarities with self-training (Lee, 2013; Pham et al., 2021) but there are some differences. In self-training, the teacher and student models are in the same architecture and focus on the same training objectives. In our proposed retriever-generator iterative training, the retriever and generator are two different models and optimized by different objectives.

Threshold Tuning. In this section, we investigate the impact of the chosen threshold τ (line 24) in our proposed retriever-generator iterative training. We tune the threshold (tau) on AcademicMKP and results are shown in Table 7. Results show that tau=5 receives the best retrieval performance. Tau=0 brings more pseudo parallel passage pairs but introduces more noise. Larger tau (10/15) reduces the number of pseudo pairs, making the iterative training less effective.

FAtNet: Cost-Effective Approach Towards Mitigating the Linguistic Bias in Speaker Verification Systems

Abstract

Linguistic bias in Deep Neural Network (DNN) based Natural Language Processing (NLP) systems is a critical problem that needs attention. The problem further intensifies in the case of security systems, such as speaker verification, where fairness is essential. Speaker verification systems are intelligent systems that determine if two speech recordings belong to the same speaker. Such human-oriented security systems should be usable by diverse people speaking varied languages. Thus, a speaker verification system trained on speech in one language should generalize when tested for other languages. However, DNN-based models are often language-dependent. Previous works explore domain adaptation to fine-tune the pre-trained model for out-of-domain languages. Fine-tuning the model individually for each existing language is expensive. Hence, it limits the usability of the system. This paper proposes the cost-effective idea of integrating a lightweight embedding with existing speaker verification systems to mitigate linguistic bias without adaptation. This work is motivated by the theoretical hypothesis that attentive-frames could help generate language-agnostic embeddings. For scientific validation of this hypothesis, we propose two frame-attentive networks and investigate the effect of their integration with baselines for twelve languages. Empirical results suggest that frame-attentive embedding can cost-effectively reduce linguistic bias and enhance the usability of baselines.

1 Introduction

Mitigating the linguistic bias in Deep Neural Network (DNN) based models is one of the critical challenges in Natural Language Processing (NLP). The linguistic bias, specifically in the security systems, such as speaker verification models, is a far more critical problem requiring much research. Speaker verification systems are biometric authentication systems that use speech signals to authenticate a speaker. These systems use the fact that every speaker has unique traits in their voice (Hansen and Hasan, 2015). Such systems have real-world applications in e-commerce, forensics, law, business, and access control mechanisms (Hansen and Hasan, 2015). These systems can be text-dependent or text-independent (Hansen and Hasan, 2015). Text-independent speaker verification systems are more user-friendly than text-dependent systems. These systems authenticate a speaker without any constraint on the content of speech.

However, speaker verification models often tend to be language-dependent (Auckenthaler et al., 2001). The reason is that a robust speaker verification system would require memory to analyze the sequential speech data and capture relevant discriminatory information. Memory helps in remembering past information. Remembering the past and predicting the future can contribute to linguistic content in the embedding (Shain and Elsner, 2020). Therefore, the generated embedding for speaker verification may contain linguistic detail.

Language-dependent speaker verification models perform relatively well on test sets containing speech recordings in the same language as the training set. However, the performance of these systems degrades on test sets containing speech recordings in different languages. The majority of the publicly available speech datasets are in English. It is a tedious task to get labeled datasets for various low-resource languages. Most of the previous works use domain adaptation to improve the performance of speaker verification models only for a limited set of languages (Rohdin et al., 2019; Xia et al., 2019; Chen et al., 2020). It is also costly to fine-tune a pre-trained speaker verification model individually for each existing language. Further, studies show that the linguistic content in the embedding increase with the temporal scope of representations (Chrupała et al., 2020).

Our proposed work is based on the theoretical hypothesis that frame-level features contain less lin-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1247 - 1258
July 10-15, 2022 ©2022 Association for Computational Linguistics

guistic information due to the low-temporal scope of frames. Thus, frame-level features may help generate a language-agnostic embedding. Furthermore, an intelligent selection of frame-level features may help in enhancing the model's generalizability to out-of-domain testing. We aim to address the problem of language dependency in text-independent speaker verification systems cost-effectively, without the overhead of domain adaptation. We propose an idea that incorporates a lightweight embedding with existing speaker verification systems which may help in improving the generalizability of these systems to out-of-domain testing. To scientifically validate the theoretical hypothesis, we present and investigate two variants of frame-attentive networks: FAtNet-v1 and FAtNet-v2. Our proposed models accept two speech recordings as input and determine if they belong to the same speaker. The speakers in the trial pair may be unknown. We qualitatively compare the generalization ability of our proposed models with two strong baselines on four publicly available data sets. We perform quantitative experiments on 12 languages to assess the integration of our proposed FAtNet embeddings with the baselines on publicly available out-of-domain test sets without domain adaptation. We have released the code[1] to encourage more research on this problem.

We summarize our main contributions below:

1. Investigate cognitive ideas such as attention, residual connection for memory, and learning parameters to generate language-agnostic embeddings.
2. To validate the theoretical hypothesis scientifically, propose two novel frame-attentive networks: FAtNet-v1 and FAtNet-v2.
3. Perform qualitative and quantitative experiments for twelve languages using two strong baselines and four publicly available datasets.

2 Background and Motivation

Language dependency in speaker verification: The current state-of-the-art explores deep neural networks (DNN) to solve speaker recognition problems (Hansen and Hasan, 2015; Li et al., 2018; Jung et al., 2020, 2019; Nagrani et al., 2017; Snyder et al., 2018; Nagrani et al., 2020; Guzewich et al., 2018; Zhao et al., 2019; Gao et al., 2018). However, most DNN-based feature extractors are language-dependent (Oleg et al., 2016). Language dependency can make the system less usable as users may belong to different geographic locations and speak varied languages. It is challenging to get labeled datasets for various low-resource languages (Brignatz et al., 2021). Moreover, when tested on multilingual datasets and features, the models that show consistent behavior may be helpful in other applications (such as code-switching) through information sharing (Belinkov et al., 2019). We know that there are approximately 7,000 languages in the world (Huang et al., 2021). One of the critical challenges in Natural Language Processing (NLP) is to develop techniques to overcome this linguistic bias and enhance the usability of the model across the globe (Huang et al., 2021).

Recent works: Transfer learning is a solution to address the problem of domain mismatch. However, it is challenging to get labeled datasets for various low-resource languages (Brignatz et al., 2021). Recent works investigate adversarial domain adaptation techniques for solving cross-lingual speaker verification problems (Rohdin et al., 2019; Xia et al., 2019; Chen et al., 2020; Brignatz et al., 2021). However, most of these approaches can improve the performance of speaker verification models for a limited set of languages as these approaches require an additional overhead of domain adaptation.

To the best of our knowledge, (Chojnacka et al., 2021) is the closest work related to our problem statement where the authors attempt to reduce linguistic bias in speaker verification without domain adaptation. In (Chojnacka et al., 2021), the authors suggest that training a speaker verification model in multiple languages can increase its generalizability to out-of-domain languages. However, they trained the model on an extensive training set consisting of 1,96,000 speakers and 2,06,18,000 utterances. Training on such an extensive dataset requires significant computational requirements, often not feasible in a realistic scenario. In addition to that, their proposed work involves a combination of text-dependent and text-independent speaker verification systems. Our proposed method involves integrating a lightweight embedding with the existing text-independent speaker verification models to reduce linguistic bias in those systems.

Linguistic components in a frame: Speech signals are non-stationary, and hence they are divided into frames. A speech signal is assumed to be stationary within a frame (Malek, 2020). The tem-

---

[1] `https://github.com/vdivyas/FAtNet.git`

poral scope of a frame is usually a few milliseconds. Researchers have investigated the role of temporal scope in their study of phonology in neural models (Chrupała et al., 2020). Studies show that Representational Similarity Analysis (RSA) applied to local representations results in lower correlations between phonemes and neural activation patterns (Chrupała et al., 2020). Thus, considering the low temporal scope of frames, it is intuitive that they carry less linguistic information.

Theoretical Hypothesis: Our proposed work investigates the theoretical hypothesis that utterance-level embedding captures more linguistic information than frame-level embedding. Therefore, a frame-level embedding can be more language-robust than an utterance-level embedding. This abstract knowledge of frame-level features can allow the model to learn relevant discriminatory information from frames and ignore the linguistic information from speech. Researchers have stated that some frames tend to be more critical than others for the final-encoded representation of speech (Havard et al., 2019). Attention mechanisms are popular in state-of-the-art speaker verification models (Zhu et al., 2018; Okabe et al., 2018). We explore the effectiveness of attention for an intelligent selection of features within a frame.

3 Proposed Approach

To investigate the theoretical hypothesis, we propose the following two variants of Frame-Attentive Networks: FAtNet-v1 and FAtNet-v2.

As illustrated in Figure 1 and Figure 2, the time-delay neural network (TDNN) paths are similar in both the FAtNet versions and the details are as follows: The model accepts a pair of Mel-frequency cepstral coefficients[2] (MFCC) for speaker verification (Chen et al., 2020; Zhu et al., 2018; Khoury et al., 2014). MFCCs finetune the features to what human beings hear (Lyons). Let d be the dimension of input MFCCs and l_1 and l_2 be the number of frames in the given pair for speaker verification. The values of l_1 and l_2 may differ due to the duration variability issue. The models were trained on 3-second chunks of speech (Nagrani et al., 2020). Eighty-dimensional MFCCs of shape (94,80) generated using these audio clips for training are input to the model. As shown in Figure 1 and Figure 2, we pass each of the input MFCCs to the AdaptiveAvgPool2d layer to get features of shape (b, 94, 80), where b is the batch-size (Yu et al., 2019). It allows the model to accept variable duration speech recordings during test time without any special augmentation strategy. It facilitates easy integration of FAtNet embedding with other speaker verification models and enhances the usability of the models.

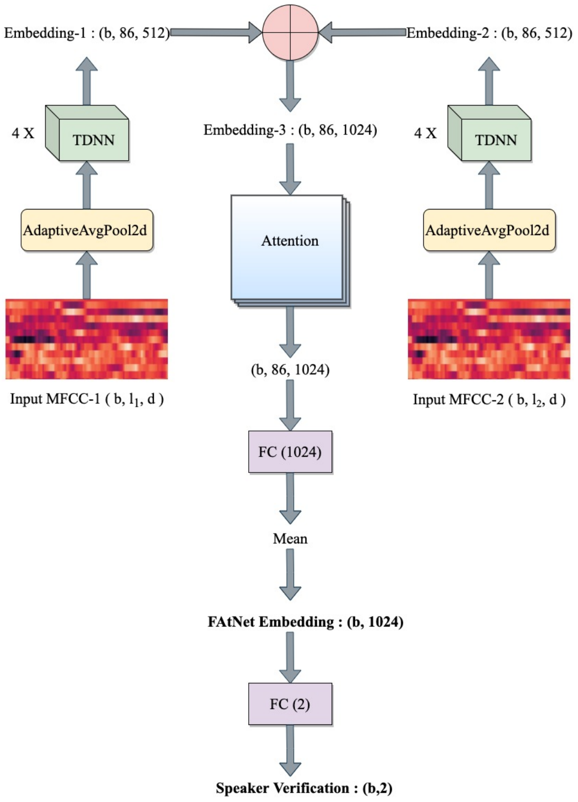

Figure 1: Architecture diagram for FAtNet-v1.

The next step is to compute frame-level features for further analysis. The abstract knowledge of frame-level features can reduce the linguistic information in the final embedding. We use four stacked TDNN[3] layers to extract the frame-level features (Vijayaditya Peddinti, 2015). Given two speech recordings as input, the problem is to determine if they belong to the same speaker or not. Thus, we have two such TDNN paths for input audio clips.

FAtNet-v1: We concatenate the frame-level features obtained for both the input speech recordings as shown in Figure 1. We apply batch normalization. We further pass these concatenated features through an eight-head frame-level attention block. In each frame, attention gives more weight to relevant features.

---

[2] We compared the performance of 80-dimensional MFCCs with 300-dimensional spectrogram (Nagrani et al., 2017) as inputs to FAtNet-v1. Details are present in the Appendix section.

[3] Hyper-parameter detail for the stacked TDNN layers is present in the Appendix section.

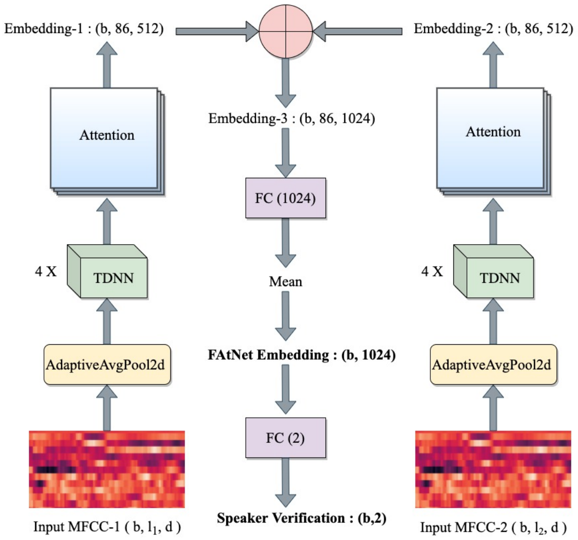

Figure 2: Architecture diagram for FAtNet-v2.

FAtNet-v2: We pass the frame-level features obtained for the input speech recordings through separate four-head attention blocks. Thus, we get embeddings 1 and 2 as shown in Figure 2. In each frame, the attention block gives more weight to relevant features. We then concatenate the outputs to get embedding 3.

Attention: Attention mechanisms are popular in state-of-the-art speaker verification models (Zhu et al., 2018; Wu et al., 2020). Our proposed FAtNet attention mechanism is inspired by (Vaswani et al., 2017; Moshnoi). The frame-level features are sent through a multi-head residual self-attention block, as shown in Figure 1 and Figure 2, respectively. The input to the attention block can be a tensor of shape (b, l, d) where b is the batch size, l is the number of frames, and d is the number of features or dimensions in each frame. Let dv be the dimension of linear space where the input needs to be projected, and nv is the number of heads in the multi-head self-attention block. We pass the same tensor to the attention block as the query tensor, key tensor, and, value tensor. The idea is to use the query tensor and key tensor to generate a weight tensor for the value tensor. The first step involves passing each of the three tensors: query, key, and value through separate fully-connected layers consisting of $dv * nv$ output units and applying the $ReLU$ activation function to get the modified query, key and value tensors, say Q, K, and V, respectively. After adequate reshaping, the dimensions of Q, K, and V should be (b, l, nv, dv).

For each example i, the following computation is performed within the attention block using Q, K, and V :

1. $K_{\text{i}}^{\text{permute}} := K_{\text{i}}.permute(0, 2, 1)$
2. $prob_{\text{i}} := Q_{\text{i}} * K_{\text{i}}^{\text{permute}}$
3. $prob_{\text{i}}^{\text{scaled}} := \frac{prod_{\text{i}}}{\sqrt{dv}}$
4. $weights_{\text{i}}^{\text{attn}}$:=Softmax($prod_{\text{i}}^{\text{scaled}}$, dim = -1)
5. $rprod_{\text{i}} := weights_{\text{i}}^{\text{attn}} * V_{\text{i}}$

We further include a residual connection that acts as a memory to combine the initial set of frame-level features with $rprod_{\text{i}}$. So, to compute the output of the residual attention block, we add $rprod_{\text{i}}$ to the original query tensor and pass it through a fully-connected layer consisting of d_{out} neurons and apply $ReLU$.

The remaining layers are similar in both FAtNet-v1 and FAtNet-v2. The details are as follows: The generated attentive-frames are batch normalized. Then these are passed through a fully connected layer for fine-grained analysis. We further apply a leaky-relu activation function with L_2-normalization. We aggregate these frame-level features by computing a mean and then pass them through a fully connected layer consisting of two units for speaker verification.

4 Experimental Setup

4.1 Datasets

Training datasets: We trained separate models of FAtNet-v1 on publicly available VoxCeleb-1[4] and VoxCeleb-2 dev sets[5] (Nagrani et al., 2017; Chung et al., 2018). FAtNet-v2 was trained on VoxCeleb-2 dev set (Zhao et al., 2019). VoxCeleb-1 speech corpus contains recordings from 1,251 speakers, out of which 799 and 215 speakers belong to the USA and UK, respectively, where English is a dominant language. It consists of utterances from 1,211 speakers in the dev set and 40 speakers in the test set. The VoxCeleb-2 dataset consists of 5,994 speakers in the dev set. We used the same dev-test split as given in (Nagrani et al., 2017; Chung et al., 2018). The VoxCeleb datasets contain mostly English speech recordings (Chen et al., 2021). Details about the training setup are present in the Appendix section.

Test datasets: Experiments were conducted using trial pairs from the following publicly available

---

[4] VoxCeleb-1: `https://www.robots.ox.ac.uk/~vgg/data/voxceleb/vox1.html`

[5] VoxCeleb-2: `https://www.robots.ox.ac.uk/~vgg/data/voxceleb/vox2.html`

datasets: VoxCeleb-1[6] test set (mostly English) (Nagrani et al., 2017), LibriSpeech[7] test set (English) (Panayotov et al., 2015), Aishell-1 test set[8] (Non-English) (Bu et al., 2017), and Voxforge[9] test set (Non-English) (Voxforge.org). Aishell-1 is a Mandarin speech corpus. Voxforge test set contains speech recordings in 10 different languages, namely, Bulgarian, Dutch, French, German, Greek, Italian, Portuguese, Russian, Spanish, and Turkish. We randomly generated the trial pairs for LibriSpeech, Aishell-1, and Voxforge from these publicly available datasets. The VoxCeleb-1 test set, LibriSpeech test set, Aishell-1 test set, and the Voxforge test set contain 37720, 47402, 23800, and 51856 trial pairs, respectively. The majority of the publicly available speech datasets are in the English language. VoxCeleb (used to train the models) datasets contain speech recordings in mostly English. Therefore we primarily investigate the effectiveness of this work on Non-English test sets without domain adaptation.

4.2 Baselines

We performed experiments using two publicly available baselines: RawNet-2[10] (Jung et al., 2020) and VGG-M[11] (Nagrani et al., 2017).

RawNet-2: RawNet-2 is an improved version of RawNet (Jung et al., 2019). It takes raw waveform as input and extracts speaker embedding. The model is pre-trained on VoxCeleb-2 for the speaker identification task to obtain 1024-dimensional embedding (Jung et al., 2020). Speech recordings from the trial pair are fed to the model individually as inputs. Thus, we get two 1024-dimensional embeddings for each input audio in the trial pair. We compute a cosine-similarity score of these two embeddings for the speaker verification task.

VGG-M: The VGG-M model was trained on the entire VoxCeleb-1 dataset for speaker identification (Nagrani et al., 2017). It generates a 4096-dimensional discriminative embedding. We used this pre-trained model to construct a siamese network for speaker verification. We fine-tuned the siamese network on VoxCeleb-1 dev for speaker verification. Speech recordings from a trial pair are inputs to the VGG-M models (frozen weights). We concatenate the generated 4096-dimensional embeddings to get a single 8,192-dimensional embedding. After batch normalization, we pass this embedding through a fully connected layer (consisting of 512-units) and apply the ReLU activation function. Then, after performing L_2-normalization, this 512-dimensional embedding (VGG-embedding) is fed to another fully connected layer consisting of two units for speaker verification.

4.3 Input strategy

For simplicity, we feed the input features to the model without any test time augmentation. The adaptive average pooling layer of the FAtNet model handles the duration variability issue. FAtNet is not a siamese network, and the weights of both the TDNN paths are learned separately. We pass the features from each input audio clip in the trial pair through both the TDNN paths. We further compute a mean as shown below: Assuming $mfcc_1$ and $mfcc_2$ are the MFCC features obtained for clips in the trial pair.

FAtNet-v1:

1. $\text{prob}_1 := \text{model}(\text{mfcc}_1, \text{mfcc}_2)$
2. $\text{prob}_2 := \text{model}(\text{mfcc}_2, \text{mfcc}_1)$
3. $\text{prob}_{\text{final}} := \text{mean}(\text{prob}_1, \text{prob}_2)$

FAtNet-v2:

1. $\text{emb}_{1a}, \text{emb}_{2a} := \text{model}(\text{mfcc}_1, \text{mfcc}_2)$
2. $\text{emb}_{2b}, \text{emb}_{1b} := \text{model}(\text{mfcc}_2, \text{mfcc}_1)$
3. $\text{emb}_1 := \text{mean}(\text{emb}_{1a}, \text{emb}_{1b})$
4. $\text{emb}_2 := \text{mean}(\text{emb}_{2a}, \text{emb}_{2b})$
5. $\text{prob}_{\text{final}} := \text{CosineSimilarity}(\text{emb}_1, \text{emb}_2)$

4.4 Evaluation Metric

Equal Error Rate (EER) is a standard evaluation metric for biometric systems (Hansen and Hasan, 2015). Therefore, we investigate the effectiveness of this work in terms of EER. A lower EER score indicates a better performance.

5 Experiments and Results

5.1 Experimental validation of hypothesis

Our proposed approach aims to reduce the linguistic bias in the existing speaker verification systems by integrating a language-agnostic embedding. To

[10] We used the pre-trained RawNet-2 model available in `https://github.com/Jungjee/RawNet`

[11] We used the pre-trained VGG-M model available in `https://github.com/Derpimort/VGGVox-PyTorch`

scientifically validate the theoretical hypothesis, we explore the effect of integrating FAtNet embedding with baselines for out-of-domain test sets.

Consider a trial pair $(clip1.wav, clip2.wav)$ having MFCCs, say, $(mfcc_1, mfcc_2)$ and spectrograms, say, $(spec_1, spec_2)$.

VGG-M $\oplus$ FAtNet-v1: In this integration, we directly pass MFCC's for the trial pair, say $(mfcc_1, mfcc_2)$, through the FAtNet-v1 model to get 1024-dimensional FAtNet embedding. We also pass spectrograms, say $(spec1, spec2)$, through the VGG-M siamese baseline to get the 512-dimensional VGG-embedding. After concatenating these embeddings, we pass it to a fully connected layer of 1024 neurons. Finally, after applying $ReLU$ and L_2-normalization, we pass it through another fully connected layer consisting of 2 units for speaker verification. We fine-tuned the last two fully connected layers on the VoxCeleb training set for speaker verification.

RawNet-2 $\oplus$ FAtNet-v2: For this integration, we obtained the 512-dimensional FAtNet embeddings for speech recordings in trial pair by feeding $(mfcc_1, mfcc_2)$ through the FAtNet-v2 model. We get these FAtNet embeddings from steps 3 and 4 of the input strategy (described in section 4.3) for FAtNet-v2. We obtained the 1024-dimensional RawNet embeddings for recordings by feeding them to the RawNet-2 baseline. We compute cosine similarity after concatenating audio1's FAtNet-v2 embedding with its RawNet-2 embedding and audio2's FAtNet-v2 embedding with its RawNet-2 embedding.

As illustrated in Table 1, we observe significant improvements in the performance of baselines on out-of-domain test sets after integration with FAtNet embeddings. This observation suggests that with a very little overhead, our proposed FAtNet embeddings may help improve the performance of these baselines on out-of-domain test sets without domain adaptation.

5.2 Language-specific analysis

For an extensive validation of the observations from the previous experiment, we created separate test sets for 11 different languages using the Voxforge dataset. The Bulgarian test set consists of 3,110 trial pairs. The other test sets contain 20,000 trial pairs each. Figure 3 and Figure 4 show that integrating the baselines with our proposed FAtNet embedding consistently reduced the equal error rate. This observation further verifies that the FAtNet embedding can help in reducing the language dependency of baselines and increase their generalizability on out-of-domain test sets. We observe an absolute improvement of 2.64% on the Dutch (Non-English) test set after integrating FAtNet-v1 with VGG-M. We observe an absolute improvement of 3.65% on the Portuguese (Non-English) set after integrating RawNet-2 with FAtNet-v2. Thus, the highest absolute improvements observed in the language-specific test sets were in Non-English test sets (Dutch and Portuguese).

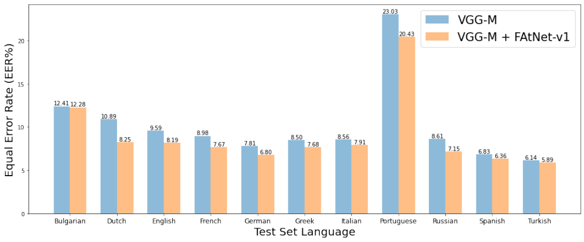

Figure 3: Figure showing that integrating VGG-M with FAtNet-v1 consistently reduced the EER on test sets generated for speech in different languages.

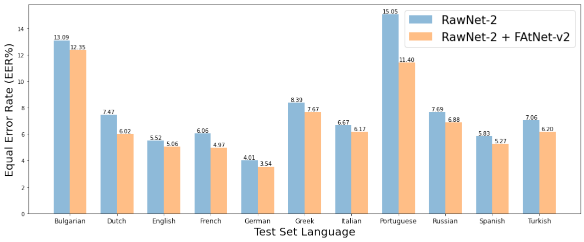

Figure 4: Figure showing that integrating RawNet-2 with FAtNet-v2 consistently reduced the EER on test sets generated for speech in different languages.

5.3 Linguistic study with augmentation

To get more linguistic insights, we study the performance of standalone FAtNet models using test-time augmentation (TTA) to feed input data to the models. We call the input strategy described in section 4.3 as S_0. In TTA Strategy, each input audio recording in the test set is either repeated several times or clipped to make its duration equal to 30-second (Nagrani et al., 2020). We further clip them into 3-second chunks. We create a batch of all possible pairs. So, we get a batch of 100 pairs. Finally, we feed the entire batch to the model (as shown for $\mathbf{S_0}$). For FAtNet-v1, we average out the probabilities in the end. For FAtNet-v2, we compute the average of 100 sets of obtained embedding$_1$'s to get the

Model	FAtNet Train set	Test Set	EER (%)	Rel. Imp. (%)
VGG-M	-	Voxforge	9.190	-
VGG-M $\oplus$ **FAtNet-v1**	VoxCeleb-1 dev	Voxforge	7.665	**+16.594%**

RawNet-2 $\oplus$ **FAtNet-v2**	VoxCeleb-2 dev	Aishell-1	3.832	**+38.213%**

Table 1: Table showing the relative improvements in the performance of VGG-M and RawNet-2 baselines after integration with FAtNet embeddings.

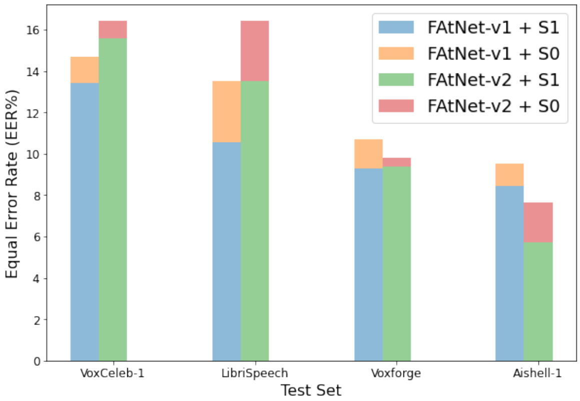

Figure 5: Figure showing the stability of the proposed FAtNet models on out-of-domain test sets. We achieved a better performance using the S_1 test-time augmentation strategy as compared to S_0.

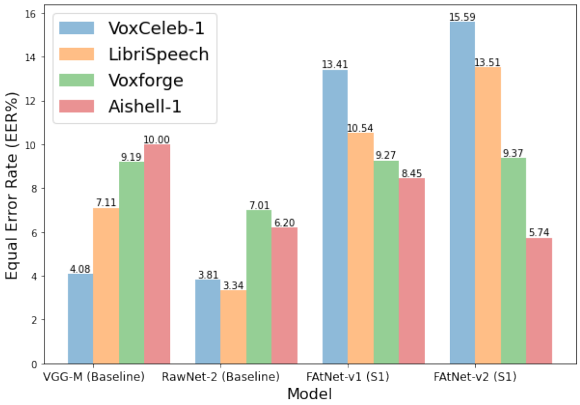

Figure 6: Figure showing that baselines' performance degraded on Non-English test sets without domain adaptation. On the contrary, the performance of FAtNet models improved on those sets without adaptation.

final tensor for embedding$_1$. We do the same for embedding$_2$. Then, we compute the cosine similarity between final embedding$_1$ and embedding$_2$. We call this input strategy S_1.

Observations: Figure 5 shows that we achieved a better performance using S_1 as compared to S_0. Interestingly, FAtNet-v2 achieved better performance on out-of-domain (Non-English) test sets than FAtNet-v1. It is reasonable as FAtNet-v2 contains two 4-head attention blocks, whereas FAtNet-v1 contains only a single 8-head attention block. It indicates that an intelligent selection of frame-level features individually from each audio clip enhances the language robustness of the model for out-of-domain sets.

5.4 Qualitative comparison with the baselines

In this experiment, we compare the generalization capabilities of our proposed networks with the baselines. We observe from Figure 6 that the baseline models performed relatively well on the VoxCeleb-1 test set (mostly English) and LibriSpeech (English) test set. However, the performance of baselines degraded on the other two out-of-domain multilingual test sets, namely, Aishell-1 (Mandarin) and Voxforge (Non-English).

On the contrary, we observe that the performance of FAtNet models improved for out-of-domain multilingual test sets. FAtNet models generalized well to out-of-domain test sets without domain adaptation. It illustrates the language dependency in VGG-M and RawNet-2 baselines. The relatively poor performance of FAtNet models on VoxCeleb-1 and LibriSpeech test sets may be due to other variability issues in these datasets. VoxCeleb-1 is a dataset collected in noisy unconstrained conditions. LibriSpeech corpus (derived from audiobooks) consists of high prosodic variations. It suggests that frame-attentive networks are generalizable but not robust to noise or prosodic variations.

5.5 Ablation Study

Intending to investigate which component of FAtNet models makes them language robust, we did an ablation study. FAtNet models contain two parts: the TDNN module and the attention block. We trained a simple TDNN-based model on the VoxCeleb-2 dev set. The architecture of this model remains the same as FAtNet models, except that this TDNN-based model does not contain the attention block. It is observed from Figure 7 and Figure 8 that our proposed FAtNet models outperformed the TDNN model on most of the test sets. The plots suggest that frame-level features make the model language robust. An intelligent selection of features using attention can help in enhancing performance. Thus, our proposed FAtNet models consisting of this TDNN model and attention blocks are language robust.

Interestingly, the TDNN model outperformed FAtNet-v1 and FAtNet-v2 on Aishell-1 and LibriSpeech. FAtNet-v1 outperformed TDNN on LibriSpeech, but FAtNet-v2 could not show that FAtNet-v1 can better handle prosodic variations than FAtNet-v2. It is reasonable as FAtNet-v1 contains a single attention block that selects intelligent features after concatenating the frame-level features of both the audio clips. Thus, the number of dimensions of each frame sent to the FAtNet-v1 attention block is higher than FAtNet-v2. However, FAtNet-v2 performed better on out-of-domain test sets than TDNN, whereas FAtNet-v1 performed poorly on the Aishell-1 test set compared to TDNN. The presence of two separate attention blocks (specific for each audio clip) in FAtNet-v2 makes it more language robust than FAtNet-v1.

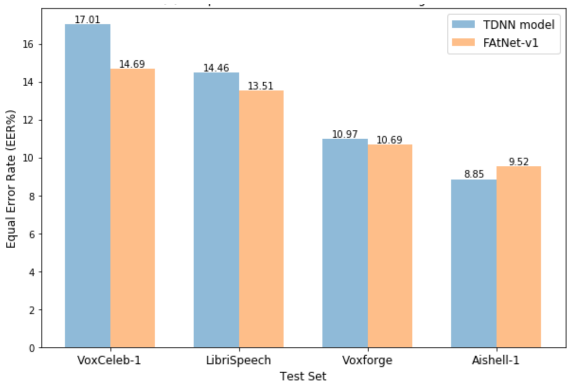

Figure 7: Comparing the performance of TDNN model with FAtNet-v1. We used the S0 strategy (FAtNet-v1 version) for both these models.

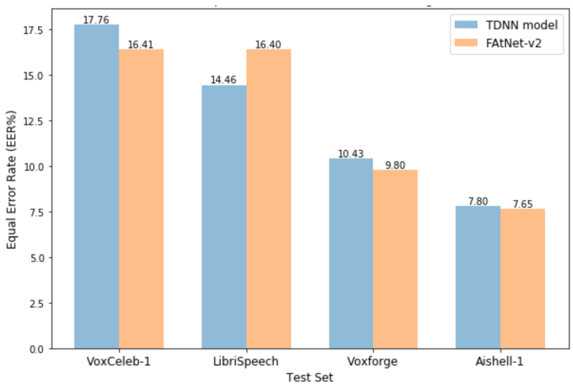

Figure 8: Comparing the performance of TDNN model with FAtNet-v2. We used the S0 strategy (FAtNet-v2 version) for both these models.

6 Discussion

This work investigates the cost-effective idea of integrating the lightweight frame-attentive embedding with heavier and stronger baselines to mitigate the linguistic bias in such baselines without adaptation. After comprehensive experimentation on twelve languages and ablation studies, we observed that the proposed method showed significant and consistent improvements in reducing the linguistic bias in the baselines. Some final considerations:

Model complexity: Table 2 illustrates that the FAtNet models consist of fewer parameters as compared to the baselines. Thus, the proposed frame-attentive networks take less time to train. The VGG-M and the RawNet-2 occupy 71.7MB and 53.6MB of disk space. Our proposed FAtNet-v1 and FAtNet-v2 occupy 41MB and 32.6MB of space. Thus, FAtNet models are lighter than the baselines.

Model	#Parameters
VGG-M	17909219
RawNet-2	13379378
FAtNet-v1	10226690
FAtNet-v2	8127490

Table 2: Table showing details about the number of parameters in the proposed networks and the baselines.

Cost-effectiveness: Mitigating the linguistic bias without adaptation is crucial for enhancing the usability of the model across the globe. However, it is also an extremely challenging problem that requires complex decision-making. Consequently, it requires more parameters in the network and some additional overhead. Below we discuss the overhead of some of the popular methods to mitigate the problem of linguistic bias:

1. Fine-tuning the pre-trained model individually for each language could help mitigate this issue. However, considering that there are approximately 7,000 languages in the world (Huang et al., 2021), it is costly to adapt the models individually for each existing language.
2. Training heavy and highly complex models on extensive datasets could help enhance the model's generalizability to out-of-domain testing. However, this approach requires significant computational overhead and storage space.

FAtNet models have lower complexity than the baseline models. We purposefully integrated our proposed lightweight embeddings with heavier and stronger baselines. We observed significant improvements after integrating the lightweight FAtNet embeddings with the baselines. Hence, with a very little overhead, FAtNet embeddings may help enhance the generalizability of baselines. Therefore, as compared to the overhead of the above two approaches, our proposed approach cost-effectively enhances the usability of baseline models across the globe.

7 Conclusions and Future Work

In this paper, we introduced the cost-effective idea of utilizing a lightweight frame-level embedding for reducing linguistic bias in existing speaker verification systems without the overhead of domain adaptation. We also explored applying attention to individual frames to focus on relevant frame-level discriminative information. For an in-depth analysis of our proposed theoretical hypothesis, we proposed two variants of frame-attentive networks: FAtNet-v1 and FAtNet-v2. We investigated the effect of their integration with the baselines for twelve languages. Empirical results showed consistent improvements in the performance of baselines on out-of-domain test sets without domain adaptation after integration with the FAtNet embedding. Qualitative comparison with baselines suggested that the proposed models are comparatively more generalizable. Additionally, we did an ablation study of our proposed networks. It turns out that frame-level embedding captures less linguistic information from speech than utterance-level embedding. An intelligent selection of features from frames can further improve the performance of speaker verification models.

Our analysis points to vital problems for future work. For instance, it may be worthwhile to explore standalone domain-invariant architectures. This work focuses on the scenario where the input speech recordings within a trial pair are in the same language. However, it may be helpful to explore this idea further for bilingual speakers where the input speech recordings in the trial pair are in different languages.

A Training Setup

We cropped the silent parts of speech recordings and clipped them into chunks of 3-seconds. We generated MFCCs of 80-dimensions as acoustic inputs to the model using the Librosa library (McFee et al., 2015). We randomly generated separate training sets consisting of 5,25,000 and 23,88,000 trial pairs for models trained on VoxCeleb-1 dev and VoxCeleb-2 dev sets, respectively. The training set consists of an equal number of positives and negatives. We shuffled the training examples before each epoch. The batch size was 128. We trained the proposed models under the joint supervision of softmax loss and center loss. Center loss helps in reducing intra-speaker variations, whereas the softmax loss helps in increasing the inter-speaker variations.(Li et al., 2018). We use Adam and RMSProp for FAtNet and center loss, respectively (Li et al., 2018; Paszke et al., 2017). For training on VoxCeleb-1 dev, the learning rate was 0.005 and 0.2 for Adam (for FAtNet) and RMSprop (for center loss), respectively. The learning rates were reduced after every ten epochs using $step\_lr$ scheduler with the gamma value of 0.5 and 0.3 for Adam and RMSprop, respectively. For training on VoxCeleb-2 dev, the learning rate was as low as 0.0005 for both Adam (for FAtNet) and RMSprop (for center loss), respectively. It is due to more steps being performed in one epoch while training on VoxCeleb-2 dev. We computed the total loss as follows: $total\_loss := softmax\_loss + 0.01 * center\_loss$ (Li et al., 2018). We used GeForce GTX 1080 GPU.

B Effect of training set size on model performance

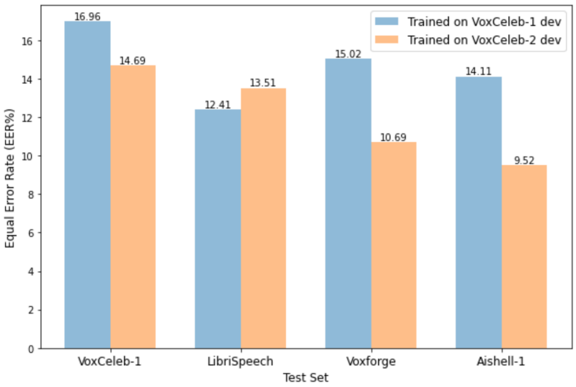

Figure 9: Figure showing the effect of training set size on the performance of FAtNet-v1. Observation: The FAtNet-v1 model trained on the VoxCeleb-2 dev set performs better than the model trained on the VoxCeleb-1 dev set for most of the test sets. It indicates that increasing the size of the training set can help in improving the performance of speaker verification models.

In this experiment, we study the effect of training set size on the model performance. It can help visualize the improvements in increasing the number of speakers in the training set. For this experiment, we trained separate models of FAtNet-v1 on VoxCeleb-1 dev and VoxCeleb-2 dev respectively. As shown in Figure 9, the model trained on the VoxCeleb-2 dev set outperformed that trained on the VoxCeleb-1 dev set for most of the test set. It is reasonable as the VoxCeleb-2 dev set is more diverse and multilingual than the VoxCeleb-1 dev set. For the LibriSpeech test set, the model trained on the VoxCeleb-1 dev set performed slightly better than that trained on the VoxCeleb-2 dev set. It is reasonable due to the high proportion of English speech recordings in VoxCeleb-1 and LibriSpeech being an English speech corpus. Thus, we used the FAtNet models trained on the VoxCeleb-2 dev set for experiments (unless explicitly specified otherwise).

C Choice of Input Features

We compared the performance of 80-dimensional MFCCs with 300-dimensional spectrogram (Nagrani et al., 2017) as inputs to FAtNet-v1. As illustrated in Table 3, we achieved better performance using the MFCC features.

Test Set	**MFCC**	**Spectrogram**
VoxCeleb-1	14.682	20.668
LibriSpeech	13.527	20.919
Voxforge	10.694	20.274
Aishell-1	9.521	21.143

Table 3: Table showing the EER(%) on training FAtNet-v1 using MFCC and Spectrogram features, respectively.

D Hyper-parameter details for the stacked TDNN

Table 4 illustrates the hyper-parameter detail for the four stacked TDNN layers in the proposed frame-attentive networks. We set the dropout and stride to 0.1 and 1, respectively, for all four layers.

Hyper-parameter	**#1**	**#2**	**#3**	**#4**
Input dimension	80	512	512	512
Output dimension	512	512	512	512
Context-size	3	5	3	1
Batch-norm	False	False	True	True

Table 4: Hyper-parameter detail for the stacked TDNN layers in FAtNet models.

A Survey on Stance Detection for Mis- and Disinformation Identification

Abstract

Understanding attitudes expressed in texts, also known as *stance detection*, plays an important role in systems for detecting false information online, be it misinformation (unintentionally false) or disinformation (intentionally false information). Stance detection has been framed in different ways, including (a) as a component of fact-checking, rumour detection, and detecting previously fact-checked claims, or (b) as a task in its own right. While there have been prior efforts to contrast stance detection with other related tasks such as argumentation mining and sentiment analysis, there is no existing survey on examining the relationship between stance detection and mis- and disinformation detection. Here, we aim to bridge this gap by reviewing and analysing existing work in this area, with mis- and disinformation in focus, and discussing lessons learnt and future challenges.

1 Introduction

The past decade is characterized by a rapid growth in popularity of social media platforms such as Facebook, Twitter, Reddit, and more recently, Parler. This, in turn, has led to a flood of dubious content, especially during controversial events such as Brexit and the US presidential election. More recently, with the emergence of the COVID-19 pandemic, social media were at the center of the first global infodemic (Alam et al., 2021), thus raising yet another red flag and a reminder of the need for effective mis- and disinformation detection online.

In this survey, we examine the relationship between automatically detecting false information online – including fact-checking, and detecting fake news, rumors, and hoaxes – and the core underlying Natural Language Processing (NLP) task needed to achieve this, namely *stance detection*. Therein, we consider mis- and disinformation, which both refer to false information, though disinformation has an additional intention to harm.

Detecting and aggregating the expressed stances towards a piece of information can be a powerful tool for a variety of tasks including understanding ideological debates (Hasan and Ng, 2014), gathering different frames of a particular issue (Shurafa et al., 2020) or determining the leanings of media outlets (Stefanov et al., 2020). The task of stance detection has been studied from different angles, e.g., in political debates (Habernal et al., 2018), for fact-checking (Thorne et al., 2018), or regarding new products (Somasundaran et al., 2009). Moreover, different types of text have been studied, including social media posts (Zubiaga et al., 2016b) and news articles (Pomerleau and Rao, 2017). Finally, stances expressed by different actors have been considered, such as politicians (Johnson et al., 2009), journalists (Hanselowski et al., 2019), and users on the web (Derczynski et al., 2017).

There are some recent surveys related to stance detection. Zubiaga et al. (2018a) discuss the role of stance in rumour verification, Aldayel and Magdy (2021) survey stance detection for social media, and Küçük and Can (2020) survey stance detection holistically, without a specific focus on veracity. There are also surveys on fact-checking (Thorne and Vlachos, 2018; Guo et al., 2022), which mention, though do not exhaustively survey, stance.

However, there is no existing overview of the role that different formulations of stance detection play in the detection of false content. In that respect, stance detection could be modelled as fact-checking — to gather the stances of users or texts towards a claim or a headline (and support fact-checking or studying misinformation) —, or as a component of a system that uses stance as part of its process of judging the veracity of an input claim. Here, we aim to bridge this gap by surveying the research on stance for mis- and disinformation detection, including task formulations, datasets, and methods, from which we draw conclusions and lessons, and we forecast future research trends.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1259 - 1277

2 What is Stance?

In order to understand the task of stance detection, we first provide definitions of stance and the stance-taking process. Biber and Finegan (1988) define stance as the expression of a speaker's standpoint and judgement towards a given proposition. Further, Du Bois (2007)) define stance as "*a public act by a social actor, achieved dialogically through overt communicative means, of simultaneously evaluating objects, positioning subjects (self and others), and aligning with other subjects, with respect to any salient dimension of the sociocultural field*", showing that the stance-taking process is affected not only by personal opinions, but also by other external factors such as cultural norms, roles in the institution of the family, etc. Here, we adopt the general definition of stance detection by Küçük and Can (2020): "*for an input in the form of a piece of text and a target pair, stance detection is a classification problem where the stance of the author of the text is sought in the form of a category label from this set: Favor, Against, Neither. Occasionally, the category label of Neutral is also added to the set of stance categories (Mohammad et al., 2016), and the target may or may not be explicitly mentioned in the text*" (Augenstein et al., 2016; Mohammad et al., 2016). Note that the stance detection definitions and the label inventories vary somewhat, depending on the target application (see Section 3).

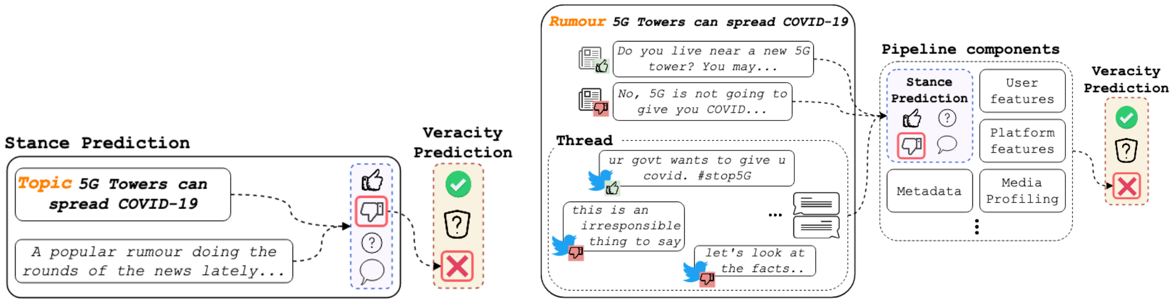
Finally, stance detection can be distinguished from several other closely related NLP tasks: (*i*) *biased language detection*, where the existence of an inclination or tendency towards a particular perspective within a text is explored, (*ii*) *emotion recognition*, where the goal is to recognise emotions such as *love, anger, etc.* in the text, (*iii*) *perspective identification*, which aims to find the point-of-view of the author (e.g., Democrat vs. Republican) and the target is always explicit, (*iv*) *sarcasm detection*, where the interest is in satirical or ironic pieces of text, often written with the intent of ridicule or mockery, and (*v*) *sentiment analysis*, which checks the polarity of a piece of text.

3 Stance and Factuality

Here, we offer an overview of the settings for mis- and disinformation identification to which stance detection has been successfully applied. As shown in Figure 1, stance can be used (a) as a way to perform fact-checking, or more typically, (b) as a component of a fact-checking pipeline. Table 1 shows an overview of the key characteristics of the available datasets. We include the *source* of the data and the *target*[1] towards which the stance is expressed in the provided textual *context*.

---

[1] The target can either be explicit, e.g., a topic such as *Public Healthcare*, or implicit, where only the context is present and the target is not directly available and is usually a topic (Derczynski et al., 2017; Gorrell et al., 2019), e.g., *Germanwings*, or '*Prince to play in Toronto*'. When the target is implicit, the task becomes similar to sentiment analysis.



(a) stance detection as fact-checking

(b) stance detection as a component of a fact-checking pipeline

Figure 1: Two stance detection formulations.

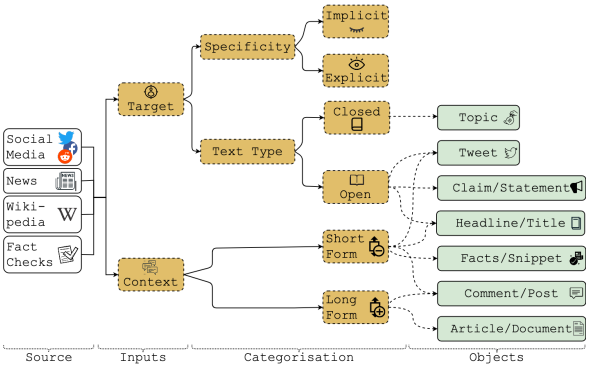


Figure 2: Types of stance. The *Target* is the object of the stance expressed in the *Context*.

We further show the type of evidence: *Single* is a single document/fact, *Multiple* is multiple pieces of textual evidence, often facts or documents, *Thread* is a (conversational) sequence of posts or a discussion. The final column is the type of the target *Task*. Finally, we present a dataset-agnostic summary of the terminology used for the different types of stance (see Figure 2), which we describe in a four-level taxonomy: (*i*) sources, i.e., where the dataset was collected from, (*ii*) inputs that represent the stance target (e.g., claim), and the accompanying context (e.g., news article), (*iii*) categorisation – meta-level characteristics of the input, and (*iv*) the textual object types for a particular stance scenario (e.g., topic, tweet, etc.). Appendix A discusses different stance scenarios with corresponding contexts and targets, with illustrations in Table 3.

3.1 Fact-Checking as Stance Detection

As stance detection is the core task within fact-checking, prior work has studied it in isolation, e.g., predicting the stance towards one or more documents. More precisely, the stance of the textual evidence(s) toward the target claim is considered as a veracity label, as illustrated in Figure 1a.

Fact-Checking with One Evidence Document Pomerleau and Rao (2017) organised the first Fake News Challenge (FNC-1) with the aim of automatically detecting fake news. The goal was to detect the relatedness of a news article's body w.r.t. a headline (possibly from another news article), based on the stance that the former takes regarding the latter. The possible categories were *positive*, *negative*, *discuss*, and *unrelated*. This was a standalone task, as it provides stance annotations only, omitting the actual "truth labels", with the motivation of assisting fact-checkers in gathering several distinct arguments pertaining to a particular claim.

Fact-Checking with Multiple Evidence Documents The FEVER (Thorne et al., 2018, 2019) shared task was introduced in 2018, aiming to determine the veracity of a claim based on a set of statements from Wikipedia. Claims can be composite and can contain multiple (contradicting) statements, which requires multi-hop reasoning, and the claim–evidence pairs are annotated as *SUPPORTED*, *REFUTED*, and *NOT ENOUGH INFO*. The latter category includes claims that are either too general or too specific, and cannot be supported or refuted by the available information in Wikipedia. This setup may help fact-checkers understand the decisions a model made in their assessment of the veracity of a claim, or assist human fact-checkers.

The second edition (2019) of FEVER evaluated the robustness of models to adversarial attacks, where the participants were asked to provide new examples to "break" existing models, then to propose "fixes" for the system against such attacks.

Note that FEVER slightly differs from typical stance detection, as it considers evidence supporting or refuting a claim, rather than the stance of an author towards a claim. An alternative way to look at this is in terms of argument reasoning, i.e., extracting and providing factual evidence for a claim.

FEVER also has a connection to Natural Language Inference, i.e., determining the relationship between two sentences. We view FEVER as requiring stance detection as it resembles FNC, which is commonly seen as a stance detection task.

Apart from FEVER, Hanselowski et al. (2019) presented a task constructed from manually fact-checked claims on Snopes. For this task, a model had to predict the stance of evidence sentences in articles written by journalists towards claims. Unlike FEVER, this task does not require multi-hop reasoning.

Chen et al. (2020) studied the verification of claims using tabular data. The TabFact dataset was generated by human annotators who created positive and negative statements about Wikipedia tables. Two different forms of reasoning in a statement are required: (*i*) linguistic, i.e., semantic understanding, and (*ii*) symbolic, i.e., using the table structure.

3.2 Stance as a (Mis-/Dis-)information Detection Component

Fully automated systems can assist in gauging the extent and studying the spread of false information online. This is in contrast to the previously discussed applications of stance detection – as a stand-alone system for detecting mis- and disinformation. Here, we review its potency to serve as a component in an automated pipeline. Figure 1b illustrates the setup, which can also include steps such as modelling the user or profiling the media outlet among others. We discuss in more detail media profiling and misconceptions in Appendix B.

Rumors Stance detection can be used for rumour detection and debunking, where the stance of the crowd, media, or other sources towards a claim are used to determine the veracity of a currently circulating story or report of uncertain or doubtful factuality. More formally, *for a textual input and a rumour expressed as text, stance detection here is to determine the position of the text towards the rumour as a category label from the set {Support, Deny, Query, Comment}*. Zubiaga et al. (2016b) define these categories as whether the author: supports (*Support*) or denies (*Deny*) the veracity of the rumour they are responding to, "asks for additional evidence in relation to the veracity of the rumour" (*Query*) or "makes their own comment without a clear contribution to assessing the veracity of the rumour" (*Comment*). This setup was widely explored for microblogs and social media.

Qazvinian et al. (2011) started with five rumours and classified the user's stance as *endorse*, *deny*, *unrelated*, *question*, or *neutral*. While they were among the first to demonstrate the feasibility of this task formulation, the limited size of their study and the focus on assessing the stance of individual posts limited its real-world applicability.

Zubiaga et al. (2016b) analysed how people spread rumours on social media based on conversational threads. They included rumour threads associated with nine newsworthy events, and users' stance before and after the rumours were confirmed or denied. Dungs et al. (2018) continued this line of research, but focused on the effectiveness of stance for predicting rumour veracity. Hartmann et al. (2019) explored the flow of (dis-)information on Twitter after the MH17 Plane Crash.

The two RumourEval (Derczynski et al., 2017; Gorrell et al., 2019) shared tasks on automated claim validation aimed to identify and handle rumours based on user reactions and ensuing conversations in social media, offering annotations for both stance and veracity. The two editions of RumourEval were similar in spirit, with the second one providing more tweets and also additionally Reddit posts. RumourEval demonstrated the importance of modelling the context of a story instead of drawing conclusions based on a single post.

Ferreira and Vlachos (2016) collected claims and news articles from rumour sites with annotations for stance and veracity by journalists as part of the Emergent project. The goal was to use the stance of a news article, summarised into a single sentence, towards a claim as one of the components to determine its veracity. A downside is the need to summarise, in contrast to FNC-1 (Pomerleau and Rao, 2017), where entire news articles were used.

Multiple languages While the above research has focused exclusively or primarily on English, interest in stance detection for other languages has started to emerge. Baly et al. (2018b) integrated stance detection and fact-checking for Arabic in a single corpus. Khouja (2020) proposed a dataset for Arabic following the FEVER setup. Alhindi et al. (2021) introduced AraStance, a multi-country and multi-domain dataset of Arabic stance detection for fact-checking. Lillie et al. (2019) collected data for stance and veracity from Danish Reddit threads Zubiaga et al. (2016b). Bošnjak and Karan (2019) studied stance detection and claim verification of comments for Croatian news articles.

4 Approaches

In this section, we discuss various ways to use stance detection for mis- and disinformation detection, and list the state-of-the-art results in Table 2.

Fact-Checking as Stance Detection Here, we discuss approaches for stance detection in the context of mis- and disinformation detection, where veracity is modelled as stance detection as outlined in Section 3.1. One such line of research is the Fake News Challenge, which used weighted accuracy as an evaluation measure (FNC score), to mitigate the impact of class imbalance. Subsequently, Hanselowski et al. (2018a) criticized the FNC score and F1-micro, and argued in favour of F1-macro (F1) instead. In the competition, most teams used hand-crafted features such as words, word embeddings, and sentiment lexica (Riedel et al., 2017; Hanselowski et al., 2018a). Hanselowski et al. (2018a) showed that the most important group of features were the lexical ones, followed by features from topic models, while sentiment analysis did not help. Ghanem et al. (2018) investigated the importance of lexical cues, and found that *report* and *negation* are most beneficial, while *knowledge* and *denial* are least useful. All these models struggle to learn the *Disagree* class, achieving up to 18 F1 due to major class imbalance. In contrast, *Unrelated* is detected almost perfectly by all models (over 99 F1). Hanselowski et al. (2018a) showed that these models exploit the lexical overlap between the headline and the document, but fail when there is a need to model semantic relations or complex negation, or to understand propositional content in general. This can be attributed to the use of n-grams, topic models, and lexica.

Mohtarami et al. (2018) investigated memory networks, aiming to mitigate the impact of irrelevant and noisy information by learning a similarity matrix and a stance filtering component, and taking a step towards explaining the stance of a given claim by extracting meaningful snippets from evidence documents. Like previous work, their model performs poorly on the *Agree/Disagree* classes, due to the unsupervised way of training the memory networks, i.e., there are no gold snippets justifying the document's stance w.r.t. the target claim.

More recently, transfer learning with pre-trained Transformers has been explored (Slovikovskaya and Attardi, 2020), significantly improving the performance of previous state-of-the-art approaches. Guderlei and Aßenmacher (2020) showed the most important hyper-parameter to be learning rate, while freezing layers did not help. In particular, using the pre-trained Transformer RoBERTa improved F1 from 18 to 58 for *Disagree*, and from 50 to 70 for *Agree*. The success of these models is also seen in cross-lingual settings. For Arabic, Khouja (2020) achieved 76.7 F1 for stance detection on the ANS dataset using mBERT. Similarly, Hardalov et al. (2022) applied pattern-exploiting training (PET) with sentiment pre-training in a cross-lingual setting showing sizeable improvements on 15 datasets. Alhindi et al. (2021) showed that language-specific pre-training was pivotal, outperforming the state of the art on AraStance (52 F1) and Arabic FC (78 F1).

Some formulations include an extra step for evidence retrieval, e.g., retrieving Wikipedia snippets for FEVER (Thorne et al., 2018). To evaluate the whole fact-checking pipeline, they introduced the FEVER score – the proportion of claims for which both correct evidence is returned and a correct label is predicted. The top systems that participated in the FEVER competition Hanselowski et al. (2018b); Yoneda et al. (2018); Nie et al. (2019) used LSTM-based models for natural language inference, e.g., enhanced sequential inference model (ESIM Chen et al. (2017)). Nie et al. (2019) proposed a neural semantic matching network, which ranked first in the competition, achieving 64.2 FEVER score. They used page view frequency and WordNet features in addition to pre-trained contextualized embeddings (Peters et al., 2018).

More recent approaches used bi-directional attention (Li et al., 2018), a GPT language model (Malon, 2018; Yang et al., 2019), and graph neural networks (Zhou et al., 2019; Atanasov et al., 2019; Liu et al., 2020b; Wang et al., 2020; Zhong et al., 2020; Weinzierl et al., 2021; Si et al., 2021). Zhou et al. (2019) showed that adding graph networks on top of BERT can improve performance, reaching 67.1 FEVER score. Yet, the retrieval model is also important, e.g., using the gold evidence set adds 1.4 points. Liu et al. (2020b); Zhong et al. (2020) replaced the retrieval model with a BERT-based one, in addition to using an improved mechanism to propagate the information between nodes in the graph, boosting the score to 70. Recently, Ye et al. (2020) experimented with a retriever that incorporates co-reference in distant-supervised pre-training, namely, CorefRoBERTa.

Wang et al. (2020) added external knowledge to build a contextualized semantic graph, setting a new SOTA on Snopes. Si et al. (2021) and Ostrowski et al. (2021) improved multi-hop reasoning using a model with eXtra Hop attention (Zhao et al., 2020), a capsule network aggregation layer, and LDA topic information. Atanasova et al. (2022) introduced the task of evidence sufficiency prediction to more reliably predict the *NOT ENOUGH INFO* class.

Another notable idea is to use pre-trained language models as fact-checkers based on a masked language modelling objective (Lee et al., 2020), or to use the perplexity of the entire claim with respect to the target document (Lee et al., 2021). Such models do not require a retrieval step, as they use the knowledge stored in language models. However, they are prone to biases in the patterns used, e.g., they can predict date instead of city/country and vice-versa when using "born in/on". Moreover, the insufficient context can seriously confuse them, e.g., for short claims with uncommon words such as "Sarawak is a ...", where it is hard to detect the entity type. Finally, the performance of such models remains well below supervised approaches; even though recent work shows that *few-shot training* can improve results (Lee et al., 2021).

Error analysis suggests that the main challenges are (*i*) confusing semantics at the sentence level, e.g., "*Andrea Pirlo is an American professional footballer.*" vs. "*Andrea Pirlo is an Italian professional footballer who plays for an American club.*", (*ii*) sensitivity to spelling errors, (*iii*) lack of relation between the article and the entities in the claim, (*vi*) dependence on syntactic overlaps, e.g., "*Terry Crews played on the Los Angeles Chargers.*" (*NotEnoughInfo*) is classified as *refuted*, given the sentence "*In football, Crews played ... for the Los Angeles Rams, San Diego Chargers and Washington Redskins, ...*", (*v*) embedding-level confusion, e.g., numbers tend to have similar embeddings, "*The heart beats at a resting rate close to 22 bpm.*" is not classified as *refuted* based on the evidence sentence "*The heart beats at a resting rate close to 72 bpm.*", and similarly for months.

Threaded Stance In the setting of conversational threads (Zubiaga et al., 2016b; Derczynski et al., 2017; Gorrell et al., 2019), in contrast to the single-task setup, which ignores or does not provide further context, important knowledge can be gained from the structure of user interactions. These approaches are mostly applied as part of a larger system, e.g., for detecting and debunking rumours (see Section 3.2, *Rumours*). A common pattern is to use tree-like structured models, fed with lexicon-based content formatting (Zubiaga et al., 2016a) or dictionary-based token scores (Aker et al., 2017). Kumar and Carley (2019) replaced CRFs with Binarised Constituency Tree LSTMs, and used pre-trained embeddings to encode the tweets. More recently, Tree (Ma and Gao, 2020) and Hierarchical (Yu et al., 2020) Transformers were proposed, which combine post- and thread-level representations for rumour debunking, improving previous results on RumourEval '17 (Yu et al., 2020). Kochkina et al. (2017, 2018) split conversations into branches, modelling each branch with branched-LSTM and hand-crafted features, outperforming other systems at RumourEval '17 on stance detection (43.4 F1). Li et al. (2020) deviated from this structure and modelled the conversations as a graph. Tian et al. (2020) showed that pre-training on stance data yielded better representations for threaded tweets for downstream rumour detection. Yang et al. (2019) took a step further and curated per-class pre-training data by adapting examples, not only from stance datasets, but also from tasks such as question answering, achieving the highest F1 (57.9) on the RumourEval '19 stance detection task. Li et al. (2019a,b) additionally incorporated user credibility information, conversation structure, and other content-related features to predict the rumour veracity, ranking 3rd on stance detection and 1st on veracity classification (RumourEval '19). Finally, the stance of a post might not be expressed directly towards the root of the thread, thus the preceding posts must be also taken into account (Gorrell et al., 2019).

A major challenge for all rumour detection datasets is the class distribution (Zubiaga et al., 2016b; Derczynski et al., 2017; Gorrell et al., 2019), e.g., the minority class *denying* is extremely hard for models to learn, as even for strong systems such as Kochkina et al. (2017) the F1 for it is 0. Label semantics also appears to play a role as the *querying* label has a similar distribution, but much higher F1. Yet another factor is thread depth, as performance drops significant at higher depth, especially for the *supporting* class. On the positive side, using multitask learning and incorporating stance detection labels into veracity detection yields a huge boost in performance (Gorrell et al., 2019; Yu et al., 2020).

Another factor, which goes hand in hand with the threaded structure, is the temporal dimension of posts in a thread (Lukasik et al., 2016; Veyseh et al., 2017; Dungs et al., 2018; Wei et al., 2019). In-depth data analysis (Zubiaga et al. (2016a,b); Kochkina et al. (2017); Wei et al. (2019); Ma and Gao (2020); Li et al. (2020); among others) shows interesting patterns along the temporal dimension: (*i*) source tweets (at zero depth) usually support the rumour and models often learn to detect that, (*ii*) it takes time for denying tweets to emerge, afterwards for false rumors their number increases quite substantially, (*iii*) the proportion of querying tweets towards unverified rumors also shows an upward trend over time, but their overall number decreases.

Multi-Dataset Learning (MDL) Mixing data from different domains and sources can improve robustness. However, setups that combine mis- and disinformation identification with stance detection, outlined in Section 3, vary in their annotation and labelling schemes, which poses many challenges.

Earlier approaches focused on pre-training models on multiple tasks, e.g., Fang et al. (2019) achieved state-of-the-art results on FNC-1 by fine-tuning on multiple tasks such as question answering, natural language inference, etc., which are weakly related to stance. Recently, Schiller et al. (2021) proposed a benchmark to evaluate the robustness of stance detection models. They leveraged a pre-trained multi-task deep neural network, MT-DNN (Liu et al., 2019), and continued its training on all datasets simultaneously using multi-task learning, showing sizeable improvements over models trained on individual datasets. Hardalov et al. (2021) experimented with cross-domain learning from 16 stance detection datasets. They proposed a novel architecture (MoLE) that applies domain adaptation at different stages of the modelling process (Luo et al., 2002): feature-level (Guo et al., 2018; Wright and Augenstein, 2020) and decision-level (Ganin and Lempitsky, 2015). They further integrated label embeddings (Augenstein et al., 2018), and eventually developed an end-to-end unsupervised framework for predicting stance from a set of unseen target labels. Hardalov et al. (2022) explored PET (Schick and Schütze, 2021) in a cross-lingual setting, combining datasets with different label inventories by modelling the task as a cloze question answering one.

Paper	**Dataset**	**Score**	**Metric**
Hardalov et al. (2021)	Rumour Has It	71.2	F1$_{macro}$
Kumar et al. (2019)	PHEME	53.2	F1$_{macro}$
Hardalov et al. (2021)	Emergent	86.2	F1$_{macro}$
Guderlei et al. (2020)	FNC-1	78.2	F1$_{macro}$
Yu et al. (2020)	RumourEval '17	50.9	F1$_{macro}$
Dominiks (2021)*	FEVER	76.8	FEVER
Wang et al. (2020)	Snopes	78.3	F1$_{macro}$
Yang et al. (2019)	RumourEval '19	61.9	F1$_{macro}$

Alhindi et al. (2021)	AraStance	78.?	F1$_{macro}$

Table 2: State-of-the-art results on the stance detection datasets. Note that some papers round their results to integers, and thus we put '**?**' for them. *Extracted from the FEVER leaderboard.[2]

They showed that MDL helps for low-resource and substantively for full-resource scenarios. Moreover, transferring knowledge from English stance datasets and noisily generated sentiment-based stance data can further boost performance.

State of the Art Table 2 shows the state-of-the-art (SOTA) results for each dataset discussed in Section 3 and Table 1. The datasets vary in their task formulation and composition in terms of size, number of classes, class imbalance, topics, evaluation measures, etc. Each of these factors impacts the performance, leading to sizable differences in the final score, as discussed in Section 4, and hence rendering the reported results hard to compare directly across these datasets.

5 Lessons Learned and Future Trends

Dataset Size A major limitation holding back the performance of machine learning for stance detection is the size of the existing stance datasets, the vast majority of which contain at most a few thousand examples. Contrasted with the related task of Natural Language Inference, where datasets such as SNLI (Bowman et al., 2015) of more than half a million samples have been collected, this is far from optimal. Moreover, the small dataset sizes are often accompanied with skewed class distribution with very few examples from the minority classes, including many of the datasets in this study (Zubiaga et al., 2016b; Derczynski et al., 2017; Pomerleau and Rao, 2017; Baly et al., 2018b; Gorrell et al., 2019; Lillie et al., 2019; Alhindi et al., 2021).

---

[1] The result from *dominiks* can be found at https://competitions.codalab.org/competitions/18814#results

This can lead to a significant disparity for label performance (see Section 4). Several techniques have been proposed to mitigate this, such as sampling strategies (Nie et al., 2019), weighting classes (Veyseh et al., 2017),[3] crafting artificial examples from auxiliary tasks (Yang et al., 2019; Hardalov et al., 2022), or training on multiple datasets (Schiller et al., 2021; Hardalov et al., 2021, 2022).

Data Mixing A potential way of overcoming limitations in terms of dataset size and focus is to combine multiple datasets. Yet, as we previously discussed (see Section 3), task definitions and label inventories vary across stance datasets. Further, large-scale studies of approaches that leverage the relationships between label inventories, or the similarity between datasets are still largely lacking. One promising direction is the use of label embeddings (Augenstein et al., 2018), as they offer a convenient way to learn interactions between disjoint label sets that carry semantic relations. One such first study was recently presented by Hardalov et al. (2021), which explored different strategies for leveraging inter-dataset signals and label interactions in both in- (seen targets) and out-of-domain (unseen targets) settings. This could help to overcome challenges faced by models trained on small-size datasets, and even for smaller minority classes.

Multilinguality Multi-linguality is important for several reasons: (*i*) the content may originate in various languages, (*ii*) the evidence or the stance may not be expressed in the same language, thus (*iii*) posing a challenge for fact-checkers, who might not be speakers of the language the claim was originally made in, and (*iv*) it adds more data that can be leveraged for modelling stance. Currently, only a handful of datasets for factuality and stance cover languages other than English (see Table 1), and they are small in size and do not offer a cross-lingual setup. Recently, Vamvas and Sennrich (2020) proposed such a setup for three languages for stance in debates, Schick and Schütze (2021) explored few-shot learning, and Hardalov et al. (2022) extended that paradigm with sentiment and stance pre-training and evaluated on twelve languages from various domains. Since cultural norms and expressed linguistic phenomena play a crucial role in understanding the context of a claim (Sap et al., 2019), we do not argue for a completely language-agnostic framework. Yet, empirically, training in cross-lingual setups improves performance by leveraging better representations learned on a similar language or by acting as a regulariser.

Modelling the Context Modelling the context is a particularly important, yet challenging task. In many cases, there is a need to consider the background of the stance-taker as well as the characteristics of the targeted object. In particular, in the context of social media, one can provide information about the users such as their previous activity, other users they interact most with, the threads they participate in, or even their interests (Zubiaga et al., 2016b; Gorrell et al., 2019; Li et al., 2019b). The context of the stance expressed in news articles is related to the features of the media outlets, such as source of funding, previously known biases, or credibility (Baly et al., 2019; Darwish et al., 2020; Stefanov et al., 2020; Baly et al., 2020). When using contextual information about the object, factual information about the real world, and the time of posting are all important. Incorporating these into a stance detection pipeline, while challenging, paves the way towards a robust detection process.

Multimodal Content Spreading mis- and disinformation through multiple modalities is becoming increasingly popular. One such example are *deepfakes*, i.e., synthetically created images or videos, in which (usually) the face of one person is replaced with another person's face. Another example are information propagation techniques such as *memetic warfare*. Hence, it is increasingly important to combine different modalities to understand the full context stance is being expressed in. Some work in this area is on fake news detection for images (Nakamura et al., 2020), claim verification for images (Zlatkova et al., 2019), or searching for fact-checked information to alleviate the spread of fake news (Vo and Lee, 2020). There has been work on meme analysis for related tasks: detecting hateful (Kiela et al., 2020), harmful (Pramanick et al., 2021; Sharma et al., 2022a), and propagandistic memes (Dimitrov et al., 2021a,b); see also a recent survey of harmful memes (Sharma et al., 2022b). This line of research is especially relevant for mis- and disinformation tasks that depend on the wisdom of the crowd in social media as it adds additional information sources (Qazvinian et al., 2011; Zubiaga et al., 2016b; Derczynski et al., 2017; Hossain et al., 2020); see Section 5.

---

[3] Weighting is not trivial for some setups, e.g., threaded stance (Zubiaga et al., 2018b)

Shades of Truth The notion of *shades of truth* is important in mis- and disinformation detection. For example, fact-checking often goes beyond binary *true*/*false* labels, e.g., Nakov et al. (2018) used a third category *half-true*, Rashkin et al. (2017) included *mixed* and *no factual evidence*, and Wang (2017); Santia and Williams (2018) adopted an even finer-grained schema with six labels, including *barely true* and *utterly false*. We believe that such shades could be applied to stance and used in a larger pipeline. In fact, fine-grained labels are common for the related task of Sentiment Analysis (Pang and Lee, 2005; Rosenthal et al., 2017).

Label Semantics As research in stance detection has evolved, so has the definition of the task and the label inventories, but they still do not capture the strength of the expressed stance. As shown in Section 3 (also Appendix 2), labels can vary based on the use case and the setting they are used in. Most researchers have adopted a variant of the *Favour*, *Against*, and *Neither* labels, or an extended schema such as *(S)upport*, *(Q)uery*, *(D)eny*, and *(C)omment* (Mohammad et al., 2016), but that is not enough to accurately assess stance. Moreover, adding label granularity can further improve the transfer between datasets, as the stance labels already share some semantic similarities, but there can be mismatches in the label definitions (Schiller et al., 2021; Hardalov et al., 2021, 2022).

Explainability The ability for a model to be able to explain its decisions is getting increasingly important, especially for mis- and disinformation detection, as one could argue that it is a crucial step towards adopting fully automated fact-checking. The FEVER 2.0 task formulation (Thorne et al., 2019) can be viewed as a step towards obtaining such explanations, e.g., there have been efforts to identify adversarial triggers that offer explanations for the vulnerabilities at the model level (Atanasova et al., 2020b). However, FEVER is artificially created and is limited to Wikipedia, which may not reflect real-world settings. To mitigate this, explanation by professional journalists can be found on fact-checking websites, and can be further combined with stance detection in an automated system. In a step in this direction, Atanasova et al. (2020a) generated natural language explanations for claims from PolitiFact[4] given gold evidence document summaries by journalists.

Moreover, partial explanations can be obtained automatically from the underlying models, e.g., from memory networks (Mohtarami et al., 2018), attention weights (Zhou et al., 2019; Liu et al., 2020b), or topic relations (Si et al., 2021). However, such approaches are limited as they can require gold snippets justifying the document's stance, attention weights can be misleading (Jain and Wallace, 2019), and topics might be noisy due to their unsupervised nature. Other existing systems (Popat et al., 2017, 2018; Nadeem et al., 2019) offer explanations to a more limited extent, highlighting span overlaps between the target text and the evidence documents. Overall, there is a need for holistic and realistic explanations of how a fact-checking model arrived at its prediction.

Integration People question false information more and tend to confirm true information (Mendoza et al., 2010). Thus, stance can play a vital role in verifying dubious content. In Appendix C, we discuss existing systems and real-world applications of stance for mis- and disinformation identification in more detail. However, we argue that a tighter integration between stance and fact-checking is needed. Stance can be expressed in different forms, e.g., tweets, news articles, user posts, sentences in Wikipedia, and Wiki tables, among others and can have different formulations as part of the fact-checking pipeline (see Section 3). All these can guide human fact-checkers through the process of fact-checking, and can point them to relevant evidence. Moreover, the wisdom of the crowd can be a powerful instrument in the fight against mis- and disinformation (Pennycook and Rand, 2019), but we should note that vocal minorities can derail public discourse (Scannell et al., 2021). Nevertheless, these risks can be mitigated by taking into account the credibility of the user or of the information source, which can be done automatically or with the help of human fact-checkers.

6 Conclusion

We surveyed the current state-of-the-art in stance detection for mis- and disinformation detection. We explored applications of stance for detecting fake news, verifying rumours, identifying misconceptions, and fact-checking. We also discussed existing approaches used in different aspects of the aforementioned tasks, and we outlined several interesting phenomena, which we summarised as lessons learned and promising future trends.

A Examples of Stance

As outlined in Section 3, there are different formulations in which the task of stance definition is materialised. In Table 3, we present some instances of these as exemplified by different stance detection datasets. The target with respect to which the stance is assessed can vary, e.g., a headline, a comment, a claim, a topic, etc., which in turn can differ in length and form. Moreover, the context where the stance is expressed can vary not only in its domain, e.g., *News* in (Ferreira and Vlachos, 2016) and *Twitter* in (Qazvinian et al., 2011), but also in its structure, as seen in the example of multiple evidence sentences in (Thorne et al., 2018) and threaded comments in (Gorrell et al., 2019).

In a more detailed view of Table 3, we see that each group of examples has its own important specifics that alter the task of stance detection for mis- and disinformation detection.

Figure 3a shows an example from the *News* domain, where we have a headline and an entire article body, and the goal is to find how the two are related in terms of the body's stance(s) towards the headline. In this scenario, the models need to be able to handle very long documents, on one hand, and on the other to reason over multiple fragments of the input text, which might potentially express different stances. It is possible to simplify the task by extracting a summary of the news article beforehand, and evaluating only the stance of that summary, as shown in Figure 3d. However, obtaining such summaries is not a trivial task: (a) they can be extracted by a human annotator (e.g., a journalist), which is time-consuming and expensive, and can require a priori knowledge about the headline/topic of interest as the article might have more than one highlight or viewpoint, or (b) they can be automatically generated using text summarisation methods, but the result can be noisy.

Stance is often expressed in social media such as Twitter, Facebook, Reddit, etc. We illustrate two such scenarios in Figures 3b and 3e. In contrast to the usually long and well-written news documents, social media posts are mostly short and depend on additional context such as the previous posts in a conversational thread (Figure 3e), or external URLs and implicit topics (Figure 3b). Moreover, these texts also need normalisation, as users tend to use slurs, emojis, and other informal language.

Next, in Figure 3c we highlight another interesting setup: claim verification using multiple pieces of evidence. Here, the reasoning is carried in multiple hops over a set of texts. In particular, there might not exists a single passage from a document/post that supports/refutes the claim directly. In that case, a large enough chain of evidence might be needed, which can cover enough contextual knowledge in order to allow the model (or a person) to assess the veracity of the input claim.

Finally, the examples in Figure 3 demonstrate that stance can be used for mis- and disinformation detection in different ways: (*i*) directly, as in the examples in Figures 3a and 3b, or (*ii*) as multiple viewpoints, which are later aggregated into a final decision, as in Figure 3c, 3d and 3e.

We thoroughly discussed all of the aforementioned setups in Section 3, including the publicly available datasets that focus on stance in the context of mis- and disinformation identification.

B Additional Formulations of Stance as a Component for Fact-Checking

Beyond the approaches that we outlined in Section 3.2, stance has also been used for detecting misconceptions and for profiling media sources as part of a fact-checking pipeline. Below, we describe some work that follows these formulations.

Misconceptions Hossain et al. (2020) focused on detecting misinformation related to COVID-19, based on known misconceptions listed in Wikipedia. They evaluated the veracity of a tweet depending on whether it *agrees*, *disagrees*, or has *no stance* with respect to a set of misconceptions. A related formulation of the task is detecting previously fact-checked claims (Shaar et al., 2020). This allows to assess the veracity of dubious content by evaluating the stance of a claim regarding already checked stories, known misconceptions, and facts.

Media Profiling Stance detection has also been used for media profiling. Stefanov et al. (2020) explored the feasibility of an unsupervised approach for identifying the political leanings (left, center, or right bias) of media outlets and influential people on Twitter based on their stance on controversial topics. They built clusters of users around core vocal ones based on their behaviour on Twitter such as retweeting, using the procedure proposed by Darwish et al. (2020). This is an important step towards understanding media biases.

  - **u4**: @u3 no she cant cos its actually not 👎
- **u5**: @u1 More on situation at Martin Place in Sydney, AU LINK 💬
- **u6**: @u1 Have you actually confirmed its an ISIS flag or are you talking shit ❓

(e) Example from Gorrell et al. (2019)

Table 3: Illustrative examples for different stance detection scenarios included in our survey. We annotate the expressed stance with 👍 (*support, for*), 👎 (*deny, against*), ❓ (*query*), and 💬 (*comment*).

The reliability of entire news media sources has been automatically rated based on their stance with respect to manually fact-checked claims, without access to gold labels for the overall medium-level factuality of reporting (Mukherjee and Weikum, 2015; Popat et al., 2017, 2018). The assumption in such methods is that reliable media agree with true claims and disagree with false ones, while for unreliable media, the situation is reversed. The trustworthiness of Web sources has also been studied from a data analytics perspective, e.g., Dong et al. (2015) proposed that a trustworthy source is one that contains very few false claims.

More recently, Baly et al. (2018a) used gold labels from Media Bias/Fact Check,[5] and a variety of information sources: articles published by the medium, what is said about the medium on Wikipedia, metadata from its Twitter profile, URL structure, and traffic information. In follow-up work, Baly et al. (2019) used the same representation to jointly predict a medium's factuality of reporting (*high* vs. *mixed* vs. *low*) and its bias (*left* vs. *center* vs. *right*) on an ordinal scale, in a multi-task ordinal regression setup. Baly et al. (2020) extended the information sources to include Facebook followers and speech signals from the news medium's channel on YouTube. Finally, Hounsel et al. (2020) proposed to use domain, certificate, and hosting information about the infrastructure of the website. See (Nakov et al., 2021) for a recent survey on media profiling.

There is a well-known connection between factuality and bias.[6] For example, hyper-partisanship is often linked to low trustworthiness (Potthast et al., 2018), e.g., appealing to emotions rather than sticking to the facts, while center media tend to be generally more impartial and also more trustworthy.

User Profiling In the case of social media and community fora, it is important to model the trustworthiness of the user. In particular, there has been research on finding opinion manipulation *trolls*, paid (Mihaylov et al., 2015b) or just perceived (Mihaylov et al., 2015a), *sockpuppets* (Maity et al., 2017; Kumar et al., 2017), *Internet water army* (Chen et al., 2013), and *seminar users* (Darwish et al., 2017).

C Systems and Applications

The systems and applications below use stance detection as part of a pipeline for identifying mis- and disinformation, see Section 4 for more details about the methods.

Wen et al. (2018) worked in a cross-lingual cross-platform rumour verification setup. They included multimodal content from fake and from real posts with images or videos shared on Twitter. They then collected supporting documents from two search engines, Google and Baidu, in English and Chinese, which they used for veracity evaluation. They trained their stance detection model on English data (FNC-1) using pre-trained multilingual sentence embeddings, and further added cross-platform features in their final neural model.

Popat et al. (2018) proposed CredEye,[7] a system for automatic credibility assessment of textual claims. The system takes a claim as an input and analyses its credibility by considering relevant articles it retrieved from the Web, by combining the predicted stance of the articles regarding the claim with linguistic features to obtain a credibility score (Popat et al., 2017).

Nguyen et al. (2018) designed a prototype fact-checker Web tool.[8] Their system leverages a probabilistic graphical model to assess a claim's veracity taking into consideration the stance of multiple articles regarding this claim, the reputation of the news sources, and the annotators' reliability. In addition, it offers explanations to the fact-checkers based on the aforementioned features, which was shown to improve the overall user satisfaction and trust in the predictions.

Zubiaga et al. (2018a) considered a four-step tracking process as a pipeline for rumour verificatioon: (*i*) *rumour detection*, i.e., given a stream of claims, determine whether they are worth verifying or they do contain no rumours, (*ii*) *rumour tracking* for finding relevant information about the rumour using social media posts, sentence descriptions, and keywords, (*iii*) *stance classification* to collect stances towards the rumour, and (*iv*) *veracity classification* to aggregate the information from the tracking component, the collected stances, and optionally other relevant information about the sources, metadata about the users, etc., to predict a truth value for the rumour.

Nadeem et al. (2019) developed FAKTA, a system for automatic end-to-end fact-checking of claims. It retrieves relevant articles from Wikipedia and as well as from selected media sources, which it then uses for verification. FAKTA uses a stance detection model, trained in a FEVER setting, to predict the stance and to obtain entailed spans. These predictions, combined with linguistic analysis, are used to provide both document- and sentence-level explanations and a factuality score.

Nguyen et al. (2020) proposed the Factual News Graph (FANG) model, which models the social context for fake news detection. In particular, FANG uses the stance of user comments with respect to the target news article as an integral component of its model, together with temporality, user–user interactions, article–source interactions, as well a source reliability information.

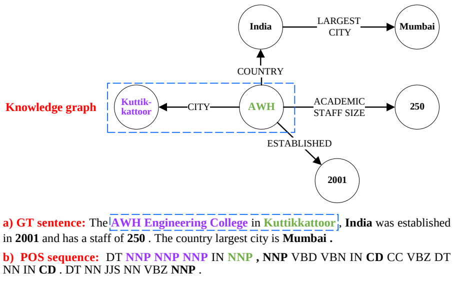
`hkx5063@psu.edu`

Abstract

The knowledge graph (KG) stores a large amount of structural knowledge, while it is not easy for direct human understanding. Knowledge graph-to-text (KG-to-text) generation aims to generate easy-to-understand sentences from the KG, and at the same time, maintains semantic consistency between generated sentences and the KG. Existing KG-to-text generation methods phrase this task as a sequence-to-sequence generation task with linearized KG as input and consider the consistency issue of the generated texts and KG through a simple selection between decoded sentence word and KG node word at each time step. However, the linearized KG order is commonly obtained through a heuristic search without data-driven optimization. In this paper, we optimize the knowledge description order prediction under the order supervision extracted from the caption and further enhance the consistency of the generated sentences and KG through syntactic and semantic regularization. We incorporate the Part-of-Speech (POS) syntactic tags to constrain the positions to copy words from the KG and employ a semantic context scoring function to evaluate the semantic fitness for each word in its local context when decoding each word in the generated sentence. Extensive experiments are conducted on two datasets, WebNLG and DART, and achieve state-of-the-art performances. Our code is now public available[1].



a) GT sentence: The AWH Engineering College in Kuttikkattoor, **India** was established in **2001** and has a staff of **250** . The country largest city is **Mumbai .**

b) POS sequence: DT NNP NNP NNP IN NNP **, NNP** VBD VBN IN **CD** CC VBZ DT NN IN **CD** . DT NN JJS NN VBZ **NNP** .

Figure 1: One example KG from DART dataset (Nan et al., 2020). AWH is short for AWH Engineering College. Text a) is the ground-truth sentence, text b) is the POS sequence obtained by NLTK, and most words copied from the KG are nouns. The linearized order of KG should correlate with the information sequence expressed in the corresponding sentence (words indicated in bold in GT sentence), and each decoded word should fit in its local semantic context (e.g. the blue dashed lines).

1 Introduction

Knowledge graphs (KGs) record the common sense knowledge in a structural way and have many potential applications, e.g., question answering (Saxena et al., 2020), recommendation system (Wang et al., 2021) and storytelling (Xu et al., 2021). One typical KG is shown in Figure 1, with circle nodes indicating entities, and the directional edges connecting the head node to the tail node and representing the relation among connected entities. This structural representation in KG is easy for information storage while not convenient for human understanding. In this paper, we focus on the task of KG-to-text generation, which aims to describe an input KG with fluent language sentences in an easy-to-understand way. Compared to the traditional text generation task, KG-to-text generation poses the extra challenge of maintaining the word authenticity in the generated sentence given the input KG. With the word authenticity and sentence fluentness in mind, existing KG-to-text generation methods (Ribeiro et al., 2020a; Koncel-Kedziorski et al., 2019; Gardent et al., 2017) phrase this task as a sequence-to-sequence generation task, where the KG is linearized as input sequence and decoded into sentences, and the word from the KG are selected to be inserted into the decoded sentence with predicted confidence at each time step. However, when the KG is linearized into a sequence, simple heuristic search-based algorithms are usually utilized, e.g., breadth-first search (BFS) or using other pre-defined rules for sorting (Li et al., 2021;

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1278 - 1291
July 10-15, 2022

Ribeiro et al., 2020a), without considering the word sequence information in the ground-truth sentences. The order inference of the KG is not tightly correlated to the word sequence information in the ground-truth sentences and is generated in a disjoint prestage. The decoded sentence is further conditioned on the linearized KG order which might incur cascaded errors (Cornia et al., 2019). To tackle this problem, we extract the order information from the ground-truth sentence and use this order information to directly supervise the KG order prediction with graph structural local context. In this case, our order prediction component for KG encodes the sentence sequence prior information and will benefit the sentence generation in the follow-up stage.

Also, most existing methods (Li et al., 2021; Koncel-Kedziorski et al., 2019) maintain the word authenticity by maximizing the copy probability of the tokens from the KG, while ignoring the syntactic correctness and semantic relevance. A simple observation from the example in Figure 1, you can find that the POS tags of most words copied from the KG are nouns. Motivated by this observation, we introduce a POS generator to guide the sentence generation process by applying the POS information as additional supervision at each time step and limit the position scope of the word selection from KG. Moreover, to further enhance semantic relevance of generated sentence, we consider the structural information and local semantic information of the KG by designing a semantic context scoring function with sliding windows of different sizes, and combine the semantic context score into the word selection process at each time step of the sentence generation.

In summary, we propose a Syntax controlled KG-to-text generation model with Order and Semantic Consistency, called S-OSC. The main contributions are summarized as follows:

- We propose a learning-based sorting network to obtain the optimal KG description order with graph structural context for more fluent caption generation.
- We enhance the authenticity of generated sentences to the KG through syntactic and semantic regularization. POS tag information is incorporated into the sentence modeling and helps to determine the word selection from KG, together with one additional semantic context scoring function.
- Extensive results on two benchmark datasets indicate that our proposed S-OSC model outperforms previous models and achieves new state-of-the-art performance.

2 Related Work

2.1 KG-To-Text Generation

KG-to-text generation task has been a hot research topic since the first dataset WebNLG was proposed (Gardent et al., 2017). Recent works for solving this task have two main categories. One category is using graph neural networks (Marcheggiani and Perez-Beltrachini, 2018; Ribeiro et al., 2020b; Li et al., 2021; Cheng et al., 2020) or graph transformers (Koncel-Kedziorski et al., 2019) to directly capture the graph structure information and decode into sentences. E.g., the recent work (Ribeiro et al., 2020b) forms four different encoder architectures for combining local and global node contexts. ENT-DESC (Cheng et al., 2020) introduces multi-graph structure to better aggregate knowledge information. The other category is first linearizing the KG (Ribeiro et al., 2020a; Yang et al., 2020; Gardent et al., 2017; Hoyle et al., 2020) and then formulating a sequence-to-sequence generation task with lineared KG nodes as input to generate sentences. E.g., Distiawan et al. (Distiawan et al., 2018) utilize a fixed tree traversal order to directly flatten the KG into a linearized representation. The structural information of the KG is not preserved when generating the KG order. In this paper, we follow the second general pipeline with local structure encoded in the order generation process.

2.2 Knowledge Graph Order Generation

A line of KG-to-text models (Ribeiro et al., 2020a; Braude et al., 2021) tries to generate sentences conditioned on the KG order, where the order generation is especially important as different KG description orders may result in various generated texts. Most previous works focus on graph traversal-based approaches (Flanigan et al., 2016; Gardent et al., 2017; Ke et al., 2021; Li et al., 2021) for KG order generation. (Li et al., 2021) proposes to use a relation-biased breadth first search (RBFS) strategy to linearize the KG. These previous graph traversal-based approaches are heuristic without considering the word sequence information in the ground-truth sentences. Inspired by previous work (Cornia et al., 2019) which generates image caption with optimal object description order, we extract the sequence information from the ground-truth sentences as supervision and train one order prediction module to generate optimal order. Moreover, our order prediction considers the local graph structure in triplet.

2.3 Captioning with POS Tags

POS tags have been used in various text generation (e.g. image captioning and video captioning) to impose the syntactic constraint. In the neural text generation work (Yang and Wan, 2021), the authors propose to use POS guided softmax function as the linguistic prior information for modeling the posterior probabilities of next-POS and next-token, in order to increase text generation diversity. In the image caption, Bugliarello et al. (Bugliarello and Elliott, 2021) claim that incorporating POS tag information in the sentence generation process consistently improves the quality of the generated text. In video captioning, Hou et al. (Hou et al., 2019) propose to define the templates of POS tag sequences to represent the syntactic structure of the generated text. In KG-to-text generation task, we not only use the POS tags to ensure the syntactic correctness of the generated text, but also use the POS tags to constrain the positions to copy words from KGs.

2.4 Pre-Trained Language Models

Pre-trained language models (PLMs) on massive corpora, such as BERT (Devlin et al., 2018), BART (Lewis et al., 2019) and T5 (Raffel et al., 2019), have achieved superior performance in various natural language generation tasks, including KG-to-text generation task (Ribeiro et al., 2020a; Peters et al., 2019; Ke et al., 2021). Ribeiro et al. (Ribeiro et al., 2020a) leverage the generation ability of PLMs and use the linearized KG as input to generate texts. We also use the PLM in our method to guarantee the model generalization ability, and at the same time, design extra order prediction and context scoring components to maintain the semantic consistency.

3 Approaches

In this section, we first formulate the KG-to-text generation problem setting and then elaborate the proposed S-OSC in detail.

3.1 Problem Formulation

Given the input KG $\mathcal{G}$, which is composed of $\{(h_1, r_1, t_1), \cdots, (h_n, r_n, t_n) | h_*, t_* \in \mathcal{E}, r_* \in \mathcal{R}\}$, where $\mathcal{E}$ denotes the entity set and $\mathcal{R}$ represents the relation set, the KG-to-text generation task aims to generate a fluent and reasonable text sequence $\mathcal{T} =< t_1, t_2, \cdots, t_k > (t_k \in \mathcal{V})$, where $\mathcal{V}$ denotes the vocabulary. In this paper, we follow the general pipeline (Ribeiro et al., 2020a; Ke et al., 2021; Ribeiro et al., 2021) of linearizing the input KG into sequence $\mathcal{G}_{linear} =< g_1, g_2, \cdots, g_m >$ consisting of m tokens, and then decoding the KG token sequence into sentences.

3.2 Our Proposed S-OSC Model

We propose S-OSC, illustrated in Figure 2, which consists of two main components: one learning-based sorting network for KG, and one copy or prediction selection module for decoding each word in the sentences. The sorting network generates the optimal description sequence for the input KG. Based on the KG order sequence, the sentence decoder generates each word with a certain probability predicted by the copy or prediction selection module to replace the decoded word with the word in the KG. Thus, the model can maintain the word authenticity in the generated sentence compared to the KG. A key innovation in our learning-based sorting network is to utilize the sequence information extracted from the ground-truth sentence to directly supervise the optimal sequence prediction instead of heuristic search in the KG without considering the description sequence prior. Our copy or prediction selection module for decoding each word in the sentences incorporates additional POS syntactic constraint and semantic context consistency scoring function evaluating the semantic fitness of each word in its sliding windows with various sizes. The details of each module in our S-OSC model are illustrated in the following sections.

3.2.1 Sorting Network

The description order of the KG will affect the content of the generated sentence. In a worse scenario, poor order may result in the loss of important information (see the example in Figure 7). To overcome the drawback of disjoint learning for KG order generation and sentence generation in the previous heuristic-based methods (Li et al., 2021; Ribeiro et al., 2020a; Yang et al., 2020), we propose a learning-based sorting network with the order supervision extracted from the ground-truth sentence. Notably, our sorting network is based on the features from the structural Triplet Encoder, where the

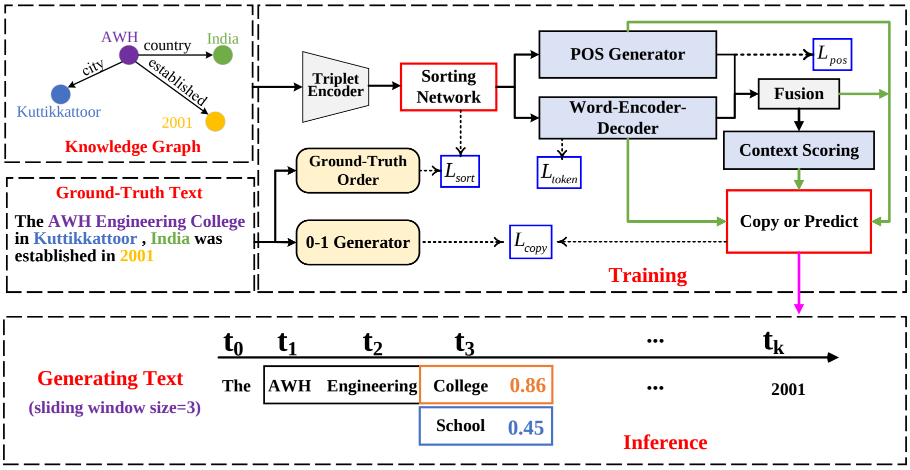

Figure 2: S-OSC model architecture. The pre-trained language model takes the KG as input and extracts head-relation-tail triplet structure features through Triplet Encoder. Then, these triplet features are fed into the Sorting Network to generate one optimal description order under the sequence supervision extracted from ground-truth sentence. Conditioned on the KG order, we further decode the sequence into sentences through Word Decoder and apply additional syntactic supervision through POS Generator. To maintain the word authenticity in the generated sentences, we further design one Copy or Prediction component incorporating the POS syntactic information and semantic context scoring with sliding windows to help determine when to copy tokens from KG, in addition to the word decoding probability from the Word-Encoder-Decoder and the binary classification probability for copy or prediction at each time step.

head-relation-tail triplet structure features are extracted through pre-trained KG embedding method TransH (Wang et al., 2014) and pre-trained language model BART (Lewis et al., 2019). Due to the variable length of the KG, we introduce a placeholder to pad it into fixed length N, which also denotes the number of possible position classes. The head-relation-tail triplet structure features F_{stru} are concatenated with the padding F_{pad} and fed through the Fully Connected (FC) layers with softmax classifier FC_s to obtain S_{matrix} and predict the sorting order S_{order}.

$$\begin{aligned} S_{matrix} &= \mathrm{FC}_s([F_{stru}; F_{pad}]) \\ S_{order} &= \mathrm{argmax}_{row}(S_{matrix}) \end{aligned} \tag{1}$$

In this paper, we treat the order prediction task as a classification problem, where N denotes the number of classes (the maximum of the triplets in KG). Thus, we measure the cross-entropy loss between the ground-truth order G_{order} and the sorting order S_{order}:

$$L_{sort} = -\sum_{n=0}^{N} \log(S^n_{matrix}) \cdot G^n_{order} \tag{2}$$

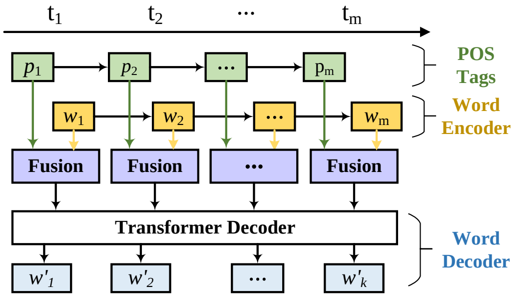

Figure 3: The architecture of the Word-Encoder-Decoder with a POS Generator.

3.2.2 Copy or Prediction Network

To maintain the authenticity of KG words in generated sentences, the model needs to selectively copy words from KG words instead of using the predicted words from Word Decoder. Besides directly predicting the copy probability from the hidden state (Koncel-Kedziorski et al., 2019; Li et al., 2021; See et al., 2017), the Copy or Prediction Network in our S-OSC model further enhances the syntactic and semantic consistency of selected words in the decoded sentence through the incorporation of POS generator (shown in Figure 3) and semantic context scoring (shown in Figure 4). Next, we will introduce each module in detail.

POS Syntactic Constraint Conditioned on the KG order G_{order}, we first linearize the KG by

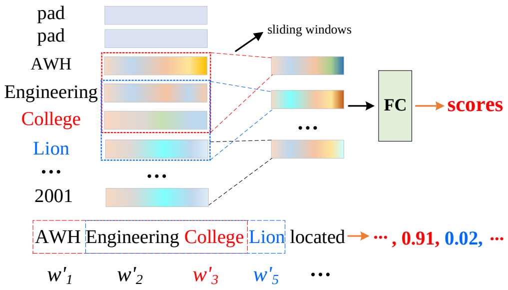

Figure 4: The architecture of semantic context scoring module with sliding windows.

adding the tokens $< Head >, < Relation >, < Tail >$ to the corresponding position for each triplet and obtain the $\mathcal{G}_{linear}$. Then, the Word Encoder and the POS Generator take G_{linear} as their inputs and output the word encoding WI=$\{w_i, i \in 1 \cdots m\}$ and POS tag encoding PI=$\{p_i, i \in 1 \cdots m\}$, respectively. Then, the token encoding w_i and POS tag encoding p_i are combined in the fusion module to get the updated token encoding w_i.

$$w_i = \text{LN}(FC([w_i; p_i]) + w_i), \tag{3}$$

where LN denotes the layer normalization. The updated token encoding w_i after fusing is decoded into sentence $\text{WI}' = \{w_i', i \in 1 \cdots k\}$ in Word Decoder.

POS generator is supervised through POS tags pre-extracted from the sentence. The loss function is formulated as:

$$L_{pos} = -\sum_{l=1}^{M} \log(P_{gen}(p_l | p_1, \cdots, p_{l-1}; G_{order})), \tag{4}$$

where P_{gen} denotes the predicted probability from POS generator. Similarly, the objective of Word-Encoder-Decoder is as follows:

$$L_{token} = -\sum_{j=1}^{K} \log(W_{gen}(w_j' | w_1', \cdots, w_{j-1}'; \text{WI}')), \tag{5}$$

where W_{gen} denotes the predicted probability of each word token.

Semantic Context Scoring Besides the syntactic constraint for copied words, we also design one semantic context scoring component, illustrated in Figure 4, to evaluate the semantic consistency of copied or predicted words in the sliding windows. Sliding windows are generated for each word to provide the local context, e.g., the sliding window size is set to 3 in Figure 4. Besides, padding is needed for the first several words when forming the sliding windows. Word features in the sliding window are contacted to get the context information $F_{context}$, and are fed into the FC layers to obtain the semantic score $X_{semantic}$.

$$X_{semantic} = \sigma(\text{FC}(F_{context})), \tag{6}$$

where σ denotes the sigmoid function.

Word Copy Probability Prediction With our newly introduced POS token embeddings v_{p_k} and the semantic context score $\text{X}_{semantic}$, the probability p_{copy}^k for copying words from KG is computed in Eq. 7, and is used in testing time for final selection between predicted words from Word Decoder and words in KG at each time step when generating sentences.

$$\begin{aligned} t_{copy}^k &= \sigma(W_1 v_{w_k} + W_2 v_{p_k} + W_3 s_k + b_{copy}), \\ p_{copy}^k &= \lambda \cdot X_{semantic} + (1 - \lambda) \cdot t_{copy}^k, \end{aligned} \tag{7}$$

where W_1, W_2, W_3 and b_{copy} are learnable parameters. v_{w_k} represents token embedding and s_k represents the last hidden state of Word-Decoder at each time step. λ is a trade-off coefficient and is set as 0.3.

The semantic context scoring module is jointly optimized with copy probability prediction and benefits the copy probability prediction. The copy or prediction loss function is defined as:

$$\begin{aligned} L_{copy} = -\sum_{k=0}^{K} (y^k \cdot \log(p_{copy}^k) + (1 - y^k) \\ \cdot \log(1 - p_{copy}^k)), \end{aligned} \tag{8}$$

where y^k is the ground-truth 0-1 label indicating copying or predicting word at $k - th$ time step, which is generated from KG and the ground-truth sentence (see more details in supplementary material).

Finally, the total training loss L_{total} in our S-OSC model is composed of four components: sorting loss L_{sort}(Eq. 2), POS generation loss L_{pos}(Eq. 4), word generation loss L_{token}(Eq. 5) and copy or prediction loss L_{copy}(Eq. 8).

$$L_{total} = L_{token} + \lambda_1 L_{pos} + \lambda_2 L_{sort} + \lambda_3 L_{copy}, \tag{9}$$

where λ_1, λ_2 and λ_3 are the trade-off coefficients.

4 Experiments

In this section, we report the comparison results with state-of-the-art methods and further analyze the performance of each component in our S-OSC model through ablation studies. We also evaluate our model performance through human evaluation and qualitative analysis.

4.1 Datasets

In this paper, two benchmarks: WebNLG (Li et al., 2021) and DART (Nan et al., 2020) are utilized to evaluate the performance of our S-OSC model.

WebNLG WebNLG (Li et al., 2021) is a most widely used dataset in KG-to-text generation task. Each graph is extracted from DBPedia and consists of two to seven triplets. The train/val/test splits are 7362/1389/5427.

DART Compared to WebNLG, DART (Nan et al., 2020) is a larger open-domain dataset, where triples are composed of tree-structured ontology. The train/val/test splits are 30348/2759/5097.

4.2 Evaluation Metrics

Following the previous works (Ribeiro et al., 2020a,b; Li et al., 2021) on WebNLG dataset, we adopt four automatic language evaluation metrics for WebNLG dataset, i.e., BLEU-4 (Papineni et al., 2002), CIDEr (Vedantam et al., 2015), Chrf++ (Popović, 2015) and ROUGE-L (Lin, 2004). Following previous works (Nan et al., 2020) on DART dataset, in addition to BLEU-4 (Papineni et al., 2002), we use four additional automatic evaluation metrics, i.e., METEOR (Banerjee and Lavie, 2005), MoverScore (Zhao et al., 2019), BERTScore (Zhang et al., 2019) and BLEURT (Sellam et al., 2020).

4.3 Implementation Details

In the sorting network, the fixed KG order length N is set to 8 and 10 for WebNLG and DART, respectively. The POS generator operates on the POS sequences parsed from ground-truth sentences via NLTK, and trains from BART-Base pretrained model (Lewis et al., 2019). For Word-Encoder-Decoder, we follow the code in JointGT (Ke et al., 2021) and utilize Bart-Base with self-attention (Shaw et al., 2018). The beam search size for generating sentences in inference time is set to 5. We optimize all the parameters under the supervision of the total loss in Eq. 9 using the OpenAI AdamW optimizer. The loss weights λ_1, λ_2 and λ_3 in total training loss (Eq.9) are set to 0.7, 0.4, and 0.3, respectively.

Datasets	WEBNLG			
Metrics	B-4	R-L	CIDEr	Chrf++
Li et al.† (Li et al., 2021)	57.10	75.20	4.20	75.00

Table 1: Results for different models on WebNLG dataset. B-4 and R-L are short for BLEU-4 and ROUGE-L, respectively. **Bold** and underline fonts represent the best and the second best performing results. "S-OSC-GT" indicate our "S-OSC" model with ground-truth order in inference (The same term is applied in the following). † denotes the results of reproduction. Other cited results are from Li et al. (Li et al., 2021).

4.4 Main Results on WebNLG and DART

We compare our S-OSC model with other state-of-the-art methods on WebNLG and DART. Results on WebNLG are shown in Table 1. It can be observed from Table 1 that our S-OSC model outperforms all the previous methods in three evaluation metrics, i.e., B-4, R-L and Chrf++, except for the CIDEr value being in the second place compared to the best performing CIDEr result reported by the model in Li et al. (Li et al., 2021). Note that our S-OSC model contains one learning-based sorting network supervised by the ground-truth order extracted from KG and the ground-truth sentence. We also report our model's results under the ground-truth order during inference time (denoted as "S-OSC-GT") which serves as the upper bound for our sorting performance. From the comparison of our model with predicted order "S-OSC" and our model with ground-truth order "S-OSC-GT", we can see that our model results with predicted order are close to the results with ground-truth order with the result gaps less than 1.2 points in most metrics, which shows the advantage of our learning-based sorting network for generating KG description order.

Results on DART are shown in Table 2. From previous models' results, we can see that pretraining on the large corpus (e.g., "T5-Large" and "Bart-Large") brings significant result improvement compared to "Seq2Seq-Att" and "End-to-End Transformer". Our S-OSC model further achieves

Datasets	DART				
Metrics	B-4	METEOR	MoverScore	BERTScore	BLEURT
Seq2Seq-Att (Nan et al., 2020)	29.66	0.27	0.31	0.90	-0.13
End-to-End Transformer (Ferreira et al., 2019)	27.24	0.25	0.25	0.89	-0.29
T5-Large (Ribeiro et al., 2020a)	50.66	0.40	0.54	0.95	0.44
BART-Large (Ribeiro et al., 2020a)	48.56	0.39	0.52	0.95	0.41
JointGT (Ke et al., 2021)	54.24	**0.44**	**0.64**	**0.96**	**0.59**
S-OSC(ours)	**62.01**	0.43	**0.64**	**0.96**	0.49
S-OSC(ours)-GT	64.53	0.44	0.66	0.96	0.51

Table 2: The results of different models on DART dataset.

new state-of-the-art results in all five metrics compared to these pre-training based models (e.g., "T5-Large") with B-4 score improved by 11.35 points, METEOR score improved by 0.03 points, Moverscore improved by 0.1 points, BERTScore improved by 0.01 points, and BLEURT improved by 0.05 points. JointGT outperforms all the previous baseline models. Compared with JointGT (Ke et al., 2021), our model can also obtain an improvement of 7.77 points in B-4 score. This result also validates the effectiveness of our model in improving the fluentness and authenticity of the generated sentences with the proposed learning-based sorting network and consistency enhancement under the POS syntactic and semantic context constraints. Similar to the results on WebNLG, our model S-OSC with predicted order can achieve the performance close to that with ground-truth order.

4.5 Ablation Study

In this section, we conduct extensive experiments on WebNLG to evaluate various factors in the word copy or prediction during sentence generation, e.g., the POS generator and semantic context (SC) scoring. We compare our full S-OSC model with the following variations: without word copy component and just use the predicted word from Word Decoder at each time step (w/o CP), without POS information in copy probability prediction (w/o POS), without semantic context scoring in copy probability prediction (w/o SC), without POS tag information and semantic context scoring in copy probability prediction (w/o POS and SC) and relying on the last hidden states to predict the copy probability as in previous methods (Koncel-Kedziorski et al., 2019; See et al., 2017). From the results in Table 3, we can observe that: (1) By removing the word copy component and directly taking the predicted word from Word Decoder at each time step (w/o CP), the results drop significantly by 3.95 points in B-4, 2.2 points in R-L, 0.41 points in CIDEr and 3 points in Chrf++. (2) We then consider incorporating the copy prediction component, but just rely on the last hidden states to predict the copy probability as in previous methods (Koncel-Kedziorski et al., 2019; See et al., 2017) without POS tag information and semantic context scoring in copy probability prediction (w/o POS and SC). The results improve slightly in all the metrics compared with that of "w/o CP". (3) We then evaluate the effectiveness of POS syntactic information and semantic context scores in improving the quality of the generated sentences by removing each of them at a time.

Methods	B-4	R-L	CIDEr	Chrf++
S-OSC	63.10	80.0	5.40	81.0
w/o CP	59.15	77.8	4.99	78.0
w/o POS and SC	59.80	77.7	5.01	78.1
w/o POS	61.00	78.5	5.10	78.6
w/o SC	61.06	78.9	5.21	79.1

Table 3: Ablation analysis for copy or prediction component in our model on WebNLG. S-OSC here is under the ground-truth order.

Compared to full S-OSC model, without POS information in copy probability prediction (w/o POS), the results drop by 2.1 points in B-4, 1.5 points in R-L, 0.3 points in CIDEr and 2.4 points in Chrf++. Compared to full S-OSC model, without semantic context scoring in copy probability prediction (w/o SC), the results drop by 2 points in B-4, 1.1 points in R-L, 0.2 points in CIDEr and 1.9 points in Chrf++. Both "w/o POS" and "w/o SC" improve consistently compared to previous copy policy in "w/o POS and SC".

To further reveal more details about our model, we conduct extra ablation studies regarding the following questions. (1) How does triplet structure encoding in the sorting network help the model compared with direct node encoding without triplet structure context? (2) How does our model perform

Methods	B-4	R-L	CIDEr	Chrf++
GT	63.10	80.0	5.4	81.0
TS	61.90	79.3	5.3	79.7
NS	60.00	77.0	5.1	78.0
RS	55.20	72.0	4.7	76.0

Table 4: The results of sorting order on WebNLG. TS denotes the triple-level sorting order, NS is the node-level sorting order (Li et al., 2021) and RS represents the random sorting order. The same symbols are as below.

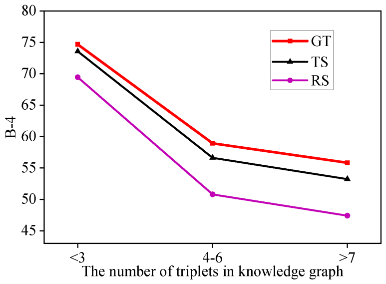

Figure 5: The B-4 results in three groups with different KG sizes on DART dataset for different sorting orders.

for different triplet numbers in KG? (3) How does the sliding window size in semantic context scoring function affect the model performance?

(1) Triplet structure encoding in sorting network. To show the effect of triplet structure encoding (triple-level) in our sorting network, we investigate the performance of direct node encoding without triplet structure (node-level), as well as our S-OSC model's results with random sorting order. Results on WebNLG are shown in Table 4 and the upper bound result is shown with ground-truth order (GT). From Table 4, sorting with triple-level sorting order "TS" outperforms random sorting order "RS" significantly, and also outperforms node-level sorting order "NS" by 1.9 points in B-4, 2.3 points in R-L, 0.2 points in CIDEr and 1.7 points in Chrf++, showing the advantage of triplet structure encoding compared to node encoding without triplet structure context. The results on DART dataset show similar trend and are reported in supplementary material.

(2) Different Knowledge Graph Sizes. To verify the effect of our S-OSC model performance on different KG sizes, we split the test dataset into three subsets according to the size of the KG, i.e., the number of triples in KG is less than 3, between 4 and 6, and more than 7, and reports results on each subset. DART is selected for experiment due to its wide distribution of KG sizes. The results of B-4 in each subset are plotted in Figure 5, showing that as the number of triples in KG increases, the difficulty of sorting and KG-to-text generation increases and the B-4 results generally decrease in all three methods ("GT", "RS" and "TS"). Also, our model's superiority exhibits significant improvement in all three subsets with different KG sizes (comparing "TS" with "RS"). Other metric results show similar trend and are reported in supplementary material.

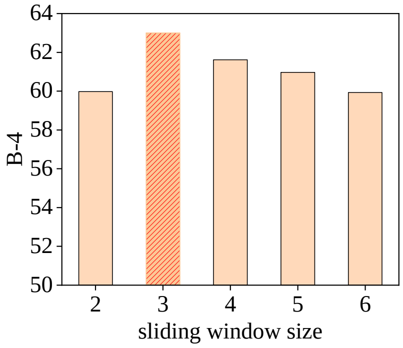

Figure 6: The B-4 results of different sliding windows on WebNLG dataset.

(3) Sliding window size in the semantic context scoring. We plot the B-4 results for different sliding window sizes of semantic context scoring function on WebNLG dataset, shown in Figure 6. From Figure 6, the model achieves the best performance when the sliding window size is 3. Other metric results show similar trend and are reported in supplementary material. Thus, we set the sliding window size to 3 in the experiments.

4.6 Human Evaluation

We conduct the human evaluation on WebNLG to further evaluate the generated text. In this paper, we adopt the same human evaluation criteria as Chen et al. (Chen et al., 2019), i.e., Factual correctness including Supp (counting the number of facts that co-exist in the KG and generated text) and Cont (counting the facts in the generated texts missing from or contradicting with KG), Language naturalness including NF (evaluating the accuracy and fluentness of generated sentences). In addition to using absolute score at 5-point metric in NF, we also use relative ranking scores (termed NA). We randomly select 100 knowledge graphs for human evaluation. Five native English speakers volunteer to score all the 100 knowledge graphs. Table 5 reports the results[2]. We can observe that: the generated texts of our S-OSC model are more authentic

and consistent with KG than the method in Li et al. (Li et al., 2021).

4.7 Qualitative Analysis

We show two qualitative examples from WebNLG and DART in Figure 7. From the example of WebNLG, we can see that the previous method in Li et al. (Li et al., 2021) generates the wrong description order with node 3 and node 2 exchanged positions. This causes the generated sentence from Li et al. (Li et al., 2021) containing the wrong text "jusuf kalla" noted in red color and missing the text "Malaysian Indian", while our S-OSC method generates the right order and consistent sentences. In the example from DART, though our S-OSC model generates relative inferior order with node 2 and node 5 exchanged positions, relying on our strong sentence generator with syntactic constraint and semantic consistency constraint, our model is able to generate semantic consistent sentence to the KG with the right words copied from KG. However, in this example, Bart-Large (Ribeiro et al., 2020a) still misses some key word description from KG, e.g., "the final fight on 10/28/2014" and "Launch Pad 0", though conditioned on the right predicted order, showing the inferior performance of their copy or prediction module in sentence generation.

5 Conclusion

This paper proposes a learning-based sorting network to obtain the optimal description order for KG-to-text generation. Additionally, our model incorporates POS generator and semantic context scoring to selectively copy words from KG and improve the word authenticity in generated sentences. Extensive experiments show that our model outperforms previous state-of-the-art approaches. In the future, we will introduce casual inference into the model to further improve the reasoning ability.

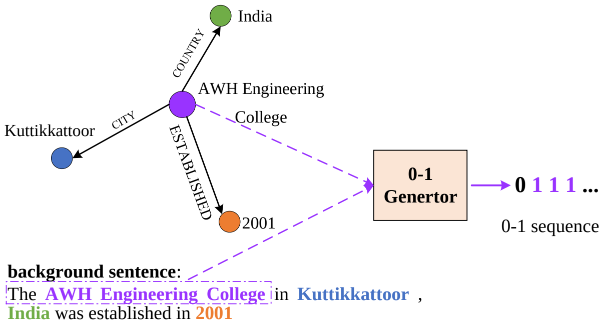

Figure 1: The steps of obtaining the 0-1 sequence. When the KG node exists in the text, all mentions of the node are masked as 1, otherwise 0.

1 0-1 Generator

In order to make the generated text more consistent with the KG, we use a 0-1 generator to obtain the ground-truth of copy or prediction order, where 0 represents a token from generation and 1 from KG. The steps are as shown in Figure 1.

2 Ground-Truth Sorting Order

The description sorting order is essential for the generation process. In this paper, we sort the order according to the triple-level. Taking Figure 1 as an example, we can obtain three triplets, i.e., (AWH Engineering College, COUNTRY, India), (AWH Engineering College, ESTABLISED, 2001) and (AWH Engineering College, CITY, Kuttikkattoor). In the reference sentence, the triple (AWH Engineering College, CITY, Kuttikkattoor) appears first, (AWH Engineering College, COUNTRY, India) appears second and (AWH Engineering College, ESTABLISED, 2001) last. Thus, we can form the order 2,0,1 for the providing KG. Note that, we only record the position of the triplet where it first appeared regardless of many times.

Datasets	WEBNLG			
Metrics	B-4	R-L	CIDEr	Chrf++
Baselines†	57.00	75.20	4.20	75.00
Li et al.(Li et al., 2021)	61.88	75.74	**6.03**	79.10
S-OSC(ours)	**61.90**	**79.30**	5.30	**79.70**

Table 1: Results for different models on WebNLG dataset. B-4 and R-L are short for BLEU-4 and ROUGE-L, respectively. Baseline is the reproduced results of Li et al. (Li et al., 2021). **Bold** and underline represent the best and the second best performing results. (the same term is used below)

3 Code Re-implementation

We re-implement the author's code in Li et al. (Li et al., 2021) as our baseline. It can be observed from Table 1 that our S-OSC model outperforms the baseline and the results of Li et al. reported from their paper in three evaluation metrics,B-4, R-L and Chrf++ metrics. Although Li et al. achieves the best CIDEr score in their reported results, this score is not replicable and our S-OSC still obtains 1.1 point higher than that of the replicated baseline.

4 Triplet Structure Encoding in Sorting Network on DART (Nan et al., 2020)

From Table 2, encoding with triple-level sorting order "TS" outperforms random sorting order "RS" significantly, and also outperforms node-level sorting order "NS" by 1.35 points in B-4, 0.01 points in METEOR, 0.02 points in BERTScore and 0.13 points in BLEURT, showing the advantage of triplet structure encoding compared to node encoding without triplet structure context.

5 Different Knowledge Graph Sizes

Table 4 shows that when the number of triples in KG increases, the difficulty of sorting and KG-to-text generation increases (see "GT" and "TS") and our model's superiority exhibits more relative im-

Methods	B-4	METEOR	MoverScore	BERTScore	BLEURT
GT	64.53	0.44	0.66	0.96	0.51
TS	62.01	0.43	0.64	0.96	0.51
NS	60.66	0.42	0.64	0.94	0.38
RS	58.67	0.42	0.62	0.93	0.34

Table 2: The results of sorting order on Dart

Methods	B-4	R-L	CIDEr	Chrf++
With local POS	63.10	80.00	5.40	81.0
With global POS	61.28	79.32	5.28	79.2

Table 3: Performance comparisons of our model with different POS information (local POS and global POS) on WebNLG dataset.

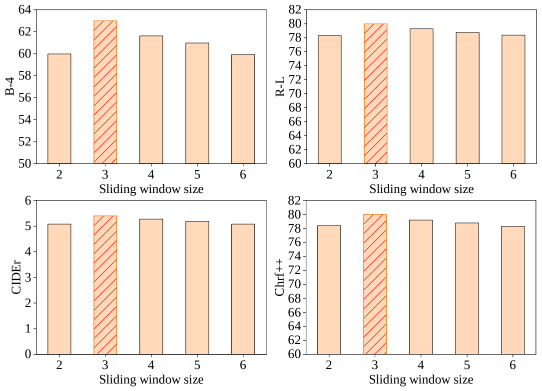

Figure 2: The results of different sliding windows on WebNLG dataset under B-4, R-L, CIDEr and CHrf++ metrics.

provement (comparing "TS" with "NS"). When the size of knowledge graphs is lower than three, these orders have similar performances. This is mainly due to the fact that less triplets have less effect for the model. However, "TS" significantly outperforms "NS" and "RS". Moreover, as the results reported in Table 4, "TS" consistently outperforms "RS" and "NS" in terms of METEOR and MoverScore metrics, and obtains similar performance to "GT" in BERTScore and BLEURT metrics.

6 Sliding Window Size in Semantic Context Scoring

As the B-4 result reported in the main paper, the other metric results in Figure 2 also show that the model achieves the best performance when the sliding window size is 3.

7 Global and Local POS Information

We further introduce two forms of POS tag information, i.e., the global tag information (the final last hidden state of POS generator) and local tag information (the last hidden states of POS generator at each time step). The results of the comparison are reported in Table 3.

We can observe that the model equipping with local POS information performs better than that of equipping with global information. This is mainly because the local POS information can provide more fine-grained syntactic information. Thus, it can further ensure the authenticity of the generated sentences.

To Answer or Not to Answer? Improving Machine Reading Comprehension Model with Span-based Contrastive Learning

Yunjie Ji, Liangyu Chen, Chenxiao Dou, Baochang Ma, Xiangang Li

Abstract

Machine Reading Comprehension with Unanswerable Questions is a difficult NLP task, challenged by the questions which can not be answered from passages. It is observed that subtle literal changes often make an answerable question unanswerable, however, most MRC models fail to recognize such changes. To address this problem, in this paper, we propose a span-based method of Contrastive Learning (spanCL) which explicitly contrast answerable questions with their answerable and unanswerable counterparts at the answer span level. With spanCL, MRC models are forced to perceive crucial semantic changes from slight literal differences. Experiments on SQuAD 2.0 dataset show that spanCL can improve baselines significantly, yielding 0.86~2.14 absolute EM improvements. Additional experiments also show that spanCL is an effective way to utilize generated questions.

1 Introduction

Machine Reading Comprehension (MRC) is an important task in Natural Language Understanding (NLU), aiming to answer specific questions through scanning a given passage(Hermann et al., 2015; Cui et al., 2016; Rajpurkar et al., 2018). As a fundamental NLU task, MRC also plays an essential role in many applications such as question answering and dialogue tasks (Chen et al., 2017; Gupta et al., 2020; Reddy et al., 2019). With the rapid development of pre-trained language models (PLMs), there is also a paradigm shift (Schick and Schütze, 2020; Dai et al., 2020; Sun et al., 2021) reformulating other NLP tasks (e.g. information extraction) into MRC format, especially for open-domain scenarios (Li et al., 2019; Yan et al., 2021a).

In most of the application scenarios, there exists a hypothesis that only answerable questions can be asked, which is somehow unrealistic and unreasonable. Thus, the model that is capable of distinguishing unanswerable questions is more welcomed than the model that can only give plausible answers (Rajpurkar et al., 2018). However, the challenge, that a slight literal change may transfer answerable questions into unanswerable ones, makes MRC models hard to gain such capability(Rajpurkar et al., 2018). For example, in Figure 1, the original answerable question becomes unanswerable by only replacing `Twilight` with `Australian`, but the small literal modification towards paraphrasing does not change the answer. Recent MRC models which predict answers using context-learning techniques and type-matching heuristics are not easy to perceive such subtle but crucial literal changes(Weissenborn et al., 2017; Jia and Liang, 2017). If different questions share many words in common, these models are most likely to give them the same answer, i.e., `2005` may be answered for all the three questions in Figure 1.

Passage:
The Legend of Zelda: Twilight Princess (Japanese: ゼルダの伝説 トワイライトプリンセス, Hepburn: Zeruda no Densetsu: Towairaito Purinsesu?) is an action-adventure game developed and published by Nintendo for the GameCube and Wii home video game consoles. It is the thirteenth installment in the The Legend of Zelda series. Originally planned for release on the GameCube in November ***2005***, Twilight Princess was delayed by Nintendo to allow its developers to refine the game, add more content, and port it to the Wii. The Wii version was released alongside the console in North America in November 2006, and in Japan, Europe, and Australia the following month. The GameCube version was released worldwide in December 2006.[b]

Original Question:
What year was the Legend of Zelda:***Twilight*** Princess originally planned for release?

Question Distortion:
What year was the Legend of Zelda: ***Australian*** Princess originally planned for release?

Question Paraphrase:
When was the legend of Zelda: ***Twilight*** Princess originally planned to be released?

Figure 1: Question Distortion and Question Paraphrase are derived by slightly changing Original Question.

To address the aforementioned challenge, we propose a span-based method of Contrastive Learning (spanCL) in this paper. By explicitly contrasting answerable questions with their paraphrases and their distortions, MRC models are forced to recognize the subtle but crucial literal changes. Using pre-trained language model (PLM) as encoder, most contrastive learning methods adopt `[CLS]` as

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1292 - 1300
July 10-15, 2022

the sentence representation (Luo et al., 2020; Wu et al., 2020; Gao et al., 2021; Yan et al., 2021b; Wang et al., 2021). However, in this problem, as the differences between contrastive questions are very subtle, `[CLS]` is inadequate to capture such small changes. To solve the challenge, we propose a novel learning method, which incorporates the comparative knowledge between answerable and unanswerable questions, and exploits the semantic information of answer spans to improve the sentence representation. Overall, our contributions are summarized as two folds:

- To improve MRC model's capability of distinguishing unanswerable questions, we propose a simple yet effective method called spanCL, which teaches the model to recognize crucial semantic changes from slight literal differences.
- Comprehensive experiments show that spanCL can yield substantial performance improvements of baselines. We also show that spanCL is an effective way to utilize generated questions.

2 Related Work

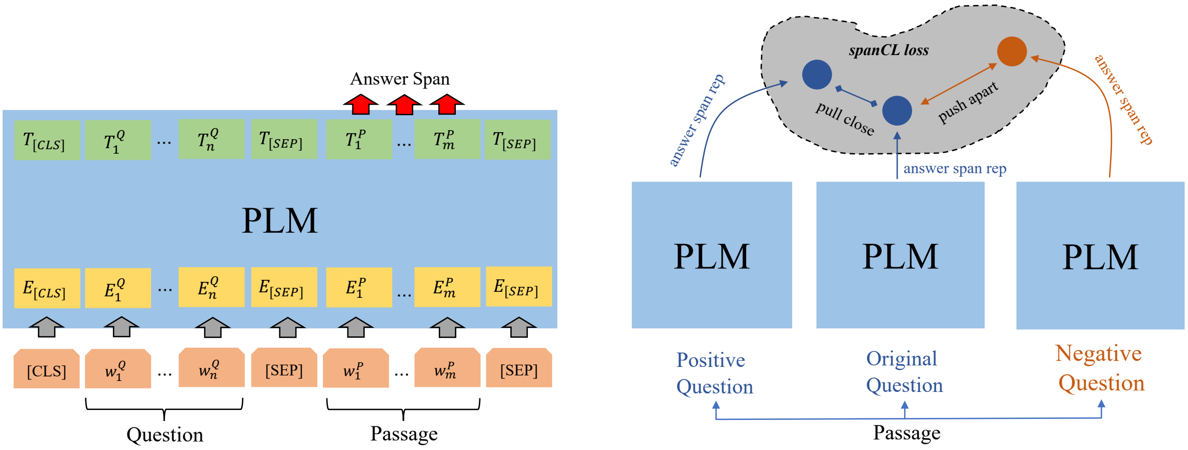
Models for MRC. With the help of various large-scale reading comprehension datasets (Hermann et al., 2015; Hill et al., 2015; Trischler et al., 2016; Rajpurkar et al., 2016; Lai et al., 2017; Rajpurkar et al., 2018), neural networks have achieved a great success on MRC in recent years. At first, these models are typically designed with a LSTM (Hochreiter and Schmidhuber, 1997) or CNN (LeCun et al., 1998) backbone, based on word embeddings (Mikolov et al., 2013; Pennington et al., 2014), leveraging various attention mechanisms to build interdependent representations of passage and question (Kadlec et al., 2016; Dhingra et al., 2016; Cui et al., 2016; Seo et al., 2016). Recently, pre-trained language models (PLMs) made a profound impact on NLP tasks (Radford et al., 2018; Devlin et al., 2018; Yang et al., 2019a; Liu et al., 2019; Lan et al., 2019; Clark et al., 2020; Brown et al., 2020; Fedus et al., 2021). With millions, billions even trillions of parameters, PLMs show a great capacity of capturing contextualized representations, and significantly boost the performance of MRC models.

MRC with Unanswerable Questions. Knowing what you do not know is a crucial aspect of model intelligence (Rajpurkar et al., 2018). In the field of MRC, a model should abstain from answering when no answer is available to the question. To deal with unanswerable questions, previous researchers mostly focused on designing a powerful answer verification module (Clark and Gardner, 2017; Liu et al., 2018; Kundu and Ng, 2018; Hu et al., 2019). Recently, a double checking strategy is proposed, in which an extra verifier is adopted to rectify the predicted answer (Hu et al., 2019; Back et al., 2019; Zhang et al., 2020a,b). Besides the idea of designing verification modules, some other studies try to solve the problem through data augmentation, namely to synthesize more QA pairs (Yang et al., 2019b; Alberti et al., 2019; Zhu et al., 2019b; Liu et al., 2020).

Contrastive Learning. To obtain rich representations of texts for down-stream NLP tasks, there have been numerous investigations of using contrastive objectives on strengthening supervised learning (Khosla et al., 2020; Gunel et al., 2020) and unsupervised learning (Chen et al., 2020; Gao et al., 2021) in various domains (He et al., 2020; Lin et al., 2020; Iter et al., 2020; Kipf et al., 2019). The main idea of contrastive learning (CL) is to learn textual representations by contrasting positive and negative examples, through concentrating the positives and alienating the negatives. In NLP tasks, CL is usually devoted to learning rich sentence representations (Luo et al., 2020; Wu et al., 2020), and the main difference between these methods is the approach to find positive and negative examples. Wang et al. (2021) argued that using hard negative examples in CL is helpful to improve the semantic robustness and sensitivity of pre-trained language models. Enlightened by the promising effects of CL, Kant et al. (2021) proposed to use CL in visual question answering. He focused on playing CL on MRC by comparing multiple answer candidates, but neglected the fact that not all questions can be answered through a given paragraph.

3 Approach

In this section, we first introduce the task of Machine Reading Comprehension with Unanswerable Questions (MRC-U). Then, a baseline MRC model based on PLM is described. At last, we propose a span-based contrastive learning method for MRC-U, named as spanCL. In this paper, question paraphrase and positive question, question distortion and negative question are used interchangeably.



(a) Base Model

(b) Span-based Contrastive Learning

Figure 2: (a) The baseline model for MRC-U. (b) Span-based contrastive learning on answer-span representation.

3.1 Task Description

In this paper, we focus on studying extractive MRC, in which the expected answer of a question is a word span of a given passage. Thus, given a textual question Q and a textual passage P, our goal is to find the answer span (y_s, y_e) to Q in P, where y_s is the answer start position in P and y_e is the answer end position in P.

3.2 Basic MRC Model

We use the model same as Devlin et al. (2018) as the basic model for MRC-U task. When a question and a passage are input, if the question is answerable, the model is expected to give a legal answer span (y_s, y_e) in the passage; if the question is unanswerable, the model is expected to output the `[CLS]` span $(0, 0)$, which indicates no related answer can be found in the passage. The overall structure of the network is presented in Figure 2.

For illustration, we denote the output of PLM's last layer as the sequence representation, $\boldsymbol{H} \in \mathbb{R}^{l \times d}$, where l is the sequence length and d is the dimension. Accordingly, the hidden representation of the i-th token in the sequence is denoted as $\boldsymbol{h}_i \in \boldsymbol{H}$. To find the start position of an answer, a start weight vector $\boldsymbol{w}_s \in \mathbb{R}^d$ is introduced to calculate the beginning possibility of each position. Formally, the probability that the answer starts at the i-th token is defined as

$$p_i^s = \frac{\exp(\boldsymbol{h}_i \cdot \boldsymbol{w}_s)}{\sum_{j \leq l} \exp(\boldsymbol{h}_j \cdot \boldsymbol{w}_s)}. \tag{1}$$

Similarly, with a end weight vector $\boldsymbol{w}_e \in \mathbb{R}^d$, the probability that the answer ends at the i-th token is defined as

$$p_i^e = \frac{\exp(\boldsymbol{h}_i \cdot \boldsymbol{w}_e)}{\sum_{j \leq l} \exp(\boldsymbol{h}_j \cdot \boldsymbol{w}_e)}. \tag{2}$$

For learning, the cross-entropy loss on identifying the answer start and end positions is taken as the training objective as

$$\mathcal{L}_{span} = -\log(p_{y_s}^s) - \log(p_{y_e}^e), \tag{3}$$

where y_s and y_e are the start and end positions of the true answer span. With the learnt model, the output answer span (y_s', y_e') is predicted according to

$$(y_s', y_e') = \arg\max_{(i,j)|i \leq j} \boldsymbol{h}_i \cdot \boldsymbol{w}_s + \boldsymbol{h}_j \cdot \boldsymbol{w}_e. \tag{4}$$

3.3 Span-based Contrastive Learning

In this section, spanCL is introduced from two aspects. First, considering the contrastive idea of CL, we give the details about how the positive and negative examples are generated. Second, the training objective of spanCL is presented.

Positive Examples. In our method, we define the positive examples as the questions which have slight literal differences but the same answers with their original questions. Back Translation is an effective data augmentation method (Xie et al., 2019; Zhang et al., 2017; Zhu et al., 2019a), in which a text is first translated to a target language (e.g. France) from its source language (e.g. English), and then back translated to the source language. The final back-translated text is taken as the example of augmentation. Thanks to Back Translation, the produced examples are lexically different

Strategy	Example
Negation	Original question: What was Beyonce's role in Destiny's Child? Negative question: What wasn't Beyonce's role in Destiny's Child?
Entity replacement	Original question: What native people lived in the San Diego area before the Europeans arrived? Negative question: What native people lived in the San Diego area before the Mexicans arrived?
Antonym	Original question: What part of Gothic buildings are often found terminated with enormous pinnacles? Negative question: What other part of Gothic buildings are often found terminated with small pinnacles?

Table 1: Strategies used to generate negative questions.

but semantically same with the original example. Specifically, for each question, we first produce three question paraphrases by Back Translation using three languages. Then we select the question that has the most literal differences with the original question as the positive question.

Negative Examples. In our method, we define the negative examples as the questions which have slight literal differences and not the same answers with their original questions. Three simple strategies are adopted to produce negative examples as the following.

- **Negation**. A negation word is inserted or removed from the original question.
- **Antonym**. First, spaCy [1] is utilized to conduct segmentation and POS for the original question. Then, one of the words (verbs, nouns, adjectives, or adverbs) are randomly replaced with its antonym.
- **Entity Replacement**. With an answerable question, one of its entity words is randomly placed with another entity word, which has the same entity type but does not appear in any questions.

Table 1 shows several negative examples derived by these strategies. Note that question generation is not the main topic of this paper.

Span-based Contrastive Learning. Using PLM as the encoder, `[CLS]` usually serve as the sentence representation in CL (Gao et al., 2021; Wang et al., 2021; Yan et al., 2021b). When the difference between the original question and its paraphrase or distortion is very subtle, a single `[CLS]` token is not adequate to capture the difference, making the model hard to answer such question. Therefore, we propose to improve MRC models by contrasting these questions according to their answer-span representations. Specifically, given a question Q_{org} and its answer span (y_s, y_e), through the augmentation methods mentioned previously, we synthesize one positive question Q_{pos} and one negative question Q_{neg}. Based on the definition of positive examples and negative examples, (y_s, y_e) is the answer span to both Q_{pos} and Q_{org} but not to Q_{neg}. Denote $\boldsymbol{h}_{y_s}^{Q_{org}}$ and $\boldsymbol{h}_{y_e}^{Q_{org}}$ as the representation vectors of the y_s-th token and y_e-th token in the input passage P for the question Q_{org}, $\boldsymbol{h}_{y_s}^{Q_{pos}}$ and $\boldsymbol{h}_{y_e}^{Q_{pos}}$ as those for Q_{pos}, and $\boldsymbol{h}_{y_s}^{Q_{neg}}$ and $\boldsymbol{h}_{y_e}^{Q_{neg}}$ as those for Q_{neg}. The concatenation of $h_{y_s}^{Q_{org}}$ and $\boldsymbol{h}_{y_e}^{Q_{org}}$ is used as the answer-span representation to Q_{org} and denoted as $\boldsymbol{z}^{Q_{org}}$. Similarly, the answer-span representation to Q_{pos} and Q_{neg} are denoted as $\boldsymbol{z}^{Q_{pos}}$ and $\boldsymbol{z}^{Q_{neg}}$ respectively. Then, our span-based contrastive loss is calculated as

$$\mathcal{L}_{spanCL} = -\log \frac{\exp(\Phi(\boldsymbol{z}^{Q_{org}}, \boldsymbol{z}^{Q_{pos}})/\tau)}{\exp(\Phi(\boldsymbol{z}^{Q_{org}}, \boldsymbol{z}^{Q_{pos}})/\tau)) + \exp(\Phi(\boldsymbol{z}^{Q_{org}}, \boldsymbol{z}^{Q_{neg}})/\tau))} \tag{5}$$

where $\Phi(\boldsymbol{u}, \boldsymbol{v}) = \boldsymbol{u}^\top \boldsymbol{v} / \|\boldsymbol{u}\| \|\boldsymbol{v}\|$ computes similarity between $\boldsymbol{u}$ and $\boldsymbol{v}$ and $\tau > 0$ is a scalar temperature parameter. With the definition, the final objective loss of our method is presented as the following:

$$\mathcal{L} = \lambda_1 \mathcal{L}_{span} + \lambda_2 \mathcal{L}_{spanCL}. \tag{6}$$

4 Experiments

4.1 Datasets and Metrics

We evaluate our method on the well-known dataset SQuAD 2.0 (Rajpurkar et al., 2018), which covers the questions of SQuAD1.1 (Rajpurkar et al., 2016) with new unanswerable questions written adversarially by crowdworkers to imitate the answerable ones. Moreover, for each unanswerable question, a

---

[1] https://github.com/explosion/spaCy

plausible answer span is annotated, which indicates the incorrect answer obtained by type-matching heuristics. The training dataset contains 87k answerable and 43k unanswerable questions, and half of the examples in the development set are unanswerable.

Two official metrics are used to evaluate the model performance on SQuAD 2.0: Exact Match (EM) and F1. EM is used to compute the percentage of predictions that match ground truth answers exactly. F1 is a softer metric, which measures the average overlap between the prediction and ground truth answer at token level.

4.2 Experimental Setup

MRC Model. We adopt the model introduced in 3.2 with various PLM encoders for the MRC-U task. Bert (Devlin et al., 2018), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2019) are selected in our experiments. We download the pre-trained weights from Hugging Face[2].

Training Data Construction. For each original answerable question, we use Back Translation to generate its paraphrase. In SQuAD 2.0, we can find the negative questions for 18,541 answerable questions in the original dataset. For the rest 68,280 answerable questions, we use our augmentation strategies to generate negative questions.

During our training, the span loss is calculated based on Q_{org} and Q_{neg}. In section 4.3, we will explain why Q_{pos} is discarded for calculating span loss.

Hyper-parameters. We use the default hyper-parameter settings for the SQuAD 2.0 task. Specifically, we set maximum sequence length, doc stride, maximum query length and maximum answer length to 512, 128, 64 and 30. For fine-tuning our model, we set the learning rate, batch size, training epoch and warm-up rate to 2e-5, 12, 2 and 0.1. The temperature in spanCL is set to 0.05. The weights of span loss and spanCL loss are $\lambda_1 = \lambda_2 = 0.5$. For each time, we fix the random seed, ensuring our results are reproducible. We run our experiments on two Tesla A100 40G GPUs with 5 GPU hours to train a model.

4.3 Main Results

From Table 2, we notice that spanCL improves the performance of each baseline model, yielding 0.86~2.14 absolute EM improvement and 0.76~2.0 absolute F1 improvement, demonstrating spanCL is model-agnostic and effective.

Model	**Dev**		**Δ**	
	EM	**F1**	**EM**	**F1**
BERT$_{base}$	73.37	76.34	-	-
+ spanCL	75.51	78.34	+2.14	+2.00
BERT$_{large}$	78.88	81.85	-	-
+ spanCL	79.76	82.61	+0.88	+0.76
RoBERTa$_{base}$	78.85	81.42	-	-
+ spanCL	80.18	82.84	+1.33	+1.42
RoBERTa$_{large}$	86.12	88.88	-	-
+ spanCL	86.98	89.70	+0.86	+0.82
ALBERT$_{base}$	77.84	81.27	-	-
+ spanCL	79.52	82.97	+1.68	+1.7
ALBERT$_{large}$	79.99	83.27	-	-
+ spanCL	81.51	84.67	+1.52	+1.4

Table 2: Results (%) on the dev set of SQuAD 2.0.

Model	**EM**		**Dev**	
	HasAns	**NoAns**	**EM**	**F1**
BERT$_{base}$	70.31	74.76	73.37	76.34
+ pos	**72.57**	68.93	72.26	75.22
+ neg	67.05	**87.74**	74.02	76.38
+ pos&neg	66.16	78.48	72.59	75.37
+ spanCL	72.52	75.91	**75.51**	**78.34**

Table 3: Training with spanCL vs Training with expanded datasets.

As additional training data (i.e. the extra positive and negative questions) is used, it is necessary to analyze if the improvements are merely brought by this additional data. We conduct experiments by training with different datasets and display the results in Table 3. BERT$_{base}$ means training BERT$_{base}$ with original SQuAD 2.0 training set. "+pos" and "+neg" mean expanding the original training set with generated positive questions and generated negative questions respectively. Surprisingly, Simply expanding the training set can not guarantee the performance improvement. We find that adding positive examples into the training set does not improve the performance of MRC model. One possible reason is that the positive questions make the model over insensitive and ignore slight literal changes, which is inappropriate for MRC-U task. By comparing BERT$_{base}$ with "+neg", we find that training with more negative examples, the model tends to predict more `NoAns` and achieve a high performance on `NoAns`, while the performance on the `HasAns` drops a lot and the overall improvement of EM is much less than "+spanCL". From the results in Table 3, we can conclude that spanCL is effective to utilize the generated questions.

---

[2] https://huggingface.co/bert-base-uncased

Model	EM	F1
BERT$_{base}$	73.37	76.34
+ CRQDA (Liu et al., 2020)	75.80	78.70
+ spanCL with simple negatives	75.51	78.34
+ spanCL with CRQDA	**76.12**	**79.09**

Table 4: Performance of spanCL with different synthetic negative questions.

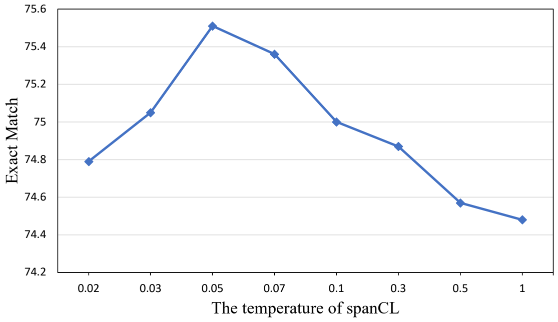


Figure 3: The influence of different temperatures in spanCL. The best performance is achieved when the temperature is set to 0.05. BERT$_{base}$ is adopted as the base model.

4.4 Influence of Negative Examples

The unanswerable questions generated by our strategies are rather plain. We believe spanCL can further boost the performance by high-quality unanswerable questions. Liu et al. (2020) proposed a context-relevant generation method called CRQDA, which generates delicate negative questions [3]. In table 4, "+CRQDA" denotes training the baseline model with the dataset including the delicate negative questions generated by CRQDA. "+spanCL with simple negatives" denotes applying spanCL with negative questions generated by our three strategies. "+spanCL with CRQDA" denotes applying spanCL with negative questions generated by CRQDA. Comparing "+spanCL with simple negatives" with "+spanCL with CRQDA", we find that spanCL can further boost the performance by delicate negative questions.

4.5 Influence of Temperature

The temperature τ in spanCL loss (Equation 5) is used to control the smoothness of the distribution normalized by the softmax operation. A large temperature smoothes the distribution while a small temperature sharpens the distribution. As shown in the Figure 3, spanCL is sensitive to the temperature value. In general, small temperature results in better performance. A practical temperature can be obtained within a small range (from about 0.02 to 0.1). We select 0.05 as the temperature in our experiments.

Model	EM	F1
BERT$_{base}$	73.37	76.34
+ spanCL	**75.51**	**78.34**
+ CL with [CLS] reps	74.18	77.05
+ CL with span and [CLS] reps	73.82	76.86

Table 5: Results (%) with different question representations used in the contrastive learning.

Base Model	Training schemes	EM	F1
BERT$_{base}$	Joint	**75.51**	**78.34**
BERT$_{base}$	Alternate	74.67	77.08
BERT$_{base}$	pre-train then finetune	72.19	74.87
BERT$_{large}$	Joint	**79.76**	**82.61**
BERT$_{large}$	Alternate	79.50	82.55
BERT$_{large}$	pre-train then finetune	77.77	80.30

Table 6: Results (%) with different training schemes.

4.6 Selection of Question Representations

In this paper, we argue that the answer span representation is better than `[CLS]`. We conduct experiments with different question representations in this section. When applying CL with `[CLS]` representations, we add a classification layer on the top of `[CLS]` to determine if a question is answerable or not (Zhang et al., 2020b), making the representation of `[CLS]` acquire the information of the question's answerability. We also play CL with both `[CLS]` and answer-span representations, in which two CL losses are calculated together. From Table 5, we can see that `CL with [CLS] reps` improves the model performance but the improvement is small than that from spanCL, and the combination of the two CL losses can confuse the model and result in a little improvement.

4.7 Comparison between Different Training Schemes

There are three training schemes to combine the span loss and spanCL loss: 1) joint training, in which these two losses are used together in each training step; 2) alternate training, in which the model is updated with spanCL loss after every M updates with span loss; 3) pre-train and fine-tune, in which we first pre-train the model with spanCL loss and then fine-tune it with span loss. For alternate training, we select M from $\{1, 2, 3\}$ and find $M = 2$ gives the best results. From Table

---

[3] https://github.com/dayihengliu/CRQDA

Passage: The Normans (Norman: Nourmands; French: Normands; Latin: Normanni) were the people who in the 10th and 11th centuries gave their name to ***Normandy***, a region in France. They were descended from Norse (\"Norman\" comes from \"Norseman\") raiders and pirates from Denmark, Iceland and Norway who, under their leader Rollo, agreed to swear fealty to King Charles III of West Francia.

....

The Norman dynasty had a major ***political, cultural and military*** impact on medieval Europe and even the Near East. The Normans were famed for their martial spirit and eventually for their Christian piety, becoming exponents of the Catholic orthodoxy into which they assimilated. They adopted the Gallo-Romance language of the Frankish land they settled, their dialect becoming known as Norman, Normaund or Norman French, an important literary language.

Question: What is France a region of ?

Answer from baseline: Normandy ✗

Answer from baseline+spanCL: no answer ✅

Question: What type of major impact did the Norman dynasty have on modern Europe ?

Answer from baseline: political, cultural and military ✗

Answer from baseline+spanCL: no answer ✅

Figure 4: Qualitative Examples.

6, we conclude that joint training gives the best performance and alternate training performs a little worse. Surprisingly, with the pre-train and fine-tune training scheme, the model performs worse than the baseline model. We guess this is because without the supervision of answer-span knowledge, it is hard to learn useful question representations.

4.8 Qualitative Analysis

We qualitatively analyze two representative unanswerable questions in Figure 4. It can be seen that the baseline model predicts a plausible answer for each question while the baseline model trained with spanCL abstain from answering.

To correctly answer the first question, the model is asked to learn the question's semantics in sentence level. To correctly answer the second question, the model is asked to recognize the literal change in word level. SpanCL can help the model perceive such crucial differences between the question and passage from both semantic and lexical aspects, and thus enable the baseline model to abstain from answering for these two questions.

5 Conclusion

In this paper, we propose a span-based method of Contrastive Learning (spanCL) to solve the MRC task with Unanswerable Questions. SpanCL is devised based on the fact that an answerable question can become unanswerable with slight literal changes. By explicitly contrasting an answerable question with its paraphrase and distortion at the answer span level, MRC models can be taught to perceive subtle but crucial literal changes. Experimental results demonstrate that spanCL is model-agnostic and can improve MRC models significantly. Additional experiments show that spanCL is more effective to utilize the generated questions than other methods. In addition, it should be noticed that how to generate high-quality question examples is not fully investigated in this paper, which may introduce a performance bottleneck to spanCL. Therefore, a study on question generation compatible with spanCL is encouraged in the future.

Abstract

Target-guided response generation enables dialogue systems to smoothly transition a conversation from a dialogue context toward a target sentence. Such control is useful for designing dialogue systems that direct a conversation toward specific goals, such as creating non-obtrusive recommendations or introducing new topics in the conversation. In this paper, we introduce a new technique for target-guided response generation, which first finds a bridging path of commonsense knowledge concepts between the source and the target, and then uses the identified bridging path to generate transition responses. Additionally, we propose techniques to re-purpose existing dialogue datasets for target-guided generation. Experiments reveal that the proposed techniques outperform various baselines on this task. Finally, we observe that the existing automated metrics for this task correlate poorly with human judgement ratings. We propose a novel evaluation metric that we demonstrate is more reliable for target-guided response evaluation. Our work generally enables dialogue system designers to exercise more control over the conversations that their systems produce.[1]

1 Introduction

Open-domain conversational systems have made significant progress in generating good quality responses driven by strong pre-trained language models (Radford et al., 2019; Devlin et al., 2019) and large-scale corpora available for training such models. However, instead of passively responding to a user, dialogue systems can take on a more proactive role to make recommendations, help users discover new services, or introduce interesting new topics to users to improve user experience. Furthermore, a proactive or target-guided system can guide the conversation towards safer conversational topics in case a conversation goes awry or a user becomes abusive towards the system, and direct the users towards topic areas that the system knows how to talk about. Prior work has used mechanisms such as emotion labels (Zhong et al., 2019), persona (Song et al., 2019), and politeness (Niu and Bansal, 2018) to control conversations. However, such approaches require labeled training data for a set of pre-determined labels, making it harder to incorporate new goals into a system. In this work, we study the problem of proactive response generation based on a target sentence. For example in Figure 1, given the context ‘I enjoy swimming’, the system guides the conversation towards the target ‘I like to travel to new places’ by mentioning ‘I like to swim at beaches when I go on vacation’. Using target sentences for proactive control is an intuitive and flexible control mechanism for dialogue developers, free of domain-specific handcrafting and annotations.

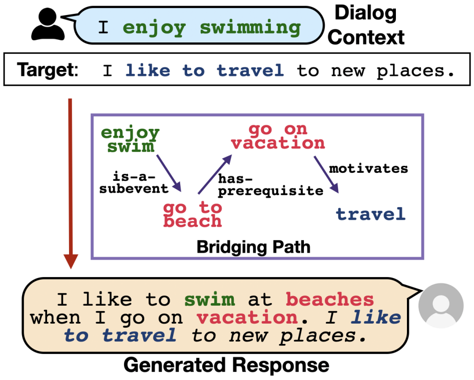

Figure 1: Given a dialogue context and a target sentence, our goal is to generate a dialogue response that smoothly transitions the conversation from context towards the target. Our proposed approach involves identifying a bridging path of entities to link the context and the target.

Existing publicly available dialogue corpora generally consists of free-flow conversations where the speakers move the conversation forward based on the dialogue history alone, with no particular agenda. We build upon the recently released *Otters*

dataset (Sevegnani et al., 2021) with one-turn topic transitions for mixed-initiative in open-domain conversations. Given a source sentence from a speaker, the task is to generate a topic transition sentence with "bridging" strategies to a target sentence from another speaker. The task is challenging on several fronts. First, the system needs to balance the trade-off between coherence with the context while smoothly transitioning towards the target. Second, the Otters training dataset is relatively small (less than 2000 training instances), making it a low-resource setting. Finally, we show that standard word-overlap metrics are insufficient for this task.

In this work, we propose methods to leverage commonsense knowledge from ConceptNet (Speer et al., 2017a) to improve the quality of transition responses. Our technique decomposes the response generation process into first generating explicit commonsense paths between the source and target concepts, followed by conditioning on the generated paths for the response generation. This is intended to mimic how humans might bridge concepts for creating transitions in conversations using commonsense knowledge. This technique offers two benefits: 1) Leveraging external ConceptNet knowledge solves the data scarcity issue and improves the model's capability to generate logical transitions; 2) Since the transition response is grounded on commonsense knowledge paths, the explicit paths used by the model can provide explanations for the concepts used by the model, as well as provide control over the generation process. Furthermore, we propose a data augmentation mechanism to help with the data scarcity issue by re-purposing training data from DailyDialog, an open-domain dialogue dataset. Both these approaches are complementary and outperform existing baselines in response quality and transition smoothness. We demonstrate how the proposed approach of using explicit bridging paths enables improved quality of transitions through qualitative and human studies.

Automated evaluation is a challenging aspect of dialogue response generation tasks (Zhao et al., 2017). We show that the existing word-overlap metrics such as BLEU can be easily fooled to assign high scores to poor responses just based on high n-gram overlap with reference responses. We propose a metric TARGET-COHERENCE which is trained using hard adversarial negative instances and achieves a high correlation with human judgement ratings of system outputs. As part of this work, we collect and release a dataset of human ratings of various system outputs for this task.

We discuss the broader impact and potential uses of the proposed system, its limitations and potential ethical issues related to this task in Section 8.

2 Related Work

Target Guided Dialogue Response Generation: Sevegnani et al. (2021) is perhaps the closest to our work described in this paper. They work on the task of generating a new utterance which can achieve a smooth transition between the previous turn's topic and the given target topic. Past work in controllable text generation has explored steering neural text generation model outputs to contain a specific keyword (Keskar et al., 2019), a knowledge graph (Wu et al., 2019), or a topic (Ling et al., 2021). Steering dialogue towards a given keyword has also been explored in past work (Tang et al., 2019; Qin et al., 2020a; Zhong et al., 2021), albeit as a retrieval task. In contrast, our goal is to generate a next utterance in a dialogue setup which can steer a conversation towards target sentence in a smooth fashion rather than generating a response for a given keyword or topic. Our work is also related to prior work on text infilling (Donahue et al., 2020; Qin et al., 2020b), though compared to them we work in a dialogue setup and utilize commonsense knowledge to perform the infilling.

Commonsense for Dialogue Generation: Commonsense knowledge resources (Speer et al., 2017b; Malaviya et al., 2020) have been used in dialogue response generation for tasks such as persona-grounded dialogue (Majumder et al., 2020) and open-domain dialogue generation (Ghazvininejad et al., 2018; Hedayatnia et al., 2020; Zhou et al., 2021c). Zhou et al. (2021a) created a dataset focusing on social commonsense inferences in dialogue and Arabshahi et al. (2020) designed a theorem prover for if-then-because reasoning. A concurrent work (Zhou et al., 2021b) proposed to train a model to explicitly generate implicit knowledge and use this knowledge to generate a response. Compared to their work, we focus on target-guided response generation, suggest mechanism for knowledge alignment with the transition response during training, and focus on multi-hop knowledge paths. More broadly, commonsense knowledge has been used in text generation tasks such as story and essay generation (Guan et al., 2019a; Yang et al., 2019).

Automated Metrics for Evaluating Dialogue Quality: Automated metrics such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and BertScore (Zhang et al., 2020) are widely used to evaluate quality of machine-generated text. However, such metrics often correlate poorly with human judgement ratings of generated text quality (Sai et al., 2020). Past work has explored trained model-based metrics such as ADEM (Lowe et al., 2017) and RUBER (Tao et al., 2017). However, training such model-based metrics often relies on tagged training data. Gupta et al. (2021a) propose ways to mitigate the need for such labelled data by automatically synthesizing negative examples. Our proposed metric is along similar lines, though we utilize different techniques for synthetic negative example generation.

3 Task Overview

We first formalize the task of target-guided response generation. Given a conversation context c between two speakers A and B, and a target utterance t for speaker B, the task is to generate a transition sentence s which serves as a smooth link between the context and the target. The target is a phrase or a sentence. *Otters* dataset (Sevegnani et al., 2021) consists of a simplified setting of one-turn topic transitions, where the conversation history consists of a single utterance u_a from speaker A, and a target utterance u_b for speaker B, and the task is to generate a transition utterance s for speaker B to serve as a smooth link between u_a and u_b. The task is challenging since a system needs to devise a strategy that balances the competitive objectives of generating a response which is coherent to the context, while smoothly driving the conversation towards the target.

In this work, we propose two approaches for the transition response generation task: 1) Commonsense-guided response generation (section 4), and 2) Data augmentation to tackle data sparsity (section 5). We refer to the proposed method as **CODA (Commonsense Path and Data Augmentation)**. We also propose a novel metric TARGET-COHERENCE to automatically evaluate the smoothness of response transitions (section 6).

4 Commonsense-Guided Response Generation

We frame the target-guided response generation task as follows. Given a conversation context c and a target t, a conditional language model learns to predict the transition response s. Target-guided generation can potentially benefit by incorporating commonsense reasoning by identifying rich connections between a pair of entities which enable us to generate logical transition responses connecting the two. Pre-trained language models are known to suffer in cases where commonsense knowledge is required during generation (Zhou et al., 2018; Guan et al., 2019b), especially in tasks where there is not enough data available for learning commonsense patterns from the text, which is true for our case. In contrast, Commonsense Knowledge Graphs like ConceptNet (Speer et al., 2017a) provide structured knowledge about entities, which enables higher-level reasoning about concepts.

In this work we use commonsense knowledge from ConceptNet for planning a transition response. ConceptNet is a large-scale semantic graph that has concepts as nodes and has commonsense relationships between them, such as 'IsA' and 'AtLocation'. However, ConceptNet suffers from severe sparsity issues (Malaviya et al., 2020; Bosselut et al., 2019). Therefore, it is not always possible to find the concepts and relationships between context and target concepts. To address the sparsity issue, we develop Knowledge Path Generator (**KPG**), a language model trained on paths sampled from ConceptNet. The model takes a pair of entities or concepts as input and generates a multi-hop path connecting the two. Since the knowledge paths are sampled from a generative model rather than retrieved from a fixed knowledge base, we are no longer limited by the entities and paths present in the ConceptNet knowledge base.

To generate commonsense based responses, we train a Commonsense Response Generator (**CRG**) model to generate the transition response conditioned on the paths generated by the KPG model (**Figure** 2). Conditioning the response generation on commonsense paths improves the reasoning capabilities of the CRG model and provides the added benefits of interpretability and control over the generation process.

4.1 Commonsense path generator

The KPG models attempts to connect a concept or entity phrase from the context to a concept from the target by creating knowledge paths between them.

Path Sampling: To create training data for the KPG models, we sample paths between entity

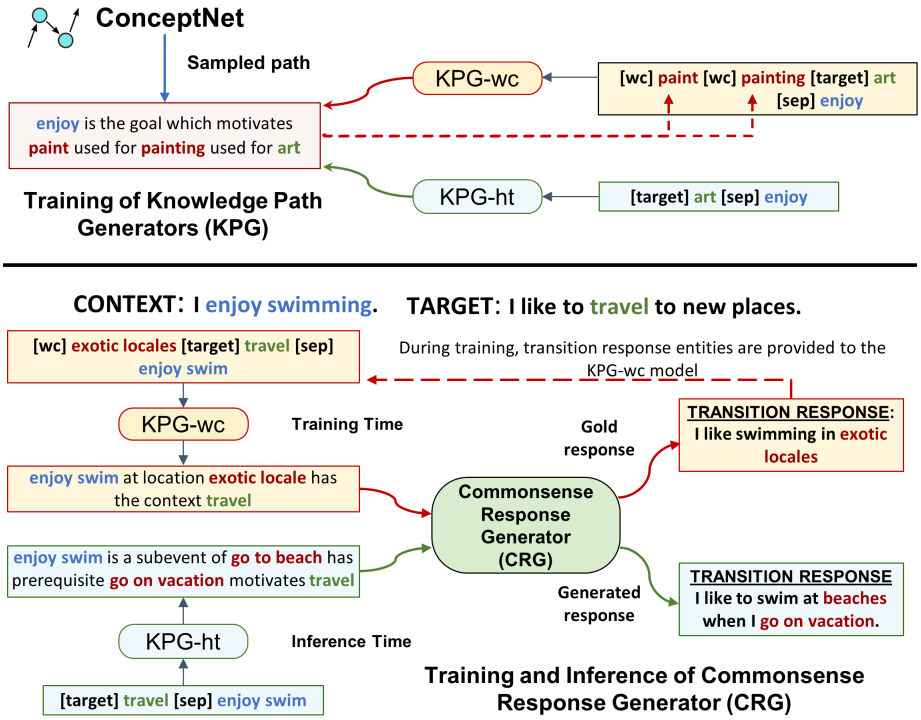

Figure 2: Model illustrations for KPGs - Knowledge Path Generators (top) and CRG - Commonsense Response Generator (bottom). Base architecture for all models is GPT-2. Given a path sampled from ConceptNet, KPG-wc learns to predict the path given the head, tail and intermediate entities of the path while KPG-ht learns to predict the path given only the head and tail entities. For the CRG model, during training, a head entity from the context, a tail entity from the target and intermediate entities from the gold transition response are fed into KPG-wc and its output path is used as input to the CRG model. During inference, a head entity from the context and a tail entity from the target are fed into the KPG-ht model. KPG-ht then generates a path with new concepts such as "go on vacation". CRG model conditions on this path for transition response generation.

phrases from ConceptNet using random walks. This step builds upon past work of Wang et al. (2020). Given nodes N and edges E from ConceptNet, we perform random walks on the graph to sample a set of paths P of the form $p = \{n_0, e_0, n_1, e_1, ..., e_{k-1}, n_k\} \in P$. Here, a path p connects a head entity phrase n_0 with the tail entity phrase n_k via intermediate entities and edges (or relations) n_i, e_i. To sample paths, the random walk begins with a random entity node n_0 and samples a path of random length $k \in \{1, 2, ..., K\}$, where we have set $K = 6$ in this work. To sample paths that are useful for our task, we prevent sampling certain edges types such as *Synonym* (Appendix A.1).

KPG-head-tails (KPG-ht): KPG-ht is a GPT-2 (Radford et al., 2019) based model which is trained to predict a knowledge path p which links a head entity n_h to a tail entity n_t. For a sample path $p = \{n_h, e_0, n_1, e_1, ..., e_{k-1}, n_t\}$ from ConceptNet, the path is formatted into the following sequence "[target] n_t [sep] n_h e_0 n_1 $e_1, \ldots, e_{k-1}$ n_t". KPG-ht is only used during CRG inference where the head entity is extracted from the context and tail entity from the target (Figure 2).

KPG-will-contain (KPG-wc): A large number of possible paths can exist for a given head-tail entity pair. Training the CRG model by conditioning on paths which are irrelevant to the gold transition response might discourage the CRG model from conditioning on the provided commonsense path. Since we do not have gold paths for a response, we instead train a model KPG-wc to generate paths which are more aligned to the gold response by enforcing the generated path to contain entities from the gold response. KPG-wc is trained to predict a path which contains a pre-specified entity set $E_p = \{k_1, ..., k_n\}$ in the generated path by formatting paths sampled from ConceptNet as the following sequence: "[wc] $k1$ [wc] $k2$... [target] n_t [sep] n_h e_0 n_1 $e_1, \ldots, e_{k-1}$ n_t" (Figure 2). The entity set E_p is a randomly permuted sequence of entities $n_1, n_2, \ldots, n_{k-1}$ from the sampled path. Here "wc" symbolizes "will contain". Training with this sequence indicates to the model that the path generated between n_h and n_t should contain the entities from the set E_p in a sensible order. Specifying the special token "[target]" followed by the tail entity n_t informs the model about the last entity it should output when generating a path. We discuss how the set E_p is constructed for CRG model training in the next section.

In practice, we train a single common GPT-2 based model for KPG-wc and KPT-ht. The model at test time is able to generate knowledge paths for either case, whether in-path entities from E_p are present (KPG-wc) in the input or not (KPG-ht).

4.2 Response generator

The Commonsense response generator conditions on the commonsense paths generated from the KPG models to generate the transition responses.

Entity extraction. We extract a set of entities E_h, E_t and E_r from the context, target and gold transition response respectively using NLTK. We designed simple grammar rules (details in Appendix A.1) to convert phrases to concise forms that match the nodes present in ConceptNet, *e.g.*, "watching the star" is converted to "watch stars".

Sampling and filtering paths: In this step, for every pair of head and tail entity from E_h and E_t, we sample multiple paths from the KGP models using topk sampling and chose one or more of these paths for training and inference. *For training* the CRG models with the commonsense paths, we need to curate paths that are relevant to and aligned with the gold response so that they are not ignored by the CRG model during inference. We achieve this by first sampling paths which are relevant to the gold response, and then apply filtering mechanisms to curate the final set of paths. For training data path sampling, we use the *KPG-wc* model (Figure 2). The input to the model is a head and tail entity pair n_h and n_t, and the entity set E_p that consists of the set of entities E_r from the gold transition response. The model then generates a set of paths that contain the head and tail entities as well as the gold response keywords. Thus, the sampled path is inherently relevant to the gold response due to the conditioning on gold keyword entities. *During inference*, the set E_r is not available, so we leverage the *KPG-ht* model that takes just the head and tail entity pair n_h and n_t as input to generate a commonsense path.

Assuming the context and target consists of m and n entities each, and we generate q number of paths per pair, we get a total of $m \times n \times q$ number of paths for each data instance. Since $m \times n \times q$ can be a large number, we use simple methods to sub-select entity pairs and paths. **(1)** Sub-selecting Entity Pairs: We score an entity pair by calculating the inverse document frequencies (computed using Gutenberg English corpus) of the entity tokens and summing up the maximum value found for a token in each entity in the pair. For training phase, we keep the top D pairs of entities, and for testing phase we keep only the highest-scoring pair. **(2)** Sub-selecting paths: We apply the following strategies to prune the set of paths for each entity pair: 1) *Perplexity* - We filter out all the paths whose perplexity values (from the KGP models) are more than double the average perplexity values of all paths between an entity pair. 2) We remove all the paths which have repetition of entities since repetition often leads to degeneration during decoding. 3) For paths in training data, we filter out paths which contain entities not present in the gold response. The final set of paths P are converted into natural language by converting the relation and inverse relations into textual format. For example, "art gallery UsedFor for art" is converted to "art gallery is used for art".

Training and inference in CRG model. The CRG model (GPT-2 based) is trained as a conditional model with the following input sequence: "*knowledge path* [target] *target sentence* [context] *context sentence* [response] *transition response*" for each *knowledge path* from the set P. We train the CRG model by minimizing the log-likelihood loss of the transition response. For inference, we create the set of paths P by entity extraction, path sampling and filtering and choose a random path p from the final set P. The model generates the transition response conditioned on the sequence of c, t, and p.

5 Data Augmentation

The task of target-guided response generation is still a relatively unexplored task, and Otters (Sevegnani et al., 2021) is the only suitable dataset for this task to the best of our knowledge. However, Otters is small and consists of only a few hundred context-target pairs. This makes learning transition concepts and strategies challenging in this low-resource setup. On the other hand, there are many publicly available dialogue datasets for training response generation models. Such datasets contain free-flow conversations, where although the speakers generate context coherent responses, they do not condition their responses on any target. We propose a technique to leverage and re-purpose such datasets for the task of target-guided response generation. We pick the DailyDialog (Li et al., 2017) dataset for experimentation and convert its conver-

Context	the restaurant looks authentic european.
Response	the chef trained in florence. the pasta tastes nice here.
SRL Output	predicate = tastes, arguments= the pasta; nice here
Target clause	the pasta tastes nice here.

Figure 3: An example to demonstrate how a conversation in DailyDialog can be re-purposed for the task of target-guided response generation.

sations to target-guided conversations in two steps: 1) Target creation, and 2) Data filtering.

For *target creation*, we run Semantic Role Labelling (SRL) to predict predicate and arguments in a response. For each predicate identified, we create a clause by putting together the predicate and arguments in a textual sequence. Finally, we only use the clause occurring towards the end of the response as a target. An example for target creation is shown in Figure 3 (More details about clause identification are in Appendix A.2).

The target creation step does not guarantee that a candidate response transitions smoothly towards the target clause. In the *data filtering* step, we introduce a TARGET-COHERENCE metric to score a transition response in terms of its coherence to the context and smoothness towards the target. The metric is described in more detail in section 6. The metric assigns a score between 0-1 for a transition response and we remove instances with a score less than a threshold k (set to 0.7) from consideration. The remaining instances are used for pretraining response generation models which are finally fine-tuned on the Otters dataset.

6 Target-Coherence Metric

Evaluating target-guided responses is a challenging task as a good transition response needs to be both - coherent to the context and smoothly transition towards the target. Furthermore, since the task is open-domain and open-ended, there are many possible correct responses which may not match with a reference response (Çelikyilmaz et al., 2020). To tackle these challenges, we propose an automatic metric for this task that does not use human references. The proposed metric **TARGET-COHERENCE** is based on a classification model trained to classify a transition response as either *positive*, that is, it is coherent to the context and smoothly transitions towards the target, or negative, that is, the response is either not coherent to the context or does not transition towards the target.

POSITIVE Gold c,r,t	CONTEXT c	the restaurant looks authentic european.
	RESPONSE r	the chef trained in florence.
	TARGET t	the pasta tastes nice here.
NEGATIVE Random t’ with gold r,c	TARGET t’	i love to drive my car.
NEGATIVE Random c’ with gold r,t	CONTEXT c’	i enjoy computers and phones.
NEGATIVE Random r’ with gold c,t	RESPONSE r’	there is no parking here.

Figure 4: We train a reference-less model-based metric TARGET-COHERENCE to score the smoothness of a generate response wrt to dialogue context and target sentence. To train the metric, we synthesize hard negative examples using an ensemble of techniques as shown in this figure.

Dataset	Train	Dev	Test
Otters-id	1,929 (693)	1,160 (404)	1,158 (303)
Otters-ood	2,034 (677)	1,152 (372)	1,130 (372)
DailyDialog	11,118	1,000	1,000

Table 1: Overview of the datasets.

We use the gold transition response from the training dataset to create positive instances for training. For a positive instance with context c, target t and response r, we create negative instances using the following mechanisms: 1) We hold two out of (c,t,r) constant while randomly sample the third one. For example, sample a random context c', which makes r incoherent to the c'. An example is shown in Figure 4. 2) We use a GPT-2 model trained on Otters dataset to generate a response r' coherent to c but conditioned on a random target t'. 3) For a target t, we chose a response r' from the Otters training set which has t as the target but context $c' \neq c$. We sample a maximum of 2 negative instance per mechanism and balance the count of positive and negative instances by repeating positive instances. We fine-tune a pre-trained BERT-base (Devlin et al., 2019) model on these instances with binary cross entropy loss.

7 Experiments

7.1 Datasets

We use two datasets in our experiments. 1) Otters (Sevegnani et al., 2021) contains instances with context-target-transition response triplets. It consists of two sets of splits. The Out-Of-Domain (OOD) split ensures that none of the context-target pairs in the test set are present in the train set. In the In-Domain (ID) split, one of either the context or the target in each pair in the test-set is allowed to appear in the train-set. DailyDialog dataset consists of casual conversations between two speakers. In Table 1 we present the number of dialogues in DailyDialog dataset and number of responses in otters, along with number of unique context-target pairs in brackets. Otters dataset consists of multiple responses per context-target pair. Some transition responses in Otters dataset are noisy - they contain sentences and phrases from the target sentences. We remove such data from the test sets (with word overlap 0.75), leaving 1019 data points in the Otters-id test set and 988 data points in the Otters-ood test set.

7.2 Baselines for generation

We report results for a number of baselines. We provide complete implementation details of CODA and all baselines in Appendix A and B.

- **GPT-2:** (Radford et al., 2019) A pretrained GPT–small language model fine-tuned on Otters data. Conditions on the context and target sentences to generate the transition response.
- **GPT2-Fudge** Yang and Klein (2021) uses a discriminator trained to distinguish good response continuations from the poor ones and guides the GPT-2 based decoder towards responses that are coherent to both the source and target sentences.
- **Multigen** (Ji et al., 2020) combines the vocabulary distribution generated by underlying GPT-2 model with a concept distribution from a commonsense knowledge base (ConceptNet).
- **Concept-Predict** leverages a concept prediction strategy from Qin et al. (2020a). The concept is predicted based on closeness to the target.
- **CS-Pretrain** model is pretrained with commonsense paths used for training the KPG models and is based on the commonsense story generation model from Guan et al. (2020).

Ablation experiments: We report results for following CODA variants:

- **CODA-ONLYDA**: CODA variant that uses DailyDialog augmentation and does not use commonsense paths from KPG models in the CRG model.
- **CODA-NODA**: CODA trained without additional data from DailyDialog.
- **CODA-NOEDGE** CODA variant that uses only entities and no edges from the path.
- **CODA-NOALIGN**: variant that relies on only KPG-ht for training and inference. Does not select paths based on alignment with responses.
- **CODA-KBPATH**: variant that retrieves paths directly from ConceptNet using the algorithm proposed in Lin et al. (2019).
- **CODA-Upper** Upper bound for CODA which uses paths inferred from the gold responses using the KPG-wc keywords model during inference.

Metric	Target as response	Context as response	Reference response	Correlation w ratings
BLEU	15.0	9.9	6.5	-0.11
METEOR	14.0	12.6	13.2	0.01
ROUGE-L	32.3	29.8	26.5	-0.04
BS-rec	38.1	38.9	41.3	0.05
BS-F1	42.8	42.6	38.9	-0.06
TARGET-COHERENCE	10.7	4.0	77.4	0.47

Table 2: We present the metric scores when using the target, context and one of the references as the response. All metrics except for TARGET-COHERENCE score the target and context higher than the reference. TARGET-COHERENCE achieves high correlation with human ratings. Underlined values represent statistically significant result with p-value<0.05.

7.3 Evaluation Metrics

We report standard automated metrics such as BLEU (Papineni et al., 2002), ROUGE-L (Lin, 2004), METEOR (Banerjee and Lavie, 2005), and BertScore (BS-rec and BS-F1) (Zhang et al., 2020). Evaluation is carried out using multiple references from the test set. Word-overlap metrics do not correlate well with human judgements (Liu et al., 2016). Additionally, we observe that on this task, even a poor transition response can get a high score on reference-based metrics if it has high overlap with the context or the target. We carry out an experiment where we use the target, context and one of the references as the transition response. An ideal metric would score the reference response high, and give low scores to target and context used as a response. In Table 2, reference-based metrics assign higher scores to target and context sentences used as responses compared to human-written responses. In contrast, TARGET-COHERENCE assigns high scores to reference responses and low scores to target and context sentences.

Correlation of metrics with human judgements: We investigate how well do the metrics correlate with human ratings of system outputs. To perform this analysis, responses from CODA, baselines, as well as reference responses are judged by crowd-source annotators who rate the smoothness of a response given the dialogue context and the target on a scale of 0 to 1. We collect a total of 440 ratings across Otters ID and OOD splits, and report Spearman rank correlation (Spearman, 1961) of the metrics and the ratings. Krippendorff's alpha for

Table 3: We present the results of automatic evaluation based on word-overlap and proposed Target-Coherence. CODA outperforms all the baselines for most of the metrics. We also present results for CODA's model ablations.

annotation is 0.42. Results, shown in last column of Table 2, depict that most standard automated metrics correlate poorly with human ratings, while the, proposed Target-Coherence achieves a very high correlation score of 0.47.

We present the Amazon Mechanical Turk interface for human ratings collection in Figure 5 in the Appendix. The workers were first shown instructions about the task with definitions and examples for all the rating criteria. We paid crowd workers on Amazon's Mechanical Turk platform $0.7 per annotation and gave bonuses to annotators with high annotation quality. Our estimated hourly pay was $13, which is above the minimum US federal hourly wage. We set the worker qualification condition as 1000 HITS completed, 95% or more approval rate and location as native English speaking countries. We release the human ratings and system outputs used for computing the metric correlations as part of this work.

7.4 Results

In this section we present the automatic and human evaluation results. Automated metric results are summarized in Table 3. Although reference-based metrics are lexically biased (subsection 7.3), we still report their scores. We observe that CODA outperforms all the baselines under in-domain (ID) as well as out-of-domain (OOD) setups of Otters data as per Target-Coherence (TC) score. For example, CODA gets a high TC score of 36.7 (ID) and 37.9 (OOD) while the TC scores of the closest baselines GPT2-Fudge, Multigen and Concept-predict are in the range of 28-31, demonstrating that the proposed method leads to significant improvements in response quality. However, CODA is far from reaching human performance (TC 77.4).

CODA Ablations: We observe that: (1) Not using commonsense knowledge (CODA-OnlyDA) leads to large performance drops, highlighting that CODA effectively utilizes commonsense knowledge. (2) Dropping data augmentation leads to a small drop in performance (CODA-NoDA), hinting at relatively small (but still significant) benefit from pretraining the model using data augmentation. (3) Low performance of CODA-NoEdge shows the importance of using edges in commonsense paths. (4) Not aligning and selecting paths based on their relevance to responses during CRG training (CODA-NoAlign) leads to a high drop in performance. (5) CODA outperforms CODA-KBPath by 8% (ID) and 14.5% (OOD). This improved performance can be attributed to the generalizability of entities and paths generated from the KPG models. (6) CODA-Upper achieves high scores, highlighting that further improvement in commonsense path generation component can significantly boost the output quality of CODA.

Criteria	Models	Win	Lose	Tie
Smooth	CODA vs GPT-2	37.5	31.6	31.0
	CODA vs Multigen	32.3	22.8	44.8
Sensible	CODA vs GPT-2	22.0	21.3	56.7
	CODA vs Multigen	25.8	25.6	48.6
Informative	CODA vs GPT-2	32.3	27.3	40.4
	CODA vs Multigen	35.5	27.8	36.7

Table 4: Human evaluation through pairwise comparison between CODA and baselines. CODA is preferred in smoothness and informativeness criteria while being comparably sensible.

Human Evaluation: We conduct human evaluations on Amazon Mechanical Turk to evaluate the quality of generated transition responses. Annotators are requested to evaluate the transition response on following criteria: (1) *Smooth*: rate whether the response serves as a smooth transition between the dialogue context and target. (2) *Sensible*: whether the response makes sense in itself i.e.

Context: i like the sand on my feet
Target: my puppy is called georgie.

GPT-2: My mom likes the water.
Multigen: My pet is the gecko.
CODA: My dog walks along the beach with sand.
CODA-Path: sand is at location beach belongs to walk is desired by puppy

Context: my favorite city is seattle.
Target: i ride my bicycle everywhere.

GPT2: Seattle is my favorite city to go to
Multigen: So what do you do when you go to the seattle
CODA: I bought my bicycle from a bike shop in seattle.
CODA-Path: favorite city is the location which has bicycle shop is a dependency of ride bicycle

Context: i am a server at a food place.
Target: i eat greasy foods.

GPT-2: I eat healthy foods at restaurants.
Multigen: I hate my food.
CODA: I am a server, but I don't want to eat too much.
CODA-Path: server is a person not desires eat greasy food

Table 5: Sample representative model outputs.The knowledge paths used by CODA provide interpretability and control over the response generation process

it is grammatical and logically coherent. (3) *Informative*: how much informative content a response carries. Human annotators compare (or mark as a tie) responses from two models. We collect two annotations for 100 randomly selected data points from the test outputs. Results in Table 4 demonstrate that CODA outputs are preferred over the baselines on 'Smooth' and 'Informative' criteria.

7.5 Qualitative Analysis

We present representative outputs from the models in Table 5. For CODA, we show the path used in response generation. We notice that GPT-2 and Multigen often tend to either generate simple outputs (*e.g.* 'I hate my food' in the last example) or simply repeat or address either the target or the context (*e.g.* 'My pet is the gecko', 'Seattle is my favorite city to go.') which leads to high BLUE and METEOR scores, but low TC scores. CODA avoids these pitfalls as it is conditioned on generated commonsense paths based on both the context and target entities leading to more informative and sensible outputs. However, CODA is susceptible to two issues: 1) Using poor keywords for path generation, and 2) Generation of irrelevant paths (*e.g.* 'server is a person not desires greasy food' in the last example).

Path quality: We conduct a human evaluation study to measure the quality of the generated paths. For randomly selected 100 generated responses, we ask annotators to judge 1) Relevance: Is the path relevant and used in the response? and 2) Makes sense: Does the path makes sense? Results reveal that 79% of the paths were judged to be relevant and 76% of the paths were judged to make sense. Thus in aggregate, the generated knowledge is good in quality, and is used in the generated response.

Path novelty: We analyzed the paths generated by CODA which were judged as sensible by human annotators and found that 26.8% of entities in the paths were not found in ConceptNet. This include entities such as 'favorite food', 'pet kitten', 'single kid' and 'online class'. Thus, the actual paths from the ConceptNet might not be able to cover a large fraction of head/tail entities. Furthermore, 81% of sensible paths are novel and do not exist in ConceptNet. For example, even though the path 'eat motivates go to restaurant has subevent dinner is the location for bread' exist in ConceptNet, the path 'eat motivates go to restaurant has subevent dinner is the location for pizza' does not exist in ConceptNet. Thus we show that CODA can generalize to new entities and paths.

In Appendix C we discuss a human-in-the-loop study for controllability. The human-in-the-loop experiment shows that even minimal human intervention in the form of domain relevant keywords input for knowledge paths can improve the quality and smoothness of the transition responses.

8 Conclusion

In this work, we propose and evaluate models for target-guided response generation using explicit commonsense bridging paths. We also introduce an automated metric to evaluate smoothness of a transition response. We showed that our model generates more smooth and informative outputs through automatic and human evaluation. Furthermore, it allows for more interpretable results. Going forward, we envision a model which could combine target and non-target guided dialogue planning.

Acknowledgments

We thank Maarten Sap and the anonymous reviewers for providing valuable feedback. This work was funded by the Defense Advanced Research Planning Agency (DARPA) under DARPA Grant N6600198-18908, and the National Science Foundation under Award No. IIS1816012. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the funding agencies.

Ethics and Broader Impact

Broader Impact and applications: Our proposed models for target-guided response generation can be used to generate responses based on target sentences that can drive the system's agenda in a conversation. Deploying a target-sentence guided dialogue model needs careful consideration and testing since designating a target sentence for all turns of a conversation might disrupt the natural flow of the conversation. Therefore, they can be deployed alongside existing non-target guided dialogue models that perform free-flow conversations without predesignated targets. At each turn of a conversation, a central system can use the target-coherence metric to decide if the system should generate a target-guided response or a simple follow-up response to the context. Target-guided systems can used for several useful applications such as creating non-obtrusive recommendations, comforting people, recommending new products and services, and introducing interesting new topics and educating users about those topics.

Potential risks and solutions: We wish to raise awareness about potential misuse of proposed systems for persuading users by people with ill intentions. For example, conversational systems can pose as humans and then proactively alter user's perceptions about specific issues, evaluations of products or services, or political inclinations. To circumvent such issues, it is necessary to improve transparency through regulations, such as informing the users that they are conversing with a bot and not a human. Regulations are necessary to avoid hazardous outcomes during deployment for specific domains. For example, European Union's regulatory framework proposal on artificial intelligence[2] defines use of AI systems for "educational or vocational training, that may determine the access to education and professional course of someone's life" as high risk. Anyone who uses or builds upon our system should comply with such regulations. Apart from regulations, recent safety and ethics related research and datasets (Baheti et al., 2021; Sun et al., 2021) in conversational AI can help in mitigating aforementioned issues. Henderson et al. (2018) and Dinan et al. (2021) highlight and discuss potential ethical and safety issues that arise in dialogue systems research. Xu et al. (2020) provides a review of recent methods that try to mitigate safety issues in open-domain dialogue generation which can be utilized for the target-guided response generation task.

Limitations and potential biases: Current conversational systems suffer from several limitations, such as, they are not good at human qualities such as empathy, morality, discretion and factual correctness. There is a risk that a target driven system would ignore these factors to achieve the target. Therefore more research is needed to equip bots with such qualities. Our models are trained on existing datasets such as Otters and DailyDialog, and also leverage external commonsense knowledge resources. Knowledge graphs such as ConceptNet have been found to contain biases and have weak representations of moral common sense knowledge (Hulpuș et al., 2020; Mehrabi et al., 2021). While grounding on knowledge paths from knowledge graphs can provide insights and explanations about the model's reasoning, our models could potentially inherit biases present in these data sources. Advancements in adding a moral dimension to KGs, and extending them with intuition of morality (such as crime is bad), can enable generation of morally correct knowledge paths. Furthermore, imbuing conversational systems with empathy (Ma et al., 2020), moral discretion (Ziems et al., 2022) and factual correctness (Gupta et al., 2021b; Dziri et al., 2022) will improve users' experience and trust in the system.

We have included the Mechanical Turk arrangements and worker pay in the last paragraph of the section 7.3. We paid well above the US federal minimum wage (around $13 hourly) and provided enough time to the workers to complete the task which was determined based on a few pilot experiments.

A Implementation Details for CODA

A.1 Training Details for CODA

Model training: We code our models using Pytorch and Huggingface [3] library. We use validation loss to do model selection. The KPG-wc, KPG-ht and CRG models are all based on GPT-2 small architecture. We use batch size of 10 for GPT-2 models. We use Adam optimizer with initial learning rate of $1e-4$. We use GeForce RTX 2080 GPUs for training models. All existing code used and datasets were CC-BY 4.0 or open sourced by original authors.

Decoding paths and responses: For decoding paths using the KPG models, we use temperature of 0.7 and nucleus sampling with top-p set to 0.9. We use the same decoding strategy and hyperparameters for decoding responses using CRG model.

Concept Extraction: Entities are extracted from the context, target and response to generate and align paths using the KPG models. For a sentence s, we first extract the set of noun and verb phrases from the sentence using NLTK. We design simple grammar rules to convert some phrases to a more concise forms that are similar to the kinds of nodes present in ConceptNet,e.g., “watching the star” is converted to “watch stars”. We use NLTK’s POS tagging combined with the following grammar rules: (1) Nouns and Adjectives, terminated with Nouns <NN.*|JJ>*<NN.*> (2) Verb and verb phrases <RB.?>*<VB.?>*<JJ>*<VB.?>+<VB>?. We normalize the verbs using NLTK. The final set of entities consist of the noun and verb phrases. We exclude phrases such as “today”, “enough” which are sometimes incorrectly detected as entities.

Sub-selecting entity pairs during training of CRG model: For every context-target pair, we have n number of pair of head-tails entities. We score an entity pair by calculating the inverse document frequencies (computed using Gutenberg English corpus) of the entity tokens and summing up the maximum value found for a token in each entity in the pair. For training phase, we keep the topD pairs of entities. The value of top D is selected based on validation performance and comes out typically between 1-3.

Knowledge graph details: The number of nodes in the ConceptNet resource we have used[4] is 382226. We perform random walks on the graph with paths of length from 1 to 6 and get a total of 3883671 number of paths.

Edges in the knowledge path: We discard some edge types which are regarded to be uninformative and offer little help for our task following Wang et al. (2020). They include RelatedTo, Synonym, Antonym, DerivedFrom, FormOf, Etymologically-DerivedFrom and EtymologicallyRelatedTo. Since the nodes in ConceptNet are directional, we also add inverse edges during path sampling. For example the path “ecosystem <– PartOf <– organism” can be sampled as “ecosystem _isPartOf organism” where the underscore indicates a reverse edge.

A.2 Clause Identification for Data Augmentation

For *target creation*, given a dialogue context c and its response r, we first break the response r into sentence clauses. For example, given a context “Is my booking complete?” and the response “your reservation is confirmed. now i need your phone number,”, we extract a clause t “i need your phone number” as the target candidate t. For clause extraction we use Allennlp’s SRL parser [5] which is trained using a BERT-based model (Shi and Lin, 2019) and is based on PropBank (Palmer et al., 2005). It identifies the arguments associated with the predicates or verbs of a sentence predicates (verbs or events) in a sentence and classifies them into roles such as agent, patient and instrument. For the example above, it identifies “need” as a predicate with agent “i” and instrument “your number”.

A.3 Data Augmentation for CODA

We filter data from the dailydialog dataset based on a threshold set to 0.7 for data augmentation. This threshold was selected using emperical performance of thr CODA model. For CODA-ONLYDA model which does not use knowledge paths, the context, target and transition response is used directly in training the CRG decoder of CODA-ONLYDA model. But for CODA model which uses the knowledge paths, the dailydialog data is

Context: i enjoy staring up at the sky. Target: i like to spend a lot of my free time with my pet.
Response 1: I like stargazing outside with my pet. (0.99) Response 2: I like stargazing outside. (0.05) Response 3: I like walking with my pet. (0.01) Response 4: My pet is a big star. (0.02)
Context: i make blogs. Target: i have a large family with babies.
Response 1: I want to blog about my children.(0.99) Response 2: My family has a lot of babies. (0.05) Response 3: My blogs are very famous. (0.01)

Table 6: Stress testing the Target-Coherence metric. We show sample responses and TC score for the responses in brackets.

converted to the same format as Otters data, that is, we first do entity detection on the target component of the responses as well as the the dialogue context. Then we generate a set of paths for each pair of entities. The CODA model is first trained on paths from the filtered dailydialog data and then fine-tuned on the Otters dataset which follows the same knowledge path format. The maximum dialogue history length is set to 2 for dailydialog dataset.

A.4 Target Coherence Metric

In Table 6, we provide examples for **stress testing** the Target-Coherence metric. TC scores for the responses are shown in brackets. Simply repeating or addressing either the target or context gets a low TC score. For example the response "I like stargazing outside" is not a smooth transition and gets a low TC score, while "I like stargazing outside with my pet" is a smooth transition and gets a high TC score. In Figure 4 we present an overview of the mechanisms used for generating negative samples for training the Target-Coherence metric. For negative examples, 1) Given gold response r, and context c, we sample a random negative target t', which creates a response which does not transition towards the target t, 2) Given gold response r, and target t, we sample a random negative context c', which creates a response which is not coherent to the context c, 3) Given gold context c, and target t, we either sample a random negative response r' or generate a response r' conditioned on random c' or t', which creates a response which does not transition to target t or is coherent to context c.

B Training Details of Baselines

Training GPT-2 Fudge model Yang and Klein (2021) proposed a future discriminator based decoding technique. The Fudge discriminator uses a discriminator trained to distinguish good response continuations from the poor ones and guides the GPT2 based decoder towards responses that are coherent to both the source and target sentences. The Fudge discriminator needs positive and negative sample data for training. We train the discriminator to distinguish a good response from a bad (not coherent to target or context). The input to train the discriminator (a LSTM model) is the concatenation of the context sentence, followed by the target sentence and finally the tokens of a response r with tokens k. The discriminator then learns to predict 1 if the next token in the response at position k belongs to the gold response or 0 if the token is a random one. We train the Fudge discriminator by preparing negative instances using the same techniques we use to train the Target-Coherence model - sampling random negative responses, responses coherent to the context but not to the target, and responses coherent to the target but not to the context.

Training CS-Pretrain model The model is based on the commonsense story generation model from Guan et al. (2020) We create training data for the CS-Pretrain model by using the same sampled paths we use for training the KPG-wc model. The paths are converted into textual format by converting edges into text sequences. The model is only pretrained with general commonsense paths and then fine-tuned on Otters dataset in a manner similar to the GPT-2 baselines (i.e. without paths). Our experiments show that pretraining with commonsense model does not help with target-guided task, probably since the task needs target conditional commonsense and general commonsense knowledge only confuses the model during decoding.

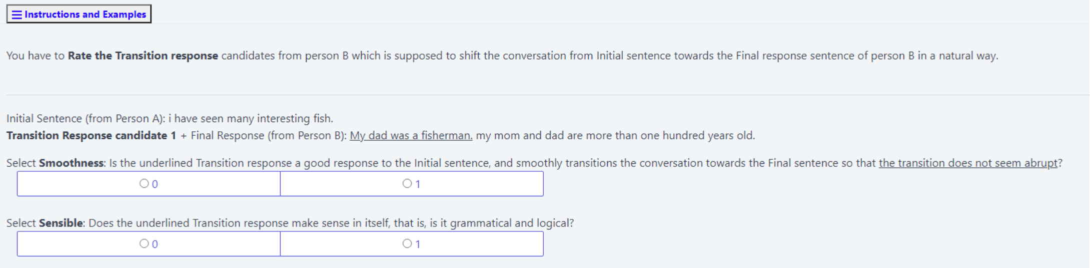
Training Concept-Predict leverages a concept prediction strategy from Qin et al. (2020a). The input to the model is the context and target and it predicts a single concept based on closeness to the target. The concept is then fed as an input to the CRG model along with the context and target sentences.

Training CODA-OnlyDA: CODA variant that uses Dailydialog augmentation and does not use commonsense paths from KPG models in the CRG model. Therefore the model consists of only a CRG model (no KPG models) which take the context and target sentences as inputs.

Training CODA-NoEdge CODA variant that uses only entities and no edges from the path. For example the path "favorite city is the location which has bicycle shop is a dependency of ride bi-

Target	Keywords
i need your address	send money; visit; mail; send gift; send coupon
you should spend time with your friends	don't be alone; mental health; be happy;
you can try our restaurant	best ingredients ; cheapest food; free delivery
our new recipe is best selling	fat free; healthy; protein; tasty
i am the best financial advisor	get rich quickly; sound advice; money management
you should have a positive attitude	mental health; others will help; peace
we should always avoid fighting	peace; happiness; injury; understand other people
i want to come to united states	freedom ;democracy; money; job; american dream; education
everyone should get vaccinated	public health; reduce hospital burden; live longer; covid; be safe
we should donate to charity	help poor; make a difference; give assistance; feel good; social benefits

Table 7: The set of manually created targets and keyword set used for each target.



You have to **Rate the Transition response** candidates from person B which is supposed to shift the conversation from Initial sentence towards the Final response sentence of person B in a natural way.

Initial Sentence (from Person A): i have seen many interesting fish.
Transition Response candidate 1 + Final Response (from Person B): My dad was a fisherman. my mom and dad are more than one hundred years old.

Select **Smoothness**: Is the underlined Transition response a good response to the Initial sentence, and smoothly transitions the conversation towards the Final sentence so that the transition does not seem abrupt?

○ 0 ○ 1

Select **Sensible**: Does the underlined Transition response make sense in itself, that is, is it grammatical and logical?

○ 0 ○ 1

Figure 5: Amazon mechanical turk interface for human ratings collection

cycle" is converted to "favorite city bicycle shop ride bicycle", which is fed as input to the CRG model.

Training CODA-NoAlign: variant that relies on only KPG-ht for training and inference. Does not select paths based on alignment with responses. The paths used during training the CRG model come from KPG-ht instead of KPG-wc.

Training CODA-KBPath: variant that samples paths directly from ConceptNet using the algorithm proposed in Lin et al. (2019). Given a pair of context and target concept, we use their algorithm to sample an actual path directly from ConceptNet. The model is pretrained on Dailydialog augmented data and fine-tuned on Otters with the sampled paths from ConceptNet. The model suffers from missing entities and missing links between entities in ConceptNet which is solved by CODA.

Context: i dye my hair.
Target: we should donate to charity.

Path (KPG-oneent): hair belongs to people motivated by give assistance has prequisite donate to charity.
CODA-controlled: I donate my hair to a non-profit that *helps people in need.*
Path (KPG-ht): hair belongs to people desires donate to charity
CODA: People who donate are very good people.

Context: i have an amazing garden.
Target: you can try our restaurant.

Path (KPG-oneent): garden is a location of grow food motivated by goal best ingredients is desired by person capable of try restaurant
CODA-controlled: My restaurant uses the *best ingredients* from the garden.
Path (KPG-ht): garden is a location of have friends over has prerequisite try restaurant
CODA: you can have friends over.

Table 8: Sample data and model outputs from the human-in-the-loop experiment. The underlined words are keyword inputs provided to the model KPG-oneent. The italicised words in the CODA controlled outputs are phrases are generated based on the input keywords.

C Human-in-the-loop Experiment

Can human involvement improve generation? Our CRG model uses explicit paths generated from the KPG models, which not only provides interpretability, it also allows human-in-the-loop intervention for finer controllability. To test this hypothesis, we create a model KPG-oneent which is a hybrid version of KPG-wc and KPG-ht model. The model takes a single entity n_k given by a user as an input and is trained to generate a path containing that entity. We test this model on a manually created set of target sentences S of size 10 belonging to domains such as healthcare and charity. The data created is shown in Table 7. An example sentence in set S is 'we should donate to charity' and we manually curate a set of keywords such as 'help poor', 'give assistance' and 'tax deductions' that are relevant to the target sentence of interest and can guide the knowledge path sampling towards meaningful paths. This data creation took the authors 30 minutes of effort. For 100 random sampled contexts from the Otters dataset, we select a random target sentence from the set S and sample a keyword k from the curated set of keywords of that target. We compare this controllable model with the KPG-ht model that was used for path generation in all our experiments. We present sample outputs of the model in Table 8. The input keywords used as intervention are underlined. The paths which use the keyword intervention generate smoother transitions compared to the paths which do not use the keyword intervention. We find that the TARGET-COHERENCE metric favors the KPG-oneent model in 59 percent of cases, confirming that even minimal human intervention in the form of domain relevant keywords can improve the quality of generation.

BanglaBERT: Language Model Pretraining and Benchmarks for Low-Resource Language Understanding Evaluation in Bangla

Abstract

In this work, we introduce *BanglaBERT*, a BERT-based Natural Language Understanding (NLU) model pretrained in Bangla, a widely spoken yet low-resource language in the NLP literature. To pretrain BanglaBERT, we collect 27.5 GB of Bangla pretraining data (dubbed 'Bangla2B+') by crawling 110 popular Bangla sites. We introduce two downstream task datasets on natural language inference and question answering and benchmark on four diverse NLU tasks covering text classification, sequence labeling, and span prediction. In the process, we bring them under the first-ever Bangla Language Understanding Benchmark (BLUB). BanglaBERT achieves state-of-the-art results outperforming multilingual and monolingual models. We are making the models, datasets, and a leaderboard publicly available at `https://github.com/csebuetnlp/banglabert` to advance Bangla NLP.

1 Introduction

Despite being the sixth most spoken language in the world with over 300 million native speakers constituting 4% of the world's total population,[1] Bangla is considered a resource-scarce language. Joshi et al. (2020b) categorized Bangla in the language group that lacks efforts in labeled data collection and relies on self-supervised pretraining (Devlin et al., 2019; Radford et al., 2019; Liu et al., 2019) to boost the natural language understanding (NLU) task performances. To date, the Bangla language has been continuing to rely on fine-tuning multilingual pretrained language models (PLMs) (Ashrafi et al., 2020; Das et al., 2021; Islam et al., 2021). However, since multilingual PLMs cover a wide range of languages (Conneau and Lample, 2019; Conneau et al., 2020), they are large (have hundreds of millions of parameters) and require substantial computational resources for fine-tuning. They also tend to show degraded performance for low-resource languages (Wu and Dredze, 2020) on downstream NLU tasks. Motivated by the triumph of language-specific models (Martin et al. (2020); Polignano et al. (2019); Canete et al. (2020); Antoun et al. (2020), *inter alia*) over multilingual models in many other languages, in this work, we present **BanglaBERT** – a BERT-based (Devlin et al., 2019) Bangla NLU model pretrained on 27.5 GB data (which we name '**Bangla2B+**') we meticulously crawled 110 popular Bangla websites to facilitate NLU applications in Bangla. Since most of the downstream task datasets for NLP applications are in the English language, to facilitate zero-shot transfer learning between English and Bangla, we additionally pretrain a model in both languages; we name the model **BanglishBERT**.

We also introduce two datasets on Bangla Natural Language Inference (NLI) and Question Answering (QA), tasks previously unexplored in Bangla, and evaluate both pretrained models on four diverse downstream tasks on sentiment classification, NLI, named entity recognition, and QA. We bring these tasks together to establish the first-ever **B**angla **L**anguage **U**nderstanding **B**enchmark (**BLUB**). We compare widely used multilingual models to BanglaBERT using BLUB and find that both models excel on all the tasks.

We summarize our contributions as follows:

1. We present two pretrained models in Bangla: BanglaBERT and BanglishBERT, and introduce new Bangla NLI and QA datasets.

2. We introduce the Bangla Language Understanding Benchmark (BLUB) and show that, in the supervised setting, BanglaBERT outperforms mBERT and XLM-R (base) by 6.8 and 4.3 BLUB scores, while in zero-shot cross-lingual transfer, BanglishBERT outperforms

them by 15.8 and 10.8, respectively.

3. We provide the code, models, and a leaderboard to spur future research on Bangla NLU.

2 BanglaBERT

2.1 Pretraining Data

A high volume of good quality text data is a prerequisite for pretraining large language models. For instance, BERT (Devlin et al., 2019) is pretrained on the English Wikipedia and the Books corpus (Zhu et al., 2015) containing 3.3 billion tokens. Subsequent works like RoBERTa (Liu et al., 2019) and XLNet (Yang et al., 2019) used more extensive web-crawled data with heavy filtering and cleaning.

Bangla is a rather resource-constrained language in the web domain; for example, the Bangla Wikipedia dump from July 2021 is only 650 MB, two orders of magnitudes smaller than the English Wikipedia. As a result, we had to crawl the web extensively to collect our pretraining data. We selected 110 Bangla websites by their Amazon Alexa rankings[2] and the volume and quality of extractable texts by inspecting each website. The contents included encyclopedias, news, blogs, e-books, stories, social media/forums, etc.[3] The amount of data totaled around 35 GB.

There are noisy sources of Bangla data dumps, a couple of prominent ones being OSCAR (Suárez et al., 2019) and CCNet (Wenzek et al., 2020). They contained many offensive texts; we found them infeasible to clean thoroughly. Fearing their potentially harmful impacts (Luccioni and Viviano, 2021), we opted not to use them. We further discuss ethical considerations at the end of the paper.

2.2 Pre-processing

We performed thorough deduplication on the pretraining data, removed non-textual contents (e.g., HTML/JavaScript tags), and filtered out non-Bangla pages using a language classifier (Joulin et al., 2017). After the processing, the dataset was reduced to 27.5 GB in size containing 5.25M documents having 306.66 words on average.

We trained a Wordpiece (Wu et al., 2016) vocabulary of 32k subword tokens on the resulting corpus with a 400 character alphabet, kept larger than the native Bangla alphabet to capture code-switching (Poplack, 1980) and allow romanized Bangla contents for better generalization. We limited the length of a training sample to 512 tokens and did not cross document boundaries (Liu et al., 2019) while creating a data point. After tokenization, we had 7.18M samples with an average length of 304.14 tokens and containing 2.18B tokens in total; hence we named the dataset '*Bangla2B+*'.

2.3 Pretraining Objective

Self-supervised pretraining objectives leverage unlabeled data. For example, BERT (Devlin et al., 2019) was pretrained with masked language modeling (MLM) and next sentence prediction (NSP). Several works built on top of this, e.g., RoBERTa (Liu et al., 2019) removed NSP and pretrained with longer sequences, SpanBERT (Joshi et al., 2020a) masked contiguous spans of tokens, while works like XLNet (Yang et al., 2019) introduced objectives like factorized language modeling.

We pretrained BanglaBERT using ELECTRA (Clark et al., 2020b), pretrained with the Replaced Token Detection (RTD) objective, where a generator and a discriminator model are trained jointly. The generator is fed as input a sequence with a portion of the tokens masked (15% in our case) and is asked to predict them using the rest of the input (i.e., standard MLM). The masked tokens are then replaced by tokens sampled from the generator's output distribution for the corresponding masks, and the discriminator then has to predict whether each token is from the original sequence or not. After pretraining, the discriminator is used for fine-tuning. Clark et al. (2020b) argued that RTD back-propagates loss from all tokens of a sequence, in contrast to 15% tokens of the MLM objective, giving the model more signals to learn from. Evidently, ELECTRA achieves comparable downstream performance to RoBERTa or XLNet with only a quarter of their training time. This computational efficiency motivated us to use ELECTRA for our implementation of BanglaBERT.

2.4 Model Architecture & Hyperparameters

We pretrained the base ELECTRA model (a 12-layer Transformer encoder with 768 embedding size, 768 hidden size, 12 attention heads, 3072 feed-forward size, generator-to-discriminator ratio $\frac{1}{3}$, 110M parameters) with 256 batch size for 2.5M steps on a v3-8 TPU instance on GCP. We used the Adam (Kingma and Ba, 2015) optimizer with a 2e-4 learning rate and linear warmup of 10k steps.

Table 1: Statistics of the Bangla Language Understanding Evaluation (BLUB) benchmark.

2.5 BanglishBERT

Often labeled data in a low-resource language for a task may not be available but be abundant in high-resource languages like English. In these scenarios, zero-shot cross-lingual transfer (Artetxe and Schwenk, 2019) provides an effective way to be still able to train a multilingual model on that task using the high-resource languages and be able to transfer to low-resource ones. To this end, we pretrained a bilingual model, named **BanglishBERT**, on Bangla and English together using the same set of hyperparameters mentioned earlier. We used the BERT pretraining corpus as the English data and trained a joint bilingual vocabulary (each language having $\sim$16k tokens). We upsampled the Bangla data during training to equal the participation of both languages.

3 The Bangla Language Understanding Benchmark (BLUB)

Many works have studied different Bangla NLU tasks in isolation, e.g., sentiment classification (Das and Bandyopadhyay, 2010; Sharfuddin et al., 2018; Tripto and Ali, 2018), semantic textual similarity (Shajalal and Aono, 2018), parts-of-speech (PoS) tagging (Alam et al., 2016), named entity recognition (NER) (Ashrafi et al., 2020). However, Bangla NLU has not yet had a comprehensive, unified study. Motivated by the surge of NLU research brought about by benchmarks in other languages, e.g., English (Wang et al., 2018), French (Le et al., 2020), Korean (Park et al., 2021), we establish the first-ever Bangla Language Understanding Benchmark (BLUB). NLU generally comprises three types of tasks: text classification, sequence labeling, and text span prediction. Text classification tasks can further be sub-divided into single-sequence and sequence-pair classification. Therefore, we consider a total of four tasks for BLUB. For each task type, we carefully select one downstream task dataset. We emphasize the quality and open availability of the datasets while making the selection. We briefly mention them below.

1. Single-Sequence Classification Sentiment classification is perhaps the most-studied Bangla NLU task, with some of the earlier works dating back over a decade (Das and Bandyopadhyay, 2010). Hence, we chose this as the single-sequence classification task. However, most Bangla sentiment classification datasets are not publicly available. We could only find two public datasets: *BYSA* (Tripto and Ali, 2018) and *SentNoB* (Islam et al., 2021). We found BYSA to have many duplications. Even worse, many duplicates had different labels. SentNoB had better quality and covered a broader set of domains, making the classification task more challenging. Hence, we opted to use the latter.

2. Sequence-pair Classification In contrast to single-sequence classification, there has been a dearth of sequence-pair classification works in Bangla. We found work on semantic textual similarity (Shajalal and Aono, 2018), but the dataset is not publicly available. As such, we curated a new Bangla Natural Language Inference (*BNLI*) dataset for sequence-pair classification. We chose NLI as the representative task due to its fundamental importance in NLU. Given two sentences, a premise and a hypothesis as input, a model is tasked to predict whether or not the hypothesis is entailment, contradiction, or neutral to the premise. We used the same curation procedure as the XNLI (Conneau et al., 2018) dataset: we translated the MultiNLI (Williams et al., 2018) training data using the English to Bangla translation model by Hasan et al. (2020) and had the evaluation sets translated by expert human translators.[4] Due to the possibility of the incursion of errors during automatic translation, we used the Language-Agnostic BERT Sentence Embeddings (LaBSE) (Feng et al., 2020) of the translations and original sentences to compute their similarity and discarded all sentences below a similarity threshold of 0.70. Moreover, to ensure good-quality human translation, we used similar quality assurance strategies as Guzmán et al. (2019).

---

[4] More details are presented in the ethical considerations section.

Models	|Params.|	SC	NLI	NER	QA	BLUB Score

Table 2: Performance comparison of pretrained models on different downstream tasks. Scores in bold texts have statistically significant ($p < 0.05$) difference from others with bootstrap sampling (Koehn, 2004).

3. Sequence Labeling In this task, all words of a text sequence have to be classified. Named Entity Recognition (NER) and Parts-of-Speech (PoS) tagging are two of the most prominent sequence labeling tasks. We chose the Bangla portion of SemEval 2022 *MultiCoNER* (Malmasi et al., 2022) dataset for BLUB.

4. Span Prediction Extractive question answering is a standard choice for text span prediction. Similar to BNLI, we machine-translated the *SQuAD 2.0* (Rajpurkar et al., 2018) dataset and used it as the training set (BQA). For validation and test, We used the Bangla portion of the *TyDiQA*[5] (Clark et al., 2020a) dataset. We posed the task analogous to SQuAD 2.0: presented with a text passage and a question, a model has to predict whether or not it is answerable. If answerable, the model has to find the minimal text span that answers the question.

We present detailed statistics of the BLUB benchmark in Table 1.

4 Experiments & Results

Setup We fine-tuned BanglaBERT and BanglishBERT on the four downstream tasks and compared them with several multilingual models: mBERT (Devlin et al., 2019), XLM-R base and large (Conneau et al., 2020), and IndicBERT (Kakwani et al., 2020), a multilingual model for Indian languages; and sahajBERT (Diskin et al., 2021), an ALBERT-based (Lan et al., 2020) PLM for Bangla. All pretrained models were fine-tuned for 3-20 epochs with batch size 32, and the learning rate was tuned from {2e-5, 3e-5, 4e-5, 5e-5}. The final models were selected based on the validation performances after each epoch. We performed fine-tuning with three random seeds and reported their average scores in Table 2. We reported the average performance of all tasks as the BLUB score.

Zero-shot Transfer We show the zero-shot cross-lingual transfer results of the multilingual models fine-tuned on the English counterpart of each dataset (SentNob has no English equivalent; hence we used the Stanford Sentiment Treebank (Socher et al., 2013) for the sentiment classification task) in Table 2. In zero-shot transfer setting, BanglishBERT achieves strong cross-lingual performance over similar-sized models and falls marginally short of XLM-R (large). This is an expected outcome since cross-lingual effectiveness depends explicitly on model size (K et al., 2020).

Supervised Fine-tuning In the supervised fine-tuning setup, BanglaBERT outperformed multilingual models and monolingual sahajBERT on all the tasks, achieving a BLUB score of 77.09, even coming head-to-head with XLM-R (large). On the other hand, BanglishBERT marginally lags behind BanglaBERT and XLM-R (large). BanglaBERT is not only superior in performance but also substantially compute- and memory-efficient. For instance, it may seem that sahajBERT is more efficient than BanglaBERT due to its smaller size, but it takes 2-3.5x time and 2.4-3.33x memory as BanglaBERT

---

[5] We removed the Yes/No questions from TyDiQA and subsampled the unanswerable questions to have equal proportion.

to fine-tune. [6]

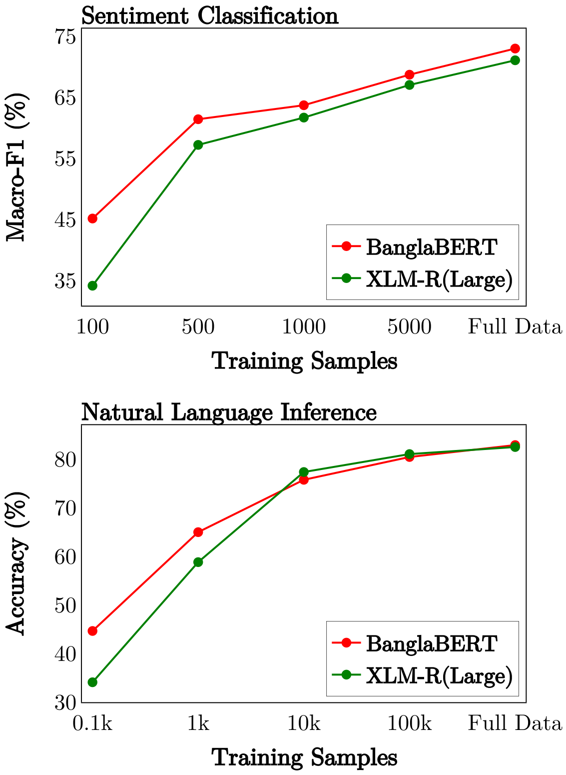

Figure 1: Sample-efficiency tests with SC and NLI.

Sample efficiency It is often challenging to annotate training samples in real-world scenarios, especially for low-resource languages like Bangla. So, in addition to compute- and memory-efficiency, sample-efficiency (Howard and Ruder, 2018) is another necessity of PLMs. To assess the sample efficiency of BanglaBERT, we limit the number of training samples and see how it fares against other models. We compare it with XLM-R (large) and plot their performances on the SC and NLI tasks[7] for different sample size in Figure 1.

Results show that when we have fewer number of samples ($\leq 1k$), BanglaBERT has substantially better performance (2-9% on SC and 6-10% on NLI with $p < 0.05$) over XLM-R (large), making it more practically applicable for resource-scarce downstream tasks.

5 Conclusion & Future Works

Creating language-specific models is often infeasible for low-resource languages lacking ample data. Hence, researchers are compelled to use multilingual models for languages that do not have strong pretrained models. To this end, we introduced BanglaBERT and BanglishBERT, two NLU models in Bangla, a widely spoken yet low-resource language. We presented new downstream datasets on NLI and QA, and established the BLUB benchmark, setting new state-of-the-art results with BanglaBERT. In future, we will include other Bangla NLU benchmarks (e.g., dependency parsing (de Marneffe et al., 2021)) in BLUB and investigate the benefits of initializing Bangla NLG models from BanglaBERT.

Acknowledgements

We would like to thank the Research and Innovation Centre for Science and Engineering (RISE), BUET, for funding the project, and Intelligent Machines Limited and Google TensorFlow Research Cloud (TRC) Program for providing cloud support.

Ethical Considerations

Dataset and Model Release The *Copy Right Act, 2000*[8] of Bangladesh allows reproduction and public release of copy-right materials for non-commercial research purposes. As a transformative research work, we will release BanglaBERT under a non-commercial license. Furthermore, we will release only the pretraining data for which we know the distribution will not cause any copyright infringement. The downstream task datasets can all be made publicly available under a similar non-commercial license.

Quality Control in Human Translation Translations were done by expert translators who provide translation services for renowned Bangla newspapers. Each translated sentence was further assessed for quality by another expert. If found to be of low quality, it was again translated by the original translator. The sample was then discarded altogether if found to be of low quality again. Fewer than 100 samples were discarded in this process. Translators were paid as per standard rates in local currencies.

Text Content We tried to minimize offensive texts in the pretraining data by explicitly crawling the sites where such contents would be nominal. However, we cannot guarantee that there is absolutely no objectionable content present and therefore recommend using the model carefully, especially for text generation purposes.

---

[6] We present a detailed comparison in the Appendix.

[7] Results for the other tasks can be found in the Appendix.

Additional Sample Efficiency Tests

We plot the the sample efficiency results of the NER and QA tasks in Figure 2.

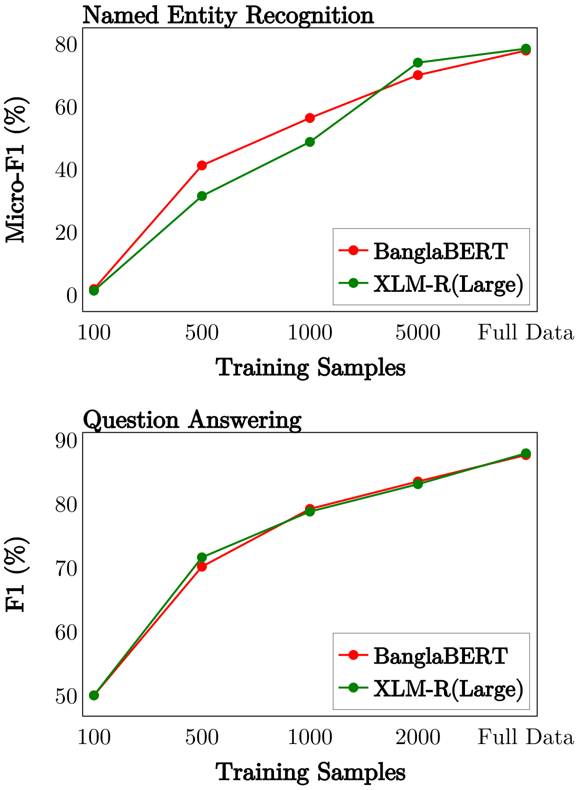

Figure 2: Sample-efficiency tests with NER and QA.

Similar results are also observed here for the NER task, where BanglaBERT is more sample-efficient when we have $\leq 1k$ training samples. In the QA task however, both models have identical performance for all sample counts.

Compute and Memory Efficiency Tests

To validate that BanglaBERT is more efficient in terms of memory and compute, we measured each model's training time and memory usage during the fine-tuning of each task. All tests were done on a desktop machine with an 8-core Intel Core-i7 11700k CPU and NVIDIA RTX 3090 GPU. We used the same batch size, gradient accumulation steps, and sequence length for all models and tasks for a fair comparison. We use relative time and memory (GPU VRAM) usage considering those of BanglaBERT as units. The results are shown in Table 3. (We mention the upper and lower values of the different tasks for each model)

Model	Time	Memory Usage
mBERT	1.14x-1.92x	1.12x-2.04x
XLM-R (base)	1.29-1.81x	1.04-1.63x
XLM-R (large)	3.81-4.49x	4.44-5.55x
SahajBERT	2.40-3.33x	2.07-3.54x
BanglaBERT	**1.00x**	**1.00x**

Table 3: Compute and memory efficiency tests

ALLSH: Active Learning Guided by Local Sensitivity and Hardness

Abstract

Active learning, which effectively collects informative unlabeled data for annotation, reduces the demand for labeled data. In this work, we propose to retrieve unlabeled samples with a local sensitivity and hardness-aware acquisition function. The proposed method generates data copies through local perturbations and selects data points whose predictive likelihoods diverge the most from their copies. We further empower our acquisition function by injecting the select-worst case perturbation. Our method achieves consistent gains over the commonly used active learning strategies in various classification tasks. Furthermore, we observe consistent improvements over the baselines on the study of prompt selection in prompt-based few-shot learning. These experiments demonstrate that our acquisition guided by local sensitivity and hardness can be effective and beneficial for many NLP tasks.

1 Introduction

Crowdsourcing annotations (Rajpurkar et al., 2016; Bowman et al., 2015) has become a common practice for developing NLP benchmark datasets. Rich prior works (Pavlick and Kwiatkowski, 2019; Nie et al., 2020; Ferracane et al., 2021) show that the time-consuming and expensive manual labeling in crowdsourcing annotations are not an annotation artifact but rather core linguistic phenomena. Active Learning (AL) is introduced to efficiently acquire data for annotation from a (typically large) pool of unlabeled data. Its goal is to concentrate the human labeling effort on the most informative data in hopes of maximizing the model performance while minimizing the data annotation cost.

Popular approaches to acquiring data for AL are uncertainty sampling and diversity sampling. Uncertainty sampling selects data that the model predicts with low-confidence (Lewis and Gale, 1994; Culotta and McCallum, 2005; Settles, 2009). Diversity sampling selects batches of unlabeled examples that are prototypical of the unlabeled pool to exploit heterogeneity in the feature space (Xu et al., 2003; Bodó et al., 2011). Different from these two perspectives, recent works focus on the informativeness of the selected data. For example, Zhang and Plank (2021) acquire informative unlabeled data using the training dynamics based on the model predictive log likelihood. Margatina et al. (2021) construct contrastive examples in the input feature space. However, these methods either ignore the local sensitivity of the input features or take no consideration of the difficulty of the learning data. Consequently, they may ignore examples around the decision boundary, or select hard-to-train or even noisy examples. Their performance may further suffer under some practical settings, such as those with imbalanced labels and when there is a very limited annotation budget.

In this work, we determine the informativeness by considering both the local sensitivity and learning difficulty. For local sensitivity, we take the classical definition from Chapelle et al. (2009), which is widely used in both classic machine learning problems (e.g. Blum and Chawla, 2001; Chapelle et al., 2002; Seeger, 2000; Zhu et al., 2003; Zhou et al., 2004) and recent deep learning settings (e.g. Wang et al., 2018b; Sohn et al., 2020; Xu et al., 2021). Specifying a local region $\mathcal{R}_{region}(\boldsymbol{x})$ around an example $\boldsymbol{x}$, we assume in our prior that all examples in $\mathcal{R}_{region}(\boldsymbol{x})$ have the same labels.[2] If the examples in $\mathcal{R}_{region}(\boldsymbol{x})$ give us different labels, we say the local region of $\boldsymbol{x}$ is sensitive. Data augmentation has been chosen as the way to create label-equivalent local regions in many recent works (*e.g.*, Berthelot et al., 2019b; Xie et al., 2020). We utilize data augmentation as a tool to capture the local sensitivity and hardness of inputs and present

ALLSH: Active Learning guided by Local Sensitivity and Hardness. Through various designs on local perturbations, ALLSH selects unlabeled data points from the pool whose predictive likelihoods diverge the most from their augmented copies. This way, ALLSH can effectively ensure the informative and local-sensitive data to have correct human-annotated labels. Figure 1 illustrates the scheme of the proposed acquisition strategy.

We conduct a comprehensive evaluation of our approach on datasets ranging from sentiment analysis, topic classification, natural language inference, to paraphrase detection. To measure the proposed acquisition function in more realistic settings where the samples stem from a dissimilar input distribution, we (1) set up an out-of-domain test dataset and (2) leak out-of-domain data ($e.g.$, adversarial perturbations) into the selection pool.

We further expand the proposed acquisition to a more challenging setting: prompt-based few-shot learning (Zhao et al., 2021), where we query a fixed pre-trained language model via a natural language prompt containing a few training examples. We focus on selecting the most valuable prompts for a given test task ($e.g.$, selecting 4 prompts for one given dataset). We adapt our acquisition function to retrieve prompts for the GPT-2 model.

Furthermore, we provide extensive ablation studies on different design choices for the acquisition function, including the designs of augmentations and divergences. Our method shows consistent gains in all settings with multiple datasets. With little modification, our data acquisition can be easily applied to other NLP tasks for a better sample selection strategy.

Our contributions are summarized as follows: (1) Present a new acquisition strategy, embracing local sensitivity and learning difficulty, such as paraphrasing the inputs through data augmentation and adversarial perturbations, into the selection procedure. (2) Verify the effectiveness and general applicability of the proposed method in more practical settings with imbalanced datasets and extremely few labeled data. (3) Provide comprehensive study and experiments of the proposed selection criteria in classification tasks (both in-domain and out-of-domain evaluations) and prompt-based few-shot learning. (4) The proposed data sampling strategy can be easily incorporated or extended to many other NLP tasks.

2 Method

In this section we present in detail our proposed method, ALLSH (Algorithm 1).

2.1 Active Learning Loop

The active learning setup consists of an unlabeled dataset $\mathcal{D}_{pool}$, the current training set $\mathcal{D}_{label}$, and a model $\mathcal{M}$ whose output probability is $p_\theta(\cdot \mid \boldsymbol{x})$ for input $\boldsymbol{x}$. The model $\mathcal{M}$ is generally a pre-trained model for NLP tasks (Lowell et al., 2018). At each iteration, we train a model on $\mathcal{D}_{label}$ and then use the acquisition function to acquire s_{acq} sentences in a batch $\mathcal{T}$ from $\mathcal{D}_{pool}$. The acquired examples from this iteration are labeled, added to $\mathcal{D}_{label}$, and removed from $\mathcal{D}_{pool}$. Then the updated $\mathcal{D}_{label}$ serves as the training set in the next AL iteration until we exhaust the budget. Overall, the system is given a budget of S queries to build a labeled training dataset of size S.

2.2 Acquisition Function Design

To fully capture the data informativeness and train a model with a limited amount of data, we consider two data-selection principals: local sensitivity and learning hardness.

Local Sensitivity Based on theoretical works on the margin theory for active learning, the examples lying close to the decision boundary are informative and worth labeling (Ducoffe and Precioso, 2018; Margatina et al., 2021). Uncertainty sampling suffers from the sampling bias problem as the model is only trained with few examples in the early phase of training. In addition, high uncertainty samples given the current model state may not be that representative to the whole unlabeled data (Ru et al., 2020). For example, if an input has high confidence while its local perturbation generates low-confidence output, then it is likely that this input lies close to the model decision boundary. This information can be captured by measuring the difference between an input example and its augmentation in the output feature space. We utilize the back-translation (Sennrich et al., 2016; Edunov et al., 2018; Zhang et al., 2021b) and TF-IDF (Xie et al., 2020) as effective augmentation methods which can generate diverse paraphrases while preserving the semantics of the original inputs (Yu et al., 2018b).

Instead of simply using augmentation, adversarial perturbation can measure the local Lipschitz and sensitivity more effectively. We therefore further exploit adversarial perturbation to more accurately measure local sensitivity. For NLP problems, generating exact adversarial perturbations in a discrete space usually requires combinatorial optimization, which often suffers from the curse of dimensionality (Madry et al., 2017; Lei et al., 2018). Hence, we choose the hardest augmentation over K random augmentations as a "lightweight" variant of adversarial input augmentation which optimizes the worst case loss over the augmented data.

Learning Hardness: From Easy to Hard Learning from easy examples or propagating labels from high-confidence examples is the key principle for curriculum learning (Bengio et al., 2009) and label propagation based semi-supervised learning algorithms (Chapelle et al., 2009). For example, FixMatch (Sohn et al., 2020), a SOTA semi-supervised method, applies an indicator function to select high confident examples at each iteration. This will facilitate the label information from high confidence examples to low-confidence ones (Chapelle et al., 2009). In our selection criterion, as the model is trained with limited data, we also want to avoid the hard-to-learn examples, which in some cases frequently correspond to mislabeled or erroneous instances (Swayamdipta et al., 2020; Zhang and Plank, 2021). These examples may stuck the model performance at the beginning of the selection.

2.3 Acquisition with Local Sensitivity and Hardness

We come to the definition of our acquisition function. Given a model p_θ and an input $\boldsymbol{x}$, we compute the output distribution $p_\theta(\cdot \mid \boldsymbol{x})$ and a noised version $p_\theta(\cdot \mid \boldsymbol{x}')$ by injecting a random transformation $\boldsymbol{x}' = g(\boldsymbol{x})$ to the inputs. Here, $g(\cdot)$ is sampled from a family of transformations and these random transformations stand for data augmentations. This procedure can select examples that are insensitive to transformation $g(\cdot)$ and hence smoother with respect to the changes in the input space (Berthelot et al., 2019b,a; Sohn et al., 2020). We calculate

$$\ell(\boldsymbol{x}, \boldsymbol{x}') = \mathbb{D}(p_\theta(\cdot \mid \boldsymbol{x}), p_\theta(\cdot \mid \boldsymbol{x}')), \qquad (1)$$

where $\mathbb{D}$ denotes a statistical distance such as the Kullback–Leibler (KL) divergence (Kullback and Leibler, 1951). Model p_θ here can be a pretrained language model such as BERT (Devlin et al., 2018).

Data Paraphrasing via Augmentation Paraphrase generation can improve language models (Yu et al., 2018a) by handling language variation. TF-IDF and backtranslation can generate diverse inputs while preserving the semantic meaning (Singh et al., 2019; Xie et al., 2020). For TF-IDF, we replace uninformative words with low TF-IDF scores while keeping those with high. Specifically, Suppose IDF(w) is the IDF score for word w computed on the whole corpus, and TF(w) is the TF score for word w in a sentence. We compute the TF-IDF score as TFIDF(w) = TF(w)IDF(w). For backtranslation, we use a pre-trained EN-DE and DE-EN translation models (Ng et al., 2019) to perform backtranslation on each sentence. We denote $\boldsymbol{x}$ as $(x_0, \cdots, x_n)$. Here, n denotes the original length of the input. For $\boldsymbol{x}$, we pass them through two translation models to get $\boldsymbol{x}' = (x'_0, \cdots, x'_m)$, where m denotes the length after backtranslating. More details can be found in Appendix A.

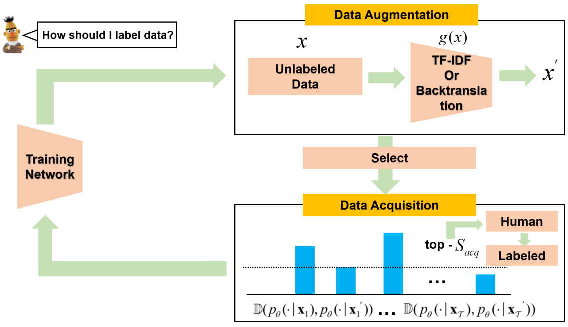

Figure 1: Overview of active learning framework guided by local sensitivity and hardness. Some notations are labeled along with corresponding components. 'Select' refers to the select worst-case augmentation.

Select Worst-Case Augmentation (WCA) In order to construct effective local sensitivity, the most direct approach is calculating the local Lipschitz constant or finding the worst case adversarial perturbation. However, estimating the Lipschitz constant for a neural network is either model dependent or computationally hard (Scaman and Virmaux, 2018; Fazlyab et al., 2019). Instead, we select worst-case augmentation over K copies, which can still roughly measure the norm of the first-order gradient without a huge computation cost and is easy to implement. Given input examples $\boldsymbol{x}$, and K augmentation of $\boldsymbol{x}$ as $\{\boldsymbol{x}'_i\}_{i=1}^K$, we propose the following acquisition function to select data:

$$\ell^{max}(\boldsymbol{x}) = \max_{i \in [K]} \ell(\boldsymbol{x}, \boldsymbol{x}'_i). \qquad (2)$$

Inspired by some simple and informal analysis in continuous space, we draw the connection between calculating $\ell^{max}(\boldsymbol{x})$ and local sensitivity by

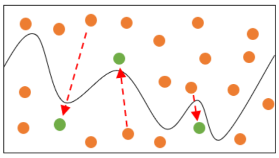

Figure 2: The solid line is model decision boundary. Orange circles refer to the unlabeled data and green circles refer to the corresponding augmentation of the orange unlabeled data.

$$\begin{aligned}\ell^{max}(\boldsymbol{x}) &= \ell(\boldsymbol{x},\boldsymbol{x}') + \left[\ell^{max}(\boldsymbol{x}) - \ell(\boldsymbol{x},\boldsymbol{x}')\right] \\ &= \ell(\boldsymbol{x},\boldsymbol{x}') + \left[\max_{i\in[K]}\langle\nabla_{\boldsymbol{x}}\ell(\boldsymbol{x},\boldsymbol{x}'),\boldsymbol{x}-\boldsymbol{x}'\rangle\right] + \mathbf{O}(\sigma^2).\end{aligned} \tag{3}$$

Recent works in computer vision (Gong et al., 2020; Wang et al., 2021) have provided more formal connections between local gradient norm estimation and K-worst perturbations.

The text sentences in NLP are in the discrete space, which lacks the definition of local Lipschitz, but finding the worst perturbation in a local discrete set can still be a better measurement of local sensitivity in the semantic space.

Choice of Divergence We use the KL divergence as the primary measure of the statistical distance between the distribution of the original examples and that over augmented examples. We also empirically provide detailed analysis of the Jensen–Shannon Distance (JSD) (Endres and Schindelin, 2003) and α-divergence (Minka et al., 2005) as a complementary measure in Section 5. The α-divergence (Pillutla et al., 2021) is a general divergence family, which includes the most popular KL divergence and reverse KL divergence. Different value of α makes the divergence trade-off between overestimation and underestimation. JSD is a metric function based on a mathematical definition which is symmetric and bounded within the range $[0, 1]$. These divergences are calculated as:

$$\begin{aligned}&\mathrm{KL}\ (\mathrm{p}\|q) = \sum_i p_i(\boldsymbol{x}) \log \frac{p_i(\boldsymbol{x})}{q_i(\boldsymbol{x})}, \\ &\mathrm{JSD}\ (\mathrm{p}\|q) = \sqrt{\tfrac{1}{2}(\mathrm{KL}(p\|m) + \mathrm{KL}(q\|m))}, \\ &\mathrm{D}_\alpha(p\|q) = \frac{1}{\alpha(\alpha-1)} \sum_i [(\frac{p_i(\boldsymbol{x})}{q_i(\boldsymbol{x})})^\alpha - 1],\end{aligned} \tag{4}$$

where p is the output probability distribution of an example, q is the output probability distribution of an augmented example, and $m = \frac{1}{2}(p+q)$.

Local Sensitivity and Informativeness The divergence objective exploits unlabeled data by measuring predictions across slightly-distorted versions of each unlabeled sample. The diverse and adversarial augmentations capture the local sensitivity and informativeness of inputs and project examples to the decision boundary (Ducoffe and Precioso, 2018). Thus, the examples and their copies with highly inconsistent model predictions lie close to the decision boundary of the model (Gao et al., 2020). These examples are valuable to have human annotations because they 1) contain high-confidence region in a local perturbation and are therefore easy to train 2) are highly likely to promote the model with large-margin improvements (see example in Figure 2). Under our local sensitivity and hardness guided acquisition, we argue the selected examples would not be necessarily the examples with the highest uncertainty, which do not always benefit the training. For instance, an example may have low-confidence prediction of both original inputs and augmented inputs thus making the samples most hard to train.

2.4 More Details

Compute Distance We compute the divergence in the model predictive probabilities for the pairs of the input and its augmentations in Eqn (1). Specifically, we use a pretrained BERT in classification tasks and GPT-2 in prompt-based few-shot learning as the base model p_θ to obtain the output probabilities for all unlabeled data points in $\mathcal{D}_{pool}$. We then compute the divergence value with Eqn (1). **Rank and Select Candidates** We apply these steps to all candidate examples from $\mathcal{D}_{pool}$ and obtain the divergence value for each. Our acquisition function selects the top s_{acq} examples that have the highest divergence value from the acquired batch $\mathcal{T}$.

3 Experimental Settings

Table 1 shows the experimental data configuration. In classification tasks, we use five datasets, including Stanford Sentiment Treebank (SST-2; (Socher et al., 2013)), Internet Movie Database (IMDB; (Maas et al., 2011)), AG's News Corpus (AG News; (Zhang et al., 2015)), Quora Question Pairs (QQP; (Wang et al., 2018a)), and Question NLI (QNLI; (Wang et al., 2018a)). The validation and test splits are provided in Margatina et al. (2021). Following Desai and Durrett (2020), we test domain generalization and robustness on three challenging out-of-domain (OD) datasets. For sentiment analysis, SST-2 and IMDB are the source and target domains, respectively, and vice versa; for paraphrase detection, TwitterPPDB (Lan et al., 2019) serves as the out-of-domain test dataset for QQP.

In the prompt-based few-shot learning, we fol-

3.1 Classification Task

We compare the proposed ALLSH against four baseline methods. We choose these baselines as they cover a spectrum of acquisition functions (uncertainty, batch-mode, and diversity-based).

Random samples data from the pool of unlabeled data $\mathcal{D}_{pool}$ following a uniform distribution.

Entropy selects s_{acq} sentences with the highest predictive entropy (Lewis and Gale, 1994) measured by $-\sum_{\boldsymbol{x}} p_\theta(\boldsymbol{x}) \ln p_\theta(\boldsymbol{x})$.

BADGE (Ash et al., 2020) acquires s_{acq} sentences based on diversity in loss gradient. The goal of BADGE is to sample a diverse and uncertain batch of points for training neural networks. It acquires data from $\mathcal{D}_{pool}$ by first passing the input through the trained model and computing the gradient embedding with respect to the parameters of the model's last layer.

CAL (Margatina et al., 2021) The acquisition function samples contrastive examples. It uses information from the feature space to create neighborhoods for unlabeled examples, and uses predictive likelihood for ranking the candidates.

3.2 Prompt-based Few-Shot Learning

Following Zhao et al. (2021), we adapt our acquisition function for state-of-the-art generation based model GPT-2 and propose to retrieve examples that are semantics and sensitivity aware to formulate its corresponding prompts. We compare ALLSH's acquisition function with *random, contextual calibrated, and uncertainty prompt*. For random prompt, we randomly select in-context examples from the training set for each test sentence. For *Calibrated*, Zhao et al. (2021) inject calibration parameters that cause the prediction for each test input to be uniform across answers. See Zhao et al. (2021) for more details. For *Uncertain*, we sample the highest uncertain prompt for the test sentences. For *ALLSH*, we augment the in-context examples and select the prompts with the highest divergence of the predicted likelihood between the original examples and their augmentations.

3.3 Implementation Details

For classification, we use BERT-base (Devlin et al., 2018) from the HuggingFace library (Wolf et al., 2020). We train all models with batch size 16, learning rate 2×10^{-5}, and AdamW optimizer with epsilon 1×10^{-8}. For all datasets, we set the default annotation budget as 1%, the maximum annotation budget as 15%, initial accumulated labeled data set $\mathcal{D}_{label}$ as 0.1% of the whole unlabeled data, and acquisition size as 50 instances for each active learning iterations, following prior work (*e.g.*, Gissin and Shalev-Shwartz, 2019; Dor et al., 2020; Ru et al., 2020). **Curriculum Learning (CL)** We further combine our acquisition function with advances in semi-supervised learning (SSL) (Berthelot et al., 2019a; Sohn et al., 2020), which also integrates abundant unlabeled data into learning. A recent line of work in SSL utilizes data augmentations, such as TF-IDF and back-translation, to enforce local consistency of the model (Sajjadi et al., 2016; Miyato et al., 2018). Here SSL can further distill information from unlabeled data and gradually propagate label information from labeled examples to unlabeled one during the training stage (Xie et al., 2020; Zhang et al., 2021c). We construct the overall loss function as

$$\mathcal{L} = \mathcal{L}_S + \alpha \cdot \underbrace{\mathbb{E}_{\boldsymbol{x} \sim \mathcal{D}_{pool}} \mathbb{D}(p_\theta(\cdot \mid \boldsymbol{x}), p_\theta(\cdot \mid \boldsymbol{x}'))}_{\mathcal{L}_U}, \qquad (5)$$

where $\mathcal{L}_S$ is the cross-entropy supervised learning loss over labeled samples, $\mathcal{L}_U$ is the consistency regularization term, and α is a coefficient (Tarvainen and Valpola, 2017; Berthelot et al., 2019b).

For prompt-based few-shot learning, we run experiments on 1.5B-parameters GPT-2 (Radford et al., 2019), a Transformer (Vaswani et al., 2017) based language model. It largely follows the details of the OpenAI GPT model (Radford et al., 2018). We take the TF-IDF as the default augmentation method and provide a rich analysis of other augmentation methods in Section 5. More detailed experimental settings are included in Appendix A.

4 Experiments

We evaluate the performance of our acquisition and learning framework in this section. We bold the best results within Random, Entropy, BADGE, CAL, and the proposed ALLSH (Ours) in tables. Then, we bold the best result within each column block. All experimental results are obtained with five independent runs to determine the variance. See Appendix A for the full results with error bars.

4.1 In-Domain Classification Task Results

In Table 2, we evaluate the impact of our acquisition function under three different annotation budgets (1%, 5%, and 10%). With a constrained annotation budget, we see substantial gains on test accuracy with our proposed acquisition: ALLSH and selecting worst-case augmentation. With this encouraging initial results, we further explore our acquisition with curriculum learning. Across all settings, ALLSH is consistently the top performing method especially in SST-2, IMDB, and AG News. With a tight budget, our proposed acquisition can successfully integrate the local sensitivity and learning difficulty to generate annotated data.

For BADGE, despite combining both uncertainty and diversity sampling, it only achieves the comparable results on QNLI, showing that gradient computing may not directly benefit data acquisitions. In addition, requiring clustering for high dimensional data, BADGE is computationally heavy as its complexity grows exponentially with the acquisition size (Yuan et al., 2020). We provide rich analysis of the sampling efficiency and running time for each method in Appendix A and include the results in Table 13. Also, ALLSH outperforms the common uncertainty sampling in most cases. Given the current model state, uncertainty sampling chooses the samples that are not representative to the whole unlabeled data, leading to ineffective sampling. CAL has an effective contrastive acquiring on QNLI. We hypothesize that due to the presence of lexical and syntactic ambiguity between a pair of sentence, the contrastive examples can be used to push away the inputs in the feature space.

	Acquired dataset size:	1%	5%	10%

4.2 Out-of-Domain Classification Task Results

We compare our proposed method with the baselines for their performance in an out-of-domain (OD) setting and summarize the results in Table 3. We test domain generalization on three datasets with two tasks, including sentiment analysis and paraphrase detection. We set the annotation budget as 15% of $\mathcal{D}_{pool}$ for all OD experiments. For OD in SST-2 and IMDB, ALLSH yields better results than all baselines with a clear margin (1.7% and 2.0%, respectively). With curriculum learning, the results are continually improved. The performance gains on out-of-domain are often greater than the gains on in-domain, implying that ALLSH can significantly help the model to generalize across domains. On QQP, ALLSH achieves comparable results as CAL without curriculum learning while the performance can be further improved by adding curriculum learning.

ID	SST-2	IMDB	QQP
OD	IMDB	SST-2	TwitterPPDB
Random	76.31	82.01	85.57
Entropy	75.88	85.32	85.18

+ CL	**80.91**	**87.07**	**86.18**

Table 3: Results of out-of-domain (OD) generalization. We report the out-of-domain accuracy on the target domain. ID refers to in-domain dataset. OD refers to out-of-domain dataset.

4.3 Prompt-Based Few-Shot Learning Results

We present the prompt-based few-shot learning results with GPT-2 in Table 4, in which we follow the setting (4-shot, 8-shot, and 12-shot) in Zhao et al. (2021). Few-shot learners suffer from the quality of labeled data (Sohn et al., 2020), and previous acquisition functions usually fail to boost the performance from labeling random sampled data. In Table 4, we observe that uncertain prompts performs similar to random selected prompts. A potential reason is that an under-trained model treats all examples as uncertainty examples and hard to distinguish the informativeness. However, our proposed acquisition demonstrates the strong capability in modeling the local sensitivity and learning from easy to hard. It comes to the best performance in most of the settings. These findings show the potential of using our acquisition to improve prompt-based few-shot learning and make a good in-context examples for GPT-2 model.

		4-shot	8-shot	12-shot
SST-2	Random	64.9	54.5	56.3
	Calibrated	73.8	64.6	73.0
	Uncertainty	59.7	64.5	66.8
	Ours	**75.3**	**77.8**	**79.7**

	Ours	**57.9**	**58.4**	**59.7**

Table 4: Results across different strategies of acquiring training examples (the prompt format is fixed). The language model here is GPT-2 (1.5B).

5 Analysis

Can we use our proposed acquisition in the imbalance setting? Extreme label imbalance is an important challenge in many non-pairwise NLP tasks (Sun et al., 2009; Zhang et al., 2017; Mussmann et al., 2020b). We set up the imbalance setting by sampling a subset with class-imbalance sample rate. For binary classification, we set the positive-class data sample rate as 1.0 and negative-class data sample rate as 0.1. As our acquisition focuses on local sensitivity and informativeness, it tends to select examples close to the decision boundary. Once too many positive examples and few negative examples are labeled, the local perturbation around negative samples are easy to be positive, and thus ALLSH selects examples that are close to the negative examples. We conduct the experiments on SST-2, IMDB, and AG News with annotation budget as 1%. In Table 5, Ours[3] indicates strong improvements. This further proves that our selection method can generalize better.

	SST-2	IMDB	AG News
Random	79.45	62.33	82.95
Entropy	81.71	65.69	82.79
CAL	83.23	72.75	83.27
Ours	**85.48**	**74.48**	**84.11**

Table 5: Main results of different active learning strategies on the imbalanced SST-2, IMDB, and AG News.

Would different augmentations make meaningful difference? We test if our results are sensitive to the choice of augmentation: TF-IDF and backtranslation. For TF-IDF, we compare the random sample augmentation and worst-case augmentation (WCA). TF-IDF and Backtranslation generate diverse paraphrases while preserving the semantics of the original sentences. Select-worst case augments the inputs by incorporating the approximate adversarial perturbations. Table 6 indicates our method is insensitive to different augmentations.

---

[3] Ours in the Section 5 refers to ours + curriculum learning.

	SST-2	IMDB	AG News
Backtranslation	86.01	75.12	88.39
TF-IDF	85.97	75.23	88.42
+ WCA	86.37	75.17	88.50

Table 6: Acquisition performance for different augmentations. We report results of our acquisition with different augmentations to get the local copies of the samples.

We also observe that WCA achieves the highest gains on two datasets. This confirms our discussion in Section 2.3 that select-worst case is capable of imposing local sensitivity.

What is the influence of the choice of divergence? We select different divergences in the statistical distance family and study their abilities in encoding different information. Corresponding to Section 2.3, we present the results in Table 7. We experiment on the KL divergence, JSD, and α-divergence (Minka et al., 2005) with the α value set as -0.5 or 0.5. We notice that for our case the difference between different divergences is small. A possible reason is that the number of class categories is small and therefore the choice of divergence does not have a large influence.

Can we use the proposed acquisition with extremely few labeled data? We have presented the results under very limited annotation budgets in Table 2. We set the annotation budget as 0.8% and 0.4%. The key observation is that the degradation of performance in the other acquisition functions are dramatic. For example, in IMDB, the uncertainty sampling (Entropy) shows the obvious performance drop. It suffers from the sampling bias problem because of the frequent variation of the decision boundary in the early phase of training with very few labeled data available, which results in ineffective sampling. Even under this extreme case, our acquisition still aims to select the most informative examples for the model. This further verifies our empirical results in Section 4.3 on prompt-based few-shot learning where only a very few in-context prompts are provided.

6 Related Work

Active Learning Active Learning has been widely used in many applications in NLP (Lowell et al., 2018; Dor et al., 2020; Ru et al., 2020). The uncertainty-based methods (Fletcher et al., 2008) have become the most common strategy. Instead of only considering uncertainty, diversity sampling has also become an alternative direction. Recent works (Geifman and El-Yaniv, 2017; Sener and Savarese, 2017; Ash et al., 2020; Yuan et al., 2020) focus on different parts of diversity. Most recent works (*e.g.* Zhang and Plank, 2021; Margatina et al., 2021) have been more on exploiting the model behavior and each individual instance. Our work focuses more on the local sensitivity and informativeness of data, leading to better performance under various limited annotation settings.

	SST-2	IMDB	AG News
KL	86.37	77.57	88.57
JSD	86.25	77.38	88.41
$\alpha = -0.5$	86.31	77.42	88.43
$\alpha = 0.5$	86.39	77.53	88.61

Table 7: Ablation study on different choices of divergences. We report KL, JSD, and α-divergence, and set $\alpha = \pm 0.5$ respectively.

	SST-2		IMDB	
Dataset size	0.4%	0.8%	0.4%	0.8%
Random	64.64	61.08	60.84	73.86
Entropy	67.88	63.94	58.96	71.32
CAL	73.81	65.72	61.65	74.15
Ours	**76.45**	**69.46**	**64.54**	**75.88**

Table 8: Results on the SST-2 and IMDB datasets under limited annotation budget (0.4%, 0.8%).

Annotation Budgeting Annotation budgeting with learning has long been studied (Turney, 2002). Sheng et al. (2008) study the tradeoff between collecting multiple labels per example versus annotating more examples. On the other hand, different labeling strategies such as providing fine-grained rationales (Dua et al., 2020), active learning (Kirsch et al., 2019), and the training dynamics approach (Swayamdipta et al., 2020) are studied. Except standard classification, class-imbalance (Mussmann et al., 2020a) or noisy label cases (Fan et al., 2021; Chen et al., 2021) have also been explored. We utilize active learning to explore the labeling strategies and aim to select the most informative data for annotations.

7 Conclusion

Our work demonstrates the benefits of introducing local sensitivity and learning from easy to hard into the acquisition strategy. The proposed acquisition function shows noticeable gains in performance across classification tasks and prompt-based few-shot learning. In this work, we conduct the detailed study with the proposed acquisition strategy in different settings, including imbalanced and extremely limited labels. We also verify the impact of different choice of designs such as the choice of divergence and augmentations. To summarize, the proposed ALLSH is effective and general, with the potential to be incorporated into existing models for various NLP tasks.

A.2 Classification Task Hyperparameters and Experimental Settings

Our implementation is based on the BERT-base (Devlin et al., 2018) from *HuggingFace Transformers* (Wolf et al., 2020). We optimize the KL divergence as the objective with the Adam optimizer (Kingma and Ba, 2014) and batch size is set to 16 for all experiments. The curriculum learning is trained for 200 iterations. The learning rate is 2×10^{-5}. The α in Eqn (5) is set as 0.01 for all experiments. With longer input texts such as IMDB, we use 256 as the maximum sequence length. For others, we use 128. Following Ash et al. (2020) and Margatina et al. (2021), for the initial training set $\mathcal{D}_{label}$, we begin the active learning loop by uniformly random sampling from $\mathcal{D}_{pool}$. For all experiments in the Section 5, we set the annotation budget as 1% and use Ours (ours + curriculum learning) as the default methods.

TF-IDF based data augmentation (Xie et al., 2020) aims to generate both diverse and valid examples. It is designed to retain keywords and replace uninformative words with other uninformative words. BERT is used as the word tokenizer. We set IDF(w) is the IDF score for word w computed on the whole corpus, and TF(w) is the TF score for word w in a sentence. Then, we compute the TF-IDF score as TFIDF(w) = TF(w)IDF(w). Suppose the maximum TF-IDF score in a sentence $\boldsymbol{x}$ is C = max$_i$ TFIDF(x_i). We set the probability to min(p(C - TFIDF(x_i))/Z, 1), where p is a hyperparameter that controls the magnitude of the augmentation and we set p =0.3. Z is the average score over the inputs sentence. For backtranslation, we use a pre-trained EN-DE[4] and DE-EN[5] translation models (Ng et al., 2019) to perform backtranslation

Task	Prompt	Label Names
SST-2	Review: At times, the movie looks genuinely pretty. Sentiment: Positive Review: The movie is amateurish, but it's a minor treat. Sentiment:	Positive, Negative
TREC	Question: Where can I find information on becoming a journalist? Answer Type: Location Question: What is the temperature today? Answer Type:	Number, Location, Person, Description, Entity, Abbreviation
RTE	The motor industry accounts for as much as 40 percent of the 450,000 installed industrial robots worldwide but their use is changing and applications are expanding. Question: The most common use for robots is the manufacture of automobiles. True or False? Answer: True Arroyo was the favorite of investors because of her experience as a trained economist and government manager. Question: Arroyo has experience as an economist and as a government manager. True or False? Answer:	True, False

Table 12: The different prompts we use for SST-2, TREC, and RTE. One training example per task is presented. The language model is used to predicted the label probability as shown in the right column.

on each sentence.

A.3 Prompt-based Few-Shot Learning Hyperparameters and Experimental Settings

We use the 1.5B parameters GPT-2 (Radford et al., 2019), with a Transformer (Vaswani et al., 2017) based architecture. The model largely follows the details of the OpenAI GPT model (Radford et al., 2018) with a few modifications. Layer normalization (Ba et al., 2016; Fan et al., 2020; Zhang et al., 2021a) is moved to the input of each sub-block and an additional layer normalization is added after the final self-attention block. Following the settings in Zhao et al. (2021), the maximum input length is 2048 tokens or 1500 words. In Table 12, we show the default prompt format for SST-2, TREC, and RTE. For datasets, Stanford Sentiment Treebank (SST-2) (Socher et al., 2013) is one of benchmarks in General Language Understanding Evaluation (GLUE) (Wang et al., 2018a). With fully labeled parse tress, This corpus allows a complete analysis of the compositional effects of sentiment in language. TREC (Voorhees and Tice, 2000) is a 6-way question classification. The target is to classify the questions based on whether their answer type is a Number, Location, Person, Description, Entity, or Abbreviation. Similarly, RTE (Recognizing Textual Entailment) (Dagan et al., 2005) is also a benchmark dataset from GLUE. It is a binary classification task to determine if a given premise entails a given hypothesis.

	SST-2	IMDB	AG News	AVG.
Random	0	0	0	0
Entropy	173	107	402	227
BADGE	25640	3816	1961	10303
CAL	708	273	1284	755
Ours	513	228	881	541
+ WCA	611	275	1023	636

Table 13: Running time (seconds) per sampling iteration (inference and selection) during AL acquisition for each datasets. AVG. refers the average acquisition time for all three datasets. For each acquisition, we report the running time under three adversarial attacks respectively

A.4 Sampling Efficiency and Running Time

We mask m as the number of labeled data in $\mathcal{D}_{label}$, n the number of unlabeled data in $\mathcal{D}_{pool}$, C the number of classes in the downstream classification task, d the dimension of embeddings, l the maximum sequence length, and s_{acq} the acquisition size. We set these values following Yuan et al. (2020) and Margatina et al. (2021). In Table 13, running time in seconds are summarized per sampling iteration (inference and selection) during AL acquisition for each dataset. Experiments in this part are performed on a Tesla V100 GPU. We keep $s_{acq} = 100, d = 768, t = 10$, and $l = 128$. For IMDB, we change the maximum sequence length to 256. As demonstrated in Table 13, BADGE requires a significantly amount of running time, since it has to cluster high-dimensional vectors and is a very computationally-heavy method. CAL also requires relative long running time as it needs to find the contrastive examples by finding nearest neighbors and computing contrastive score for unlabeled candidates. Our method achieves the second best efficiency. Even with the select worst-case augmentation, our acquisition function is still computationally productive as the augmentation and ranking candidates can be well deployed in the current computational machines. Entropy is overall the most efficient method as it only requires to rank the list of uncertainty scores, while it tends to have weaker performance.

Low-resource Entity Set Expansion: A Comprehensive Study on User-generated Text

Yutong Shao[1*], **Nikita Bhutani**[2†], **Sajjadur Rahman**[2†], **Estevam Hruschka**[2]
[1]University of California, San Diego [2]Megagon Labs
`yshao@eng.ucsd.edu, {nikita,sajjadur,estevam}@megagon.ai`

Abstract

Entity set expansion (ESE) aims at obtaining a more complete set of entities given a textual corpus and a seed set of entities of a concept. Although it is a critical task in many NLP applications, existing benchmarks are limited to well-formed text (e.g., Wikipedia) and well-defined concepts (e.g., countries and diseases). Furthermore, only a small number of predictions are evaluated compared to the actual size of an entity set. A rigorous assessment of ESE methods warrants more comprehensive benchmarks and evaluation. In this paper, we consider user-generated text to understand the generalizability of ESE methods. We develop new benchmarks and propose more rigorous evaluation metrics for assessing performance of ESE methods. Additionally, we identify phenomena such as non-named entities, multifaceted entities, vague concepts that are more prevalent in user-generated text than well-formed text, and use them to profile ESE methods. We observe that the strong performance of state-of-the-art ESE methods does not generalize well to user-generated text. We conduct comprehensive empirical analysis and draw insights from the findings.

1 Introduction

Entities are integral to applications that require understanding natural language text such as semantic search (Inan et al., 2021; Lashkari et al., 2019), question answering (Chandrasekaran et al., 2020; Cheng and Erk, 2020) and knowledge base construction (Goel et al., 2021; Al-Moslmi et al., 2020). To this end, entity set expansion (ESE) is a crucial task that uses a textual corpus to enhance a set of seed entities (e.g., 'mini bar', 'tv unit') with new entities (e.g., 'coffee', 'clock') that belong to the same semantic concept (e.g., room features).

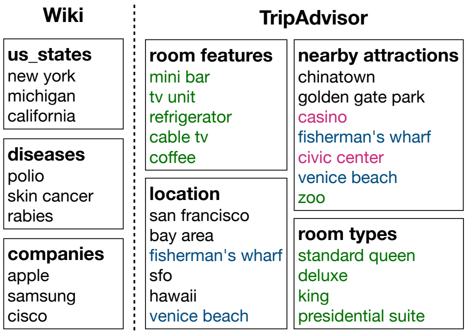

Figure 1: Example concepts and entities from Wiki vs. Tripadvisor. We highlight example multifaceted entities in blue, non-named entities in green and vague entities in magenta.

Since training data in new domains is scarce, many existing ESE methods expand a small seed set by learning to rank new entity candidates with limited supervision. Broadly speaking, there are two types of such low-resource ESE methods: (a) corpus-based methods (Shen et al., 2018; Huang et al., 2020a; Yu et al., 2019a) that bootstrap the seed set using contextual features and patterns, and (b) language model-based methods (Zhang et al., 2020a) that probe a pre-trained language model with prompts to rank the entity candidates.

Despite the recent progress, reported success of ESE methods is largely limited to benchmarks focusing on named entities (e.g., countries, diseases) and well-written text such as Wikipedia. Furthermore, the evaluation is limited to top 10-50 predictions regardless of the actual size of the entity set. As a result, it is unclear whether the reported effectiveness of ESE methods is conditional to datasets, domains, and/or evaluation methods.

In this paper, we conduct a comprehensive study to investigate the generalizability of ESE methods in low-resource settings. Specifically, we focus on

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1343 - 1353
July 10-15, 2022 ©2022 Association for Computational Linguistics

domains with user-generated text such as reviews. User-generated text data is abundant and is largely unlabeled. Enabling NLP applications including semantic search and question answering (Li et al., 2019; Bhutani et al., 2020; Dai and Song, 2019) over user-generated text requires entities mined from these largely unlabeled data. Furthermore, user-generated text has distinctive characteristics than well-written text, making it appropriate for this study. Due to lack of benchmarks on user-generated text, we create new benchmarks from three domains – *hotels*, *restaurants* and *jobs*.

We found that these benchmarks exhibit characteristics (illustrated in Figure 1) distinct from existing benchmarks: (a) *multifaceted* entities (entities that belong to multiple concepts — *e.g.*, 'venice beach' can belong to concepts location and nearby attractions); (b) *non-named* entities (entities that are typically noun phrases but not proper names — *e.g.*, 'coffee'); and (c) *vague* entities (human annotators have subjective disagreement on their concept labels — *e.g.*, 'casino' for nearby attraction). We explain why these characteristics emerge in user-generated text in Section 3.

We found that user-generated text can have up to 10× more *multifaceted* entities and 2× more *non-named* entities compared to well-curated benchmarks. Furthermore, concepts that do not have well-defined semantics result in *vague* entities. We use these characteristics to profile ESE methods, showing that the performance difference between well-curated and user-generated text can partially be attributed to these characteristics.

Contributions. To summarize, our key contributions include: a) identifying and verifying several important new characteristics in user-generated text that are not explored in evaluation of existing ESE methods, b) constructing three new user-generated text benchmarks (we publicly release two[1]), c) proposing new metrics for evaluating ESE methods, d) deriving insights through a cross-domain (user-generated text vs. well-curated) comparison study on different ESE methods.

Key findings. Our main findings are listed below:

- Widely used evaluation metrics such as (mean average precision (MAP) at $k \leq 20$) is an inadequate indicator of the performance of ESE methods on both well-curated and user-generated text. Evaluating top-k_g[2] predictions is potentially more robust, especially for benchmarking.
- Performance of state-of-the-art (SOTA) ESE methods drops dramatically on user-generated text compared to well-curated text.
- Deviating from prior observations, simple corpus-based and language model-based methods that underperform SOTA methods on well-curated text can outperform SOTA methods on user-generated text.
- Simple rank-based ensemble methods can provide further improvements on user-generated text. The degree of overlap of correct predictions from candidate methods is indicative of the effectiveness of their ensemble.

2 Background and Related Work

We now introduce the task of entity set expansion (ESE), existing paradigms and evaluation methods.

2.1 Problem Definition

Given a textual corpus and a user-defined seed set of entities (*e.g.*, 'coffee', 'table') of concepts (*e.g.*, room features), the task of ESE is to output a ranked list of entities (*e.g.*, 'clock', 'tv') that belong to the same concept. Following previous work, we focus on the *low-resource setting* where the seed set is small (3-10 entities per concept).

2.2 Entity Set Expansion Paradigms

To expand the seed set, ESE methods rank candidate entities extracted from a textual corpus (Shang et al., 2018). We limit our scope to low-resource setting and exclude methods (Mao et al., 2020; Takeoka et al., 2021) that require large training examples sub-concepts hierarchy or external knowledge from ontologies and knowledge bases. We organize ESE methods into the following categories.

Corpus-based Methods. These methods (Huang et al., 2020b; Shen et al., 2017, 2018; Yu et al., 2019a) obtain contextual features and distributed representations of entity candidates from the corpus and use them to estimate similarity of candidates to entities in the seed set. This is either done in a single step (Mamou et al., 2018; Yu et al.,

---

[1] https://github.com/megagonlabs/eseBench

[2] k_g denotes the actual entity set size of a concept.

Characteristics	Examples	Comments
Multifaceted entities	**R1**: Be sure to book in advance an early morning trip to Alcatraz, go to fisherman's wharf . . . **R2**: I would not stay here again. I'd rather pay more and stay by fisherman's wharf . . .	R1 refers to concept *nearby_attraction* while R1 refers to *location*. Entities that fall into multiple semantic concepts might influence other entity candidates for a target concept.
Vague entities	**R1**: . . . see the majestic Frenchy-looking civic center surrounded since 8pm by a crowd . . . **R2**: The Monticello Inn is five to ten minute cab ride from civic center . . .	R1 indicates the entity of interest is a nearby attraction but R2 is vague. Popular concepts such as nearby attractions in user generated text can be inherently subjective.
Non-named entities	**R1**: There was tea and coffee available round the clock in the lounge. **R2**: The room rate included a large and varied continental breakfast with excellent coffee. {concept: room features}	Concepts of interest in user-generated text domain often exhibit non-named entities. In fact, user-generated Tripadvisor dataset has 1.7× more non-named entities (such as "coffee") compared to well-curated Wiki dataset.

Table 1: Exploring different characteristics of well-curated and user-generated text domains.

2019a) or iteratively (Shen et al., 2018; Huang et al., 2020b; Yan et al., 2021).

Language Model-based Methods. Studies have shown that pre-trained language models (LMs) can be used as knowledge bases when queried with prompts (Petroni et al., 2019; Liu et al., 2021). Following this, ESE methods (Zhang et al., 2020a; Takeoka et al., 2021) probe an LM to rank entity candidates. These methods rely on knowledge stored in LMs instead of using them to obtain contextualized representations of entities in the corpus.

Ensemble Methods. CaSE (Yu et al., 2019b) combines context feature selection with pre-trained word embeddings to compute similarities between entities. A similar mechanism, mean reciprocal ranking (MRR) ensemble, has been shown to be effective in combining rankings from different features, views or subsets of seeds (Shen et al., 2017; Zhang et al., 2020b; Huang et al., 2020b).

2.3 Benchmark and Evaluation Metrics

Widely-used benchmarks for ESE, such as Wiki and APR (Shen et al., 2017), are based on well-formed text corpora like Wikipedia and focus only on well-defined concepts such as countries, US states, and diseases. Furthermore, the ranked expansion results are evaluated against the ground truth using Mean Average Precision (MAP) at different top-k positions where k is much smaller than the size of entity set. For example, there are 195 countries but only 10-50 predictions are evaluated. In following sections, we argue that existing benchmarks and evaluation metrics may not be adequate enough to estimate the real-world performance of the ESE methods and introduce new benchmarks and evaluation metrics to address their limitations.

3 Case Study

Existing work suggest that user-generated text differs from well-curated text in writing style (Bražinskas et al., 2020; Huang et al., 2020d) and cleanliness (Van der Wees et al., 2015; Dey et al., 2016). In this section, we discuss one of the use cases of ESE for a downstream NLP application and highlight new characteristics in user-generated text that are particularly relevant to the ESE task.

3.1 Motivating Example

Let us consider a scenario where Tajin, a data scientist at an online travel company (similar to TripAdvisor), has to develop a semantic search feature that helps users explore relevant reviews corresponding to their queries. For example, when a user searches for 'amenities' at a hotel, the feature should display reviews with mentions of different amenities highlighted. Since the reviews are unlabeled, Tajin first consults an expert to compile a list of frequently queried concepts and corresponding example entities that may appear in the reviews (similar to Figuure 1). To discover more entities for each concept, she formulates it as an ESE task, where the goal is to achieve a high coverage of entities in the reviews.

Given a review corpus and seed, Tajin employs a state-of-the-art ESE method that has been evaluated on well-curated text. She finds that it does not perform well in achieving a high coverage of entities in the hotel domain and wonders why. To explain her findings, we explore the characteristics of the TripAdvisor (Miao et al., 2020) and Wiki datasets next and discuss the potential factors that may impact the performance of the SOTA method.

3.2 Observations

Multifaceted entities. Unlike in Wiki benchmark where concepts are well-defined, concepts in Tripadvisor are domain-specific and can have overlapping semantics (see Figure 1). As a result, an entity can belong to multiple concepts. For example, in Table 1, the entity ‘fisherman’s wharf’ can be both location of and nearby attraction to a hotel. We refer to such entities as *multifaceted entities* (Rong et al., 2016). The overlapping semantics of entities can pose challenges to ESE methods that expand multiple concepts simultaneously.

Vague entities. Concept definitions in Wiki benchmark are strict (*e.g.*, countries, states) and ground truth about concept-entity pairs can be obtained by referring to external resources or commonsense. However, some concepts in Tripadvisor are open-ended and subjective, leading to vagueness in interpretation. For example, in Table 1, the terms “nearby” and “attraction” in the concept nearby attractions are subjective. An entity ‘civic center’ may be neither an attraction nor a nearby one depending on the context in the review. As a result, human annotators independently labeling the entity may disagree on the ground truth label. We refer to entities with subjective disagreements between annotators as *vague entities*. Intuitively, ESE methods may find it difficult to learn to disambiguate the context of vague entities.

Non-named entities. Non-named entities (*e.g.*, ‘coffee’ and ‘tv unit’) are typically noun phrases that are not proper names (Paris and Suchanek, 2021). Recent studies (Mbouopda and Melatagia Yonta, 2020; Bamman et al., 2019) have identified that non-named entities are prevalent even in well-curated domains and yet are ignored in existing benchmarks. Non-named entities are even more prevalent in user-generated text. As shown in Table 1, Tripadvisor benchmark contains almost 2× non-named entities than Wiki. Since non-named entities are not canonicalized and can have broader semantics, they can make the ESE task more challenging.

Evaluation Metric. Existing evaluation metrics only consider top 10-50 entities for each target concept (Shen et al., 2017; Zhang et al., 2020a). There are multiple limitations of these metrics. First, there may not be sufficient representation of multifaceted, vague, and non-named entities in a small set ($<$50 entities). Second, the actual number of correct entities per concept (referred to as *concept size*) may be much larger or smaller than 50. For example, both Tripadvisor and Wiki have larger and varying concept sizes with the median size being 121 and 205, respectively (check Table 2 for more detailed statistics). As a result, focusing only on precision of a small, fixed set of predictions may not reflect the recall of correct entities with respect to concept size.

3.3 Discussion

While multifaceted, vague, and non-named entities can be present in well-curated data, the corresponding benchmarks and downstream applications target real-world named entities and ignore non-named entities (Paris and Suchanek, 2021). In contrast, in most user-generated text domains, the concepts of interest for downstream applications (semantic search feature as discussed above) are not limited to named-entities only and may exhibit multifaceted, vague, and non-named entities (*e.g.*, facts about a hotel such as amenities and attractions). With the increasing use of user-generated text in NLP applications (Xu et al., 2021), it is therefore important to investigate the impact of the aforementioned characteristics on the performance of the ESE methods.

4 Experimental Set-up

We now outline our experiment set-up designed to explore the suitability of existing benchmarks, metrics, and methods.

4.1 Methods

We first describe the ESE methods we evaluate. Following prior work (Shen et al., 2018; Zhang et al., 2020a), we use AutoPhrase (Shang et al., 2018) to generate candidate entity lists from the corpus of a given domain. We then use the following representative publicly available ESE methods from different paradigms to expand the seed set[3].

SetExpan. SetExpan (Shen et al., 2017) is a SOTA corpus-based method that iteratively ranks entity candidates by filtering out noisy skip-gram features. It incorporates other context features such as POS tags and syntactic head tokens in ranking.

---

[3] All methods were released under Apache 2.0 license.

Embedding baseline (Emb-Base). In order to make use for more robust context embeddings, we develop a simple baseline that uses a pre-trained language model (LM) to derive context embeddings of entity candidates. To derive an entity embedding, we average context embedding of the sentences that mention the entity using BERT (Devlin et al., 2018). We compute concept embeddings by averaging embeddings of its seed entities, and rank entity candidates based on the cosine similarity of concept and entity embeddings.

CGExpan. CGExpan (Zhang et al., 2020b) is a SOTA LM-based method that iteratively uses Hearst patterns (Hearst, 1992) as prompts to obtain scores for ranking candidates. In addition, it considers how a candidate in turn ranks the target concept name to improve the quality of rankings.

LM Probing Baseline (LM-Base). We develop a simpler baseline that also uses Hearst patterns to prompt LMs and obtain scores for entity candidates. However, it does not include any other mechanisms such as concept name guidance and iterative expansion like CGExpan.

Ensemble Methods. We use mean reciprocal rank (MRR) as the representative for ensemble methods since it does not require any additional training data. Given the rankings from multiple methods, we compute MRR score of each entity: $MRR(e) = \frac{1}{n}\sum_{i=1}^{n}\frac{1}{r_i(e)}$, where n is the number of methods combined, and $r_i(e)$ is the ranking of entity e under method i. We then re-rank all entities based on their MRR score. In this work, we study combinations of two ESE methods leading to 6 ensembles. We study 4 settings that offer interesting combinations across different paradigms:

- MRR-Baseline: Emb-Base + LM-Base.
- MRR-SOTA: SetExpan + CGExpan.
- MRR-Corpus: SetExpan + Emb-Base.
- MRR-LM-Probe: CGExpan + LM-Base.

4.2 Datasets

We use widely adopted well-curated benchmarks: Wiki and APR (Zhang et al., 2020b; Shen et al., 2017). In addition, we create 3 new benchmarks based on user-generated text from Yelp (Huang et al., 2020c), Tripadvisor (Miao et al., 2020) and a proprietary Jobs dataset. All the datasets are in English. We first select concepts for the seed by referring to the features on the corresponding websites, to ensure their relevance for immediate downstream tasks. For example, we select concepts from various facets such as room type, amenities, and distance from attractions that help visitors search hotels on the Tripadvisor website[4]. Table 2 shows selected concepts in the benchmarks.

Data Collection and Annotation. In order to collect ground-truth to construct benchmarks for new domains, we collect top 200 predictions for each concept from each of the ESE methods described in Section 4.1. The first three authors of the paper labeled the predictions, 1 if a concept-entity pair is correct and 0 otherwise. We consider the majority vote as the final label for a concept-entity pair. For entities with rank > 200, we label the corresponding concept-entity pairs to be all negatives based on our preliminary observations that most of them are incorrect. We release the new benchmarks except for the Jobs dataset.

4.3 Metrics

In order to profile the benchmarks, we compute multifacetedness (m) as the fraction of entities in a benchmark that have been assigned to more than one concept. We compute non-named rate (r) as the fraction of non-named entities in the benchmark. We use Spacy[5] to identify named entities in the benchmarks. To avoid bias in estimating vagueness, we hire two additional in-house annotators who are unfamiliar with the concept definitions and entities. They label the ground truth concept-entity pairs — 1 if correct and 0 otherwise[6]. We compute vagueness (κ) in a benchmark using Fleiss' Kappa (Falotico and Quatto, 2015) which measures agreement among the annotators.

Since the benchmarks we constructed are intended to be comprehensive, we propose to estimate mean average precision (MAP) at *gold-k* (k_g) which equals the concept size, *i.e.*, number of entities in the concept. In comparison to smaller and fixed k, evaluation at k_g has several advantages: (a) it can adapt to different concept sizes and (b) it gives an estimate of recall[7] which is crucial to estimate effectiveness in real-world settings with commonly large concept sizes. Intuitively, using

---

Jobs	318k	company, dress code, job position, pay schedule, benefits, payment option (14)	5.143	8028	{36, 100, 316}	-0.1902	0.0837	0.7957

Table 2: Statistics of datasets: no. of documents, example concepts in the seed, avg. no. of entities in the seed, no. of entity candidates and concept size *{min, median, max}* across different concepts. Statistics of benchmarks: multifacetedness (m), non-named rate (r) and vagueness (κ). †: for well-curated datasets, there is no subjective disagreement since the concept-entity pairs are factually verifiable.

k_g would include more instances of multifaceted, vague and non-named entities that would otherwise be ignored in small k. Notice that in certain real-world scenarios, *e.g.*, developing ESE methods for a new domain, estimating k_g may be difficult, thus previous metrics with smaller and fixed k can be useful. However, for other scenarios, especially for evaluation on benchmarks where the goal is to stress test methods, evaluation at k_g is more appropriate.

5 Findings

We next share our findings from analyzing the ESE methods. Note that all the results are obtained from single run of each experiment.

5.1 Appropriateness of Existing Benchmark and Metrics

Q1. Do we need new benchmarks based on user-generated text?

Table 2 compares the characteristics of the various benchmarks using measures described in Section 4.3. As can be seen, user-generated text benchmarks exhibit a higher degree of multifacetedness (m) and non-named rate (r) compared to well-curated Wiki and APR benchmarks. Moreover, poor agreement between annotators ($\kappa < 0$) indicates the presence of vagueness or subjectivity in user-generated text which does not exist in well-curated benchmarks. While all benchmarks exhibit diversity in concept sizes, the diversity is higher in user-generated text than well-curated benchmarks.

Takeaway 1 *User-generated text benchmarks exhibit more multifaceted entities, non-named entities, and vagueness than well-curated benchmarks.*

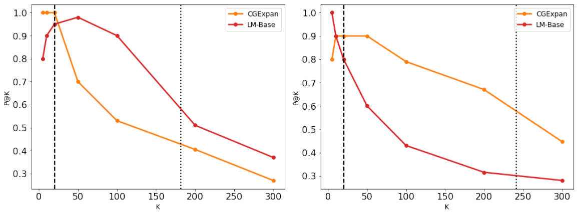
Q2. Do existing evaluation metrics accurately estimate the performance of ESE methods?

Table 3 shows the % drop in MAP of different ESE methods when k is increased from 20 to k_g. The performance drop is consistent across both well-curated and user-generated text benchmarks with the largest being 62% for CGExpan on the Jobs benchmark. This indicates that existing metrics overestimate the real-world performance of all ESE methods. However, simpler baselines, Emb-Base and LM-Base, tend to show lower performance drop than more sophisticated counterparts on user-generated text. This indicates that existing well-curated benchmarks do not reliably capture progress in this field.

Method/Datasets	Jobs	Yelp	TripAdvisor	Wiki	APR
SetExpan	-36.66%	-41.74%	**-43.16%**	-40.76%	-14.25%
CGExpan	**-61.99%**	**-54.37%**	-42.82%	-39.67%	-38.21%
Emb-Base	-54.10%	-43.96%	-36.41%	-35.45%	**-56.33%**
LM-Base	-36.17%	-35.15%	-34.47%	**-56.40%**	-43.96%

Table 3: Drop in performance of different ESE methods from MAP@20 to MAP@k_g. Largest drops in each dataset are highlighted in bold.

We further observed that, across all the benchmarks, the performance drops are higher for concepts with large entity sets. We show two such cases in Figure 2 — one with user-generated text (Figure 2a) and another with well-curated text (Figure 2b) — which illustrate precision curves at different values of k for concepts with large k_g in various benchmarks. As shown, two ESE methods that may show similar performance at k=20 (widely adopted metric) have much larger performance margins at k_g. Thus, evaluation results on only top 20 predictions may be an incomplete depiction of method robustness, especially for concepts with large entity sets.



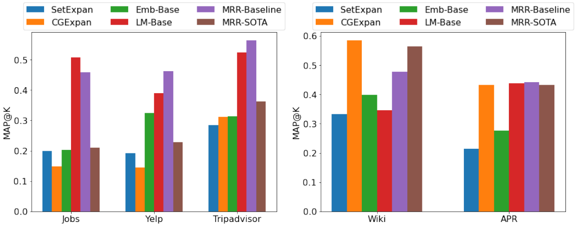
(a) TripAdvisor: amenities (b) Wiki: tv channel

Figure 2: Precision@k of LM-Base and CGExpan for example concepts. Dashed line indicates k=20 and dotted line indicates k_g. Performance margins at k=20 and k_g vary significantly.

Takeaway 2 *Existing evaluation metrics tend to overestimate the real-world performance of ESE methods and may be unreliable for evaluating concepts with large entity sets.*

5.2 Performance on new benchmarks

Q3. How effective SOTA methods are for entity set expansion on user-generated text benchmarks?



(a) user-generated text. (b) well-curated datasets.

Figure 3: Overall MAP@k_g performance of each method on (a) user-generated text and (b) well-curated benchmarks. SOTA methods (CGExpan, SetExpan) are outperformed by simple baselines and ensemble methods on user-generated text.

Given new benchmarks and evaluation metrics, we now compare the performances of various ESE methods. Figure 3 shows that SOTA method CGExpan outperforms other methods on existing well-curated benchmarks which aligns with the reported success of the method. Surprisingly, simpler baseline methods (Emb-Base and LM-Base) that were not optimal on well-curated benchmarks, significantly outperform their SOTA counterparts (SetExpan and CGExpan, respectively) on user-generated text benchmarks, with LM-Base obtaining the best performance. We also observe that ensemble-based methods tend to perform better than or at least similar to the ESE methods they combine.

Takeaway 3 *Performance of SOTA methods do not generalize to user-generated text benchmarks. Ensemble-based methods may improve over the corresponding standalone methods.*

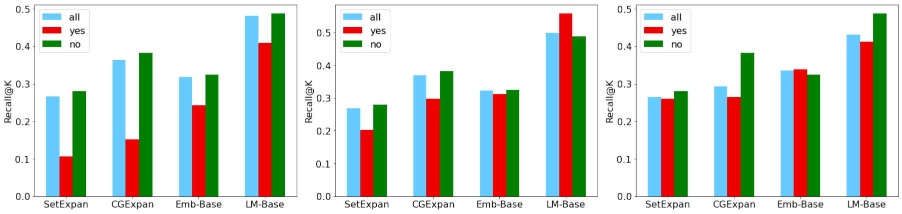
We now examine why SOTA approaches may underperform on user-generated text. Given the success of LM-based contextual representations, it is expected that Emb-Base may outperform lexical feature-based SetExpan. Furthermore, as SetExpan eliminates noisy features of a candidate entity before ranking candidates, it may disregard some context features of multifaceted and vague entities that are mentioned in diverse contexts in user-generated text, leading to sub-optimal ranking of entities. Similarly, CGExpan, which scores each candidate entity by selecting one positive concept and multiple negative concepts, may penalize entities belonging to multiple concepts (multifaceted entities) or mentioned in different contexts (vague entities). Therefore, many of the carefully designed approaches useful on well-curated domains may not generalize to user-generated text.

Takeaway 4 *SOTA methods implement techniques that avoid selecting ambiguous context of an entity. Such a design choice potentially penalizes multifaceted and vague entities when ranking entity candidates for concepts.*

Q4. How do characteristics of user-generated text affect performance of ESE methods?

We now discuss how different characteristics of user-generated text impact the behavior of ESE methods. To understand this, we compare the recall of entities that exhibit one of the target characteristics (multifaceted/non-named/vague) with recall of entities that do not exhibit any of the characteristics. This enables us to analyze the influence of a target characteristic independent of other characteristics. To compute recall, we consider an entity as retrieved if it is ranked in the top-k_g predictions.

Figure 4 compares the recall of entities across different characteristics. For ease of visualization, we combine entities across the 3 benchmarks. As shown, almost all methods show lower recall of entities that exhibit challenging characteristics than entities without these characteristics, and SOTA methods suffer larger drops than simple methods. This supports our hypothesis that characteristics of user-generated text negatively affect performances,



(a) vague entities (b) multifacetedness (c) non-named entities

Figure 4: Recall@k_g of an ESE method typically drops with the presence of (a) vague, (b) multifaceted, and (c) non-named entities in user-generated text (show by red bars) compared to the case when none of these entities are present (shown by green bars).

company **Jobs**
Seed: walmart, amazon, subway, microsoft, target
CGExpan (0.48): costco, apple, AT&T, starbucks, fedex, ALDI, kroger,...
LMBase (0.45) : nike, apple, IBM, sears, starbucks, target, google, intel,...

seating arrangement **Yelp**
Seed: indoor area, outdoor bar, roof top, patio seating
CGExpan (0.02): restaurant, atmosphere, live music, music, free wifi, casino..
LMBase (0.57): bar lounge, outside patio, pool deck, restaurant, rooftop..

Figure 5: Example concepts on which CGExpan and LM-Base have similar (*company*) or different (*seating arrangement*) performances (indicated in parenthesis). Incorrect entities are shown in red.

especially for SOTA methods which tend to penalize entities with diverse contexts. Future work may investigate how to overcome these challenges.

To provide a qualitative comparison between the behaviors of SOTA methods (*e.g.*, CGExpan) and our proposed baselines (*e.g.*, LM-Base), we show their predictions on two representative concepts in Figure 5. CGExpan and LM-Base have comparable performance on well-formed concepts (*e.g.*, company) in Jobs. However, LM-Base outperforms CGExpan for concepts (*e.g.*, seating arrangement) with entities having characteristics of user-generated text. CGExpan retrieves entities that co-occur frequently with seating arrangement.

Takeaway 5 *Due to the presence of challenging characteristics in user-generated text, performance of all ESE methods are negatively impacted with SOTA methods exhibiting larger drops.*

5.3 Improvement Opportunities

Q5. How do we design ensemble methods for benchmarks with user-generated text?

We analyze ensemble methods further since they tend to outperform other ESE methods (Figure 3). It is trivial that ensemble methods perform well when both combined methods are strong. We are more interested in other factors that may impact performance. Specifically, we investigate what influences the *effectiveness* of a MRR method that combines two ESE methods. An MRR combination is more effective when it outperforms both candidate methods by a larger margin. We define *effectiveness* of combining methods as:

$$Eff(m_1, m_2) = \frac{S(m_1 + m_2)}{\max(S(m_1), S(m_2))} - 1 \quad (1)$$

where $S(m)$ means the performance (MAP@k_g in our study) of method m, and $m_1 + m_2$ means the MRR combination of method m_1, m_2.

As discussed in Section 5.2, multifaceted and vague entities may appear in diverse contexts which SOTA approaches fail to capture, leading to lower recall. Intuitively, it is advantageous to combine methods that capture differing contexts and in the process predict collections of correct entities with minimal overlap. In other words, in order for a MRR method to achieve higher recall, the ESE methods must be *compatible*. We measure *compatibility* of two ESE methods as:

$$Comp(m_1, m_2) = \frac{\|P(m_1) \cup P(m_2)\|}{\max(\|P(m_1)\|, \|P(m_2)\|)} - 1 \quad (2)$$

where $P(m)$ is the set of *correct* entity predictions of method m, i.e. positive benchmark entities ranked among top-k_g by m. $\|\|$ denotes the size of a set. When one of the correct prediction set of m_1, m_2 is a subset of the other, their compatibility is 0. When the two methods find two disjoint sets of correct entities, their compatibility is 1.

We illustrate the correlation between compatibility of method pairs and effectiveness of their MRR combination in Figure 6 using a scatter plot. Each of the points represent the compatibility and effectiveness of the four ensemble methods (MRR-

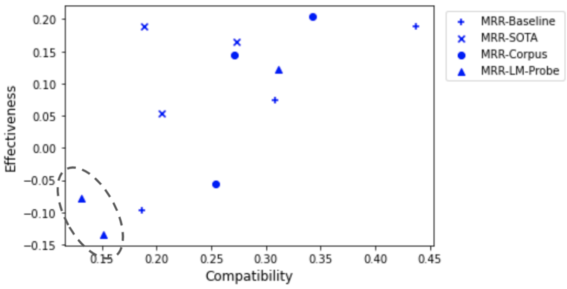


Figure 6: Scatter plot showing the positive correlation between compatibility of methods and effectiveness of their MRR combination on three user-generated text benchmarks. The least compatible and effective combination results (in dashed circle) are from MRR-LM-Probe.

SOTA, MRR-Base, MRR-Corpus, and MRR-LM-probe) on all three user-generated text datasets. We observe that LM-based methods are least compatible due to their similarity in design. The resulting ensemble, MRR-LM-probe, has poor effectiveness (highighted by the dashed ellipse in Figure 6). Other method pairs have less homogeneity in their design and the resulting ensembles often show higher effectiveness. The corresponding compatibility and effectiveness values have a strong positive correlation (Pearson correlation, $R = 0.69$). Therefore, compatibility can be a useful metric for deciding whether combining two methods method may improve performance or not.

Takeaway 6 *Two effective ESE methods on user-generated text with high compatibility (diversity in correct predictions) may achieve higher performance when combined using rank-based ensemble.*

6 Discussion

We now discuss the implications of the proposed benchmark, metrics, and experiment observations.

Capturing the silent majority. Recent work (Paris and Suchanek, 2021) shows that the majority of the entities in Wikipedia articles — which feeds knowledge-bases such as DBpedia (Auer et al., 2007) and YAGO (Suchanek et al., 2007) — are non-named and recommends adding the silent majority to these KBs for completeness. To this end, our proposed benchmark highlights the importance of capturing multifaceted, vague, and non-named entities present in user-generated text. For example, domain-specific KBs such as the Amazon Product Knowledge Graph (Karamanolakis et al., 2020) rely on user-generated text to collect entities for concepts of interest. These KBs power many downstream tasks such as semantic search, question answering, and conversational AI. Therefore, these KBs would remain incomplete without capturing the different types of entities identified in our benchmark.

Practical usage. The goal of our evaluation metrics (evaluation at k_g) is to characterize the performance of ESE methods in the presence of entity types that are typically present in user-generated text. Note that we do not recommend replacing the existing metric MAP@$K = 20$. Our proposed MAP@K_g metric is complementary and is designed to stress test ESE methods in scenarios where coverage is an important criteria (*e.g.*, KB population.) Top-20 predictions do not have enough representation of non-named, multifaceted, and vague entities. Therefore, when evaluating ESE methods designed for user-generated text on our benchmark, the proposed evaluation at k_g metric may help practitioners measure the suitability of a method.

Towards domain-specific ESE. Our study highlights that compared to simple ESE baselines, SOTA methods exhibit poor performance on user-generated text. On the other hand, for well-curated text, SOTA methods outperform the baselines. However, the purpose of this study is not to show that there are better approaches than SOTA methods. Instead, we draw attention to the fact that, there is potential for future research on developing methods for user-generated text domain.

7 Conclusion

We conduct a comprehensive study to analyze the performance of ESE in user-generated text. We observe that user-generated text has characteristics that are not captured in existing benchmarks, and propose new benchmarks and evaluation metrics. Our findings indicate that state-of-the-art methods are not very effective in user-generated text and are often outperformed by simpler baselines.

Abstract

Ideology is at the core of political science research. Yet, there still does not exist general-purpose tools to characterize and predict ideology across different genres of text. To this end, we study Pretrained Language Models using novel ideology-driven pretraining objectives that rely on the comparison of articles on the same story written by media of different ideologies. We further collect a large-scale dataset, consisting of more than 3.6M political news articles, for pretraining. Our model POLITICS outperforms strong baselines and the previous state-of-the-art models on ideology prediction and stance detection tasks. Further analyses show that POLITICS is especially good at understanding long or formally written texts, and is also robust in few-shot learning scenarios.

1 Introduction

Ideology is an ubiquitous factor in political science, journalism, and media studies (Mullins, 1972; Freeden, 2006; Martin, 2015). Decades of work has gone into measuring ideology based on voting data (Poole and Rosenthal, 1985; Lewis et al., 2021), survey results (Preoţiuc-Pietro et al., 2017; Ansolabehere et al., 2008; Kim and Fording, 1998; Gabel and Huber, 2000), social networks (Barberá et al., 2015), campaign donation records (Bonica, 2013), and textual data (Laver et al., 2003; Diermeier et al., 2012; Gentzkow et al., 2019; Volkens et al., 2021). Each of those approaches has its strengths and weaknesses. For instance, many political figures do not have voting records; surveys are expensive and politicians are often unwilling to disclose ideology. By contrast, political text is abundant, ubiquitous, yet challenging to work with since language is complex in nature, often domain-specific, and generally unlabeled. There thus remains a strong need for general-purpose tools for measuring ideology using text that can be applied across multiple genres.

News Story: *Donald Trump tests positive for COVID-19.*

Daily Kos (left): It's now clear that Donald Trump **lied** to the nation about when he received a positive test for COVID-19. . . . they're continuing to act as if nothing has changed—and that **disregarding science** and **lying** to the public are the only possible strategies.

The Washington Times (right): *Trump says he's "doing very well"* . . . *President Trump thanked the nation for supporting him* Friday night as he left the White House to be hospitalized for COVID-19. *"I want to thank everybody for the tremendous support. . . ."* Mr. Trump said in a video recorded at the White House.

Breitbart (right): *President Donald Trump thanked Americans for their support* on Friday as he traveled to Walter Reed Military Hospital for further care after he was diagnosed with coronavirus. *"I think I'm doing very well. . ."* Trump said in a video filmed at the White House and posted to social media.

Figure 1: Article snippets by different media on the same news story. Contents that indicate stances and ideological leanings are highlighted in **bold** (for subjective phrases) and in *italics* (for objective events).

Using text as data, computational models for ideology measurement have rapidly expanded and diversified, including classical machine learning methods such as ideal point estimation (Groseclose et al., 1999; Shor and McCarty, 2011), Naive Bayes (Evans et al., 2007), support vector machines (Yu et al., 2008), latent variable models (Barberá et al., 2015), and regression (Peterson and Spirling, 2018); and more recent neural architectures like recurrent neural networks (Iyyer et al., 2014) and Transformers (Baly et al., 2020; Liu et al., 2021). Nonetheless, most of those models leverage datasets with ideology labels drawn from a single domain, and it is unclear if any of them can be generalized to diverse genres of text.

Trained on massive quantities of data, Pretrained Language Models (PLMs) have achieved state-of-the-art performance on many text classification problems, with an additional fine-tuning stage on labeled task-specific samples (Devlin et al., 2019; Liu

---

[*] Equal contribution by the first two authors.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1354 - 1374
July 10-15, 2022 ©2022 Association for Computational Linguistics

et al., 2019). Though PLMs suggest the promise of generalizable solutions, their ability to acquire the knowledge needed to detect complex features such as ideology from text across genres remains an open question. PLMs have been shown to capture linguistic structures with a *local focus*, such as task-specific words, syntactic agreement, and semantic compositionality (Clark et al., 2019; Jawahar et al., 2019). Although word choice is indicative of ideology, ideological leaning and stance are often revealed by which entities and events are selected for presentation (Hackett, 1984; Christie and Martin, 2005; Enke, 2020), with the most notable strand of work in framing theory (Entman, 1993, 2007). One such example is demonstrated in Figure 1, where Daily Kos criticizes Trump's dishonesty while The Washington Times and Breitbart emphasize the good condition of his health.

In this work, we propose to train PLMs for a wide range of ideology-related downstream tasks. We argue that it is critical for PLMs to consider the *global context* of a given article. For instance, as pointed out by Fan et al. (2019), one way to acquire such context is through comparison of news articles on the same story but reported by media of different ideologies. Given the lack of suitable datasets, we first collect a new large-scale dataset, **BIGNEWS**.[1] It contains 3,689,229 English news articles on politics, gathered from 11 United States (US) media outlets covering a broad ideological spectrum. We further downsample and cluster articles in BIGNEWS by different media into groups, each consisting of pieces aligned on the same story. The resultant dataset, BIGNEWSALIGN, contains 1,060,512 stories with aligned articles.

Next we train a new PLM, **POLITICS**, based on a Pretraining Objective Leveraging Inter-article Triplet-loss using Ideological Content and Story. Concretely, we leverage continued pretraining (Gururangan et al., 2020), where we design an **ideology objective** operating over clusters of *same-story* articles to compact articles with similar ideology and contrast them with articles of different ideology. The learned representation can better discern the embedded ideological content. We further enhance it with a **story objective** that ensures the model to focus on meaningful content instead of overly relying on shortcuts, e.g., media boilerplate. Both objectives are used together with our specialized masked language model objective that focuses on entities and sentiments to train POLITICS.

Our main goal here is to create **general-purpose tools** for analyzing ideological content for researchers and practitioners in the **broad community**. Furthermore, when experimenting on 11 ideology prediction and stance detection tasks using 8 datasets of different genres, including a newly collected dataset from AllSides, POLITICS outperforms both a strong SVM baseline and previous PLMs on 8 tasks. Notably, POLITICS is particularly effective on long documents, e.g., achieving 10% improvements on both ideology prediction and stance detection tasks over RoBERTa (Liu et al., 2019). We further show that our model is more robust in setups with smaller training sets.

2 Related Work

Ideology prediction is a critical task for quantitative political science (Mullins, 1972; Freeden, 2006; Martin, 2015; Wilkerson and Casas, 2017). Both classical methods (e.g., Naive Bayes, SVM; Evans et al., 2007; Yu et al., 2008; Sapiro-Gheiler, 2019) and deep learning models (e.g., RNN; Iyyer et al., 2014) have been used to predict ideology on a variety of datasets where ideology labels are available, such as legislative speeches (Laver et al., 2003) and U.S. Supreme Court briefs (Evans et al., 2007). Notably, Liu et al. (2021) pretrains a Transformer-based language generator to minimize the ideological bias in generated text. As generative models are not as effective as masked language models (MLMs) at text classification, our goal differs in that we train MLMs to recognize ideological contents in various domains and tasks.

Stance detection is a useful task for ideology analysis because co-partisans are generally positive towards each other and negative towards counter-partisans (Aref and Neal, 2021). There has been a large body of work on identifying individuals' stances towards specific targets from the given text (Thomas et al., 2006; Walker et al., 2012; Hasan and Ng, 2013). On the methodology side, Mohammad et al. (2016b) and Küçük and Can (2018) apply statistical models, e.g., SVM, with handcrafted text features. Neural methods have also been widely investigated, including CNN (Wei et al., 2016), LSTM (Augenstein et al., 2016), hierarchical networks (Sun et al., 2018), and representation learning (Darwish et al., 2020).

Recent research focus resides in leveraging

Table 1: Statistics of BIGNEWSBLN. Media outlets are sorted by ideology from left (L), center (C), to right (R) based on AllSides and Media Bias Chart. HPO: Huffington Post; WaPo: The Washington Post; NYT: The New York Times; TWT: The Washington Times. Additional statistics of raw data size before downsampling and the corresponding publish dates can be found in Table A4.

PLMs for predicting stances, e.g., incorporating extra features (Prakash and Madabushi, 2020). Kawintiranon and Singh (2021) share a similar spirit with our work by upsampling tokens to mask. However, they pre-define a list of tokens customized for the given targets, which is hard to generalize to new targets. We aim to train PLMs relying on general-purpose sentiment lexicons and important entities, to foster model generalizability.

Domain-specific Pretrained Language Models. PLMs, such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), have obtained state-of-the-art results on many NLP tasks. Inspired by the observation that a continued pretraining phase on in-domain data yields better performance (Gururangan et al., 2020), domain-specific PLMs are introduced (Beltagy et al., 2019; Yang et al., 2020; Huang et al., 2019; Lee et al., 2020). However, they only use the default MLM objective, without considering domain knowledge. In this work, we design ideology-driven pretraining objectives to inject domain knowledge to discern ideologies and related stances.

Focusing on the news domain, PLMs have been primarily used for factuality prediction (Jwa et al., 2019; Zellers et al., 2019; Kaliyar et al., 2021) and topic classification (Liu et al., 2020; Büyüköz et al., 2020; Gupta et al., 2020) by fine-tuning on task-specific datasets. Few work has investigated PLMs for understanding political ideology evinced in texts. One exception is Baly et al. (2020), where they also leverage the triplet loss as the pretraining objective. However, our work is novel in at least three aspects. First, our triplet loss is designed to capture the ideological (dis)similarity among articles *on the same story*, while the loss used by Baly et al. (2020) operates on articles *of the same topic*. As a result, their approach can falsely compact representations of very different news contents, e.g., articles on "Japan Economics" and "Indian Troops" both belong to the topic of "Asia". Moreover, our newly introduced story objective can effectively prevent the model from relying on media-specific language (e.g., "for the New York Times"), while their objective may fail to do so, and thus lacks generalizability to languages used by different media and other ideology-related tasks. Finally, we use BIGNEWS that contains more than 3M articles, which is more suitable for pretraining large models than the small dataset (35k articles) used by Baly et al. (2020). To the best of our knowledge, we are the first to systematically study and release PLMs for ideology-related study in the US political domain.

3 Pretraining Datasets

3.1 Data Crawling

We collect pretraining datasets from online news articles with diverse ideological leanings and language usage. We select 11 media outlets based on their ideologies (from far-left to far-right) and popularity.[2] We convert their ideologies into three categories: left, center, and right, and crawl all pages published by them between January 2000 and June 2021, from Common Crawl and Internet Archive. We then follow Raffel et al. (2020) for data cleaning, and, additionally, only retain news articles related to US politics. Appendix A describes in detail the steps for removing non-articles pages, duplicates, non-US pages, and boilerplate.

The cleaned data, dubbed **BIGNEWS**, contains 3,689,229 US political news articles. To mitigate the bias that some media dominate the model training, we downsample the corpus so that each ideology contributes equally. The downsampled corpus, **BIGNEWSBLN**, contains 2,331,552 news articles, with statistics listed in Table 1. We keep 30K held-out articles as validation set.

---

[2] We use `https://www.allsides.com` and `https://adfontesmedia.com` to decide ideology and `https://www.alexa.com/topsites` to decide popularity.

3.2 Aligning Articles on the Same Story

We compare how media outlets from different sides report the same story, which intuitively better captures ideological content. To this end, we design an algorithm to align articles in BIGNEWSBLN that cover the same story. We treat each article as an anchor, and find matches from other outlets based on the following similarity score:

$$\text{sim}(p_i, p_j) = \alpha * \text{sim}_t(p_i, p_j) + (1-\alpha) * \text{sim}_e(p_i, p_j) \quad (1)$$

where p_i and p_j are two articles, sim_t is the cosine similarity between TF-IDF vectors of p_i and p_j, sim_e is the weighted Jaccard similarity between the sets of named entities[3] in p_i and p_j, and $\alpha = 0.4$ is a hyperparameter. During alignment, for an article from an outlet to be considered as a match, it must be published within three days before or after the anchor, has the highest similarity score among articles from the same outlet, and the score is at least $\theta = 0.23$. Hyperparameters α and θ are searched on the Basil dataset (Fan et al., 2019), which contains manually aligned articles.[4] After deduplicating articles in each story cluster, we obtain **BIGNEWSALIGN**, containing 1,060,512 clusters with an average of 4.29 articles in each. Appendix B details the alignment algorithm.

4 POLITICS via Continued Pretraining

Here we introduce our continued pretraining methods based on a newly proposed **ideology objective** that drives representation learning to better discern ideological content by comparing same-story articles (§4.1), which is further augmented by a **story objective** to better focus on content. They are combined with the masked language model objective, which is tailored to focus on entities and sentiments (§4.2), to produce POLITICS (§4.3).

4.1 Ideology-driven Pretraining Objectives

To promote representation learning that better captures ideological content, we leverage BIGNEWSALIGN with articles grouped by stories to provide story-level background for model training. That is, we use triplet loss (Schroff et al., 2015) that operates over **triplets** of <anchor, positive, negative> to encourage anchor and positive samples to have closer representations while contrasting anchor from negative samples.

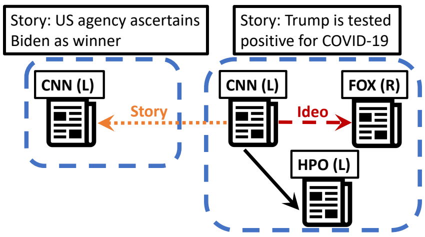

Figure 2: Construction of the ideology and story objectives. The middle CNN article is the anchor in this example. Solid black arrow represents positive-pair relation for both objectives; red dashed arrow denotes negative-pair for ideology objective; orange dashed arrow indicates negative-pair for story objective.

Our primary pretraining objective, i.e., ideology objective, uses the triplet loss to teach the model to acquire **ideology-informed representations** by comparing *same-story* articles written by media of *different ideologies*. As shown in Figure 2, given a story cluster, we choose an article published by media on the left or right as the *anchor*. We then take articles in the same cluster with the same ideology as *positive* samples, and articles with the opposite ideology as *negative* ones. The ideology objective is formulated as follows:

$$\mathcal{L}_{\text{ideo}} = \sum_{t \in \mathcal{T}_{\text{ideo}}} \left[\left\| \mathbf{t}^{(\mathbf{a})} - \mathbf{t}^{(\mathbf{p})} \right\|_2 - \left\| \mathbf{t}^{(\mathbf{a})} - \mathbf{t}^{(\mathbf{n})} \right\|_2 + \delta_{\text{ideo}} \right]_+ \quad (2)$$

where $\mathcal{T}_{\text{ideo}}$ is the set of all ideology triplets, $\mathbf{t}^{(\mathbf{a})}$, $\mathbf{t}^{(\mathbf{p})}$, and $\mathbf{t}^{(\mathbf{n})}$ are the `[CLS]` representations of anchor, positive, and negative articles in triplet t, δ_{ideo} is a hyperparameter, and $[\cdot]_+$ is $max(\cdot, 0)$.

Next, we augment the ideology objective with a story objective to allow the model to focus on **semantically meaningful content** and to prevent the model from focusing on “shortcuts” (such as media-specific languages) to detect ideology. To construct story triplets, we use the same <anchor, positive> pairs as in the ideology triplet, and then treat articles from the same media outlet but on different stories as negative samples, as depicted in Figure 2. Similarly, our story objective is formulated as follows:

$$\mathcal{L}_{\text{story}} = \sum_{t \in \mathcal{T}_{\text{story}}} \left[\left\| \mathbf{t}^{(\mathbf{a})} - \mathbf{t}^{(\mathbf{p})} \right\|_2 - \left\| \mathbf{t}^{(\mathbf{a})} - \mathbf{t}^{(\mathbf{n})} \right\|_2 + \delta_{\text{story}} \right]_+ \quad (3)$$

where $\mathcal{T}_{\text{story}}$ contains all story triplets, and δ_{story} is a hyperparameter searched on the validation set.

---

[3] Extracted by Stanford CoreNLP (Manning et al., 2014).

[4] Our algorithm achieves a mean reciprocal rank of 0.612 on Basil, with detailed evaluation in Appendix B.

4.2 Entity- and Sentiment-aware MLM

Here we present a specialized MLM objective to collaborate with our triplet loss based objectives for better representation learning. Notably, political framing effect is often reflected in which entities are selected for reporting (Gentzkow et al., 2019). Moreover, the occurrence of sentimental content along with the entities also signal stances (Mohammad et al., 2016b). Therefore, we take a masking strategy that upsamples *entity* tokens (Sun et al., 2019; Guu et al., 2020; Kawintiranon and Singh, 2021) and *sentiment* words to be masked for the MLM objective, which improves from prior pretraining work that only considers article-level comparison (Baly et al., 2020).

Concretely, we consider named entities with types of PERSON, NORP, ORG, GPE and EVENT. We detect sentiment words using lexicons by Hu and Liu (2004) and Wilson et al. (2005). To allow MLM training to focus on entities and sentiment, we mask them with a 30% probability, and then randomly mask remaining tokens until 15% of all tokens are reached, as done in Devlin et al. (2019). Masked tokens are replaced with `[MASK]`, random tokens, and original tokens with a ratio of 8:1:1.

4.3 Overall Pretraining Objective

We combine the aforementioned objectives as our final pretraining objective as follows:

$$\mathcal{L} = \beta * \mathcal{L}_{\text{ideology}} + \gamma * \mathcal{L}_{\text{story}} + (1-\beta-\gamma) * \mathcal{L}_{\text{MLM}} \quad (4)$$

where $\beta = \gamma = 0.25$. Using $\mathcal{L}$, POLITICS is produced via continued training on RoBERTa (Liu et al., 2019).[5] We do not try to train the model from scratch since BIGNEWSBLN only has $\sim$10GB data, smaller than corpus for RoBERTa ($\sim$160GB). Hyperparameters are listed in Table A5.

5 Experiments

Given the importance of ideology prediction and stance detection tasks in political science (Thomas et al., 2006; Wilkerson and Casas, 2017; Chatsiou and Mikhaylov, 2020), we conduct extensive experiments on a wide spectrum of datasets with 11 tasks (§5.1). We then compare with both classical models and prior PLMs (§5.2), and among our model variants (§5.3). We present and discuss results in §5.5, where POLITICS outperform all three baselines on 8 out of 11 tasks. For all models, MLM objectives are trained with BIGNEWSBLN, and ideology and story objectives are trained on BIGNEWSALIGN. Details are in Appendix C.1.

Data	Genre	# Train	Len.	Split
Congress Speech (Gentzkow et al., 2018)	speech	7,000	538	rand.
AllSides (*newly collected*)	news	7,878	863	time

SemEval (Mohammad et al., 2016a)	tweet	2,251	17	rand.†
Twitter (Preoţiuc-Pietro et al., 2017)	tweet	1,079	2,298	user

Table 2: Datasets used for evaluating PLMs vary in text genre, training set size (# Train), length (Len.), and split criterion. Rand. denotes random split. Time split means training on the "past" data and test on the "future". Story split divides articles according to story clusters. User split indicates users in the test are unseen in the training. †: by the original work.

5.1 Datasets and Tasks

Our tasks are discussed below, with statistics listed in Table 2 and more descriptions in Appendix D.

Ideology prediction tasks for predicting the political leanings are evaluated on the following datasets.

- `Congress Speech` (**CongS**; Gentzkow et al., 2018) contains speeches from US congressional records, each labeled as liberal or conservative.
- `AllSides` [6] (**AllS**, new) is a website that assesses political bias and ideology of US media. In this study, we collect articles from AllSides with their ideological leanings on a 5-point scale.
- `Hyperpartisan` (**HP**; Kiesel et al., 2019) is a shared task of predicting a binary label for an article as being hyperpartisan or not. We convert it into a 3-way classification task by splitting hyperpartisan news into left and right.
- `YouTube` (**YT;** Wu and Resnick, 2021) contains discussions on YouTube. **cmt.** and **user** refer to predicting left/right at the comment- and user-level, respectively.
- `Twitter` (**TW;** Preoţiuc-Pietro et al., 2017) collects a group of Twitter users with self-reported ideologies on a 7-point scale. We merge them into 3-way labels.

Stance detection tasks, which predict a subject's attitude towards a given target from a piece of text, are listed below. All tasks take a 3-way label

Table 3: Macro F1 scores on 11 evaluation tasks (average of 5 runs). Tasks are sorted by text length, short to long, within each group. "All avg" is the average of all 11 tasks. **Best** results are in bold and second best are underlined. Our models with triplet-loss objectives that outperform RoBERTa are in blue. Our models with specialized sampling methods that outperform the one with vanilla MLM (Random) are in green. POLITICS uses Ideology + Story Obj. and Upsamp. Ent. + Sentiment. Results where POLITICS outperforms all baselines are in red, with * indicating statistical significance (Mann–Whitney U test; Mann and Whitney, 1947, $p \leq 0.05$). Standard deviations (std) are reported in Table A11. The range of std over tasks is $[0.31, 3.42]$ for POLITICS, and $[0.48, 7.35]$ for RoBERTa.

(positive, negative, and neutral) except for **BASIL (sent.)** that labels positive or negative.

- `BASIL` (Fan et al., 2019) contains news articles with annotations on authors' stances towards entities. **BASIL (sent.)** and **BASIL (art.)** are prediction tasks at sentence and article-levels.
- `VAST` (Allaway and McKeown, 2020) collects online comments from "Room for Debate", with stances labeled towards the debate topic.
- `SemEval` (Mohammad et al., 2016a) is a shared task on detecting stances in tweets. We consider two setups to predict on seen, i.e. **SEval (seen)**, and unseen, i.e., **SEval (unseen)**, entities.

5.2 Baselines

We consider three baselines. First, we train a linear **SVM** using unigram and bigram features for each task, since it is a common baseline in political science (Yu et al., 2008; Diermeier et al., 2012). Hyperparameters and feature selection are described in Table A8. We further compare with **BERT** and **RoBERTa**, following the standard fine-tuning process for ideology prediction tasks and using the prompt described in §5.4 for stance detection.

5.3 Model Variants

We consider several variants of POLITICS. First, using **triplet loss objective only**, we experiment on models trained with ideology objective (*Ideology Obj.*), story objective (*Story Obj.*), or both.

Next, we continue pretaining RoBERTa with **MLM objective only**, using vanilla MLM objective (*Random*), entity focused objective (*Upsamp. Ent.*), sentiment focused objective (*Upsamp. Sentiment*), or upsampling both entity and sentiment.

5.4 Fine-tuning Procedure

We fine-tune each neural model for up to 10 epochs, with early stopping enabled. We select the best fine-tuned model on validation sets using F1. Details of experimental setups are in Table A7.

Ideology Prediction. We follow common practice of using the `[CLS]` token for standard fine-tuning (Devlin et al., 2019). For `Twitter` and `YouTube User` data, we encode them using sliding windows and aggregate by mean pooling.

Stance Detection. We follow Schick and Schütze (2021) on using prompts to fine-tune models for stance detection. We curate 11 prompts (in Table A6) and choose the best one based on the average F1 by RoBERTa on all stance detection tasks:

p `[SEP]` *The stance towards* {target} *is* `[MASK]` .

The model is trained to predict `[MASK]` for stance, conditioned on the input p and {target}.

5.5 Main Results

Table 3 presents F1 scores on all tasks. POLITICS achieves the best overall average F1 score across the board, 3.6% better than the strongest baseline, RoBERTa. More importantly, POLITICS alone outperforms all three baselines listed in §5.2 on 8 out of 11 tasks, including more than 10% of improvement for ideology labeling on `Hyperpartisan` and `Youtube` user-level. We attribute the performance gain to our proposed ideology-driven pretraining objective, which helps capture partisan content. Note that, on some tasks, other model variants lead POLITICS by a small margin, and this may be of interest to practitioners performing specific tasks.

We further compare with the model proposed by Baly et al. (2020), which also leverages triplet loss as pretraining objective but on articles of the same topics. We implement two versions of their model, using the original data released by Baly et al. (2020)[7] and our BIGNEWSBLN. First, pretraining on our BIGNEWSBLN yields better results on ideology prediction tasks than using the original data, indicating the value of BIGNEWSBLN. Second, using the triple construction method by Baly et al. (2020) with BIGNEWSBLN does not generalize well on the stance detection task, compared to POLITICS and its variants. This highlights the advantage of our objectives that enable content comparison among articles of the same stories.

Moreover, *our ideology-driven objectives help acquire knowledge needed to discern ideology as well as stance detection.* When equipping the RoBERTa model with ideology and story objectives but no MLM objective, it achieves the second best overall performance.

Next, *focusing on entities better identifies stance.* Simply continuing training RoBERTa with vanilla MLM objective (*Random*) does not yield performance gain on stance detection, while our upsampling methods make a difference, i.e., increasing sampling ratios of entities improves F1 by 2%.

Comparisons with Previous State-of-the-arts. Using the *original* binary prediction setup (i.e., hyperpartisan or not) on `Hyperpartisan` data (Kiesel et al., 2019), POLITICS obtains an accuracy of 85.2, leading previous state-of-the-art results by at least 3 points, as shown in Table 4.

POLITICS achieves an F1 of 77.0 on the *original* `VAST` data where the previous state-of-the-art model obtained 69.2 (Jayaram and Allaway, 2021). On `SemEval`, POLITICS yields an F1 of 71.3 where the best performance is 76.5 by Al-Ghadir et al. (2021). Notably, we adopt one single classifier in our setup, while they include separate models for different prediction targets, which have been shown to outperform one single classifier (Mohammad et al., 2016a). Full comparisons with previous methods are included in Appendix F. For other tasks, there is no direct comparison as the datasets are either originally used for different prediction tasks (e.g., Basil is used for detecting media bias spans) or newly collected by this work.

Models	Hyperpartisan			
	Acc.	Precision	Recall	F1
Jiang et al., 2019 (ELMo+CNN)	82.2	87.1	75.5	80.9
Srivastava et al., 2019 (Logistic Regression)	82.0	81.5	82.8	82.1
Hanawa et al., 2019 (BERT)	80.9	82.3	78.7	80.5
Isbister and Johansson, 2019 (SVM)	80.6	85.8	73.2	79.0
Yeh et al., 2019 (ULMFiT)	80.3	79.3	81.8	80.6
RoBERTa	84.3	**87.2**	80.6	83.7
POLITICS	**85.2**	86.3	**83.7**	**84.9**

Table 4: Comparison with the previous state-of-the-art models on `Hyperpartisan` using the original binary prediction setup. Best results are in bold. POLITICS obtains the best accuracy, recall and F1. Note, precision, recall, and F1 are measured for the hyperpartisan class.

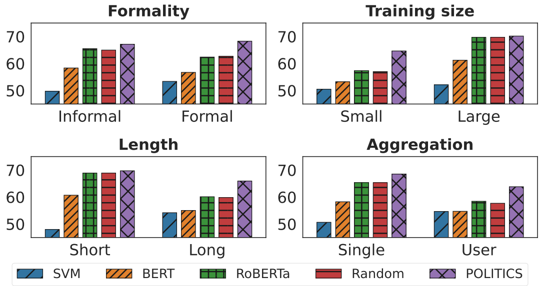

Figure 3: Macro F1 aggregated over tasks of different *formality*, *training size*, *document length* and *aggregation method (single post vs. posts by each user)*. POLITICS performs better on handling formal language, small training sets, and longer text.

On Texts of Different Characteristics. Based on Table 2, we further study the model's performance on data of different properties: *language formality*, *training size*, *document length*, and *aggregation level*. As shown in Figure 3, with each property (concrete criterion in Appendix E), we divide tasks into two categories. POLITICS yields greater improvements on more formal and longer text, since pretraining is done on news articles. POLITICS is also more robust to training sets with

Table 5: Ablation study results on POLITICS. POLITICS + Ideo. Pred.: triplet-loss objective is replaced with a hard label prediction objective on ideology of articles (left vs. right). **Best** results are in bold. Darker red shows greater improvements. Darker blue indicates larger performance drop. The ideology objective contributes the most to POLITICS, followed by the story objective.

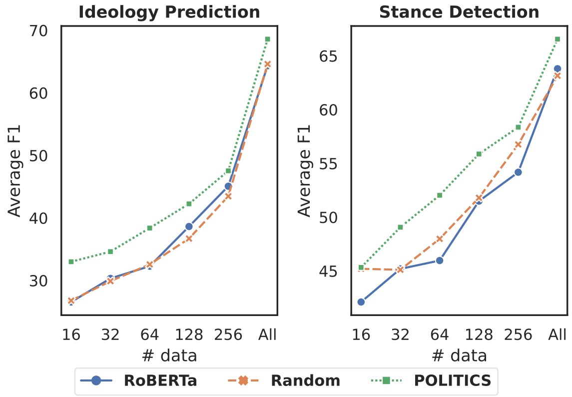

Figure 4: Average of ideology prediction and stance detection performances with few-shot learning. POLITICS uniformly outperforms RoBERTa and it being continued pretrained with vanilla MLM (*Random*).

small sizes, showing the potential effectiveness in few-shot learning, which is echoed in §6.1.

6 Further Analyses

6.1 Few-shot Learning

We first fine-tune all PLMs on small numbers of samples. POLITICS consistently outperforms the two counterparts on both tasks, using small training sets (Figure 4). More importantly, naively training RoBERTa on the large BIGNEWSBLN does not help ideology prediction. By contrast, our ideology-driven objective can better capture ideology than the baselines, even when using only 16 samples for fine-tuning on the ideology tasks.

6.2 Ablation Study on POLITICS

We show the impact of removing each ideology-driven pretraining objective and upsampling strategy from POLITICS in Table 5. First, removing the ideology objective results in the most loss on both tasks. This again demonstrates the effectiveness of our triplet-loss formulation over same-story articles. Removing the story objective also hurts the overall performance by 1% but improves the ideology prediction marginally. This shows that the story objective functions as an auxiliary constraint to avoid over-fitting on the "shortcuts" for discerning ideologies. Moreover, removing upsampling strategies generally weakens POLITICS's performance, but only to a limited extent.

We also experiment with a setup with hard-ideology learning (i.e., directly predicting the ideology of each article without using triplet-loss objectives). Not surprisingly, this variant (POLITICS +*Ideo. Pred.*) outperforms POLITICS on ideology prediction since it can directly learn ideology from the annotated labels. However, it has been overfitted to ideology prediction tasks and lacks generalizability, thus yields worse performance on stance detection.

6.3 Visualizing Attentions

On the `Hyperpartisan` task, we visualize the last layer's attention weights between the `[CLS]` token and all other tokens by POLITICS and RoBERTa pretrained with vanilla MLM on BIGNEWSBLN (*Random*). We randomly sample 20 test articles, and for 13 of them, POLITICS is able to capture salient entities, events, and sentiments in the text whereas *Random* cannot. We present one example in Figure 5 where POLITICS captures "Ashley Judd", "the worst", and "Trump". More examples are given in Appendix G. This finding confirms that our ideology-driven objective and upsampling strategies can help the model focus more on entities of political interest as well as better recognize sentiments.

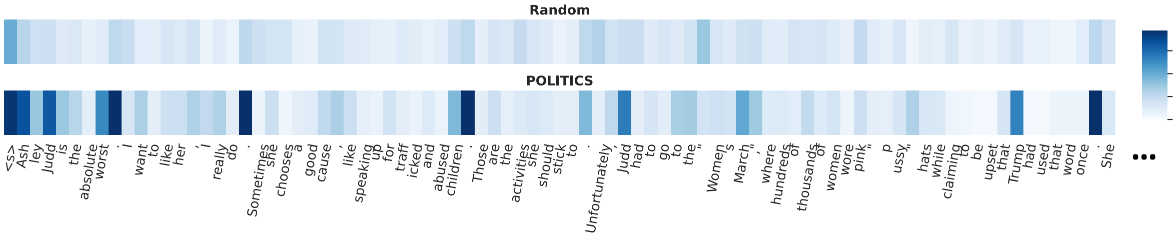

Figure 5: Last layer attention scores between `[CLS]` token and other input tokens (aggregated over all heads). POLITICS captures "Ashley Judd", "worst", and "Trump".

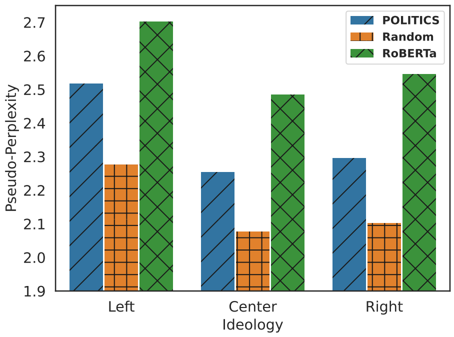

Figure 6: Model perplexities on 30K validation articles in BIGNEWSBLN. Perplexities do not drop sharply on POLITICS compared with RoBERTa being continued pretrained with MLM objective (*Random*), suggesting POLITICS can yield superior predictive performance while not overfitting with ideological languages.

6.4 POLITICS on Different Ideologies

Finally, we measure whether PLMs would acquire ideological bias as measured by whether they fit with languages used by a specific ideology. Concretely, we follow Salazar et al. (2020) to evaluate PLMs on 30K held-out articles of different ideologies from BIGNEWSBLN with *pseudo-perplexity*. For efficiency, we estimate the *pseudo log-likelihood* based on 200 random tokens in each article as used by Wang and Cho (2019). As illustrated in Figure 6, while MLM objective (*Random*) is effective at fitting a corpus, i.e., having the lowest perplexities, triplet-loss objectives act as regularizers during pretraining, shown by the higher perplexity of POLITICS compared to *Random*. Interestingly, we find center and right articles have lower perplexity than that of left articles. We hypothesize that it relates to political science findings that, over recent periods of political polarization in US, Republicans have become somewhat more coherent and similar than Democrats (Grossmann and Hopkins, 2016; Benkler et al., 2018), and are thus easier to predict.

7 Conclusion

We study the problem of training general-purpose tools for ideology content understanding and prediction. We present POLITICS, trained with novel ideology-driven pretraining objectives based on the comparisons of same-story articles written by media outlets of different ideologies. To facilitate model training, we also collect a large-scale dataset, BIGNEWS, consisting of news articles of different ideological leanings. Experiments on diverse datasets for ideology prediction and stance detection tasks show that POLITICS outperforms strong baselines, even with a limited amount of labeled samples for training, and state-of-the-art models.

Acknowledgments

This work is supported in part through National Science Foundation under grants IIS-2100885 and IIS-2127747, and computational resources and services provided by Advanced Research Computing (ARC), a division of Information and Technology Services (ITS) at the University of Michigan, Ann Arbor. We appreciate the anonymous reviewers for their helpful comments. We thank the members of the LAUNCH group at the University of Michigan for discussions and suggestions. We also thank Changyuan Qiu for helping collect the AllSides articles, Siqi Wu for giving us access to the Youtube comments, and Daniel Preotiuc-Pietro for sharing the Twitter user accounts used in the original study to allow the collection of the corresponding users' tweets in this work.

8 Ethical Considerations

8.1 BIGNEWS Collection

All news articles were collected in a manner consistent with the terms of use of the original sources as well as the intellectual property and the privacy rights of the original authors of the texts, i.e., source owners. During data collection, the authors honored privacy rights of content creators, thus did not collect any sensitive information that can reveal their identities. All participants involved in the process have completed human subjects research training at their affiliated institutions. We also consulted Section 107[8] of the U.S. Copyright Act and ensured that our collection action fell under the fair use category.

8.2 Dataset Usage

All of the newly collected datasets in this work will be made available upon request. Pretraining corpus details are included in Section 3. The other seven datasets used for downstream evaluation are obtained in the following ways. **CongS**, **HP**, **BASIL**, **VAST** and **SEval** are acquired by direct download. **CongS** is released under the ODC-BY 1.0 license (free to share, create, and adapt). **HP** and **SEval** are developed in shared tasks by the NLP community, which allow the use of copyrighted material without permission from the copyright holder for research purposes (Escartín et al., 2017). For **VAST**, the author explicitly states "We make our dataset and models available for use". **BASIL** is developed by the last author and her collaborators. For **YT** and **TW**, we consult with the corresponding authors and obtain the datasets by agreeing that we will not further distribute them. Dataset details are listed in Section 5.1 and Appendix D.

8.3 Benefit and Potential Misuse

Intended use. The models developed in this work can assist the general public to measure and understand ideological language used in diverse genres of texts. For example, POLITICS can help the general public know where their representatives stand on key issues. Our experiments in Section 5 demonstrate how POLITICS would be deployed in real life when handling applications in both ideology prediction and stance detection. We deem that our extensive experiments have covered the major usage of POLITICS.

Failure mode is defined as situations where POLITICS fails to correctly predict the ideology of an individual or a given text. In such cases, POLITICS might deliver misinformation or cause misunderstanding towards a political figure or a policy. For vulnerable populations (e.g., people who maybe not be able to make the right judgements), the harm could be tremendously magnified when they fail to interpret the model outputs or blindly trust machine responses. Ideally, the interpretation of our model's predictions should be carried out within the broader context of the source text.

Misuse potential. Users may mistakenly take the machine prediction as a golden rule or a fact. We would recommend any politics-related machine learning models, including ours, put up an "use with caution" message to encourage users to check more sources or consult political science experts to reduce the risk of being misled by single source. Moreover, POLITICS might also be misused to label people with a specific political leaning that they do not want to be associated with. We suggest that when in use the tools should be accompanied with descriptions about their limitations and imperfect performance, as well as allow users to opt out from being the subjects of measurement.

Potential limitation. Although multiple genres are considered, the genre coverage is not exhaustive, and does not include other trending media or content of different modalities for expressing opinions, such as TV transcripts, images, and videos. Thus, the predictive performance of POLITICS may still be under investigated. Further, in downstream evaluation, POLITICS is only trained and tested in the same domain, so its cross-genre ability needs further evaluation.

Bias Mitigation. During data preprocessing, we create BIGNEWSBLN to ensure that all ideologies have almost equal presence to minimize potential bias. POLITICS is not designed to encode bias. In Figure 6, the discrepancy in perplexities among different ideologies is more related to the greater coherence among Republicans than Democrats, rather than POLITICS encoding biased knowledge.

In conclusion, there is no greater than minimal risk/harm introduced by either BIGNEWSBLN or POLITICS. However, to discourage the misuse, we will always warn users that model predictions are for informational purpose only and users should always resort to the broader context to reduce the risk of absorbing biased information.

Appendix A BIGNEWS Cleaning Steps

In this section, we provide the details of our data cleaning steps for BIGNEWS. We adopt the following cleaning steps to only keep news articles that relate to US politics.

Removing Non-article Pages. Online news websites also post non-news content. We remove such pages by checking their page titles and URLs based on a list of patterns. Sample patterns are shown in Table A1.

Removing Duplicate Pages. We use character-level edit distance to identify duplicate pages. Specifically, we use the following formula to calculate the difference between page a and page b:

$$\text{diff}(a, b) = \text{dist}(a, b) / \max(\text{len}(a), \text{len}(b)) \quad (5)$$

where $\text{dist}(a, b)$ is the Levenshtein distance between a and b. If the value is less than 0.1, we consider two pages as duplicates and we only keep the one with earlier publication date. Following this procedure, we remove duplicated pages within each media outlet.

	Filter Patterns
URL	/video/, /gallery/, /slideshow/
Title	weekly digest, 10 sites you should know, day's end roundup, photos of the week, 5 things you need to know

Table A1: Examples of patterns used to filter out pages that are not news stories.

Removing Non-politics Pages. To filter out non-politics pages, we build a classifier using training data from BIGNEWS. Since URL typically indicates a page's topic, we use keywords in the URL to retrieve politics and non-politics training data. The lists of keywords are shown in Table A2. This results in a training dataset with $400,462$ politics pages and $310,377$ non-politics pages. We also randomly sample 888 pages from the remaining dataset and manually annotate them to use as the test set.

We train a logistic regression model based on unigram and bigram TF-IDF features. To include pages not covered by the lists of keywords in Table A2, we use the trained classifier to classify remaining pages and add those classified with high probability[9] to the training data. This results in a larger training set with 957,424 politics pages and 987,898 non-politics pages. We train the final classifier on the larger training set, and achieve an 88.18% accuracy on the test data.

	Keywords
Politics	/politics/, /political/, /policy/, /election/, /elections/, /allpolitics/
Non-politics	/travel/, /sports/, /life/, /movie/, /entertainment/, /science/, /music/, /plated/, /leisure/, /showbiz/, /lifestyle/, /fashion/, /art/, /sport/

Table A2: Full list of keywords used to retrieve positive and negative training data for the politics classifier.

URL Keywords	Text Keywords
/world/, /international/, /europe/, /africa/, /asia/, /latin-america/, /middle-east/	U.S., United States, Obama, Trump, Bush, Biden, Pompeo, Clinton, Pence

Table A3: Examples of keywords used to filter out non-US articles. For text keywords, we collect the names of all presidents, vice presidents, and secretaries of state of US since 2000.

Removing Non-US Pages. We filter out pages that are not related to US by searching for non-US keywords in the URL. For each of those pages, we only remove it if its text contains no US-related keywords. Examples of keywords used are shown in Table A3.

Removing Media Leaking Phrases. To prevent the model from learning features specific to individual media outlets, we perform a two-step cleaning. First, we mask phrases that mention the media outlet itself (e.g., New York Times, NYTimes, and nytimes.com). Second, we create a list of patterns for frequently appearing sentences (more than 100 times), for each media outlet. For example, as in "`author` currently serves as a senior political analyst for `[MASK]` Channel and contributes to all major political coverage", both the author name and the sentence itself can leak media outlet information. Since sentences with media leaking information usually appear at the beginning or end of the article, we remove any of the first and last two

---

[9] We use 0.95 for politics pages and 0.9 for non-politics pages.

	# article before downsample	Earliest date	Latest date

Table A4: Statistics of BIGNEWS corpus. Media outlets are sorted by ideology from left to right.

Hyperparameter	Value
number of steps	2,500
batch size	2048
maximum learning rate	0.0005
learning rate scheduler	linear decay with warmup
warmup percentage	6%
optimizer	AdamW (Loshchilov and Hutter, 2019)
weight decay	0.01
AdamW beta weights	0.9, 0.98
δ_{ideo}	0.5
δ_{story}	1.0

Table A5: Hyperparameters for continued pretraining.

paragraphs, if they contain a sentence that matches such pattern.

Appendix B News Story Alignment

As shown in Equation 1, we combine text similarity and entity similarity to be the final story similarity score. Only title and the first five sentences are considered in the calculation. We further require aligned articles a and b to satisfy two constraints:

- The difference in publication dates of a and b is at most three days.
- a and b must contain at least one common named entity in the title or in the first three sentences.

We use CoreNLP to extract named entities in articles (Manning et al., 2014). For the second constraint, we further apply Crosswikis to map each entity to a unique concept in Wikipedia (Spitkovsky and Chang, 2012). When calculating entity similarity, we split each entity into single words and remove stop words. After alignment, we use the procedure described in Appendix A to remove duplicate articles in the same story cluster. The hyperparameters are $\alpha = 0.4$ and $\theta = 0.23$.

Evaluating Alignment Algorithm. We search the hyperparameters on the Basil dataset (Fan et al., 2019) and test the algorithm on the Allsides dataset collected in Cao and Wang (2021). The Allsides dataset consists of manually aligned news articles from 251 media outlets. After removing media outlets not in BIGNEWSBLN, we obtain $2,904$ articles on $1,316$ stories.

To evaluate the performance of the alignment algorithm, we add the evaluation dataset into BIGNEWSBLN and treat each evaluation article as the anchor article for the alignment algorithm. We use the remaining evaluation articles in the same story as relevant articles, which becomes the target to be identified. The algorithm achieves 0.612 mean reciprocal rank (MRR) on the Basil dataset and 0.679 MRR on the Allsides dataset.

Appendix C Continued Pretraining and Fine-tuning

C.1 Continued Pretraining

We initialize all variants of POLITICS with a RoBERTa-base model (Liu et al., 2019), which contains about 125M parameters. Our implemen-

Prompt	**Verbalizer**
p `[SEP]` *The stance towards* {target} *is* `[MASK]`.	negative or positive
p `[SEP]` *It reveals a* `[MASK]` *stance on* {target}.	negative or positive
p `[SEP]` *The speaker holds a* `[MASK]` *attitude towards* {target}.	negative or positive
p `[SEP]` *What is the stance on* {target}? `[MASK]`.	Negative or Positive
p `[SEP]` *The previous passage* `[MASK]` {target}.	opposes or favors
p `[SEP]` *The stance on* {target} *is* `[MASK]`.	negative or positive
p `[SEP]` *The stance towards* {target}: `[MASK]`.	negative or positive
p `[SEP]` *The author* `[MASK]` {target}.	opposes or favors
p `[SEP][MASK]` {target}	oppose or favor
p `[SEP][MASK].` {target}	No or Yes
p `[SEP][MASK]` {target}	No or Yes

Table A6: List of prompts used for stance detection tasks. p is the input text, and {target} is the target of interest. Verbalizer maps the label (e.g., against) to the token (e.g., negative). Some datasets use a third label (neutral).

Hyperparameter	**Value**
number of epochs	10
patience	4
maximum learning rate	0.00001 or 0.00002
learning rate scheduler	linear decay with warmup
warmup percentage	6%
optimizer	AdamW
weight decay	0.001
AdamW beta weights	0.9, 0.999
# FFNN layer	2
hidden layer dimension in FFNN	768
dropout in FFNN	0.1
sliding window size	512
sliding window overlap	64

Table A7: Hyperparameters used to fine-tune PLMs.

tation is based on the HuggingFace transformers library (Wolf et al., 2020).[10] We train each model using 8 Quadro RTX 8000 GPUs for 2,500 steps. The total training time for POLITICS is 20 hours, with shorter time for other variants. Table A5 lists the training hyperparameters.

Training Details. For triplet loss objectives, we only consider triplets in each mini-batch. We skip a batch if it contains no triplet. For the MLM objective, we truncate the article if it has more than 512 tokens. When masking entities and sentiment words, we only consider those with at most five tokens. When both triplet loss and MLM objectives are enabled, we adopt alternating training strategy as in Ganin et al. (2016) to apply these two objectives for parameter updates in an alternating manner.

Hyperparameter	**Value**
kernel	linear
regularization strength	0.3, 1, or 3
features	unigram and bigram TF-IDF
minimum document frequency	5
maximum document frequency	$0.7 * \|D\|$

Table A8: Hyperparameters used to train SVM. $|D|$ is the number of documents in the training set.

C.2 Fine-tuning

For both ideology prediction and stance detection tasks, we fine-tune each model for up to 10 epochs. We use early stopping and select the best checkpoint on validation set among 10 epochs. For ideology prediction tasks, we follow standard practice of using `[CLS]` token and feed-forward neural networks (FFNN) for classification. For stance detection tasks, we use prompts to fine-tune PLMs. We curate 11 prompts as shown in Table A6, and select the best prompt based on the performance of RoBERTa. Fine-tuning hyperparameters are listed in Table A7.

For the SVM classifier, we use the implementation of TF-IDF feature extractor and linear SVM classifier in scikit-learn (Pedregosa et al., 2011). The classifier's hyperparameters are listed in Table A8.

---

Models	VAST		
	F_{favor}	$F_{against}$	F_{avg}
BERT-joint (Allaway and McKeown, 2020)	54.5	59.1	65.3
TGA Net (Allaway and McKeown, 2020)	57.3	59.0	66.5
BERT-base (Jayaram and Allaway, 2021)	64.3	58.1	69.2
prior-bin:gold (Jayaram and Allaway, 2021)	64.5	54.6	68.4
RoBERTa	67.2	71.4	76.5
POLITICS	**68.0**	**72.2**	**77.0**

Table A9: Comparison with state-of-the-art results on the original VAST dataset. Best results are in bold.

Appendix D Downstream Evaluation Datasets

This section lists more details of the eight datasets used in our downstream evaluation as well as their processing steps.

D.1 Ideology Prediction

- `Congress Speech`[11] (**CongS**; Gentzkow et al., 2018): We filter out speeches with less than 80 words and use the speaker's party affiliation as the ideology of the speech.
- `AllSides`[12] (**AllS**): We crawl articles from AllSides and use the media outlet's annotated ideology as that of the article.
- `Hyperpartisan`[13] (**HP**; Kiesel et al., 2019): We convert the benchmark into a 3-way classification task by projecting media-level ideology annotations to articles.
- `YouTube` (Wu and Resnick, 2021) contains cross-partisan discussions between liberals and conservatives on YouTube. In our experiments. we only keep controversial comments: 1) A video must have at least 1,500 comments and 150,000 views; 2) A comment must have at least 20 replies. The original dataset annotates users' ideology on a 7-point scale. We further convert it into a 3-way classification task for left, center, and right ideologies. For the comment-level prediction task on **YT (cmt.)**, we use the provided user-level ideology annotation. For user-level prediction on **YT (user)**, we concatenate all comments by a user.
- `Twitter` (**TW;** Preoţiuc-Pietro et al., 2017): We crawl recent tweets by each user and remove replies and non-English tweets. We assume users' ideologies do not change after their self-report since prior work has shown that people's ideology is less likely to change across the political spectrum (Fiorina and Abrams, 2008). We sort all tweets from a user chronologically and concatenate them.

Models	SemEval (Seen)		
	F_{favor}	$F_{against}$	F_{avg}
WKNN (Al-Ghadir et al., 2021)	**84.49**	68.36	**76.45**
PNEM (Siddiqua et al., 2019)	66.56	**77.66**	72.11
MITRE (Zarrella and Marsh, 2016)	59.32	76.33	67.82
pkudblab (Wei et al., 2016)	61.98	72.67	67.33
SVM-ngrams (Mohammad et al., 2016a)	62.98	74.98	68.98
Majority class (Mohammad et al., 2016a)	52.01	78.44	65.22
BERT	62.89	70.75	66.82
RoBERTa	67.33	75.52	71.43
POLITICS	67.36	75.29	71.33

Table A10: Comparison with the state-of-the-art models on SemEval. Prior work (top panel) trains five models (one per target label). On the contrary, in this work, we target a more generalizable approach, i.e., one unified classifier for all labels. Due to different setups, POLITICS and baselines like RoBERTa perform worse.

D.2 Stance Detection

- `BASIL`[14] (Fan et al., 2019): We convert the original dataset such that the new tasks are to predict the stance towards a target at two granularities: article (**art.**) and sentence (**sent.**) levels. The targets in the dataset can be a person (e.g., Donald Trump) or an organization (e.g., Justice Department).
- `VAST`[15] (Allaway and McKeown, 2020) predicts the stance of a comment towards a target. The targets in the dataset are noun phrases covering a broad range of topics (e.g., immigration, home schoolers). We notice the original dataset contains contradictory samples, where the same comment-target pair is annotated with opposite stances, and therefore remove duplicate and contradictory samples.
- `SemEval`[16] (**SEval;** Mohammad et al., 2016a) predicts a tweet's stance towards a target. The dataset contains six targets: Atheism, Climate Change, Feminist, Hillary Clinton, Abortion, and Donald Trump. Notably, the last target is not seen during training, and only appears in testing.

Table A11: Macro F1 scores on 11 evaluation tasks (average of 5 runs) with standard deviations. Tasks are sorted by text length, short to long, within each group. "All avg" is the average of all 11 tasks. **Best** results are in bold and second best are underlined. Our models with triplet-loss objectives that outperform RoBERTa are in blue . Our models with specialized sampling methods that outperform vanilla MLM (Random) are in green . POLITICS uses Ideology + Story Obj. and Upsamp. Ent. + Sentiment. Results where POLITICS outperforms all baselines are highlighted in red . POLITICS has the smallest standard deviations on 5 tasks, showing its stable performance.

Appendix E Task Property

This section introduces detailed definitions of four properties, based on which we divide tasks into two categories reported in Figure 3.

- Formality: Speech and news genres are considered as formal, and others are informal.
- Training set size: Datasets with more than 2,000 training samples are categorized as large, and small otherwise.
- Document length: Datasets with average document length larger than 500 are treated as "long", and others are short.
- Aggregation level: If a dataset is a collection of single articles/posts/tweets, then it is in the category of "Single". If posts are concatenated and aggregated at user level, then it is marked as "User". Specifically, only `YouTube User` and `Twitter` in Table 2 are in the "User" category.

Appendix F Comparison with Previous State-of-the-art Models

Here we compare POLITICS with previous state-of-the-art models on three selected datasets: `Hyperpartisan` (§5.5), `VAST` (§F.1), and `SemEval` (§F.2). §F.3 discusses why direct comparisons are not applicable on the other 5 datasets.

F.1 VAST

POLITICS outperforms all previous state-of-the-art models in the literature as well as the strong RoBERTa baseline, as can be seen in Table A9. Following Allaway and McKeown (2020) and Jayaram and Allaway (2021), F_{avg} is defined as the macro-averaged F1 over all three classes (favor, against, and neutral). The results are reported on the original VAST dataset which contains contradictory samples, where the same comment-target pairs are annotated with opposite stances so they are counted in both categories.

F.2 SemEval

Table A10 show the results of state-of-the-art models and POLITICS on SemEval. Following Mohammad et al. (2016a), F_{avg} is defined as the macro-averaged F1 over favor and against classes. State-of-the-art models train separate classifiers, one for each target, thus yield better results than POLITICS. Similar observation is made by Mohammad et al. (2016a), where one single SVM that is trained on all five targets performs worse than five one-versus-rest SVM classifiers.

F.3 Reasons for Inapplicable Comparisons

We are unable to directly compare with existing models on datasets other than `Hyperpartisan`, `VAST`, and `SemEval` for the following reasons:

- The original dataset either is used for different tasks that are not ideology prediction or stance detection: `Congress Speech` (Gentzkow et al., 2018), `BASIL` (Fan et al., 2019), and `YouTube` (Wu and Resnick, 2021).
- The dataset is newly collected (`AllSides`) or contains newly collected samples (`Twitter`; Preoţiuc-Pietro et al., 2017).

Appendix G Visualize Attention Weights

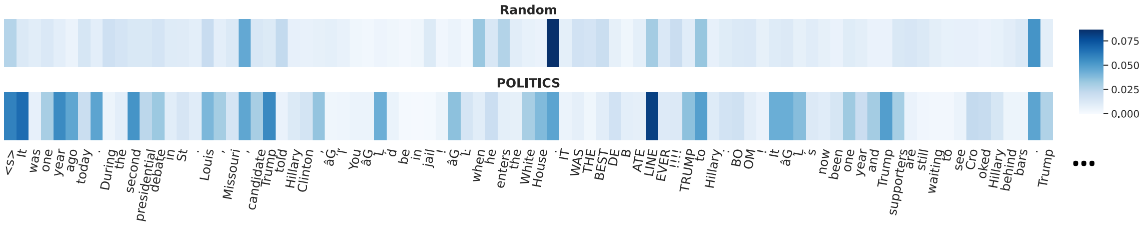

Figure A1: Example 1 for attention visualization. Last layer attention weights between [CLS] token and other tokens in the input. We illustrate the first 85 tokens of the article.

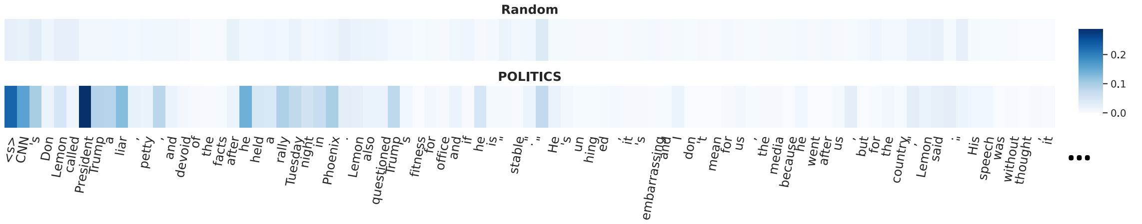

Figure A2: Example 2 for attention visualization. Last layer attention weights between [CLS] token and other tokens in the input. We illustrate the first 85 tokens of the article.

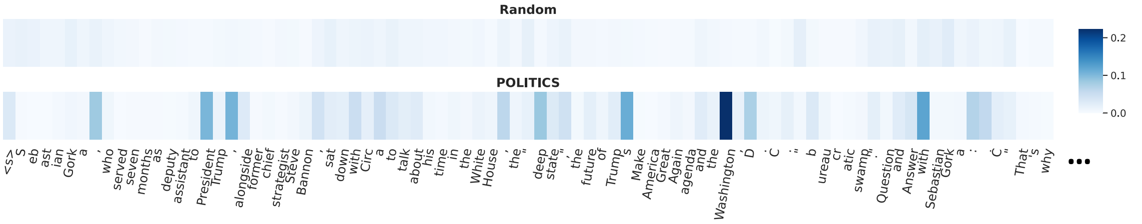

Figure A3: Example 3 for attention visualization. Last layer attention weights between [CLS] token and other tokens in the input. We illustrate the first 85 tokens of the article.

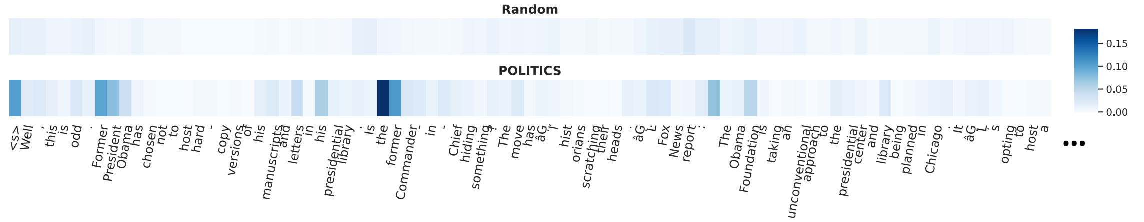

Figure A4: Example 4 for attention visualization. Last layer attention weights between [CLS] token and other tokens in the input. We illustrate the first 85 tokens of the article.

Empowering Parameter-Efficient Transfer Learning by Recognizing the Kernel Structure in Attention

Abstract

The massive amount of trainable parameters in the pre-trained language models (PLMs) makes them hard to be deployed to multiple downstream tasks. To address this issue, parameter-efficient transfer learning methods have been proposed to tune only a few parameters during fine-tuning while freezing the rest. This paper looks at existing methods along this line through the *kernel lens*. Motivated by the connection between self-attention in transformer-based PLMs and kernel learning, we propose *kernel-wise adapters*, namely *Kernel-mix*, that utilize the kernel structure in self-attention to guide the assignment of the tunable parameters. These adapters use guidelines found in classical kernel learning and enable separate parameter tuning for each attention head. Our empirical results, over a diverse set of natural language generation and understanding tasks, show that our proposed adapters can attain or improve the strong performance of existing baselines.

1 Introduction

Transfer learning using large-scale transformer-based pre-trained language models (PLMs) (Radford et al., 2019) has become the standard scheme for various natural language processing (NLP) tasks. Among many strategies, fine-tuning these PLMs emerges as the predominant strategy to adapt the generic models to a specific task (Howard and Ruder, 2018). However, deploying these models is a challenge as curating customized models across a wide variety of tasks would lead to scalability issues. It requires one to store (and sometimes move) multiple copies of the PLM parameters for different tasks, which is inefficient.

A popular approach to tackling such scalability issues is to make the PLM-based transfer learning more parameter-efficient. This can be done by freezing most of the PLM parameters and inserting small trainable modules into the PLM. Adapters (Houlsby et al., 2019; Pfeiffer et al., 2020; Mahabadi et al., 2021; Hu et al., 2021) and Prefix-/Prompt-tuning (Shin et al., 2020; Li and Liang, 2021; Lester et al., 2021; Liu et al., 2021c,b) have emerged as the prominent approaches under this paradigm. These methods are incredibly parameter-efficient and have comparable performance to full fine-tuning models on many common NLP tasks (mainly in Natural Language Understanding) by tuning only 0.1-3% task-specific parameters of the original PLMs.

However, most of these studies take the PLMs as a black box, i.e., these methods are not customized to transformers. This raises whether parameter-efficient fine-tuning has fully utilized the transformer structure in PLMs. Therefore in this work, we propose *kernel-wise adaptation*, which recognizes and utilizes the kernel structure within self-attention—the core component in a transformer. Specifically, we take inspiration from recent work that connects self-attention to kernel learning (Choromanski et al., 2020; Chen et al., 2021; Tsai et al., 2019) to treat the different attention heads in a transformer's attention sub-layer as separate kernel estimators. We hypothesize that parameter-efficient tuning can benefit from some useful guidelines in classical kernel learning literature and incorporate them into our proposed methods. These include:

1. By interpreting attention heads as kernel estimators, we design the adaptation to be head-specific;
2. We assign more budgets of tunable parameters to learn the *value* components in the attention mechanism, which correspond to *coefficients* in kernel methods.

We discuss these guidelines in detail in § 4.1. We also evaluate our hypotheses through rigorous

empirical evaluation. First, we test the effectiveness of the two guidelines above by comparing the default LoRA (Hu et al., 2021)—a state-of-the-art approach for efficient adaptation—and two of its variants that implement the two guidelines, respectively. Next, we evaluate our variant of kernel-wise adaptation on three Natural Language Generation (NLG) benchmarks and two Natural Language Understanding (NLU) tasks using the GPT-2 architecture. While parameter-efficient work has extensively covered NLU tasks, it is unknown how well the results transfer to NLG tasks. As language generation typically requires more expressive models, we put more emphasis on multiple NLG tasks that include data-to-text, free-form question answering (QA), and summarization. The empirical results in § 6 demonstrate that with the same parameter budgets, our proposed method can attain better generation quality and classification accuracy than previous techniques, and in many settings, it is close to or even outperforms the full parameter fine-tuning.

2 Related Work

The literature on parameter-efficient adaptation can be broadly categorized as follows:

Adapters. Originally proposed by Houlsby et al. (2019); Pfeiffer et al. (2020), adapters modulate the output of a transformer layer by inserting small Multi-layer Perception (MLP) bottleneck layers. Recent work has proposed many variants of the original adapters, including dropping adapters across several layers (Rücklé et al., 2020) or constraining adapters to be low-rank operators (Mahabadi et al., 2021).

A recent line of work focused on identifying the important subset of parameters within the PLMs. Ben Zaken et al. (2021) proposed to only tune the bias terms in the PLMs. MPOP (Liu et al., 2021a) suggested decomposing the weight matrices in PLMs through matrix product operators (MPO) and only trained the matrices of small size (freezing the large matrices) obtained from the decomposition, which implicitly recognizes the small matrices as the important subset.

Low-rank adaptation (LoRA) (Hu et al., 2021) directly assumes that the update of the weight matrices during training can be approximate low-rank, and accordingly proposed to re-parameterize the original weight matrix $\boldsymbol{W}$ by $\boldsymbol{W} + \boldsymbol{B}\boldsymbol{A}$, where $\boldsymbol{W}$ is frozen to its pre-trained weights whereas $\boldsymbol{A} \in \mathbb{R}^{r \times N_h p}, \boldsymbol{B} \in \mathbb{R}^{N_h p \times r}$ are updated in training [1]. We note that LoRA too introduces new weights $\boldsymbol{A}$ and $\boldsymbol{B}$ similar to adapters, but they are used only to re-parameterize the existing weights and do not add extra sandwiched layers that modify the original model architecture.

Prefix-tuning. Originally shown in GPT-3 (Brown et al., 2020), prompts are extra tokens that help in the task adaptation of PLMs. Transitioning from the manual design of prompts, Shin et al. (2020) searched for the prompts over the discrete space of tokens based on the task-specific training data; Li and Liang (2021); Lester et al. (2021); Liu et al. (2021c,b) further extended the search space to continuous prompts and tuned the prompts through back-propagating the error in training. Prompt-based methods have been shown to be similar to adapters by (He et al., 2021).

3 Preliminaries

We start by providing a brief introduction to the transformer architecture (§ 3.1) and then revisit the connection between attention and kernel estimators (§ 3.2), building on which we propose the kernel-wise adapter in § 4.

3.1 Transformer Architecture

Transformers (Vaswani et al., 2017) are composed of L stacked layers, where each layer comprises of a multi-headed attention and a fully connected feed-forward network (FFN) sub-layer.[2] The attention sub-layer, assuming N_h heads and dimension size p for each head, first maps an input $\boldsymbol{X} \in \mathbb{R}^{n \times N_h p}$ into the query ($\boldsymbol{Q}$), key ($\boldsymbol{K}$), and value ($\boldsymbol{V}$) matrices through the following affine transformations:

$$\boldsymbol{Q}/\boldsymbol{K}/\boldsymbol{V} = \boldsymbol{X}\boldsymbol{W}_{[q/k/v]} + \mathbf{1}\boldsymbol{b}^T_{[q/k/v]}, \quad (1)$$

where $\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V} \in \mathbb{R}^{n \times N_h p}$, $\boldsymbol{W}_q, \boldsymbol{W}_k, \boldsymbol{W}_v$ are $N_h p$-by-$N_h p$ weight matrices, and $\boldsymbol{b}_q, \boldsymbol{b}_k, \boldsymbol{b}_v \in \mathbb{R}^{N_h p}$ are the bias terms[3]. After the transformation, the three components $\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}$ are split into N_h blocks corresponding to different heads. For example, $\boldsymbol{Q}$ is re-written as $\boldsymbol{Q} = \left(\boldsymbol{Q}^{(1)}, \cdots, \boldsymbol{Q}^{(N_h)}\right)$, where each block $\boldsymbol{Q}^{(h)} = \boldsymbol{X}\boldsymbol{W}_q^{(h)} + \mathbf{1}(\boldsymbol{b}_q^{(h)})^T$ is an

---

[1] In implementation, LoRA also trains the bias terms in the linear transform besides the matrices $\boldsymbol{A}, \boldsymbol{B}$, while for brevity, the bias terms are omitted throughout the paper.

[2] For simplicity we omit the cross-attention module in transformer-based encoder-decoder models.

[3] To ease the notations we adopt the setting where $\boldsymbol{X}, \boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}$ have the same shape.

n-by-p matrix, and $\boldsymbol{W}_q^{(h)}, \boldsymbol{b}_q^{(h)}$ are the corresponding parts in $\boldsymbol{W}_q, \boldsymbol{b}_q$. The attention output for the h^{th} head is then computed as:

$$\begin{aligned}\boldsymbol{L}^{(h)}\boldsymbol{V}^{(h)} &:= \text{softmax}(\boldsymbol{Q}^{(h)}(\boldsymbol{K}^{(h)})^T/\sqrt{p})\boldsymbol{V}^{(h)} \\ &= (\boldsymbol{D}^{(h)})^{-1}\boldsymbol{M}^{(h)}\boldsymbol{V}^{(h)}, \end{aligned} \tag{2}$$

where $\boldsymbol{M}^{(h)} := \exp\left(\boldsymbol{Q}^{(h)}(\boldsymbol{K}^{(h)})^T/\sqrt{p}\right)$ and $\boldsymbol{D}^{(h)}$ is a diagonal matrix in which $\boldsymbol{D}_{ii}^{(h)}$ is the sum of the i-th row in $\boldsymbol{M}^{(h)}$, corresponding to the normalization part in softmax.

After we obtain the outputs in each head, they are concatenated as,

$$\boldsymbol{L} := (\boldsymbol{L}^{(1)}\boldsymbol{V}^{(1)}, \dots, \boldsymbol{L}^{(N_h)}\boldsymbol{V}^{(N_h)}),$$

followed by the overall output,

$$\boldsymbol{L}\boldsymbol{W}_o + \boldsymbol{1}\boldsymbol{b}_o^T, \tag{3}$$

where $\boldsymbol{W}_o$ and $\boldsymbol{b}_o$ are similarly sized as the other matrices in Equation (1).

3.2 Attention as Kernel Estimators

For each head in the attention module, we have given the expression of attention output in Equation 2. In this subsection, we will re-write attention as a kernel estimator to show the connection.

In computing the attention output (of a single head), we have a length-n input sequence $\{x_i\}_{i=1}^n$ (the rows in $\boldsymbol{X}$) and accordingly we can obtain N [4] key vectors $\{k_j\}_{j=1}^N \subset \mathbb{R}^p$ (from the *key* matrix $\boldsymbol{K}$) and query vectors $\{q_i\}_{i=1}^n \subset \mathbb{R}^p$ (from $\boldsymbol{Q}$).[5] The original goal of self-attention is to obtain the representation of each input token x_i: $g(x_i)$. By denotation exchange: $q_i := x_i$ and $f(q_i) := g(x_i)$, we can also understand the aforementioned self-attention module as returning the representation $f(q_i)$ of the input query vector q_i through $\{k_j\}_{j=1}^n$, which behaves as a kernel estimator (Choromanski et al., 2020; Peng et al., 2020; Chen et al., 2021). Specifically, for a single query vector q_i, a Nadaraya–Watson kernel estimator (Wasserman, 2006, Definition 5.39) models its representation as,

$$f(q_i) = \sum_{j=1}^n \ell_j(q_i)c_j, \tag{4}$$

$$\text{where} \quad \ell_j(q_i) := \frac{\kappa(q_i, k_j)}{\sum_{k=1}^N \kappa(q_i, k_j)}.$$

Here, $\kappa(\cdot,\cdot)$ is a kernel function, and c_j's are the coefficients (c_j can either be a scalar or a vector in different applications) that are learned during training. In this estimator, $\{k_j\}_{j=1}^n$ serve as the *supporting points* which help construct the representation for an input q_i.

For kernel function $\kappa(x, y) = \exp\left(\langle x, y\rangle / \sqrt{p}\right)$, we slightly abuse the notation $\kappa(\boldsymbol{Q}, \boldsymbol{K})$ to represent an n-by-N empirical kernel matrix, whose element in the i-th row and the j-th column is $\kappa(q_i, k_j), \forall i \in [n], j \in [N]$. With these notations, the representation of the whole sequence $\boldsymbol{Q}$ will be,

$$\boldsymbol{D}^{-1}\kappa(\boldsymbol{Q}, \boldsymbol{K})\boldsymbol{C}, \tag{5}$$

where $\boldsymbol{D}$ is a diagonal matrix for row normalization in Eq. (4), and $\boldsymbol{C}$ is an N-by-p matrix whose j-th row is c_j. Considering the correspondence between Equation (5) and the standard softmax attention in Equation (2), we can have a finer division of the attention module: the empirical kernel matrix $\kappa(\boldsymbol{Q}, \boldsymbol{K})$ ($\boldsymbol{D}$ is decided by $\kappa(\boldsymbol{Q}, \boldsymbol{K})$) and the coefficient part $\boldsymbol{C}$, which includes but is *not* limited to *value* matrices in attention (see § 4). In what follows, we will discuss how we build adapters for these two parts.

4 Method

We introduce our *Kernel-mix* method in this section, which builds upon the proposed *Kernel-wise* adaptation. To explain the principle behind Kernel-wise, we first illustrate the guidelines we aim to adopt in our adapter design and show that existing methods fail to satisfy them (§ 4.1). With these details, we finally propose our method in § 4.2 and § 4.3.

4.1 *Guidelines* Motivated by Kernel Learning

Given the analogy between attention in PLMs and kernel estimators, we hypothesize that parameter-efficient adaptation should be aware of this connection in transformer-based PLMs and utilize desirable guidelines emerging from the literature on kernel learning. Here we discuss the guidelines introduced in § 1 in further detail.

Guideline-1 suggests that the adaptation should be head-specific. Conceptually, different heads correspond to different empirical kernel matrices (distinct distribution of attention scores), and it will be beneficial to adapt the attention module in a head-specific manner. The effect of head-specific

---

[4] Note that N may not always equal n, such as in cross attention ($N \neq n$) or in prefix-tuning ($N > n$ due to the prefix prepended to the key matrix) (Li and Liang, 2021).

[5] In this subsection we omit the superscript (h) for simplicity since the discussion is limited within a single head

adaptation is also observed by other work, e.g., (He et al., 2021) that mentioned multi-head influence can make methods such as prefix-tuning more expressive.

Guideline-2 is that we should assign more parameter budgets to the coefficient (or *value*) part of attention compared to the empirical kernel matrix part (*query* and *key*). This guideline comes from the classical optimization procedure in kernel learning (Wasserman, 2006, Definition 5.29) where we fix the kernel in use and only perform the unconstrained optimization for the coefficients (c_j's in Equation (4)). This practice in kernel learning can be justified by Representer Theorem (Schölkopf et al., 2001) that the minimizer f^* of some certain empirical risks admits a representation of the form:

$$f^*(\cdot) = \sum_{j=1}^{N} \alpha_j \kappa(\cdot, k_j),$$

where α_j's are the free parameters to optimize. Representer Theorem indicates that the target estimator $f^*(\cdot)$ is simply a linear combination of $\kappa(\cdot, k_j)$'s, and therefore many kernel methods focus on optimizing the coefficients α_j's. Revisiting Equation (4), we find $\alpha_j = \frac{c_j}{\sum_{j'=1}^{N} \kappa(q_i, k_{j'})}$ under the setting of transformers, which motivates us to apply Guideline-2 to better model the tunable coefficient part c_j's in attention.

In addition, kernel learning theory concludes that the sample efficiency of a Nadaraya-Watson kernel estimator is mainly influenced by its bandwidth (the scaling factor, corresponding to the factor $\frac{1}{\sqrt{p}}$ in Equation (2)), rather than the concrete form of the empirical kernel matrix $\kappa(\boldsymbol{Q}, \boldsymbol{K})$ (Wasserman, 2006, Section 5.4). This implies that the adaptation to the empirical kernel matrix can be conservative. This is also similar to the conjecture by (He et al., 2021), which mentions "attention learns pairwise positional interactions which do not require large capacity for adapting to new tasks."

Do Existing Adapters Satisfy the Guidelines? Adapters are designed to modify the hidden states in a certain step in a transformer, and their mechanism can be stated as,

$$\boldsymbol{H} \leftarrow \boldsymbol{H} + \Delta \boldsymbol{H},$$

where $\boldsymbol{H}$ is the "hidden state" in a certain step, and $\Delta \boldsymbol{H}$ is the update given by the adapter. As shown in (He et al., 2021), this definition embodies most of the recent proposals for efficient adaptation, such as adapters, prefix-tuning, LoRA, and similar variants.

The original MLP-based adapters, which only adjust the output of a particular layer (Houlsby et al., 2019), do not modify the empirical kernel matrix in the attention sub-layer.

Prefix-tuning satisfies the first guideline as it is head-specific by nature (it prepends trainable continuous prefixes to both key and value matrices in each head). However, it fails to satisfy the second guideline as it enforces an equal assignment of tunable parameters to both the kernel and the coefficient parts (since the prefixes for *key* matrices and *value* matrices correspond to each other).

As for weight-updating adapters, such as LoRA (Hu et al., 2021), its proposed setup disobeys both guidelines. The original LoRA updates the whole weight matrix, which is not head-specific. To explain this, consider the weight matrix $\boldsymbol{W}_q$ as an example [6]. In each training step, LoRA updates $\boldsymbol{W}_q$ with a low-rank matrix $\boldsymbol{BA}$ of the same size as $\boldsymbol{W}_q$. However, if we denote the r-by-$N_h p$ matrix $\boldsymbol{A}$ as $(\boldsymbol{A}^{(1)}, \boldsymbol{A}^{(2)}, \ldots, \boldsymbol{A}^{(N_h)})$, $\boldsymbol{A}^{(h)} \in \mathbb{R}^{r \times p}, \forall i \in [N_h]$, the modification to the weight matrix $\boldsymbol{W}_q^{(h)}$ for each head would be $\boldsymbol{BA}^{(h)}$'s, $\forall i \in [N_h]$. We observe that the updates for all the heads share the same column space spanned by $\boldsymbol{B}$. In the extreme case of rank-1 $\boldsymbol{B}$ (for example), the updates for each column in the weight matrix will be in the same direction, which is not ideal for adapting all the heads. Further, as suggested by Hu et al. (2021), LoRA evenly assigns the parameter budgets to the weight matrices for $\boldsymbol{Q}$ and $\boldsymbol{V}$, which deviates from the second guideline.

4.2 Kernel-wise Adaptation

We choose LoRA as our primary base to develop our method because of its flexibility in assigning parameters to different weight matrices—both in empirical kernel matrix and coefficient components.

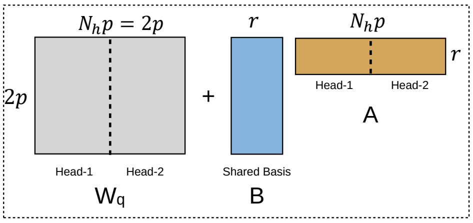
4.2.1 Guideline-1: Head-specific Adaptation

To incorporate Guideline-1, we extend the framework of LoRA and propose **Kernel-wise** [7] that sat-

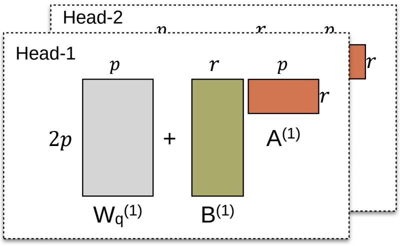
---

[6] The case of $\boldsymbol{W}_v$ is similar to $\boldsymbol{W}_q$, while for $\boldsymbol{W}_o$, the role of $\boldsymbol{A}$ and $\boldsymbol{B}$ would be exchanged. For simplicity, we will always assume we are modifying $\boldsymbol{W}_q$ and discuss how to make $\boldsymbol{B}$ head-specific throughout the paper.

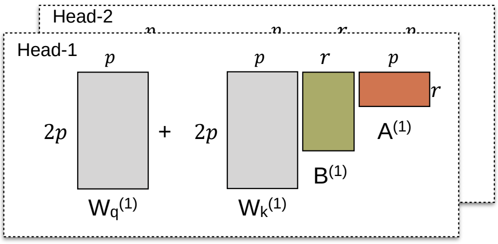
[7] Kernel-wise is a concrete scheme to adjust a specific weight matrix. It will have multiple variants modifying different weight matrices.



(a) LoRA



(b) Kernel-wise



(c) Kernel-wise-lite

Figure 1: (a) Original LoRa with two heads. (b) Kernel-wise variant of LoRa that satisfies Guideline-1 (c) lightweight version of (b) that uses $\boldsymbol{W}_k^{(h)}$ to reduce the trainable parameters in $\boldsymbol{B}^{(h)}$. Note that colored matrices are tunable, whereas gray-scale matrices are fixed (Best viewed in color).

isfies the first guideline.

Here, we allow the low-rank weight matrix updates for each head to have customized column spaces, by training distinct $\boldsymbol{B}^{(h)} \in \mathbb{R}^{N_h p \times r}$ for head-h, $\forall h \in [N_h]$. In this case, the weight matrix $\boldsymbol{W}^{(h)}$ in head-h would be updated by

$$\boldsymbol{W}^{(h)} \leftarrow \boldsymbol{W}^{(h)} + \boldsymbol{B}^{(h)}\boldsymbol{A}^{(h)},$$

and is expected to be more expressive due to the non-shared column spaces (see Figure 1(b)).

On the downside, this design suffers from inflexibility with a small parameter budget. For all the $\boldsymbol{B}^{(h)}$'s, to provide rank-r updates in each head, the new adaptation takes around $N_h^2 pr$ parameters. However, if, for instance, only $4N_h p$ parameters are assigned to modulate a weight matrix, we can still implement the original LoRA by using rank-2 $\boldsymbol{A}, \boldsymbol{B}$, while the construction of Kernel-wise would be prohibited since even rank-1 updates in each head will require more parameters than the budget.

To resolve the issue, we provide a lightweight alternative to the head-specific adaptation above, which we call **Kernel-wise-lite**. In this version, we propose to use the frozen $\boldsymbol{W}_k^{(h)} \in \mathbb{R}^{N_h p \times p}$ as the head-specific basis for head-h ($\boldsymbol{W}_k^{(h)}$ is the h-th block in the weight matrix $\boldsymbol{W}_k$, c.f. § 3.1). Therefore any target weight matrix $\boldsymbol{W}^{(h)}$ would be updated by

$$\boldsymbol{W}^{(h)} \leftarrow \boldsymbol{W}^{(h)} + \boldsymbol{W}_k^{(h)}\boldsymbol{B}_k^{(h)}\boldsymbol{A}^{(h)},$$

where $\boldsymbol{B}_k^{(h)}$ is a p-by-r matrix (see Figure 1(c)).

Utilizing this $\boldsymbol{W}_k^{(h)}$ with a smaller $\boldsymbol{B}_k^{(h)}$ allows the adaptation to be head-specific while containing the same number of trainable parameters as the original LoRA, which is $2N_h pr$. This comes at the cost of restricting the basis spaces of updates for each head from the unconstrained $\boldsymbol{B}^{(h)}$ to $\boldsymbol{W}_k^{(h)}\boldsymbol{B}_k^{(h)}$, where $\boldsymbol{W}_k^{(h)}$ is fixed.

But why should we choose $\boldsymbol{W}_k$ *for the lightweight updates?* The motivation comes from results in kernel learning that encourage adapting of the *coefficient* part using the basis spaces spanned by *key* matrices. In a kernel estimator, the coefficient $\boldsymbol{C}$ is independent of the query sequence $\boldsymbol{Q}$ as it is trained solely by the supporting points $\boldsymbol{K}$—asymptotically, c_j, the j-th row in $\boldsymbol{C}$, is only decided by $k_j, j \in [N]$ (Yang et al., 2017). Concretely, given the loss function and the kernel function, c_j is in general influenced by k_j and $\boldsymbol{K}_{-j}$ (all the points except k_j), while when $N \to \infty$, $\boldsymbol{K}_{-j}$ can be fully specified by a fixed distribution. This implies that in attention, compared to *queries*, *keys* are more related to *values*, and following which, we turn to $\boldsymbol{W}_k$ to form the basis for the low-rank updates for the conceptual motivation.

Combining LoRA with Kernel-wise. Our proposed adaptation can make fine-grained adjustments to each attention head and thus improve the representations. However, increased representation power might at times trade-off with lower-rank updates. As such, we propose our main variant—**Kernel-mix**, to combine the original LoRA and Kernel-wise, to attain the best of both worlds—larger basis (therefore higher rank updates) and specific adaptation to each head. Its update expression is as follows,

$$\boldsymbol{W}^{(h)} \leftarrow \boldsymbol{W}^{(h)} + (\boldsymbol{B}_{LoRA}, \boldsymbol{B}^{(h)}) \begin{pmatrix} \boldsymbol{A}_{LoRA}^{(h)} \\ \boldsymbol{A}^{(h)} \end{pmatrix},$$

where $\boldsymbol{B}_{LoRA}$ is shared among all the heads, while $\boldsymbol{B}^{(h)}$'s are head-specific. We remark Kernel-mix also has a lightweight alternative, **Kernel-mix-lite**, which is the combination of the original LoRA and Kernel-wise-lite. We compare different variants through experiments in § 6.

4.2.2 Guideline-2: Making Coefficients more Expressive

To incorporate Guideline-2, we propose to make coefficients more expressive by allowing the modification of both $\boldsymbol{W}_v$ and $\boldsymbol{W}_o$ for the coefficient part, compared to only updating $\boldsymbol{W}_v$ in the original LoRA. We achieve this by re-writing the attention sub-layer under the kernel estimator perspective, which extends the scope of attention by including $\boldsymbol{W}_o$ in its head-specific computation as well. If we represent $\boldsymbol{W}_o$ as,

$$\begin{pmatrix} \boldsymbol{W}_o^{(1)} \\ \vdots \\ \boldsymbol{W}_o^{(N_h)} \end{pmatrix},$$

where, the i-th block $\boldsymbol{W}_o^{(h)} \in \mathbb{R}^{p \times N_h p}$ corresponds to head-h (i.e., $\boldsymbol{L}^{(h)}\boldsymbol{V}^{(h)}$) in the attention output matrix, we can re-write the attention sub-layer as,

$$\sum_{h=1}^{N_h} \boldsymbol{L}^{(h)}\boldsymbol{V}^{(h)}\boldsymbol{W}_o^{(h)}, \tag{6}$$

and propose to take each summand as the complete form of a head (kernel estimator). We thus extend the coefficient part from the value matrices to the matrix products $\boldsymbol{V}^{(h)}\boldsymbol{W}_o^{(h)}$'s, which naturally results in N-by-$N_h p$ coefficients (with rank-p).

4.3 Final Model

Combining the two pieces together, we report the concrete adaptation scheme under two settings:

- With very limited parameter budgets (less than 0.2% of the total PLM parameters), similar to LoRA, we modify $\boldsymbol{W}_q$ and $\boldsymbol{W}_v$ with equal parameter budgets using Kernel-mix-lite(qv). (The suffix (qv) means the method will adjust $\boldsymbol{W}_q$ and $\boldsymbol{W}_v$.) In this case, we omit Guideline-2 and only incorporate Guideline-1 to apply head-specific updates.
- With intermediate parameter budgets (around 1.6% of the total parameters in the PLM), we suggest using Kernel-mix(qvo), which instead modifies $\boldsymbol{W}_q$, $\boldsymbol{W}_v$, and $\boldsymbol{W}_o$, assigning more budgets to the coefficient part (Guideline-2). Given the increased parameter budgets, we allow Kernel-mix scheme for $\boldsymbol{W}_q$ and $\boldsymbol{W}_o$, while continue to utilize Kernel-mix-lite scheme for $\boldsymbol{W}_v$. Kernel-mix(qvo) incorporates both the guidelines.

5 Experiments

While parameter-efficient tuning methods have been extensively studied for NLU tasks, their applicability towards NLG tasks is not well-known. This section performs empirical experiments of our proposed methods on three NLG tasks. To show the consistent effectiveness of our methods, we provide results on two NLU tasks as well. [8]

5.1 Experimental Setup

We mainly evaluate the performance of our methods on NLG tasks, in which there is still a gap between fine-tuning and most parameter-efficient adaptation techniques (He et al., 2021). Specifically, we conduct our experiments on the following datasets: WebNLG-challenge (Gardent et al., 2017) for table-to-text tasks, CoQA (Reddy et al., 2019) for conversational question answering, and CNN/Daily-Mail (CNN/DM) (Hermann et al., 2015) for summarization (SUM). CNN/DM has only one domain, while CoQA has five domains [9], and WebNLG has 14 domains. Descriptions of the datasets and evaluation metrics are provided in Appendix A.

Our experiments mainly follow the setting used by Lin et al. (2020), which takes GPT-2$_{\text{SMALL}}$ (124M parameters) (Wolf et al., 2019) as the backbone for all the NLG tasks. We choose the smaller model size as compared to the larger models used in other related studies it is generally difficult for smaller models to attain the same performance as full-model fine-tuning (Lester et al., 2021; Liu et al., 2021b). This creates a challenging testbed to evaluate our proposed approaches.

In addition to the NLG experiments, we also study two NLU tasks: MNLI (Williams et al., 2018) and SST2 (Socher et al., 2013), to show the performance of our methods on encoder-only transformers. The Multi-Genre Natural Language Inference (MNLI) Corpus (sentence pairs of hypotheses and premises with entailment annotations) will be given, and the task is to predict whether

---

[8] The code release info will be available in this page.

[9] We use the official dev set as the test set and randomly select 500 examples from the train set as the new dev set.

Table 1: Performance (%) on NLG tasks [a]. The methods are divided into 4 groups based on the number of parameters to store, and the methods in the same group have similar sizes. We **boldface** the best score in each group for different metrics. In the group of intermediate budget, we further conduct the significance tests between Kernel-wise and the best baseline for each metric (* means the test p-value < 0.05).

[a] We follow the notations in prefix-tuning (Li and Liang, 2021) that S, U, A represent SEEN, UNSEEN, and ALL respectively; SEEN categories are used in training; UNSEEN categories only appear in the test set; and ALL consists of all the categories.

the premise entails, contradicts, or is neutral to the hypothesis; the Stanford Sentiment Treebank (SST2) is composed of movie reviews and corresponding human-annotated sentiment and specifies a task to predict the sentiment of a review sentence (positive/negative). We implement the backbone under the setting used by He et al. (2021) and use RoBERTa$_{\text{BASE}}$ (125M parameters) (Liu et al., 2019) for both MNLI and SST2.

5.2 Baselines

We compare our method with several other representative methods: fine-tuning (Howard and Ruder, 2018), adapters (Houlsby et al., 2019) used by Lin et al. (2020), Compacter (Mahabadi et al., 2021), Bitfit (Ben Zaken et al., 2021), prefix-tuning (Li and Liang, 2021), LoRA (Hu et al., 2021), and MAM-adapter (He et al., 2021). In Table 1 we use a postfix of adapters / LoRA / prefix-tuning to indicate their bottleneck size / rank of updates / prefix length, respectively. For instance, Adapter-4 means that the bottleneck size of the two-layer MLP in the inserted adapter is 4.

For some adaptation techniques, the number of parameters to train is not flexible to tune. For instance, Bitfit proposes to tune all the bias terms within the PLMs, and, as a result, the maximum parameters to tune are limited; as for Compacter, the weight matrices in the adapter modules are constructed through the Kronecker product, and the parameter complexity is $\mathcal{O}(\frac{L}{n} + n^3)$ (Mahabadi et al., 2021), where n is the size of a square matrix used in the Kronecker product and L is the number of layers. We choose a particular setting to make the number of trainable parameters in Compacter close to Bitfit and a tiny size adapter. The parameter size of Compacter is not further increased since a larger n would significantly retard the training.

For prefix-tuning, Li and Liang (2021) suggest to utilize a re-parametrization trick to mitigate its initialization issue, and therefore, the number of parameters to train will be much larger than the actual number of parameters to store, while these two numbers are the same for all other methods. In deciding the model size, we manage to make the number of parameters to **store** in prefix-tuning roughly the same as its adapter counterpart by adjusting the prefix length.

6 Results

6.1 Main Results

Table 1 compares our proposed methods against other baselines on the aforementioned generation tasks. The performance of our proposed Kernel-mix method on text classification is reported in Table 2. We summarize our observations as follows.

Tasks with long input. As shown in Table 1, all previous parameter-efficient methods fail to attain comparable performance to fine-tuning on CoQA and CNN/DM tasks which have a longer input than the table-to-text generation task WebNLG. This indicates that current parameter-efficient methods still fall behind fine-tuning in those more challenging generation tasks with longer sequences. However, Kernel-mix, encloses this gap and even outperforms fine-tuning in some NLG tasks, e.g. the CoQA task, with solely 1.61% tunable parameters of GPT-2$_{\text{SMALL}}$.

Impact of parameter sizes. The results in Table 1 show that overall, as the tunable parameter size increases, the performance of various parameter-efficient methods also increases, getting closer to fully fine-tuning. This indicates that a large enough parameter budget is still a prerequisite for the excellent performance of parameter-efficient adaptation methods. This finding can help us explain why the performance of Compacter can be better than Adapter-4 over all the tasks when the parameter budget is tiny (*Tiny Budget* $< 0.1\%$ in the second group in Table 1), considering that the Compacter can construct a larger MLP than the adapter with the same parameter budget due to the usage of Kronecker product. Inspired by this finding, we can also clearly see the limitation of Bitfit and Compacter as their parameter budgets are constrained to be small and cannot be elevated of free will. As for the original LoRA, the impact of parameter sizes is somewhat tricky—LoRA-4 shows competitive performance while LoRA-54 is not improved as greatly as other methods on WebNLG and CoQA. A similar phenomenon on different datasets is also observed by Hu et al. (2021); He et al. (2021).

Performance of our proposed Kernel-mix(qvo). Our proposed Kernel-mix(qvo) can generally improve the performance on all three NLG datasets. On WebNLG, Kernel-mix(qvo) provides a 1.1 increase in BLEU score compared to Adapter-108 and a 2.6% increase compared to LoRA-54; on CoQA, our method is even more greatly better than LoRA-54, obtaining 2.7 exact-match and F1 improvement, and even outperforms fine-tuning by around 1% in both of the metrics; On CNN/DM, all the parameter-efficient methods have close performance, while through a test, we show our method Kernel-mix has a significantly higher Rouge-2 score than the best baseline, LoRA-54. Overall, Table 1 demonstrates that kernel-mix adaptation better exploits the attention structure in PLMs and improves the overall generation quality under all three kinds of parameter budgets.

Method (# params)	MNLI	SST2
Fine-tuning (100%)	$87.6_{\pm.4}$	$94.6_{\pm.4}$
Bitfit (0.1%)	84.7	93.7
Prefix-tuning (0.5%)	$86.3_{\pm.4}$	$94.0_{\pm.1}$
LoRA (0.5%)	$87.2_{\pm.4}$	$94.2_{\pm.2}$
Adapter (0.5%)	$87.2_{\pm.2}$	$94.2_{\pm.1}$
MAM-Adapter (0.5%)	$87.4_{\pm.3}$	$94.2_{\pm.3}$
Kernel-mix(qvo) (0.5%)	$87.4_{\pm.2}$	$94.3_{\pm.3}$

Table 2: Accuracy on the dev set of MNLI and SST2. Bitfit numbers are copied from Ben Zaken et al. (2021), and all the other results (except for Kernel-mix) are from He et al. (2021, Table 2).

Performance on NLU tasks. Table 2 shows the performance of Kernel-mix(qvo) when it is extended to encoder-only transformers. For a fair comparison, we specify a new parameter budget (0.5%) for Kernel-mix(qvo), different from the previous settings in Table 1. With the new budget, Kernel-mix(qvo) attains close accuracy to the other parameter-efficient methods on both MNLI and SST2. We remark that the parameter budget used here is slightly tight for Kernel-mix(qvo), as the ranks assigned for head-wise adaptation (1 for W_q and 2 for W_v, W_o) are limited (see Table B.5).

6.2 Ablation Studies

Besides the main results in Table 1, we also perform ablation studies to verify the effectiveness of our propositions. We additionally implement four variants of Kernel-wise to help ablate the effects of our proposed guidelines. Among the new variants, Kernel-wise-lite(qv), Kernel-wise(mq), and Kernel-wise(mv) only adjust $\boldsymbol{W}_q$, $\boldsymbol{W}_v$; Kernel-wise-lite(qv) takes the strategy in LoRA-4 to evenly assign parameters to $\boldsymbol{W}_q$ and $\boldsymbol{W}_v$; Kernel-wise(mq) leaves more budget to $\boldsymbol{W}_q$ than $\boldsymbol{W}_v$ with a ratio of 3:1, while Kernel-wise(mv) is set up in the reversed way. In contrast, Kernel-wise(qvo) simultaneously adjusts $\boldsymbol{W}_q$, $\boldsymbol{W}_v$, and $\boldsymbol{W}_o$ (with a budget ratio of 5:1:10). The experimental results are summarized in Table 3. The settings of the variants designed for ablation are described in Appendix B.4.

Head-specific adaptation (Guideline-1). For "LoRA-4", the setting recommended by Hu et al. (2021), we compare it with its head-specific

Kernel-mix(qvo)	1.61%	1.61%	59.8	36.7	49.3	0.43	0.33	0.38	0.37	0.57	0.46	59.9	68.4	15.34

Table 3: Performance on new variants of Kernel-wise compared to LoRA-4 and our proposed Kernel-mix(qvo) (both copied from Table 1). The methods with similar budgets of tunable parameters are grouped. The exact settings of the methods to compare are illustrated in § 6.2 and Appendix B.4.

counterpart—Kernel-wise-lite(qv). In almost all the tasks, Kernel-wise-lite(qv) can attain better performance with the same number of parameters.

More parameters for the coefficient part (Guideline-2). Hu et al. (2021) (Section 7.1) indeed have already done some preliminary exploration to find the relatively more important weight matrices in transformers. Their experimental results (copied as Table C.6 in Appendix C) clearly show that "putting all the parameters in $\Delta \boldsymbol{W}_q$ or $\Delta \boldsymbol{W}_k$ results in significantly lower performance". In this work, we additionally show that by simply moving some trainable parameters from $\boldsymbol{Q}$, the empirical kernel matrix part, to $\boldsymbol{V}$, the coefficient part, Kernel-wise(mv) can improve the performance upon Kernel-wise(mq) as well.

Extending the scope of attention. To show the benefits of both adjusting $\boldsymbol{W}_v$ and $\boldsymbol{W}_o$, we compare the new variant Kernel-wise(mv) against Kernel-wise(qvo). They both assign more budgets to the coefficient part; Kernel-wise(qvo) would update both $\boldsymbol{W}_q$, $\boldsymbol{W}_v$ and $\boldsymbol{W}_o$, while Kernel-wise(mv) only adjusts $\boldsymbol{W}_q$, $\boldsymbol{W}_v$. We can observe that Kernel-wise has better performance in most tasks.

Combining the shared and the head-specific basis. Lastly, we find that Kernel-mix(qvo) (our proposed method) outperforms Kernel-wise(qvo), which justifies combining the two types of basis, as opposed to pure head-specific adaptation.

7 Conclusion and Future Work

In this work, we revisit the connection between the attention module and kernel estimators, and accordingly propose kernel-wise adaptation, which adopts the guidelines from kernel learning to strengthen the low-rank adaptation (LoRA). We verify that with the same parameter budgets, our proposed adaptation techniques can have better performance on three generation tasks than the existing parameter-efficient methods, including adapters, prefix-tuning, and LoRA, and attain close accuracy on two classification tasks as well.

One possible extension of our work is combining our proposed method with other adapters in feed-forward sub-layers. In MAM-adapter, He et al. (2021) suggest applying prefix-tuning to adapt the parameters in self-attention sub-layers and assigning budgets to feed-forward sublayers as well; it can be beneficial to replace prefix-tuning with Kernel-mix for adaptation in the attention part.

Another direction of future research is the extension of our method to the feed-forward sub-layers, which are interpreted as key-value memories in recent work and behave like attention blocks (Geva et al., 2021). It will be interesting to study if kernel-specific guidelines could help design better adapters employed in the feed-forward layers.

A Dataset Details

- The **WebNLG** dataset consists of mapping sets of RDF triples to text. The training data are Data/Text pairs where the data is a set of (subject, property, object) triples. There are 9 categories extracted from DBpedia in the train and the development (dev) set, while the test set contains 5 more unseen categories, which can be used to evaluate the generalization of the adaptation methods. We adopt the official evaluation script and reports BLEU (Papineni et al., 2002), METEOR, (Lavie and Agarwal, 2007) and TER (Snover et al., 2006) [10].

- **CoQA** is a large-scale conversational question answering dataset. It contains over 127K questions with answers collected from more than 8K conversations. The problem involves generating answers to the questions based on related conversation histories and documents. We follow the official evaluation script and use the macro-average F1 score of word overlap as the main evaluation metric (Reddy et al., 2019).

- **CNN/DM** is a benchmark for text summarization, involving more than 300K news articles provided by CNN and the Daily Mail. We report ROUGE-2 scores (Lin, 2004) as evaluation metrics.

- **MNLI** The Multi-Genre Natural Language Inference Corpus (Williams et al., 2018) provides sentence pairs of hypotheses and premises with entailment annotations. There are $393k$ pairs in the training set, $10k$ in the dev set, and another $10k$ pairs in the test set. (Only the dev set is used in Table 2.) The premise sentences come from ten different sources, and the model performance can be evaluated on both the matched (in-domain) and mismatched (cross-domain) sections. In Table 2, we follow the setting used by Hu et al. (2021) and report mismatched accuracy as the metric.

- **SST2** The Stanford Sentiment Treebank (Socher et al., 2013) is a corpus with fully labeled parse trees. In this corpus, $11,855$ single sentences extracted from movie reviews were parsed with the Stanford parser (Klein and Manning, 2003), generating $215,154$ unique phrases from those parse trees (3 human judges annotate each phrase). Wang et al. (2019) incorporated the task into the GLUE benchmark, with $67k$ sentences in the training set, $0.9k$ in the dev set, and $1.8k$ instances in the dev set. (Only the dev set is used in Table 2.) The metric is the accuracy of the decision whether the sentiment of a review sentence is positive or negative.

B Training Details

B.1 General Training Settings

We avoid the sentence-level knowledge distillation trick used in (Lin et al., 2020), as it might interfere in analyzing our hypotheses. However, we retain the usage of "task embeddings" as they are required by the original GPT-2 model. These task embeddings act as specialized segment embeddings that indicate the different components of the text input (e.g., the three components of a triple in NLG, questions and answers in CoQA, etc.). [11]

We state the specific task embedding used in each task. For CoQA and CNN/DM, we follow the task embedding suggested by Lin et al. (2020); for WebNLG, we similarly set up the special tokens for the different components in the triples. We conclude the details of the special tokens in each dataset in Table B.4. Notably, the parameter budget for task embedding is neglectable compared to the size of the aforementioned parameter-efficient adaptation techniques.

B.2 Hyper-parameters

We apply an AdamW optimizer and a linear learning rate scheduler with a 500-step warmup duration in training. At generation time, we use a greedy search for all the tasks, the same as Lin et al. (2020). For the choice of some hyperparameters, we mainly follow the setting used by Lin et al. (2020); Hu et al. (2021) and He et al. (2021), including the number of epochs and the argument for weight decay. Specifically, for WebNLG, CNN/DM, MNLI, and SST2, we train the model for 10 epochs; for CoQA, we train the model for 5 epochs. For the other important hyper-parameters, such as batch size and learning rate, we tune the hyper-parameters for different methods according to the loss on the validation set. For our Kernel-mix methods in Table 1, they share the same batch size and learning rate in each task. Specifically, for WebNLG, the learning

---

[10] For TER, the lower the metric is, the better the performance is.

[11] The task embedding for the special tokens will also be updated during training, while we do not count them in Table 1.

Datasets	Special tokens	# of trainable parameters for task embedding
WebNLG	`<bos_webnlg>`, `<eos_webnlg>`, `<subject>`, `<property>`, `<object>`, `<target_webnlg>`	$6 * 768 = 4608$
CoQA	`<bos_qa>`, `<eos_qa>`, `<question>`, `<answer>`, `<document>`	$5 * 768 = 3840$
CNN/DM	`<bos_sm>`, `<eos_sm>`, `<source_sm>`, `<target_sm>`	$4 * 768 = 3072$

Table B.4: The special tokens used in different tasks and the corresponding size of trainable parameters.

rate we use is 0.00125, and the batch size is 16; for CoQA, the learning rate we use is 0.005, and the batch size is 8; for CNN/DM, the learning rate we use is 0.001, and the batch size is 16; for MNLI, the learning rate we use is 0.0002, and the batch size is 32; for SST2, the learning rate we use is 0.0001, and the batch size is 16;

We train each variant for multiple independent runs to account for variability. In particular, for WebNLG, we train models over 5 runs, for CoQA 3 runs, for CNN/DM 2 runs, for MNLI 3 runs, and for SST2 3 runs.[12] The reported numbers in Tables 1 and 2 are the mean value averaged over the runs.

B.3 Implementation and Training Efficiency

All the models in this work are implemented by PyTorch. For the devices, we perform the distributed training using 8 Tesla V100 16GB GPUs. On WebNLG, it will take our method around 1 minute to finish one epoch; on CoQA, the time cost is around 20 minute / epoch; on CNN/DM, the training time per epoch will be 30 minutes. For the NLU tasks, the task implementation by He et al. (2021) cannot be adapted to distributed training (can only be trained with one graphic card), and thus the training time is longer: it will take our method around 2 hours to finish one epoch in MNLI, and 25 minutes in SST2.

We additionally report there is actually an implementation trick in Kernel-wise-lite. We can simply associate the h^{th} head's *key* matrix $\boldsymbol{K}^{(h)}$ to the computation of any weight matrix, say $\boldsymbol{Q}^{(h)}$, as follows,

$$\begin{aligned}\boldsymbol{Q}^{(h)} &= \boldsymbol{X}\boldsymbol{W}_q^{(h)} + \boldsymbol{X}\boldsymbol{W}_k^{(h)}\boldsymbol{B}_k^{(h)}\boldsymbol{A}^{(h)} \\ &= \boldsymbol{X}\boldsymbol{W}_q^{(h)} + \boldsymbol{K}^{(h)}\boldsymbol{B}_k^{(h)}\boldsymbol{A}^{(h)}.\end{aligned}$$

In that case we can reuse the given $\boldsymbol{K}$ to save the computation of the product $\boldsymbol{X}(\boldsymbol{W}_k^{(h)}\boldsymbol{B}_k^{(h)}\boldsymbol{A}^{(h)})$.

B.4 Specific settings for each method

We report the exact setting for the methods that need further explanation in this subsection. For Compacter, the bottleneck size of the adapter is 192, and the number of components is 4, as suggested by Karimi Mahabadi et al. (2021); for the original LoRA and the variants of our proposed methods, we summarize their settings in Table B.5. In this table, the numbers in columns Q_wise, V_wise, and O_wise are the rank used for Kernel-wise; if the number is followed by “(lite)", we apply Kernel-wise-lite with the listed rank to adjust the corresponding weight matrices. The numbers in columns Q_LoRA, V_LoRA, and O_LoRA are the rank of the update used as in the original LoRA. For Kernel-mix methods, the numbers in columns Q_wise and Q_LoRA (for example) will be non-zero.

C Partial Experimental Results Reported in LoRA (Hu et al., 2021)

For ease of reading, we copy Table 5 from the paper (Hu et al., 2021) as a piece of evidence to show “putting all the parameters in $\Delta \boldsymbol{W}_q$ or $\Delta \boldsymbol{W}_k$ results in significantly lower performance”.

---

[12] We reduce the number of runs for larger datasets given computation budget.

	Budget	Q_wise	Q_LoRA	V_wise	V_LoRA	O_wise	O_LoRA

Abstract

Intermediate layer knowledge distillation (KD) can improve the standard KD technique (which only targets the output of teacher and student models) especially over large pre-trained language models. However, intermediate layer distillation suffers from excessive computational burdens and engineering efforts required for setting up a proper layer mapping. To address these problems, we propose a RAndom Intermediate Layer Knowledge Distillation (RAIL-KD) approach in which, intermediate layers from the teacher model are selected randomly to be distilled into the intermediate layers of the student model. This randomized selection enforces that all teacher layers are taken into account in the training process, while reducing the computational cost of intermediate layer distillation. Also, we show that it acts as a regularizer for improving the generalizability of the student model. We perform extensive experiments on GLUE tasks as well as on out-of-domain test sets. We show that our proposed RAIL-KD approach outperforms other state-of-the-art intermediate layer KD methods considerably in both performance and training-time.

1 Introduction

Pre-trained Language Models (PLMs), such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2020) and XLNet (Yang et al., 2019) have shown remarkable abilities to match and even surpass human performances on many Natural Languages Understanding (NLU) tasks (Rajpurkar et al., 2018; Wang et al., 2018, 2019). However, the deployment of these models in real world applications (e.g. edge devices) come with challenges, mainly due to large model size and inference time.

In this regard, several model compression techniques such as quantization (Shen et al., 2019; Zafrir et al., 2019; Kumar et al., 2022; Prato et al., 2020), pruning (Guo et al., 2019; Gordon et al., 2020; Michel et al., 2019),matrix factorization (Tahaei et al., 2021; Lioutas et al., 2020), optimizing the Transformer architecture (Fan et al., 2019; Wu et al., 2020b; Lu et al., 2020), and knowledge distillation (Sanh et al., 2019a; Jiao et al., 2019; Sun et al., 2020b; Wang et al., 2020a; Rashid et al., 2021; Passban et al., 2021; Jafari et al., 2021; Rezagholizadeh et al., 2021) have been developed to reduce the model size and latency, while maintaining comparable performance to the original model.

KD, which is the main focus of this work, is a neural model compression approach that involves training a small *student* model with the guidance of a large pre-trained *teacher* model. In the original KD technique (Buciluǎ et al., 2006; Hinton et al., 2014; Turc et al., 2019), the teacher output predictions are used as soft labels for supervising the training of the student. There has been several attempts in the literature to reduce the teacher-student performance gap by leveraging data augmentation (Fu et al., 2020; Li et al., 2021; Jiao et al., 2019; Kamalloo et al., 2021, 2022), adversarial training (Zaharia et al., 2021; Rashid et al., 2020, 2021), and intermediate layer distillation (ILD) (Wang et al., 2020b,a; Ji et al., 2021; Passban et al., 2021).

When it comes to BERT compression, ILD leads to clear gains in performances (Sanh et al., 2019a; Jiao et al., 2019; Wang et al., 2020a) due to its ability to enhance the knowledge transfer beyond logits matching. This is done by mapping intermediate layer representations of both models to a common space[1], and then matching them via regression (Sun et al., 2019) or cosine similarity (Sanh et al., 2019a) losses. One major problem with ILD is the absence of an appropriate strategy to select layers to be matched on both sides, reacting to the *skip*

---

[*] Work done while at Huawei.

[1] In some cases, the representations are directly matched if the teacher and student have the same hidden size.

and search problem (Passban et al., 2021). Some solutions in the literature mostly rely on layer combination (Wu et al., 2020a), attention-based layer projection (Passban et al., 2021) and contrastive learning (Sun et al., 2020a). While these solutions are all effective to some extent, to the best of our knowledge, there is no work in the literature doing a comprehensive evaluation of these techniques in terms of both efficiency and performance.

A case in point is that the aforementioned solutions to the layer skip and search problem do not scale to very deep networks. We propose RAIL-KD (RAndom Intermediate Layer KD), a simple yet effective method for intermediate layer mapping which randomly selects k out of n intermediate layers of the teacher at each epoch to be distilled to the corresponding student layers. Since the layer selection is done randomly, all the intermediate layers of the teacher will have a chance to be selected for distillation. Our method adds no computational cost to the training, still outperforming all aforementioned methods on the GLUE benchmark (Wang et al., 2018). Moreover, we observe larger gains when distilling from large teacher models, as well as when student models are evaluated on out-of-domain datasets. Last, we report the results on 5 random seeds in order to verify the contribution of the random selection process, thus making the comparison fair with previous methods. The main contributions of our paper are as follows:

- We introduce RAIL-KD, a more efficient and scalable intermediate layer distillation approach.
- To the best of our knowledge, we are the first to perform a comprehensive study of the ILD techniques in terms of both efficiency and performance.
- We consider the distillation of models such as BERT and RoBERTa, and compare different up-to-date distillation techniques on out-of-domain test sets.

2 Related Work

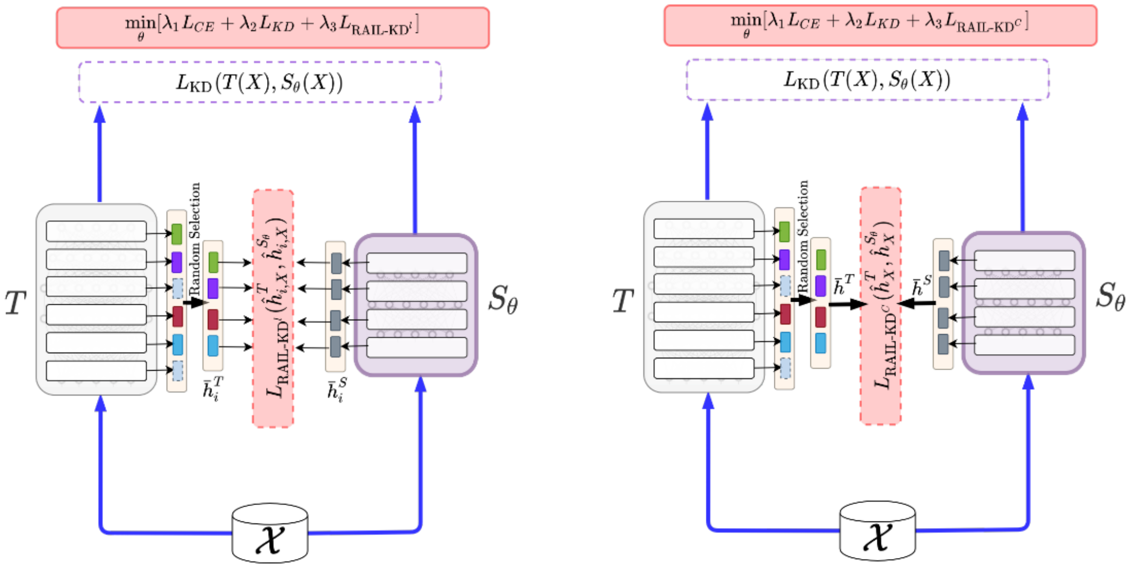
In recent years, a wide range of methods have tried to expand knowledge transfer of transformer-based (Vaswani et al., 2017) NLU models beyond logits matching. DistillBERT (Sanh et al., 2019a) added a cosine similarity loss between teacher and student embeddings layers. TinyBERT (Jiao et al., 2019), MobileBERT (Sun et al., 2020b), and MiniLM (Wang et al., 2020b) matched the intermediate layers representations and self-attention distributions of the teacher and the student.

In PKD, Sun et al. (2019) used deterministic mapping strategies to distill a 12-layer BERT teacher to a 6-layer BERT student. PKD-LAST and PKD-SKIP refer to matching layers $\{1-5\}$ of the student with layers $\{7-11\}$ and $\{2,4,6,8,10\}$ of the teacher respectively. However, these works ignored the impact of layer selection, as they used a fixed layer-wise mapping.[2]

Researchers have found that tuning the layer mapping scheme can significantly improve the performance of ILD techniques (Sun et al., 2019). Nevertheless, finding the optimal mapping can be challenging, which is referred to as the *layer skip and search problems* by Passban et al. (2021). To address the layer skip problem, CKD (Wu et al., 2020a) is built on top of PKD by partitioning all the intermediate layers of the teacher to the number of student layers. Then, the combined representation of the layers of each partition is distilled into a number of subset corresponding to the number of student layers. However, finding the optimal

---

[2] e.g. matching the first (or last) k layers of the student with their corresponding teacher layers.



(a) Layer-wise Representation Distillation **(b) Concatenated Representation Distillation**

Figure 1: Proposed RAIL-KD technique for efficient intermediate layer distillation. (a) This version shows a layer-wise projection which is indicated as RAIL-KD^l in the paper. (b) This variant named RAIL-KD^c, concatenates the intermediate representations of each network before distillation.

partitioning scheme requires running exhaustive experiments. Given teacher and student BERT models with n and m layers respectively (where $n >> m$), it is not trivial to choose the teacher layers that can be incorporated in the distillation process and how we should map them to the student layers (*search*).

ALP-KD (Passban et al., 2021) overcomes this issue by computing attention weights between each student layer and all the intermediate layers of the teacher. The learned attention weights for each student layer are used to obtain a weighted representation of all teacher layers. Although ALP-KD has shown promising results on 12-layer BERT-based compression, attending to all layers of the teacher adds considerable computational overhead to the training phase. This can become computationally prohibitive when scaling to very large models such as RoBERTa-large (Liu et al., 2020) or GPT-2 (Radford et al., 2019). Alternatively, CoDIR (Sun et al., 2020a) exploited contrastive learning (Tian et al., 2019) to perform intermediate layers matching between the teacher and the student models with no deterministic mapping. Similar to ALP-KD, this approach also requires excessive training time due to the contrastive loss calculation and the use of negative samples from a memory bank.

Table 1 summarizes the main characteristics of the existing state-of-the-art intermediate layer distillation techniques (PKD, CKD, and CoDIR) used for pre-trained language models compared with our proposed RAIL-KD. First, PKD and CKD treat the mapping as an extra hyperparameter that requires extensive experiments in order to find the optimal mapping. Second, ALP-KD (Passban et al., 2021) and CoDIR (Sun et al., 2020a) use the attention mechanism and contrastive learning respectively to address the issue, but at the expense of extra computational cost.

Our proposed RAIL-KD method does not add any computational cost to the distillation process, while empirically outperforming previous methods. For instance, RAIL-KD is roughly two-times faster than CoDIR in a 24 to 6 layer compression. In addition, it does not require extensive experiments to find the optimal mapping scheme. In this work, we position ourselves to works that tackle the *skip and search problem*.[3] In other words, we don't compare with works like TinyBERT (Jiao et al., 2019) or MiniLM (Wang et al., 2020b), which use extra losses like self-attention distribution matching. However, we expect that these methods, as well as state-of-the-art (Rashid et al., 2021; He et al., 2021) ones can take full advantage of RAIL-KD, since they use a deterministic layer mapping scheme.

---

[3] This only concerns works that perform intermediate layer distillation

3 RAIL-KD

The RAIL-KD method is sketched in Figure 1. RAIL-KD transfers intermediate knowledge of a pre-trained teacher T with n intermediate layers to a student model S_θ with m intermediate layers. In contrast to traditional intermediate layer distillation techniques which keep the selected layers of the teacher for distillation fixed during training, in RAIL-KD, at each epoch, a few intermediate layers from the teacher model are selected randomly for distillation. Here for simplicity, we set the number of selected intermediate layers of the teacher model equal to that of the student model.

Let (X, y) denote a training sample $X = (x_0, \cdots, x_{L-1})$ which is a sequence of L tokens and y its corresponding label. In Figure 1, our Random Selection operator is applied to the intermediate layers of the teacher to randomly select m out of n layers. The intermediate layer representations of the m selected layers of the teacher and the student model corresponding to the X input can be described as $\mathcal{H}^T_X = \{H^T_{1,X}, \cdots, H^T_{m,X}\}$ and $\mathcal{H}^{S_\theta}_X = \{H^{S_\theta}_{1,X}, \cdots, H^{S_\theta}_{m,X}\}$ respectively, where $H^T_{i,X} = \cup_{k=0}^{L-1}\{h^T_{i,x_k}\} \in R^{L\times d_1}$ and $H^{S_\theta}_{i,X} = \cup_{k=0}^{L-1}\{h^{S_\theta}_{i,x_k}\} \in R^{L\times d_2}$. Here, d_1 and d_2 indicate the hidden dimension of the layers of the teacher and the student models respectively. To obtain $H^T_{i,X}$ and $H^S_{j,X}$, we need to find the individual representation of each token x_k at each layer i, which is indicated as h^T_{i,x_k} and h^S_{i,x_k} for the teacher and student networks respectively.

At this stage, we need to obtain an aggregated representation of the sequence X at each layer. In this regard, one can either use the <CLS> token representation or use the mean-pooling of the sequence representations of the layer. Since in Sun et al. (2020a), the mean-pooling representation shows better results, we adopt it to compute the sentence representation of each layer. Mean-pooling is a row-wise average over $H^T_{i,X}$, $H^{S_\theta}_{i,X}$ to get $\bar{h}^T_{i,X} \in R^{d_1}$ $\bar{h}^{S_\theta}_{i,X} \in R^{d_2}$ (Sun et al., 2020a):

$$\bar{h}^T_{i,X} = \frac{1}{L}\sum_{k=0}^{L-1} h^T_{i,x_k} \;\; ; \;\; \bar{h}^{S_\theta}_{i,X} = \frac{1}{L}\sum_{k=0}^{L-1} h^{S_\theta}_{i,x_k} \qquad (1)$$

After obtaining aggregated layer representations for both the student and teacher networks, our RAIL-KD proposal is to randomly select m layer representations from the teacher through training to perform the intermediate layer distillation (ILD). RAIL-KD does ILD in two different forms: using layer-wise distillation (see Fig. 1(a)) or by concatenating layer representations (see Fig. 1(b)) which are described in the following two sub-sections.

3.1 Layer-wise RAIL-KD

In this setting, the representations $\bar{h}^T_{i,X} \in R^{d_1}$ and $\bar{h}^{S_\theta}_{i,X} \in R^{d_2}$ are projected into a same-size lower-dimensional space $\hat{h}^T_{i,X}, \hat{h}^{S_\theta}_{i,X} \in R^u$ using $(d_1 \times u)$ and $(d_2 \times u)$ linear mappings respectively. Assume that the set $\mathcal{A} = \{a_\kappa | a_\kappa \sim \{1, 2, ..., n\}, 1 \le \kappa \le m\}$ contains indices of selected m layers from the teacher, then to calculate the layer-wise loss we have:

$$L_{\text{RAIL-KD}^l} = \sum_{X\in\mathcal{X}}\sum_{i\in\mathcal{A}} \alpha_i \left(|| \frac{\hat{h}^T_{i,X}}{||\hat{h}^T_{i,X}||_2} - \frac{\hat{h}^{S_\theta}_{i,X}}{||\hat{h}^{S_\theta}_{i,X}||_2} ||^2_2 \right) \qquad (2)$$

where $\mathcal{X}$ denotes the training set, and α_i is a hyper-parameter to assign a custom weights to the layer-wise distillation loss. It is worth mentioning that in our experiments we set $\alpha_i = 1$.

3.2 Concatenated RAIL-KD

In this setting, intermediate layer representations are concatenated and then distilled: $\bar{h}^T_X = [\bar{h}^T_{i,X}]_{i\in\mathcal{A}}$, $\bar{h}^{S_\theta}_X = [\bar{h}^{S_\theta}_{j,X}]_{j=1}^m$ which are further mapped into the same lower-dimensional space $\hat{h}^T_X, \hat{h}^{S_\theta}_X \in R^u$ using $(md_1 \times u)$ and $(md_2 \times u)$ linear mappings to calculate the concatenated distillation loss.

$$L_{\text{RAIL-KD}^c} = \sum_{X\in\mathcal{X}} || \frac{\hat{h}^T_X}{||\hat{h}^T_X||_2} - \frac{\hat{h}^{S_\theta}_X}{||\hat{h}^{S_\theta}_X||_2} ||^2_2 \qquad (3)$$

Any type of loss such as contrastive (Sun et al., 2020a), or mean-square-error (MSE) (Passban et al., 2021; Sun et al., 2019) can be applied for our RAIL-KD approach.

3.3 Training Loss

The intermediate representation distillation loss $L_{\text{RAIL-KD}}$ is combined with the original KD loss L_{KD}, which is used to distill the knowledge from the output logits of the teacher model T to the output logits of the student model S_θ, and the original cross-entropy loss L_{CE}. The total loss function for training the student model is:

$$\mathcal{L} = \lambda_1 L_{\text{CE}} + \lambda_2 L_{\text{KD}} + \lambda_3 L_{\text{RAIL-KD}^{l/c}} \qquad (4)$$

where λ_1, λ_2, and λ_3 are hyper-parameters of our model to minimize the total loss, and $\lambda_1 + \lambda_2 + \lambda_3 = 1$.

4 Experimental Protocol

4.1 Datasets and Evaluation

We evaluate RAIL-KD on 8 tasks from the GLUE benchmark (Wang et al., 2018): 2 single-sentence (CoLA and SST-2) and 5 sentence-pair (MRPC, RTE, QQP, QNLI, and MNLI) classification tasks, and 1 regression task (STS-B). Following prior works (Sun et al., 2019; Passban et al., 2021; Jiao et al., 2019; Sun et al., 2020a), we use the same metrics as the GLUE benchmark for evaluation. Moreover, to further show the generalization capability of our RAIL-KD method on out-of-domain (OOD) across tasks, we use Scitail (Khot et al., 2018), PAWS (Paraphrase Adversaries from Word Scrambling) (Zhang et al., 2019), and IMDb (Internet Movie Database) (Maas et al., 2011) test sets to evaluate the models fine-tuned on MNLI, QQP, and SST-2 tasks respectively.

4.2 Implementation Details

We run extensive experiments on 3 different teachers in order to ensure a fair comparison with a wide range of prior works, and also to show the effectiveness of RAIL-KD. We experiment with the 12-layer BERT-base-uncased (Devlin et al., 2019) model as teacher (BERT$_{12}$) and the 6-layer DistilBERT (Sanh et al., 2019a) as student (DistillBERT$_6$) to compare with PKD (Sun et al., 2019) and ALP-KD (Passban et al., 2021). Also, we consider 24-layer RoBERTa-large (Liu et al., 2020) and 6-layer DistilRoberta (Sanh et al., 2019b) as the backbone for teacher (RoBERTa$_{24}$) and student (DistilRoberta$_6$) respectively to compare results when $n >> m$. Furthermore, we perform evaluation using the 12 layers RoBERTa-base (RoBERTa$_{12}$) model as a teacher to be able to directly compare our figures with the ones of CoDIR.

We re-implement PKD (Sun et al., 2019) and ALP-KD (Passban et al., 2021) approaches using the default settings proposed in the respective papers. We used early stopping based on performance on the development set, while making sure that the figures are in line with the ones reported in the papers. More precisely, the best layer setting for PKD teacher BERT$_{12}$ is $\{2, 4, 6, 8, 10\}$ to distill into DistilBERT$_6$. For DistilRoBERTa$_6$, we choose the intermediate layers 4, 8, 12, 16, 20 from the teacher RoBERTa$_{24}$ model for distillation that we found to work the best on the development set.

Using ALP-KD, we compute attention weights for the intermediate layers of the teacher (i.e., 1 to 11 for BERT$_{12}$ and 1 to 23 for RoBERTa$_{24}$ models) to calculate the weighted intermediate representations of the teacher for each intermediate layer of the student model (i.e., 1 to 5 layers of the student models). Since, the hidden dimensions of the RoBERTa$_{24}$ and DistilRoBERTa$_6$ are different, we linearly transform them into same lower-dimensional space. We train the PKD and ALP-KD models following (Sun et al., 2019; Passban et al., 2021).

For RAIL-KD^l, at each epoch we randomly select 5 layers from the intermediate layers of the teacher (i.e., from layers 1 to 11 for BERT$_{12}$ model and 1 to 23 for RoBERTa$_{24}$ model). Then, we sort the layer indexes and perform layer-wise distillation (Figure 1(a)) for RAIL-KD^l. For RAIL-KD^c, we concatenated the representations of the sorted randomly selected intermediate layers and then perform concatenated representation distillation (Figure 1(b)).

We use a linear transformation to map the intermediate representations (layer-wise or concatenated representations) into 128-dimensional space ($u = 128$) and normalize them before computing the loss $L_{\text{RAIL-KD}^{l/c}}$ for both BERT$_{12}$ and RoBERTa$_{24}$ distillations. We fixed $\alpha_i = 1$, $\lambda_1, \lambda_2, \lambda_3 = 1/3$ for our proposed approaches [4]. We search learning rate from {1e-5, 2e-5, 5e-5, 4e-6}, batch size from {8, 16, 32}, and fixed the epoch number to 40 for all the experiments. we run all experiments 5 times and report average score, in order to validate the credibility of our results. We ran all the experiments on a single NVIDIA V100 GPU using mixed-precision training (Micikevicius et al., 2018) and PyTorch (Paszke et al., 2019) framework.

5 Results

Table 2 shows the performances of models trained on GLUE tasks, and evaluated on their respective DEV and TEST sets for 12-layer to 6-layer distillation. BERT^{12} and DistilBERT^6 are used as backbone for the teacher and student models respectively. The baselines are fine-tuned without KD (w/o KD) and with Vanilla KD. Moreover, we di-

Table 4: GLUE test results of RAIL-KD^c when using Roberta$_{12}$ and DistilRoBERTa$_6$ as backbone for teacher and students. Results of CoDIR are directly copied from their paper (Sun et al., 2020a).

rectly compare RAIL-KD^{lc} results with PKD and ALP-KD as more competing techniques.

First, we observe that the performance gap between ILD methods and vanilla-KD is tight (0.8% and 0.3% on DEV and TEST sets respectively). Moreover, as we expect, ALP-KD performs better on DEV and similar on TEST compared to PKD with 0.2% improvement on the DEV results. Second, results show that RAIL-KD outperforms the best ILD methods by a margin of 0.5% and 0.3% on average on DEV and TEST sets respectively. We notice that, except on RTE TEST, our RAIL-KD variants obtained the highest per-task performances. Third, we observe that RAIL-KD variants perform very similarly, which indicates that our method is effective on concatenated as well as layer-wise distillation.

Similar trends are seen on the 24- to 6-layer model compression experiments, which are reported in Table 3. In this experiment, we used Roberta$_{24}$ and DistillRoberta$_6$ as teacher and students models respectively. Overall, RAIL-KD outperforms the best baseline by 1.2% and 0.3% on DEV and TEST sets respectively. Interestingly, the gap on DEV compared with PKD and ALP-KD is larger than the one reported on BERT^{12} experiments, and PKD TEST socres are much lower from that of ALP and RAIL-KD. This might be because PKD skips a large number of intermediate layers on RoBERTa$_{24}$, and the computational cost of ALP-KD attention weights over a large number of teacher layers might produce smaller weights on Roberta$_{24}$ compared to BERT$_{12}$.

Furthermore, we demonstrate the effectiveness of RAIL-KD by directly comparing it with CoDIR (Sun et al., 2020a), the current state-of-the-art ILD method. It uses the contrastive objective and a memory bank to extract a large number of negative samples for contrastive loss calculations. Table 4 shows GLUE test results of both approaches when distilling RoBERTa$_{12}$ to DistillRoberta$_6$. CoDIR results are adopted from their paper, and we followed their experimental protocol by not reporting scores on STS-B. On average, RAIL-KD performs on par with CoDIR (+0.2%) and outperforms it on 5 out of 8 datasets, while being almost two-times faster as shown in the next section.

5.1 Training Speed-up

Table 5 shows the training time speed up against the teacher of different techniques on 8 GLUE tasks. We measured the speed up by calculating the $student\_train\_time/teacher\_train\_time$ using RoBERTa^{2}4 and DistilRoBERTa^6 as backbone for teacher and student respectively. We used this configuration because CoDIR pretrained student models are not available and we can only run CoDIR code out-of-the-box.

Model	Teacher	PKD	ALP	CoDIR	RAIL^l	RAIL^c
Speed-up	1.00×	1.89×	1.75×	1×	1.89×	**1.96**×

Table 5: Training time speedup against the teacher for different techniques using the same setting of Table 4.

Our results indicate that random layer mapping not only delivers consistently better results than the deterministic mapping technique such as PKD, but it has less computational overhead during training (two-times faster than CoDIR), while avoiding extensive search experiments to find an optimal mapping. Furthermore, using attention for layer selection (ALP-KD) or contrastive learning (CoDIR) leads to slightly worse performance result than random selection.

5.2 Impact of Random Layer Selection

To evaluate the impact of random layer selection on the performance of RAIL-KD, we report the standard deviation of the DistilBERT$_6$ student models (Table 2 models) on the 8 GLUE tasks. As Table 6 shows, the variances of RAIL-KD is in the same range for each task, for instance, RAIL-KD variance is at the same scale compared with PKD and ALP-KD on CoLA and MRPC, and even lower on RTE. This indicates that the gains of RAIL-KD are significant, and are not due to chance in our random selection of layers to distill.

5.3 Out-of-Distribution Test

We further validate the generalization ability of student models by measuring their robustness to in-domain and out-of-domain evaluation. We do so by evaluating models finetuned on MLI, QQP and SST-2 and then evaluated on SciTail, PAWS, and IMDB respectively. These datasets contains counterexamples to biases found in the training data (McCoy et al., 2019; Schuster et al., 2019; Clark et al., 2019). Performances of BERT$_{12}$/Roberta$_{24}$ teacher and

RAIL-KD^c	**68.7**/75.6	**43.7**/36.2	**85.0**/85.9	**65.8**/65.9

Table 7: Out-of-domain performances of models trained on MNLI, QQP, SST-2 and evaluated on SciTail, PAWS, and IMDB respectively. BERT$_{12}$/Roberta$_{24}$ and DistilBERT$_6$/DistilRoBERTa$_6$ are used as backbone for the teacher and students respectively. For each setting, we report the unweighted average score on the 3 tasks.

DistilBERT$_6$/DistilRoBERTa$_6$ student variants are reported in Table 7. Also, we compute the unweighted average score of the three tasks.

First, we notice high variability in models rank and some inconsistencies in performances across tasks when compared with in-domain results. This was also reported in prior works on out-of-domain training and evaluation (Clark et al., 2019; Mahabadi et al., 2020; Utama et al., 2020; Sanh et al., 2020). Still, RAIL-KD clearly outperforms all baselines across tasks. Surprisingly, we observe that PKD and ALP-KD perform poorly (on all three tasks) compared to the Vanilla KD baseline.

Interestingly, we observe that RAIL-KD^l performs consistently better (1.1% on average) than RAIL-KD^c on Roberta$_{24}$ compression, while RAIL-KD^c performs better (1.1% on average) on BERT$_{12}$. These results suggest that layer-wise distillation approach is more effective than concatenated distillation when we have a large capacity gap (layer number) between the teacher and the student, and vice versa.

6 Analysis

We run extensive analysis to better understand why RAIL-KD performs better than the other baselines. We visualize the layer-wise cosine similarity between the intermediate representations of the teacher and the student networks. Figure 2 shows the cosine similarity score between three intermediate layer representations of BERT^{12} teacher (i.e. layers 2, 4 and 6) and the first three layer representations of the student for PKD, ALP-KD, RAIL-$\text{KD}^{l/c}$ students on 100 samples randomly selected from the SST-2 dataset. Due to space constraints, we only plot the scores for the first three layers of the student model. Similar trends are seen from the other layers.

We found that RAIL-KD allows the student to mimic teacher layers similar to PKD and much better than ALP-KD, despite that the mapping scheme varies at each epoch. Moreover, we observe that ALP-KD results have less similarity scores in the upper intermediate layers. PKD gives lower similarity scores in the lower layers while improving in the upper layers. In contrast, our approach gives more stable similarity scores for all layers while getting closer to the teacher representation in the upper layers.

We further investigate the attention weights learned by ALP-KD, and find out that they mostly focus on few layers (sparse attention). Figure 3 illustrates the distribution of weights, averaged on all training samples of DistilBERT_6 ALP-KD studnet on CoLA (left), RTE (middle), and MRPC (right) [5]. The figure clearly shows (light colors) that most of ALP weights are concentrated on top layers of the teacher. For instance, layers 1,2,5 of the three students mostly attend to the last layer of BERT_{12}. This is an indicator that ALP-KD overfits to the information driven from last layers. In contrast, the randomness in layer selection of RAIL-KD ensures a *uniform focus* on teacher layers. This may explain the poor performance of ALP-KD on out-of-domain evaluation compared with RAIL-KD.

From Figure 3, we see clearly that ALP-KD mostly prefers the upper layers of the teacher. On the other hand, the deterministic nature of PDK allows it to match better particular layers of the teacher (e.g. bottom ones as shown in Figure 2), but PKD never sees the layers that are skipped by the mapping. Consequently, it is expected that even though PDK can mimic bottom layers well, it is worse overall because it completely ignores some layers of the teacher. Random layer selection allow RAIL-KD to mimic all teacher layers while delivering high performances.

7 Conclusion and Future Work

We introduced a novel, simple, and efficient intermediate layer KD approach that outperforms the conventional approaches with performance improvement and efficient training time. RAIL-KD selects random intermediate layers from the teacher which equals to the number of intermediate layers of the student model. The selected intermediate layers are then sorted to distill their representations into the student model. RAIL-KD yields better regularization, which helps performance. Furthermore, our approach shows better performance for larger model distillation with faster training time, which opens up an avenue to investigate our approach for super-large models.

Abstract

In this paper, we revisit the solving bias when evaluating models on current Math Word Problem (MWP) benchmarks. However, current solvers exist solving bias which consists of data bias and learning bias due to biased dataset and improper training strategy. Our experiments verify MWP solvers are easy to be biased by the biased training datasets which do not cover diverse questions for each problem narrative of all MWPs, thus a solver can only learn shallow heuristics rather than deep semantics for understanding problems. Besides, an MWP can be naturally solved by multiple equivalent equations while current datasets take only one of the equivalent equations as ground truth, forcing the model to match the labeled ground truth and ignoring other equivalent equations. Here, we first introduce a novel MWP dataset named UnbiasedMWP which is constructed by varying the grounded expressions in our collected data and annotating them with corresponding multiple new questions manually. Then, to further mitigate learning bias, we propose a Dynamic Target Selection (DTS) Strategy to dynamically select more suitable target expressions according to the longest prefix match between the current model output and candidate equivalent equations which are obtained by applying commutative law during training. The results show that our UnbiasedMWP has significantly fewer biases than its original data and other datasets, posing a promising benchmark for fairly evaluating the solvers' reasoning skills rather than matching nearest neighbors. And the solvers trained with our DTS achieve higher accuracies on multiple MWP benchmarks. The source code is available at https://github.com/yangzhch6/UnbiasedMWP.

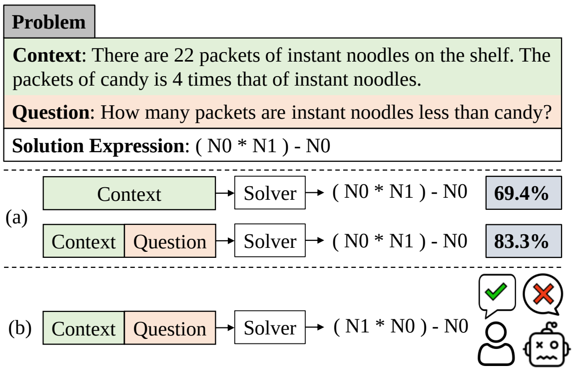

Figure 1: Illustration of solving bias in MWP. A typical MWP problem can be divided into context and question. (a) shows that 69.4% of the problems in Math23K can be answered by the solver (Bert2Tree) without looking at the question, verifying its severe data bias. (b) shows that the current training procedure ignores the equivalent expressions, indicating the possible learning bias.

1 Introduction

Math Word Problem (MWP) solving is a long-standing challenging task in Natural Language Processing (NLP) and has attracted lots of attention recently (Upadhyay and Chang, 2017; Upadhyay et al., 2016; Huang et al., 2018; Wang et al., 2017, 2018, 2019; Qin et al., 2020; Huang et al., 2021; Shen et al., 2021; Qin et al., 2021; Wu et al., 2021). An automatic MWP solver should not only understand the problem's semantic information but also reason the grounded mathematical relationships implicit in the problem, so that it can transform natural language into solution expression.

More recently, deep learning methods (Wang et al., 2017, 2018; Huang et al., 2021; Shen et al., 2021; Wu et al., 2021) have made great progress in MWP solving and achieved impressive results on several popular benchmarks, such as Math23K (Wang et al., 2017) and MAWPS (Koncel-Kedziorski et al., 2016). However, there exists some severe possible solving bias in these benchmarks, consisting of data bias and learning bias. Here, the **data bias** is introduced since the training dataset does not fully cover diverse questions for each problem narrative of all MWPs, leading to the situation that a solver only learns shallow heuristics rather than deep seman-

July 10-15, 2022 ©2022 Association for Computational Linguistics

tics for understanding problems. Besides, even the question of an MWP is deleted, a solver still can solve it correctly, as shown in Figure 1(a). On the other hand, an MWP can be solved by multiple equivalent equations while current popular datasets only take one of the equivalent equations as the ground truth output for each sample, forcing the model to learn the labeled ground truth and ignore other equivalent equations which may be more suitable for a solver to learn, leading to **learning bias** during training. As shown in Figure 1(b), if a solver may generate an answer-corrected expression that is different from ground-truth expression, it will be thought an error and the loss between the answer-corrected expression and the ground-truth expression will be back-propagated to the solver during training, leading to over-correct the solver. This learning bias makes it harder to learn to reason out answer-corrected expressions.

To mitigate the solver bias for pushing advanced models to learn underlying reasoning skills rather than solely matching nearest results, we first build a novel MWP dataset, UnbiasedMWP, to cover diverse questions for each problem narrative of all MWPs. It is constructed by varying the grounded expressions in our collected data and annotating them with corresponding new questions manually, thus mitigating data bias. Then, to mitigate the learning bias, we propose a Dynamic Target Selection (DTS) Strategy to dynamically select the most suitable target expression by applying the longest prefix match between the current model output and candidate equivalent equations obtained by applying commutative law during training. Our experimental result shows that our UnbiasedMWP has significantly fewer biases than its original data and other datasets, and the solvers equipped with our equivalent expression matching loss can achieve higher accuracy on multiple MWP benchmarks such as Math23K and our UnbiasedMWP. Our main contributions are in two folds:

- We propose a large-scale data-unbiased dataset named UnbiasedMWP consisting of 10264 MWPs with diverse questions. The dataset is constructed by varying the grounded expressions and annotated corresponding questions. With this dataset, we can force a model to learn deep semantics rather than shallow heuristics for solving an MWP.
- We propose a Dynamic Target Selection (DTS) Strategy to dynamically select a more suitable target expression, thus eliminating the learning bias caused by ignoring equivalent expressions during the training procedure. Experimental results demonstrate that the models trained with DTS achieve better performances on multiple benchmarks. Our DTS can improve the baseline model up to 1%, 2.5%, and 1.5% on Math23K, UnbiasedMWP-Source, and UnbiasedMWP-All, respectively.

2 UnbiasedMWP dataset

In this section, we introduce the construction procedure of our UnbiasedMWP dataset. Based on the newly-collected raw data, we design a pipeline for pre-processing and rewriting questions according to formula variations, which is strictly performed by the annotators to obtain unbiased data.

2.1 Data Collection and Pre-processing

To collect UnbiasedMWP, we crawl 2907 examples from an online education website[1]. During pre-processing, the number mapping (Wang et al., 2017) is deployed to replace the numbers in solution expression with symbolic variables (e.g., $N0$, $N1$). Then, the workers are asked to split the problem text into two parts: context (a narrative implicated with numerical relationships) and question (a short text that requires the solution of a mathematical relationship).

2.2 Expression Variation

As shown in Figure 1, a neural network model can solve problems even without questions, this shows that a solver solves problems mainly by relying on shallow heuristics rather than deep semantic understanding. Besides, current popular and large-scale datasets do not fully cover any possible questions for the context in each MWP, which also results in data bias. To mitigate this issue, we annotate each narrative with various possible questions to construct an unbiased MWP benchmark by enumerating various expressions according to the number in the context, asking workers to design questions for each expression. If an expression can not be assigned with a suitable question, we remove it.

To enumerate various possible expressions, we design three types of variation to create different expressions for each context: **Variable assortment (Va) variations**: Selecting two variables from the context and combining them with the operators

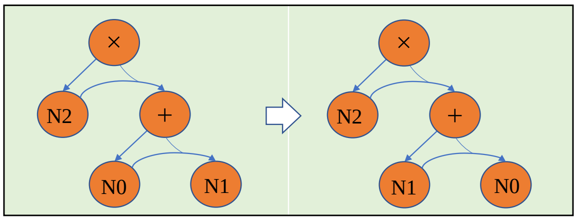
(a) From one expression to equivalent expression list



(b) One of the example generation procedure

Figure 2: Equivalent Expression Tree Generation. (a) shows the results of generation, (b) shows one of the generation examples.

"$+, -, *, /$", such as $n_0 + n_1$, $n_0 - n_1$, etc. **Sub-expression (Sub) variations**: From the original expression, we choose all sub-expressions of it and change the operators to get new expressions. **Whole-expression (Whole) variations**: We get new expressions by changing the operators in the original expression. Besides, workers also can propose new expressions and annotate them.

Various expressions are first acquired by applying the variation processing. Then, we ask workers to write a practical question for each meaningful expression variation. For those meaningless expressions that can not be annotated with any practical question, we filtered out them. The details of data split and statistics are listed in the appendix.

3 Dynamic Target Selection Strategy

During the common MWP training procedure, only one expression is used as ground truth while the equivalent expressions are ignored. Consider the following case: the ground truth label is "$(N1 * N0) - N0$" while the model output is "$(N0 * N1) - N0$". Although they are mathematical equivalent, the model output is judged to be incorrect. Therefore, models are prone to be biased during training. To address this issue, we generate the equivalent expressions of the original ground truth expression and then select an equivalent expression matching the longest prefix with the current model output as target expression in the training procedure.

3.1 Equivalent Expression Tree Generation

To generate equivalent expressions, we consider swapping sub-expressions on the two sides of symmetric binary operators such as: $+$ and $\times$. Firstly, we construct an expression tree for each expression

Algorithm 1: Equivalent Expression Tree Generation

```
Function: Variation(tree, root, equList)
Input: Expression tree: $tree$; Root node of the input
       tree: $root$;
Output: Equivalent expression list: equList.
if $root$ is null then
    return
Variation(tree, root.left, equList)
Variation(tree, root.right, equList)
if root.value is symmetric operator then
    swap(root.left, root.right)
    equList.append(tree)
    Variation(tree, root.left, equList)
    Variation(tree, root.right, equList)
    swap(root.left, root.right)
return
```

following (Xie and Sun, 2019). Then, we recursively examine each operator node from bottom to up and swap the left and right sub-trees of the node if it is a symmetric operator, and then we add the result new tree to a list. Finally, we iterate all the trees in the list into infix or prefix expressions to get multiple equivalent expressions. The generation procedure is illustrated in Algorithm 1. An example of the generation is illustrated in Figure 2 (b), we exchange the position of 'N0' and 'N1', and get a new equivalent expression. An example of generated equivalent expressions is shown in Fig. 2 (a).

3.2 Dynamic Target Selection (DTS)

During the training procedure, the solver may generate the correct start part expression which matches the prefix of one of the equivalent expressions but not matches the prefix of the ground truth labeled in the dataset. If we still use the ground truth as the target to train the solver, this will lead to oversize error to correct the model prediction, leading to sub-optimal learning and learning bias. To mitigate this issue, we dynamically choose a new equivalent target expression as a training target that can match the current model output with the longest prefix. In this way, the loss will not be oversized so that we can make the solver easier to solve problems correctly.

4 Experiments

4.1 Experimental Setup

Datasets. We conduct experiments on Math23K (Wang et al., 2017) dataset and our UnbiasedMWP dataset. We use **UnbiasedMWP-Source** to represent the initial collection of samples while using

	Math23K		UnbiasedMWP -Source		UnbiasedMWP -All	
Methods	Ori	Del_q	Ori	Del_q	Ori	Del_q
Math-EN	68.4	55.2	62.0	42.5	52.5	20.4
Group-Attn	69.5	57.9	61.5	42.0	53.1	20.1
GTS	75.6	61.9	64.5	49.0	63.6	25.1
Graph2Tree	77.4	63.2	65.0	50.0	64.0	25.0
Bert2Tree	83.3	69.4	73.0	55.0	78.1	22.5

Table 1: Experimental results on Math23K, UnbiasedMWP-Source, and UnbiasedMWP-All. Ori indicates the original data and the Del_q indicates data with the question removed.

UnbiasedMWP-All to represent the initial collection of samples and their various variations.

Baselines. We validate our UnbiasedMWP dataset and DTS training strategy with multiple models: **Math-EN** (Wang et al., 2018): a seq2seq model with equation normalization for reducing target space. **GROUPATT** (Li et al., 2019): a solver borrowing the idea of multi-head attention from Transformer (Vaswani et al., 2017). **GTS** (Xie and Sun, 2019): a tree-structured neural network in a goal-driven manner to generate expression trees. **Graph2Tree** (Zhang et al., 2020): an enhanced GTS with quantity graph. **BERT2Tree**: a strong baseline we constructed by replacing RNN encoder with BERTEncoder(Cui et al., 2020) in GTS. More details can be referred to the appendix.

4.2 Experimental Results

Bias Analysis on MWP Datasets We conduct similar experiments in (Patel et al., 2021) by removing question text on Math23K datasets and our collected UnbiasedMWP source data to show the solver mainly relied on shallow heuristics. As shown in Table 1, the experimental results on Math23K and UnbiasedMWP-Source show that all models still perform well even lack the question information. This suggests the patterns in the context have a strong correlation with the output expression, thus causing the model to learn bias in MWPs. We also conduct the same experiments on the UnbiasedMWP-All dataset. From Table 1, we can observe that the accuracies of the MWP without questions (Del_q) are significantly lower on UnbiasedMWP-All than the other two datasets. This shows that our UnbiasedMWP can force the solver to solve an MWP with less bias.

Robustness Analysis To further validate the advantages of our different variation data and how to improve a solver's robustness, we train two solvers on UnbiasedMWP-Source (Src) and UnbiasedMWP-All (All) and compare their performances on different test sets (Src, Src+Va, Src+Sub, Src+Whole, and All). From Table 2, we can observe that the solver trained with different variation data is more robust than the solver trained only with the initially collected samples on various test sets. This shows that our UnbiasedMWP can mitigate the learning bias of an MWP solver.

Test Train	Src	Src+Va	Src+Sub	Src+Whole	All
Src	73.0	37.3	49.7	53.1	34.9
All	**75.5**	**82.4**	**79.5**	**71.1**	**78.1**

Table 2: Comparison of results using different training and testing set. *Va*, *Sub*, and *Whole* stand for the three variations mentioned in Section 2.2. *All* denotes combining all three variations (*Va* + *Sub* + *Whole*) on source (*Src*) dataset.

Methods	DTS	Math23K	UnbiasedMWP -Source	UnbiasedMWP -All
GTS	✗	75.6	64.5	63.6
GTS	✓	**76.4**	**65.5**	**63.7**
Graph2Tree	✗	77.4	65.0	64.0
Graph2Tree	✓	**77.8**	**65.5**	**64.6**
Bert2Tree	✗	83.3	73.0	78.1
Bert2Tree	✓	**84.3**	**75.5**	**79.6**

Table 3: Comparison of experimental results with or without DTS of GTS-based (Xie and Sun, 2019) model.

Analysis on DTS strategy We conduct our DTS training strategy on Math23K and UnbiasedMWP. As shown in Table 3, our DTS training strategy helps several models achieve better performance. Especially, our DTS improves the accuracy of the Bert2Tree model from 83.3% to 84.3% on Math23K, from 73.0% to 75.5% on UnbiasedMWP-Source, and from 78.1% to 79.6% on UnbiasedMWP-All. In summary, the experimental results verify the validity of our DTS strategy.

5 Conclusion

In this paper, we revisit the solving bias in MWP. To mitigate the data bias caused by lacking question diversity, we construct a data set called UnbiasedMWP by variating the expressions in new-collected data. The experimental results illustrate that the solver trained on UnbiasedMWP is more robust than on our collected data. To mitigate the learning bias caused by loss overcorrect with taking only one ground-truth, we proposed a strategy to generate the equivalent expressions and select the longest prefix with the current model output during training, called Dynamic Target Selection (DTS). Experimental results show that our DTS helps several models achieve better performance.

A Appendix

A.1 Data Split

To ensure that the model does not see the context from the /testing set during training, We first split the training, validation, and testing set on our newly collected source dataset. Then we further apply the expression variation (mentioned in Section 2.2) to expand the data on different subsets. The size of the split of our collected data and variation data is shown in Table 4.

A.2 Examples of data variation

Figure 3 shows some examples of our data variation.

Split	UnbiasedMWP -Source	UnbiasedMWP -All
Train	2507	8895
Validation	200	684
Test	200	685

Table 4: Size of UnbiasedMWP data split.

Example 1

Context: There were 892 tourists in the morning, 255 left at noon, and 304 came in the afternoon.

Question: How many tourists were there at this time?

Solution Expression: (892 - 255) + 304

Variation:

(1) How many times as many tourists arrive in the afternoon as leave at noon? —— 304 / 255
(2) How many more tourists came in the afternoon than left at noon? —— 304 - 255
(3) How many times as many tourists come in the morning as in the afternoon? —— 892 /=/ 304
(4) How many more tourists came in the morning than in the afternoon? —— 892 - 304
(5) How many tourists came to the science park on this day? —— 892 + 304
(6) How many tourists were left at noon? —— 892 - 255

Example 2

Context: The school has 26 basketballs. There are 4 fewer volleyballs than 12 times as many basketballs.

Question: How many volleyballs are there?

Solution Expression: (26 * 12) - 4

Variation:

(1) How many volleyballs and basketballs are there? —— 26 + ((26 * 12) - 4)
(2) How many more volleyballs are there than basketballs? —— ((26 * 12) - 4) - 26

Example 3

Context: 6 groups from class A of a primary school donated $624 to the earthquake-stricken area, while 5 groups from Class B donated A total of $705 yuan.

Question: What is the average donation per group in Class A?

Solution Expression: 624 / 6

Variation:

(1) How much did the two classes contribute altogether? —— 624 + 705
(2) How many times did Class A donate as much as class B? —— 624 / 705
(3) How much more did Class B donate than Class A? —— 705 – 624
(4) How much does the average group in Class B donate? —— 705 / 5
(5) How much more per group did Class B donate than class A? —— (705 / 5) - (624 / 6)
(6) How many times did the average group in Class B donate as much as the average group in Class A? —— (705 / 5) / (624 / 6)

Figure 3: Some examples of our data variation.

A.3 Data statistic

We analyze the proportions of data of different prefix expression lengths in UnbiasedMWP dataset and the result is shown in Table 5. We analyze our UnbiasedMWP to count the size of different variation data, the statistical result is shown in Table 6. Note that the count of All data is not equal to the sum of the above rows in the table, because there will be some overlap between the variation data obtained in the three data variation methods mentioned in Section 2.2.

Expression Length	3	5	7	9	11	>11
Count	6357	2560	1011	215	90	31

Table 5: Statistics analyse on prefix expression length.

	Count
Source	2907
Variable assortment	5083
Sub-expression	2843
Whole expression	2205
All data	10264

Table 6: Statistics analyse on variation data.

We also analyze the accuracy of data of different prefix expression lengths for Bert2Tree model shown in Table 7. Experimental results show that the longer the expression, the lower the accuracy.

Expression Length	3	5	7	>= 9
Count	85.3	74.3	60.30	26.5

Table 7: Performance of Bert2Tree on different prefix expression length of UnbiasedMWP-All.

A.4 Implementation details

Pytorch[3] is used to implement our our MWP solver on Linux with NVIDIA RTX1080Ti GPU card. Our **Bert2Tree** model is constructed by replacing the encoder in **GTS** model with the Chinese Bert(Cui et al., 2020). The learning rate is set as $5e^{-5}$ and $1e^{-3}$ for Bert encoder and tree-decoder respectively. Adam is set as the optimizer of **Bert2Tree** while β_1 = 0.9, β_2 =0.999, and ϵ = $1e^{-8}$. The batch size is 32. Dropout weight is set as 0.5 with weight decay $1e^{-5}$. For the other four models, **Math-EN**, **Group-Attn**, **GTS** and **Graph2Tree**, we follow their original parameter settings in (Hong et al., 2021). Since the data preprocessing code in **Graph2Tree** is not open, we do not evaluate this model on our own data.

In the experiments, we train Bert2Tree for 100 epochs on Math23K while 50 epochs on our UnbiasedMWP-Source and UnbiasedMWP-All data, because Math23K is a larger benchmark dataset whch contains 23K samples. For the Del_q experiments, We intercept the last sentence (question) by detecting punctuation marks in Math23K which may cause some very small errors but does not affect the overall results of the experiment. For our UnbiasedMWP dataset, we directly use the context to do the Del_q experiment.

A.5 Related Work

Math Word Problem Solving

In recent years, deep learning models especially Seq2Seq models(Wang et al., 2017; Li et al., 2019; Wang et al., 2018; Xie and Sun, 2019; Zhang et al., 2020; Qin et al., 2021; Shen et al., 2021; Wu et al., 2021), have made great progress in MWPs by learning to translate problem text in natural language into mathematical solution expression. (Wang et al., 2017) is the first to apply deep learning in MWPs and propose a widely used dataset called Math23K. (Li et al., 2019) propose a group attention mechanism to extract multi-dimensional features. (Xie and Sun, 2019) propose a tree decoder to decode expression as prefix order. Based on (Xie and Sun, 2019), (Zhang et al., 2020) improve the encoder embedding by fusing a graph encoder's output. (Qin et al., 2021) propose a framework by applying multiple auxiliary tasks to improve the problem embedding and the ability to predict commonsense constants. (Shen et al., 2021) devise a new ranking task for MWP and propose the Generate & Rank, a multi-task framework based on a generative pretrained language model. (Wu et al., 2021) propose a novel Edge-Enhanced Hierarchical Graph-to-Tree model (EEH-G2T), in which the math word problems are represented as edge-labeled graphs.

Challenging Datasets and Adversarial Examples of MWP More challenging datasets in MWP are proposed in recent years, Ape210K (Zhao et al., 2020) provides a large-scale benchmark for evaluating MWP solvers, HMWP (Qin et al., 2020) is a Chinese MWP benchmark including examples with multiple-unknown variables requiring non-linear equations to solve.

Although solvers have achieved impressive performance on these datasets, the robustness of the

---

[3] http://pytorch.org

solvers is questioned in (Kumar et al., 2021). Besides, (Patel et al., 2021) also points out that MWP solvers rely on shallow heuristics to achieve high performance and propose SVAMWP dataset. SVAMWP is more reliable and robust for measuring the performance of MWP solvers, because it raises the requirement for the model's sensitivity to question text through applying variations over word problems. Unlike SVAMWP, our variations are applied to expressions to get different expression-question pairs.

A.6 Analysis on Effects of PLM

We conduct experiments on our UnbiasedMWP dataset as shown in Table 1. In the experiments, for models without PLMs such as **Math-EN** (Wang et al., 2017), **GROUPATT** (Li et al., 2019), **GTS** (Xie and Sun, 2019), **Graph2Tree** (Zhang et al., 2020), they perform worse on UnbiaseMWP-All dataset than on UnbiasedMWP-Source dataset, whereas for **Bert2Tree** model with Bert (Cui et al., 2020), it performs significantly better on UnbiasedMWP-All dataset. This shows that the UnbiasedMWP-ALL dataset with diverse questions is more likely to confuse the model, because the context of the sample remains unchanged and only changes the question. However, Bert2tree can better distinguish the difference between diverse questions through the pre-trained language model.

Learn To Remember: Transformer with Recurrent Memory for Document-Level Machine Translation

Yukun Feng[1], Feng Li[2], Ziang Song[1], Boyuan Zheng[1], and Philipp Koehn[1]

Abstract

The Transformer architecture has led to significant gains in machine translation. However, most studies focus on only sentence-level translation without considering the context dependency within documents, leading to the inadequacy of document-level coherence. Some recent research tried to mitigate this issue by introducing an additional context encoder or translating with multiple sentences or even the entire document. Such methods may lose the information on the target side or have an increasing computational complexity as documents get longer. To address such problems, we introduce a recurrent memory unit to the vanilla Transformer, which supports the information exchange between the sentence and previous context. The memory unit is recurrently updated by acquiring information from sentences, and passing the aggregated knowledge back to subsequent sentence states. We follow a two-stage training strategy, in which the model is first trained at the sentence level and then finetuned for document-level translation. We conduct experiments on three popular datasets for document-level machine translation and our model has an average improvement of 0.91 s-BLEU over the sentence-level baseline. We also achieve state-of-the-art results on TED and News, outperforming the previous work by 0.36 s-BLEU and 1.49 d-BLEU on average.

1 Introduction

Most previous machine translation methods are designed for sentence-level translation. Recent studies have shown that the effective use of contextual information between sentences can achieve better performance in document-level machine translation (Garcia et al., 2015; Maruf and Haffari, 2018; Miculicich et al., 2018; Zhang et al., 2020; Bao et al., 2021). Built on the Transformer model (Vaswani et al., 2017), a general approach is to incorporate neighboring sentence states (Tiedemann and Scherrer, 2017; Zheng et al., 2020) into the attention mechanism, which has also been widely used in many long sequence modeling methods (Dai et al., 2019; Rae et al., 2020; Yang et al., 2019; Beltagy et al., 2020). Zhang et al. (2018); Maruf et al. (2019) have introduced an additional context encoder to solve the limitation of sentence-level translation, which, however, is separated from the original translation model and context states is only applied on the source side. Other works (Junczys-Dowmunt, 2019; Scherrer et al., 2019; Zhang et al., 2020; Bao et al., 2021) concatenated sentences or the entire document and feed into the attention module of the Transformer. Since more extended contexts may confound attention on meaningful portions of the current sentence, the model is difficult to select valuable inputs from extra contexts to navigate the redundancy of information. Such methods also suffer from the quadratically increasing complexity when documents get longer.

We solve such problems by introducing a memory mechanism to recurrently integrate contextualized knowledge from intermediate state in Transformer layers. As recurrent memory has been widely researched since RNN (Rumelhart et al., 1986), which has been incorporated with Transformer by Transformer-XL (Dai et al., 2019) and further extended by Rae et al. (2020) who compress previous states into a two-layer hidden memory. In our approach, we update the memory through an attention module to select practical information from sentences and reduce the context space into multiple dense vectors in the memory. Besides, we use another attention module to pass the knowledge retained in the memory back to the sentence state in the next step. Such information exchange is expected to convey contextualized dependency between sentences. This memory mechanism can be applied in each layer for both the source and target documents, and our study shows that incorporating memory only in the last layer achieves the

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1409 - 1420
July 10-15, 2022

best performance. Also, as sentences are ordered in documents, our model reads one sentence pair at each step, keeping the computational cost as same as the sentence-level translation.

We experiment across three widely used datasets for document-level translation: TED, NEWS, and Europarl, and evaluate our model with s-BLEU and d-BLEU. We first train a vanilla Transformer on sentence-level translation as the baseline and finetune the model for the documents by initializing the memory mechanism to the Transformer. Our model outperforms previous SOTA work by 0.5 s-BLEU and 2.30 d-BLEU on TED, and 0.21 s-BLEU and 0.57 d-BLEU on News. We do not achieve the SOTA result on Europarl, which might be caused by the different results between the baselines for sentence-level translation. However, we further evaluate the improvement of previous works from their reported baseline Transformer, and we achieve the most relative gain on all three datasets. We also analyze our model from the memory usage, long-range effect, context dependency, and computational complexity, and demonstrate the effectiveness and efficiency of our approach in the general understanding of the document machine translation.

Overall, this paper makes several contributions: **(i)** Our work reduces the contextualized knowledge space of sentences states to multiple dense vectors, and considers the sentence dependency for both source and target documents, while keeping computational complexity in sentence-level. **(ii)** Our model significantly improves the sentence level baseline by 0.91 s-BLEU average and achieved the SOTA results on TED and News. **(iii)** Our model shows the effective use of memory, long-range influence, context-dependency across sentences, and decoding efficiency through convincing analysis.

2 Related Works

Recurrent Sequence Modeling RNN (Rumelhart et al., 1986) was the first class of models that introduced hidden states as the memory in neural models. Although improved on sequential-oriented tasks, RNN has unsatisfactory learning of long-term information due to gradient vanishing and explosion. LSTM (Hochreiter and Schmidhuber, 1997) improved RNN by introducing gate mechanisms to selectively retain knowledge at each step.

This RNN variant dominated NLP models until the Transformer replaced the memory unit with a self-attention mechanism and achieved great success in a wide range of NLP applications. Although we cannot deny the robustness and effectiveness of the Transformer model, the quadratically increased computational cost as the increase of token numbers makes Transformer unable to fit the long-range sequence. Some studies (Parmar et al., 2018; Child et al., 2019; Beltagy et al., 2020; Ainslie et al., 2020; Qiu et al., 2020; Zaheer et al., 2020; Martins et al., 2021) try to mitigate this issue by reducing the complexity of the attention module. However, such work still suffers from the problems by unlimited the document length and the document modeling is hard to solve.

Transformer-XL (Dai et al., 2019) broke this dilemma by introducing the recurrent memory into Transformer-based models. It cached previous hidden sentences computation and mapped such states to subsequent sentences states. Theoretically, Transformer-XL could handle infinite length text but storing uncompressed hidden state requires tremendous memory space, which impeded Transformer-XL from good performance on dealing with practical long-sequence tasks. The Compressive Transformer (Rae et al., 2020) further addressed this problem by mapping the evicted hidden state from cached memory to a more compressed representation. However, two-layer caching still requires a huge memory space and may be improved with trainable memories.

Document Machine Translation Machine Translation has been a widely researched area for decades. A series of models have addressed various translation problems (Koehn et al., 2003; Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2015; Luong et al., 2015). As most of them target translation at the sentence level, document-level translation poses a fundamental challenge requiring models to pass intra-sentential information throughout consecutive sequences of sentences, and it has been addressed by Gong et al. (2011); Hardmeier et al. (2013); Pouget-Abadie et al. (2014); Garcia et al. (2015); Koehn and Knowles (2017); Läubli et al. (2018); Agrawal et al. (2018) among others.

Recent studies have attempted to incorporate additional contextual information into the Transformer structure to improve the performance of neural machine translation models further. The intuitive way is to leverage neighboring sentences from paragraphs or the documents (Tiedemann and

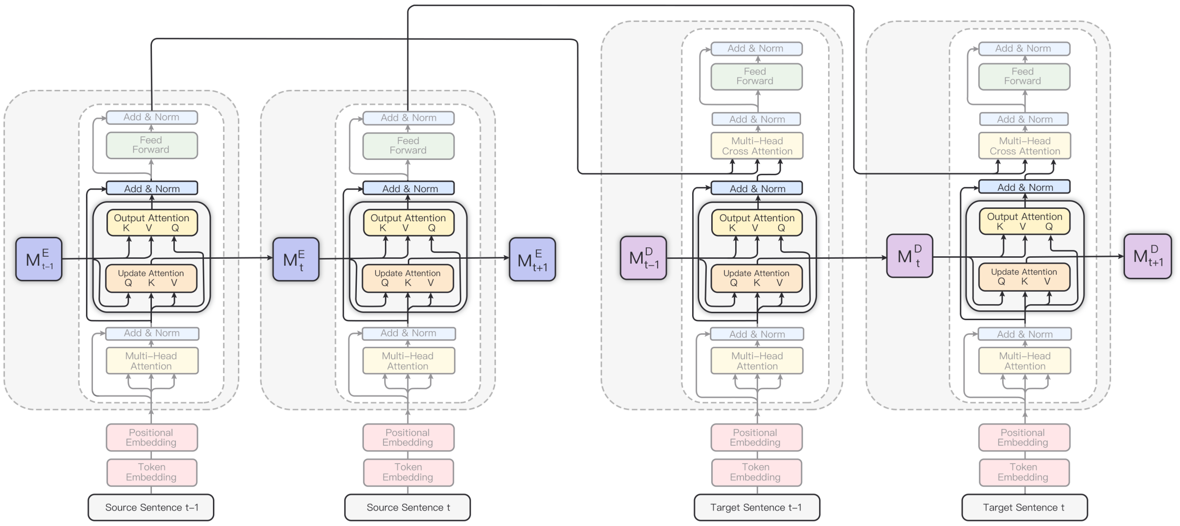

Figure 1: An overview of the model architecture, where E and D refers to Encoder and Decoder respectively.

Scherrer, 2017; Maruf and Haffari, 2018; Zheng et al., 2020), demonstrating the effectiveness of the additional contexts. Specifically, in the first class of methodologies for document-level translation, independent from the architecture of vanilla Transformer processing current sentences, some studies (Miculicich et al., 2018; Zhang et al., 2018; Maruf et al., 2019; Voita et al., 2019a,b; Ma et al., 2020; Donato et al., 2021) introduces context-aware components only attend to source or target contexts and usually jointly train with the rest of the network from scratch. The second class of models follows the pattern of concatenating multiple sentences for translation (Agrawal et al., 2018; Scherrer et al., 2019; Junczys-Dowmunt, 2019; Zhang et al., 2020). Such a method is expected to capture the contextual correlations between sentences. However, one of its drawbacks is the quadratically increased computational complexity in the face of longer contexts sequences. Also, longer sequences usually confound document-level attention and sometimes even overlook key information on the current sentences. Bao et al. (2021) uses group masks to introduce locality constraints to reinforce sentence information in multi-head attention to resolve the confounding issue in long contexts.

Our work incorporates the idea of the recurrent memory to document-level machine translation. It follows the locality assumptions by reducing the context space into multiple memory vectors and passes dependencies between sentences. The mechanism to update and output memory is similar to models which store cached bilingual sentence pairs in the memory to enhance the sentence-level translation (Feng et al., 2017; He et al., 2021; Jiang et al., 2021). We believe our approach is intuitive to efficiently store sentence states and transfer context information across sentences.

3 Approach

Our model is shown in Figure 1. Additional to the vanilla Transformer, we introduce a contextual memory unit and two attention modules to manipulate the memory defined as Update Attention and Output Attention. These modules can be applied at each layer in both the encoder and decoder.

As input sentences are ordered from left to right in the document, our model only reads one sentence every time. The memory is expected to store contextualized information from the input sentence states and convey such knowledge to the next sentence. At each step, the Update Attention step maps the contextual information from the sentence state to the memory, and updates the memory to the next step. Meanwhile, the Output Attention step fuses the information from the current sentence and the contextual memory, and outputs the aggregated knowledge to the remaining modules of the layer.

Formally, we define h^{t} as the sentence state from self-attention module in Transformer layer, and M^{t} refers to the contextual memory M at step t, where t refers to the index of t^{th} sentence in the document. M^{t} and h^{t} are updated and outputted as:

$$\begin{aligned}\mathrm{M}^{\mathrm{t}+1} &= \mathrm{UpdateAttention}(\mathrm{M}^{\mathrm{t}}, \mathrm{h}^{\mathrm{t}}) \\ \widetilde{\mathrm{h}}^{\mathrm{t}} &= \mathrm{OutputAttention}(\mathrm{M}^{\mathrm{t}}, \mathrm{h}^{\mathrm{t}})\end{aligned} \quad (1)$$

3.1 Contextual Memory

Memory $\mathrm{M} \in \mathbb{R}^{\mathrm{d_M} \times \mathrm{d_{model}}}$ where $\mathrm{d_{model}}$ refers to the hidden dimension and $\mathrm{d_M}$ is a hyper-parameter, indicating how many vectors will be allocated for memory. To avoid the redundancy of memory space, we set $\mathrm{d_M}$ to 16. Detailed analysis is discussed later.

3.2 Update Attention

We update contextual memory through an attention module (Vaswani et al., 2017). Attention is a mapping function between input vectors of query (Q) and key-value (K-V) pairs. The output is the weighted sum of values with corresponding scores.

$$\mathrm{Attention}(\mathrm{Q}, \mathrm{K}, \mathrm{V}) = \mathrm{Softmax}(\frac{\mathrm{QK^T}}{\sqrt{\mathrm{d_k}}})\mathrm{V}$$

Multi-Head attention extends the vanilla attention by projecting input vectors $(\mathrm{Q}, \mathrm{K}, \mathrm{V})$ to different representation subspaces, and attention is performed in parallel in each head. Attention outputs from multiple heads will be concatenated and projected to the expected space.

$$\mathrm{MHA}(\mathrm{Q}, \mathrm{K}, \mathrm{V}) = \mathrm{Concat}(\mathrm{head_1}, .., \mathrm{head_n})\mathrm{W^o}$$
$$\mathrm{head_i} = \mathrm{Attention}(\mathrm{QW_i^q}, \mathrm{KW_i^k}, \mathrm{VW_i^v})$$

where $\mathrm{d_k}$ is the hidden dimension of the K, $\mathrm{W^q}$, $\mathrm{W^k}$, $\mathrm{W^v} \in \mathbb{R}^{\mathrm{d_{model}} \times \mathrm{d_h}}$, and $\mathrm{W^o} \in \mathbb{R}^{\mathrm{n} \times \mathrm{d_h} \times \mathrm{d_{model}}}$ are learnable parameters. $\mathrm{d_{model}}$ and $\mathrm{d_h}$ refer to the hidden dimension of the model and each head.

To update the contextual memory $\mathrm{M^t}$ to next step, sentence state $\mathrm{h^t}$ is mapped to $\mathrm{M^t}$ through the Multi-Head Attention. Both the memory and context state are projected into different sub-spaces and contextualized knowledge is expected to be mapped to each memory vector from different perspectives. The memory at step t is updated as:

$$\widetilde{\mathrm{M^t}} = \mathrm{AddNorm}(\mathrm{MHA}(\mathrm{M^t}, \mathrm{h^t}, \mathrm{h^t})) \quad (2)$$

A Feed-Forward Network is then used to further enhance the memory representation from the attention output.

$$\mathrm{M^{t+1}} = \mathrm{AddNorm}(\mathrm{FeedForward}(\widetilde{\mathrm{M^t}})) \quad (3)$$

In the memory matrix M, each vector is expected to select contextualized information from different perspectives. However, it is hard to distinguish such vectors since they do not have actual positional meanings, and the same key-value pairs are mapped to these vectors in the attention phase resulting in the same representation in each memory vector. To solve such a problem, we use the positional encoding PE() as introduced in Vaswani et al. (2017) to differentiate multiple memory vectors. M is added by such position-level bias in each update phase.

$$\mathrm{M^t} = \mathrm{M^t} + \mathrm{PE}(\mathrm{M^t}) \quad (4)$$

3.3 Output Attention

To map the contextualized knowledge from $\mathrm{M^t}$ to the sentence state $\mathrm{h^t}$, multi-head attention is used to take the representation of $\mathrm{h^t}$ and $\mathrm{M^t}$ as query and key-value, respectively.

$$\widetilde{\mathrm{h^t}} = \mathrm{MHA}(\mathrm{h^t}, \mathrm{M^t}, \mathrm{M^t}) \quad (5)$$

$\widetilde{\mathrm{h_t}}$ will be passed to the subsequent modules in the Transformer layer.

Similar approaches have been discussed in previous works. Simply increasing the context space does not help but introduces a lot of noise. Instead of incorporating multiple sentences to the context attention, we compress contextualized information into multiple memorized vectors and map such vectors back to the sentence state at the next step. We find that both the BLEU score and the information gained from the context attention space do not increase when the memory length increases from 64 to 128. Therefore, a large context space in M seems redundant for the model to learn, and we find $\mathrm{d_M} = 16$ for the most effectiveness and efficiency.

3.4 Document Neural Machine Translation

In the task of document-level machine translation, the source and target documents are represented as sequences of sentences $\mathrm{X} = \{\mathrm{x_t} | 1 \leq \mathrm{t} \leq \mathrm{n}\}$, and $\mathrm{Y} = \{\mathrm{y_t} | 1 \leq \mathrm{t} \leq \mathrm{n}\}$ respectively, where t refers to the sentence index. Given a vanilla Transformer and its parameters θ, the objective is to maximize the target document probability conditioned on the source document.

$$\operatorname*{argmax}_{\theta} \mathrm{P}(\mathrm{Y} | \mathrm{X}, \theta)$$

Our approach recurrently translates an ordered document sentence by sentence, and the objective is:

$$\operatorname*{argmax}_{\widetilde{\theta}} \prod_{\mathrm{t}} \mathrm{P}(\mathrm{Y_t} | \mathrm{X_{\leqslant t}}, \mathrm{Y_{<t}}, \widetilde{\theta})$$

where $\widetilde{\theta}$ refers to Transformer parameters including Memory, Update Attention and Output Attention.

Table 2: Dataset Statistics for Train/Valid/Test

As suggested by Beltagy et al. (2020); Bao et al. (2021), context would be better applied in higher layers and keep only local information in lower layers. Therefore we only apply the memory unit M in the top layer of encoder and decoder, and in lower layers, we keep using the original Transformer structure. Analysis regarding the location of memory is discussed in Section 5.1.

Training During training, our model takes an input of $\mathrm{x_t}$ and $\mathrm{y_t}$, which refer to sequences of tokens of the $\mathrm{t^{th}}$ sentence in source and target documents. Memory unit M is initialized trainable parameters before the first input of each document, and it will be updated after each input sentence pair, which are batched as the sentence order in the document. For computational convenience, the gradients are only back-propagated to the current sentence and the most recent sentence in each update step, and we stop the gradient for M before it is passed to the next step.

Inference In the decoding phase, our model translates the source document sentence by sentence. In the generation of each sentence, tokens are decoded in an auto-regressive order until the stop sign or exceeds the max length. The memory M will not be updated until the complete sentence is generated since the update of M depends on all tokens in the current sentence. If M is updated after each token generation, the attention space in the output attention does not represent the complete contextualized information of the expected sentence. The computational complexity keeps in sentence-level since we only feed one sentence every time, and there is no cache vector besides M.

4 Experiment

4.1 Datasets

We experiment across three widely used datasets for English→German document translation.

TED Training data for TED comes from IWSLT'17. We use tst2016-2017 as test set and a held-out set from training as valid.

News The corpus comes from News Commentary v11. We use tst2016-2017 as test set and a held-out set from training as valid.

Europarl Train, valid and test sets are extracted from the corpus Europarl v7, as mentioned in (Maruf et al., 2019).

Detailed statistics for the datasets is in Table 2. Moses (Koehn et al., 2007) is used for data processing and BPE (Sennrich et al., 2016) is used with vocab-size of 30K for all datasets.

4.2 Settings

We adopt Transformer model with the transformer-base configurations as the baseline, which has six layers with a hidden size of 512 and an intermediate size of 2048. Token embedding is shared for source and target languages, and token indexes are encoded with a learnable embedding matrix. We first train a baseline model with vanilla Transformer architecture for sentence-level translation and finetune our model based on the sentence-level baseline. We use the AdamW optimizer with an ini-

Table 3: Evaluation on TED with memory on different sides and layers. We adopt the 6-layer Transformer model finetued on the sentence-level baseline, and 0 refers to the first layer, and 5 refers to the last layer.

tial learning rate of 5×10^{-4} and warm-up steps of 4000 for training sentence-level baseline. The drop-out rate is set to 0.3 for TED and News and 0.1 for the Europarl. As for finetuning after sentence-level Transformer, the learning rate is set as 3×10^{-4} for newly initialized parameters and 6×10^{-5} for pre-trained parameters, and warm-up steps of 1000 are set for TED and 2000 for News and Europarl. The drop-out rate is set to 0.1 for the Europarl and 0.2 for the TED and News during finetuning. We also apply gradient accumulation, and detailed studies are discussed in the section 5.3. Models are trained with a patience of 5 for both sentence-level and document-level. We use the beam size of 5 during inference and compute the BLEU score in a max order of 4 after removing BPE-tokens. s-BLEU and d-BLEU are used as evaluation metrics, where s-BLEU refers to the BLEU score for sentences, and d-BLEU is the score for documents.

4.3 Results

Experiment results are shown in Table 1. Our method shows consistent improvements over three datasets from sentence-level Transformer. We achieve the state-of-the-art results of s-BLEU of 25.62 and d-BLEU of 29.47 on TED and s-BLEU of 25.73 and d-BLEU of 27.78 on News . Though our results do not outperform G-Transformer (Bao et al., 2021) on Europarl, we think the difference mostly comes from the gap between sentence-level baselines. Such difference may be caused by the implementation framework and computing resources, which they use Fairseq library and multiple GPUs, while we adopt the code from HuggingFace and only a single 1080-Ti GPU is used for our training. We further report the score of works gained from their reported baseline, and our model makes the greatest improvement on all three datasets. Overall, the results could demonstrate the advantages of our method in the general understanding of the document machine translation.

5 Analysis

In this section, we discuss our model from memory usage, long-range modeling, context effect, and computational complexity, respectively. Experiments are conducted with the model finetuned on the sentence baseline and evaluated on the TED, since TED has the most average sentence number per document, which is more likely to reflect the performance of our model for long documents.

5.1 Discussion of Memory

Memory Size Memory size is evaluated through information gain (IG) between the random initialized memory and well trained memory. It is calculated from attention maps in Update Attention and Output Attention. IG from Update Attention indicates the difference of selected information in the memory, and IG from Output Attention refers to how much contextualized knowledge in memory is mapped to the next sentence state. Figure 2 shows IG keeps increasing as memory size increases from 8 to 64, but it dramatically drops at the size of 128 and 512. While increasing the memory size can fit more contextual information, an excessively large memory space is likely to introduce redundant noise. Therefore, it indicates that contextualized knowledge should be better distributed into a relatively dense space. Based on the corresponding s-BLEU score, we set memory size to 16 in all other experiments for the most effectiveness.

Memory Side To analyze the effect of the memory on source and target documents, we set the memory on encoder, decoder and both sides respectively. We find that it is not only necessary to have the memory to convey the dependency between sentences on the source side but also in the decoding process for the target document. As shown in Table 3, applying the memory on either side can outperform the baseline but the model achieves better scores when incorporating the memory on both sides. It indicates the necessity of contextualized information for both source and target documents.

Memory Position Previous work (Bao et al., 2021; Beltagy et al., 2020) has shown that Transformer lower layers are more likely to have local information while the context is better incorporated into higher layers. We set the memory in lower, intermediate, and higher layers respectively. The results as shown in Table 3 are consistent with the claim. Applying memory in higher layers outperforms the others, and it is even better to have it on only the top layer, which satisfies that the model is more likely to focus on the locality on lower layers and fuse the contextualized information on the top.

5.2 Discussion of Long Dependency

Metric Breakdown To find out on what kind of sentences our model outperforms the sentence-level Transformer, we evaluate the TED dataset with respect to the sentence index in the document. Sentences are ordered fed into the model. We compute and average the s-BLEU for sentences at each sentence index in the document. We further average the scores for every ten index range. As in Figure 3, the x-axis refers to the index range of sentences (e.g., 20 refers to sentences with indexes from 10 to 20), and the y-axis indicates the s-BLEU difference between our model and sentence Transformer. Our model has consistently greater performance, especially for sentences in later part of documents, indicating our model has the superiority than the sentence-level Transformer on longer document translation and long-range modeling.

Long-Range Influence We also analyze the long-range dependency of our model through gradient attribution test introduced by Ancona et al. (2018); Sundararajan et al. (2017). The gradient attribution test reflects the significance of the model input feature to its output prediction. We perform this test by calculating the gradients of our well-trained model on the test set of TED. Since sentences are ordered when fed into the model, evaluating previous sentences' gradient attribution to the current sentence infers if the model supports the long-range dependency. More formally, we define the gradient of the previous sentence i computed by the loss propagated from current sentence j as:

$$\mathrm{G}(\mathrm{Sent_i}, \mathrm{Sent_j}).$$

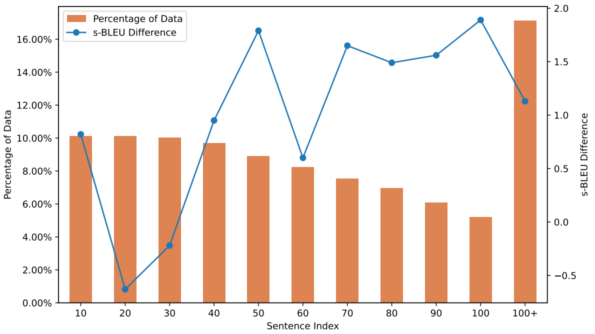

Figure 3: TED datset separated by sentences from different indexes in documents, evaluated with Sentence-Transformer and Context-Aware Model.

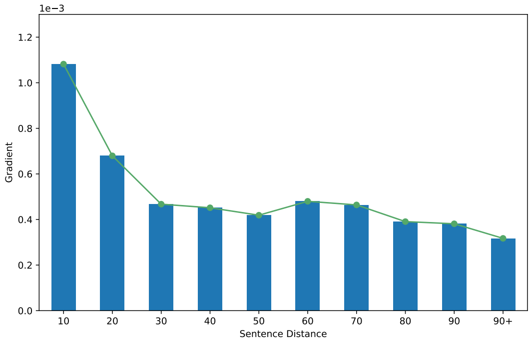

Figure 4: TED dataset evaluated by gradients computed from different sentences ranges. x-axis refers to the difference between the sentence indexes for gradient calculation and loss computation.

Specifically, the gradient of a certain token in previous sentences is retrieved from its corresponding embedding weight. We conducted experiments for different sentence ranges k for the test with ten sentences intervals, and the gradient for each range k is computed as:

$$\mathrm{Score(k)} = \mathrm{Avg}(\sum_{\mathrm{d=1}}^{\mathrm{D}} \sum_{\mathrm{s=1}}^{\mathrm{S_d}} \sum_{\mathrm{i=s+k}}^{\mathrm{s+k+10}} \mathrm{G}(\mathrm{Sent_s}, \mathrm{Sent_i}))$$

where D refers to number of documents, $\mathrm{S_d}$ refers to number of sentences in Document d. To prevent the gradient attribution accumulated by the same token within the evaluated range, only unique tokens within this range are considered. As shown in Figure 4, our model has gradients propagated to sentence tokens even by 90+ sentences from the computed loss, indicating our model does have the ability for long-range sequence modeling.

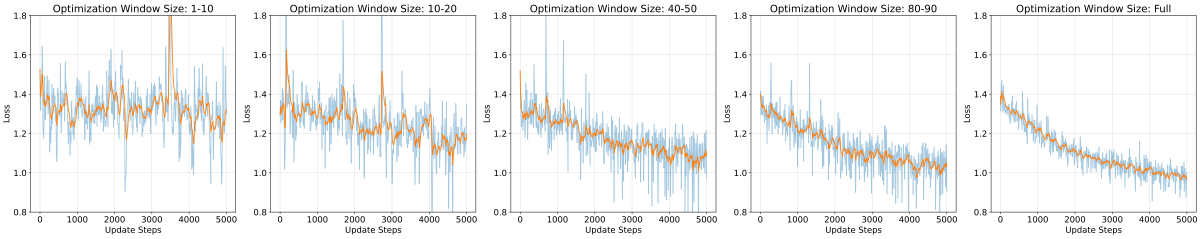

Figure 5: Training Loss on TED Dataset, with different optimization window sizes

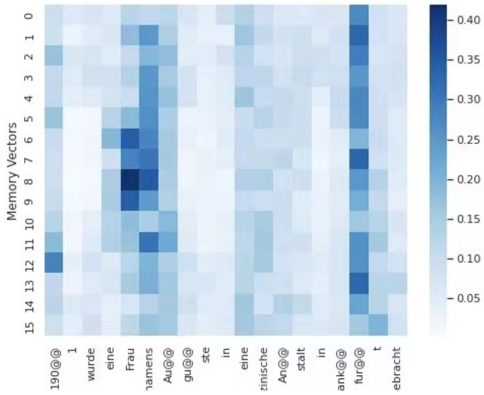

Figure 6: Attention map from Update Attention, each token at sentence t is mapped to each memory vector.

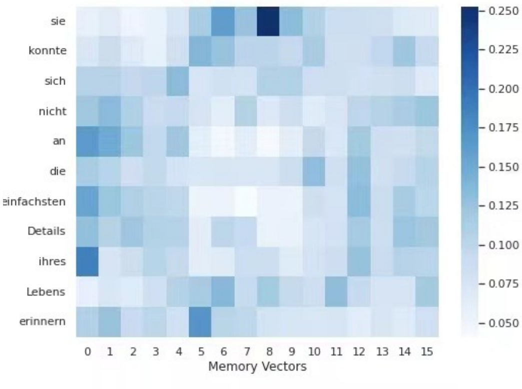

Figure 7: Attention map from Output Attention, memory vectors are mapped to each token in sentence t+1.

5.3 Discussion of Context

Convergence Our model is trained concerning the sentence order in the document. We find the model hard to converge during training as the loss oscillates within a wide range. Because of the various distribution of consecutive sentences in documents, the directions of continuing optimization steps vary greatly, resulting in an unstable convergence curve. To mitigate this issue, we use group optimization to update the model, considering the dependency among sentences. Specifically, a number from the optimization window is randomly sampled, and the gradients are accumulated. The model will not be updated until the accumulated steps reach the sampled number. We conduct experiments with different optimization window sizes for the update of 5000 steps, and the loss curves are shown in Figure 5, where full means the total number of sentences in the document. The result shows that the model converges faster and more stable with increasing optimization window size. Such improvement benefits from the grouped update steps concerning the difference of contextualized distribution among sentences.

Dependency Across Sentences We evaluate the attention maps from Update Attention and Output Attention to determine what contextualized information is passed in and out from memory. In Figure 6, tokens from t^{th} sentence are mapped to each memory vector, and the 8^{th} memory vector has a substantial attention weight on token "Frau". Figure 7 shows memory vectors are mapped back to the following sentence and the token "sie" has a high probability on the 8^{th} memory vector. German words "Frau" and "sie" refer to "Mrs" and "she" in English. Hence, the memory mechanism has the ability to parse the word dependency between sentences at different steps.

5.4 Discussion of Complexity

We further analyze our model's space and time complexity during the inference phase. Since we only evaluate the decoding speed and memory efficiency in this case, we use dummy tokens to perform the inference. We randomly generate a sequence of tokens as the source inputs and let the model decode the same number of tokens as the target. We compare our model with both the sentence-level Transformer and document-level Transformer. For the sentence-level Transformer, we split the sequence of tokens into chunks, and each chunk has a length of 100. The decoding complexity is

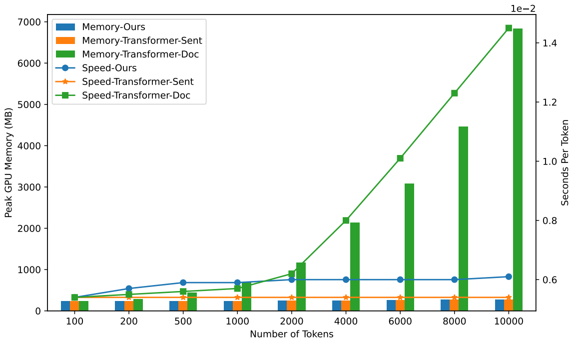

Figure 8: Space and Time Complexity for different number of tokens during inference.

evaluated over all chunks. For the document-level Transformer, we use the entire sequence of tokens as the source input and evaluate the complexity of decoding the entire target sequence. Similar to the sentence-level Transformer, our model is evaluated by the chunk by chunk decoding, and meanwhile, we keep the contextual memory updated. As shown in Figure 8, our model keeps the same space complexity as the sentence-level Transformer and takes a slightly more time cost because of the update of contextual memory. However, the document-level Transformer has an increasing cost for both space and time complexity, especially when the target sequence has a length greater than 1,000 tokens. Overall, results have shown the decoding efficiency of our model, which keeps the computational complexity as low as the sentence-level Transformer, even in the case of over thousands of tokens.

6 Conclusion

This paper introduces a memory unit that recurrently maps information into and out of Transformer intermediate states and addresses the limitation about the context dependency and computational complexity in document-level machine translation. We have achieved the SOTA score on TED and News and a great improvement from the sentence-level baseline. Our model demonstrates the effectiveness and efficiency of reduced memory space, context dependency for both source and target document, and long range influence across documents. The limitation of our work is the training cost since we accumulate the update steps and retain the graph for memory update at each step. Our work does not conduct experiments for pretrained settings due to the time limitation. However, it should be easy to apply our method to any Transformer-based pretrained models, such as Liu et al. (2020). Also, this paper only experiments on document-level machine translation, and future works may apply this approach for other tasks that need long-range sequence modeling.

Improving Few-Shot Image Classification Using Machine- and User-Generated Natural Language Descriptions

Kosuke Nishida, Kyosuke Nishida, Shuichi Nishioka
NTT Human Informatics Laboratories, NTT Corporation
`kosuke.nishida.ap@hco.ntt.co.jp`

Abstract

Humans can obtain the knowledge of novel visual concepts from language descriptions, and we thus use the few-shot image classification task to investigate whether a machine learning model can have this capability. Our proposed model, LIDE (Learning from Image and DEscription), has a text decoder to generate the descriptions and a text encoder to obtain the text representations of machine- or user-generated descriptions. We confirmed that LIDE with machine-generated descriptions outperformed baseline models. Moreover, the performance was improved further with high-quality user-generated descriptions. The generated descriptions can be viewed as the explanations of the model's predictions, and we observed that such explanations were consistent with prediction results. We also investigated why the language description improved the few-shot image classification performance by comparing the image representations and the text representations in the feature spaces.

1 Introduction

Humans can efficiently learn about new concepts from language (Chopra et al., 2019). Hence, in this paper, we focus on the few-shot image classification problem to verify machine learning models' capability to understand new concepts from language. This problem is a kind of meta-learning problem in which a model first learns from the concepts of classes by training on a few instances and then learns unseen classes in the same way.

In our problem setting, the model can use language descriptions of images as additional information. This setting is similar to teaching a new concept to others by explaining it deductively from small amounts of data, unlike most machine learning models that learn inductively from large amounts of data.

For this setting, we propose a new model, called *LIDE (Learning from Image and DEscription)*. As shown in Figure 1, LIDE consists of an image encoder, an image classifier, a text decoder, and a text encoder.

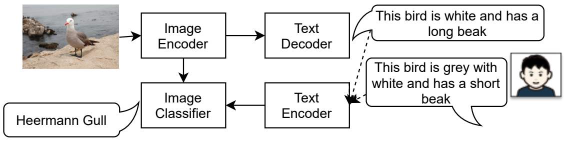

Figure 1: Concept of the LIDE model.

LIDE has the advantage of providing explainablity. It passes an image representation encoded by the image encoder to the text decoder, which then generates a language description of the image as an explanation of the model's prediction. The image classifier then classifies the image in accordance with the text representation, which is encoded by the text encoder, in addition to the image representation.

LIDE also provides high accuracy due to its explainability. It has been difficult to use machine-generated descriptions to improve image classification performance because of their low quality (Mu et al., 2020). Therefore, we design a training algorithm and a text encoding method to obtain robust text representations. In addition, LIDE includes a feature fusion module added to the image classifier to combine the information from both the image representation and the text representation.

Moreover, LIDE can take user-generated descriptions as input instead of machine-generated descriptions. We can use a description that contains textual features captured from an input image by human perception or a post-edited text in the text decoder output. The resulting high-quality descriptions provided by users can improve the image classification accuracy.

Our contributions are summarized as follows:

- We confirmed that LIDE with machine-generated descriptions outperformed previous models, and thus the explanations of the

Findings of the Association for Computational Linguistics: NAACL 2022, pages 1421 - 1430
July 10-15, 2022 ©2022 Association for Computational Linguistics

model's predictions were helpful to improve the classification accuracy.

- We observed that the performance improved further when gold captions were fed to LIDE as users' high-quality descriptions.
- We investigated whether the generated explanations were consistent with the image classification predictions, and we found a positive correlation between the quality of the generated captions and the classification accuracy.
- We thoroughly investigated why the text representations explaining the input image contributed to the image classification task, specifically in terms of the distributions of the representations in the feature space, the robustness of the representations for noisy images, and the knowledge of concepts that can be extracted from the representations.

2 Background

2.1 Few-Shot Image Classification

N-way K-shot classification involves three data splits, $\mathcal{T}_{train}, \mathcal{T}_{dev}$, and $\mathcal{T}_{test}$, and each split consists of many classes and instances. The classes in the splits are disjoint. Each N-way K-shot classification task is a classification problem with N classes. Each task provides K training instances for each class, called *support* instances. A task entails the evaluation of M instances for each class, called *query* instances. The tasks, which consist of the classes and instances, are randomly sampled from the data splits.

This problem is a meta-learning problem. In the training phase, we use the episodic training (Ravi and Larochelle, 2017), where many mini-batches of size B consisting of B tasks, each of which consists of N classes and $N(K+M)$ instances, are independently sampled from $\mathcal{T}_{train}$. In the test phase, the model learns new N-way K-shot classification tasks with unseen classes and instances sampled from $\mathcal{T}_{dev}$ or $\mathcal{T}_{test}$. For each sampled task, a model learns from the supports, and we evaluate the classification performance of the queries.

A major approach for N-way K-shot classification is the prototypical network (ProtoNet) (Snell et al., 2017). In both the training and test phase, instead of updating the model parameters for each sampled task with few support instances, the prototypical network computes the class prototypes. Let h_k^c be the k-th support feature of class c. Here, the class prototype z^c is

$$z^c = \frac{1}{K}\sum_k W_{proto} h_k^c.$$

In the training phase, the model is trained with the cross-entropy loss of the queries from $\mathcal{T}_{train}$:

$$L_{class} = -\frac{1}{M}\sum_i \sum_c y_i^c \log \frac{\exp\left[s(z^c, h_i)\right]}{\sum_{c'} \exp\left[s(z^{c'}, h_i)\right]},$$

where h_i is the i-th query feature, $s(z_c, h_{mm,i}) = z_c^\top W_{proto} h_{mm,i}$ is a score function containing W_{proto} as a trainable parameter, and $y_i^c \in \{0, 1\}$ is the ground-truth label of the i-th query. In the test phase, the class prototypes are obtained from the supports, and the average score over the sampled tasks is reported.

2.2 Few-Shot Image Classification with Language Description

We focus on the few-shot image classification to verify the machine learning models' capability to learn new concepts from language descriptions in addition to the images. Previous studies have used the language description to improve the few-shot image classification. The classifiers in the studies are based on ProtoNet, which corresponds to the model with the image encoder and prediction module in Figure 2. Mu et al. (2020) proposed LSL by introducing a text decoder to ProtoNet to avoid overfitting by training the image encoder with a language generation loss. They observed that a text representation from a noisy machine-generated description was harmful for image classification. Accordingly, they viewed the text decoder as a regularizer and did not use a text encoder. RS-FSL (Afham et al., 2021) replaced the GRU (Cho et al., 2014) text decoder of LSL with a bi-directional transformer (Vaswani et al., 2017).

Andreas et al. (2018) were interested in describing the hidden states with natural language, but not in improving the image classification performance. They proposed L3 by adding both a text decoder and encoder to ProtoNet. They encoded an image into an image representation and decoded it into an explanation. The input of their image classifier was only the text representation encoded by the text encoder. L3 provided the explainability, but their model performance decreased.

All of the aforementioned papers assumed that the image encoder was not pre-trained in a super-

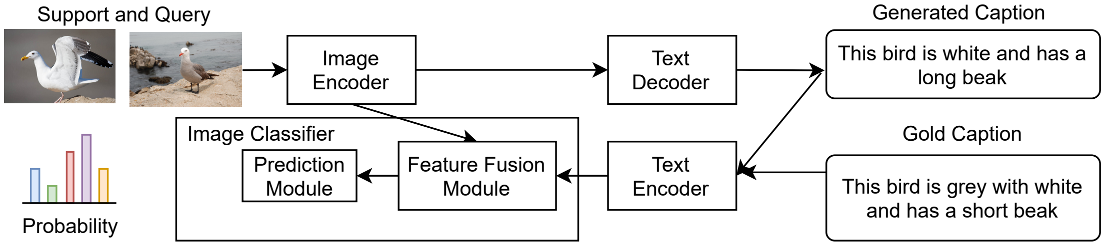

Figure 2: Overall structure of LIDE. The text decoder generates a caption on the basis of the image representation encoded by the image encoder. The text encoder obtains the text representation from the generated caption or a gold caption. The feature fusion module combines the image and text representation to generate the multi-modal representations. The prediction module outputs the classification probability.

vised or self-supervised fashion with external images. Our motivation is to clarify the benefit of the language description to learn novel visual concepts, and so we follow their setting.

3 Methods

3.1 Model

We show the overall model structure of LIDE in Figure 2. The model components are explained in the following.

Image Encoder We can use any network as the image encoder, and we used a 4-layer CNN as in the previous studies. The output is the image feature h_{img}.

Text Decoder First, we map the image feature to the text feature space as follows:

$$f_{I2T}(h_{img}) = \text{Linear}(\text{LayerNorm}(h_{img})),$$

where LayerNorm is layer normalization (Ba et al., 2016). Then, we pass the text feature vector to the text decoder as an encoder hidden state sequence of length 1. The text decoder autoregressively generates the j-th token t_j . The j-th token generation probability p_j is written as

$$p_j = \Pr(t_j; f_{I2T}(h_{img}), t_{0:j-1}).$$

We used a uni-directional three-layer transformer.

Text Encoder We use BERT (Devlin et al., 2019) for the text encoder, which outputs the last hidden states H_{BERT}. The text feature h_{text} is a weighted average pooling of H_{BERT}:

$$h_{text} = \frac{1}{\sum p_j w_j} \sum p_j w_j h_{BERT,j},$$

where the weight p_j is the token generation probability in the text decoder. If a caption is user-generated, then p_j is 1 for all tokens. The weight w_j is 1 if the j-th token is not a stop word; otherwise, $w_j = 0$.

The use of weighted average pooling with the text generation probability has two advantages. First, the text encoder can ignore the low-confidence tokens. Second, the image classification loss back-propagates to the text decoder through the weight p_j. Because the discrete operation of text generation breaks the computation graph, we cannot back-propagate the gradient of H_{BERT} to the decoder without the method.

Feature Fusion Module The feature fusion module combines the single-modal features h_{img} and h_{text} into a multi-modal feature h_{mm}. Let $[;]$ be the vector concatenations, f_{T2I} be a mapping function from the text feature space to the image feature space, and g be a linear function to $\mathbb{R}^2$. f_{T2I} is a three-layer FFNN with ReLU activation. The feature fusion operation is the weighted sum of the two features:

$$[w_{img}; w_{lang}] = \text{softmax}(g([h_{img}; h_{text}])),$$

$$h_{mm} = w_{img}h_{img} + w_{text}f_{T2I}(h_{text}).$$

Prediction Module We use ProtoNet for the prediction module and replace h with h_{mm}.

3.2 Algorithms

Loss Function For image classification, we compute two image classification losses: $L_{class,gold}$ is computed from the image feature and the gold caption, while $L_{class,gen}$ is computed from the image feature and the generated caption. For text generation, we compute L_{text} with teacher-forcing and cross-entropy loss.

To enrich the mapped text feature $f_{T2I}(h_{text})$, we use the contrastive loss (Sohn, 2016; Oord et al., 2018) between the gold and generated captions.

Let v^c_{gold} and v^c_{gen} be the averages of the mapped support text features in class c from the gold and generated captions, respectively. The similarity is $\cos({v^c_{gold}}^\top v^{c'}_{gen})$. Then, the contrastive loss L_{cntr} is

$$L_{cntr} = -\frac{1}{2N}\sum_c \log \frac{\exp\left[\cos({v^c_{gold}}^\top v^c_{gen})/\tau\right]}{\sum_{c'} \exp\left[\cos({v^c_{gold}}^\top v^{c'}_{gen})/\tau\right]} - \frac{1}{2N}\sum_{c'} \log \frac{\exp\left[\cos({v^{c'}_{gold}}^\top v^{c'}_{gen})/\tau\right]}{\sum_{c} \exp\left[\cos({v^c_{gold}}^\top v^{c'}_{gen})/\tau\right]},$$

where τ is a temperature parameter.

The total loss that we minimize in the training phase to optimize the whole model parameters in an end-to-end manner is

$$L = L_{class,gold} + L_{class,gen} + \lambda_{text} L_{text} + \lambda_{cntr} L_{cntr},$$

where λ_{text} and λ_{cntr} are hyperparameters.

Pre-Training Following Afham et al. (2021); Wang et al. (2019), we pre-train the model with the training data for the downstream task. The pre-training consists of the standard image classification task, and we replace the prediction module with a linear classifier for all training classes. The loss function is $L = L_{class,gen} + \lambda_{text} L_{text}$.

Caption Generation In the training phase, we use a greedy algorithm and random sampling for computational reasons. In each step, we uniformly and randomly choose between the two algorithms. In random sampling, we restrict the candidate tokens to the top 20 tokens at each position.

In the test phase, we input the generated captions to the text encoder in the setting where the user-generated description is not available. The generation algorithm is beam search with a beam width of five and a length penalty of 0.5. Thus, the token sequence $t_{1:l}$ is generated as

$$\mathrm{argmax}_{l, t_{1:l}} \frac{1}{l^{0.5}} \sum_{j=1}^{l} \log \Pr(t_j; f_{I2T}(h_{img}), t_{1:j-1}),$$

where l is the text length. The length penalty reduces the preference for words consisting of multiple subwords, such as 'point _y' ('pointy').

4 Evaluation

4.1 Dataset

We used the Caltech-UCSD Birds (CUB) dataset (Wah et al., 2011) for evaluation. It contains 200 bird species (classes) and 40-60 images for each class. The classes are split into 100 training classes, 50 development classes, and 50 test classes. We used this dataset for the $N = 5$-way $K = 1$-shot classification problem. The number of query instances M per class was 15.

The CUB dataset has 10 captions for each image (Reed et al., 2016). For each step, we randomly sampled one caption from the 10 gold captions.

4.2 Metrics

For the image classification, we report the average accuracy over 600 tasks, following the previous studies. To evaluate the generated caption quality, we used major metrics for image captioning, BLEU_4 (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and $\mathrm{ROUGE}_\mathrm{L}$ (Lin, 2004).

4.3 Implementation

We pre-processed the images in the same way as Mu et al. (2020). The dimension of the image feature h_{img} was 1600. The text encoder and tokenizer were the pre-trained BERT-base-uncased model. The text encoder output dimension was 768. The configuration of the transformer layers in the text decoder was the same as that of the T5-base decoder model (Raffel et al., 2020), but we did not use the pre-trained parameters for the text decoder because they did not contribute to the performance. The parameter size of W_{proto} was 1600×1600. The other hyperparameters and optimization details are given in Appendix A.

4.4 Compared Models

ProroNet (Snell et al., 2017) was the baseline, with only the image encoder. As for the other compared models, L3 (Andreas et al., 2018) used a 200-dimensional GRU text encoder and decoder but did not use image representation for classification. LSL (Mu et al., 2020) used a 200-dimensional GRU text decoder for regularization. RS-FSL (Afham et al., 2021) used a 2-layer, 768-dimensional, bidirectional transformer as the text decoder. All models used a 4-layer CNN as the image encoder, along with the ProtoNet-based prediction module.

4.5 Ablated Models

To evaluate the models that use a single-modal representation for image classification, we introduced the models "No Text," "No Image," and "No Text Encoder" by removing the feature fusion module

Model	Text Dec.	Text Enc.	Modal	Baseline
No Text			Image	ProtoNet
No Image	✓	✓	Text	L3
No Text Enc.	✓		Image	LSL, RS-FSL

Table 2: Performance of the compared models.

from LIDE. Each model corresponds to our implementation of the baseline models, as shown in Table 1.

4.6 Evaluation Results for LIDE as Few-Shot Image Classification Model

4.6.1 Main Results

Performance with Machine-generated Description Table 2 summarizes the results. LIDE outperformed ProtoNet, LSL, and RS-FSL, which use an image classifier using image representations only. LIDE improved the image classification performance with the mechanism of encoding text and combining multi-modal representations, while L3, which uses an image classifier with text representations only, harmed their performance.

Performance with User's Description The advantage of the text encoder is that it enables textual input by users. Specifically, a user can use language as an explanation from humans to machines by feeding the textual features captured from the input image to the model. In addition, if a user objects to the model's explanations, the user can edit them to correct the model's misunderstanding.

To evaluate LIDE in this setting, we viewed the gold captions as user descriptions. As the CUB dataset has 10 gold captions per image, we selected one gold caption and fed it to the model to maximize the similarity to a generated caption and thus simulate a user editing the generated caption. The similarity was defined as the bi-gram precision of the gold caption with respect to the generated caption.

Table 3 shows that the performance was improved significantly when a high-quality gold caption was given. However, the performance declined when a wrong caption was given, which was a randomly sampled caption from all captions in $\mathcal{T}_{test}$. We conclude that the model's output depends on the quality of the description.

Random Description	58.89 ±0.93
Generated Description	67.53 ±0.91
Gold Description	**73.08** ±0.88

Table 3: Performance with each kind of description.

4.6.2 Ablation Study

Evaluation on modalities The first set of rows in Table 4 lists ablation study results for the different modalities that LIDE uses. We confirmed that LIDE using all the modalities outperformed the compared models using part of the modalities. The image and text representations complemented each other, as will be discussed later.

Evaluation on introduced techniques The second set of rows in Table 4 lists the techniques that were introduced in LIDE: image classification loss with generated captions, contrastive learning, weighted average pooling, and random sampling during caption generation. We confirmed that all of these techniques contributed to the performance of LIDE.

We assume that the loss with the generated captions decreases the discrepancy between the train and test phases. The contrastive loss enriches the text representation and makes the representations of the generated text and the gold caption close. The weighted average pooling reduces the effect of noisy generated text. The random sampling in the training phase contributes to the generation of diverse captions.

Evaluation on pre-training of text encoder We also found that the multi-modal feature was useful even when the text encoder was trained from scratch. The text representation could assist in the image representation without BERT pre-training, because the captions in the CUB dataset are restricted to the descriptions of birds, and the training data thus covers the space of the captions well.

4.7 Evaluation Results for LIDE as Interpretable Machine Learning Model

Evaluation on quality of generated captions First, generated captions are insufficient as explanations if they are not accurate. The upper bound was the CNN-LSTM model pre-trained with the

MSCOCO (Lin et al., 2014) dataset from Chen et al. (2017). Although we had no training data without the CUB dataset, Table 5 shows that the differences between LIDE and the upper bound were only 2.0 points for METEOR and 3.3 points for ROUGE.

Evaluation on consistency between generated captions and image classification When the generated captions are correct (respectively, incorrect), the classification results should also be correct (incorrect) in terms of the consistency between explanations and classification results.

Accordingly, we calculated the Spearman rank-order correlation coefficient between the captioning scores and the classification scores. We divided 2,953 test-split images into 30 bins in accordance with the ascending order of each captioning score, and we computed the average image classification accuracy in each bin.

Table 5 lists the results. We confirmed a positive correlation between the quality of the generated captions and the prediction accuracy of LIDE. However, LIDE without the text encoder, which corresponds to LSL (Mu et al., 2020) and RS-FSL (Afham et al., 2021), showed a low correlation. This result demonstrated the importance of the text encoder and the feature fusion modules introduced in LIDE.

	Ours	this bird is yellow with black and has a very short beak.
	Gold	the bird has a small black bill and a yellow crown
	Ours	this bird has wings that are brown and has a white belly.
	Gold	a small bird with a red face black crown white cheeks brown back and black and yellow wings

Figure 3: Examples of generated captions and gold captions.

Qualitative analysis on generated captions Figure 3 shows examples of the generated captions. We found that the captions captured the birds' characteristics. However, the structures of the captions were uniform, and they could not describe a birds' most distinctive element, such as the red face in the second example. We believe that overfitting to the 5-class classification problems with the small dataset caused this problem.

We restricted the image encoder to a 4-layer CNN for fair comparison to the existing models, and we did not use external training data to validate the ability to learn novel classes from language descriptions. Removal of the limitations would improve the performance of LIDE as an explainable machine learning model.

4.8 Discussion

In this section, we clarify four reasons why text representations are useful in the few-shot image classification task. Specifically, we compared the multi-modal feature space of LIDE with the gold captions to the image feature space of the "No Text" and "No Text Encoder" models.

How are classes distributed in each modal feature space? First, we calculated the inner- and inter-class distances in each feature space. Table 6 lists the results. The inner-class distances in the multi-modal feature space of LIDE were smaller than those in the image feature space; the inter-class distances of LIDE were larger. As a result, the clusters were distributed well in the multi-modal feature space.

We believe that this is because the captions describe the similarities and differences between the images more obviously than the images themselves do. For example, to determine that two birds belong to different species, one piece of evidence is the belly color. The captions can explain this information clearly, e.g., "yellow belly" and "white belly". From the image, however, the extraction of this information requires multiple steps such as locating the belly and specifying its color.

	Inner-Class Dist.	Inter-Class Dist.	LID
No Text (Image)	0.504	0.592	17.8
No Text Enc. (Image)	0.526	0.609	19.0
LIDE (Fusion)	0.459	0.709	6.73

Table 6: Distribution of feature representations.

What are characteristics of latent feature spaces? Second, we examined the dimensions of the feature spaces. Lee and Chung (2021) observed that the features embedded in a manifold with a smaller latent dimension are more generalized. They evaluated the latent dimension by using the average of the local intrinsic dimensions (LID) of the features. The LID measures the number of dimensions of a feature manifold in the neighbor of x, and it can be estimated as

$$\hat{\mathrm{LID}}(x) = -\left\{ \frac{1}{n_{nn}} \sum_{i}^{n_{nn}} \log\left(\frac{r_i(x)}{r_{n_{nn}}(x)}\right)\right\}^{-1}$$

by maximum likelihood estimation, where n_{nn} is the number of the nearest neighbors and r_i is the Euclidean distance from x to the i-th nearest neighbor (Levina and Bickel, 2005; Amsaleg et al., 2015). We set $n_{nn} = 20$ in accordance with the previous studies.

Table 6 lists the estimated LIDs of the features of each model. In addition, we applied principal component analysis (PCA) to the features, and Figure 4 shows the cumulative contribution rates. All features were embedded in $\mathbb{R}^{1600}$.

The multi-modal features existed in a manifold with a smaller latent dimension than those of the image-only representations. Therefore, the text representation contributed to shrinking the representation manifold to a smaller dimension. We assume that the text controlled the main focus among the many objects in an image. For example, the captions in the CUB dataset describe the characteristics of birds. As a result, the model can extract the important information from captions for the downstream image classification task. In contrast, an image has much information, such as the background, and image features thus require a larger-dimension manifold.

Are multi-modal representations robust for noisy images? Next, we hypothesize that language descriptions can help to classify noisy or obscure images. To verify our hypothesis, we performed experiments in two heuristic noisy settings: One consisted of grayscale images and the other consisted of images that were adversarially attacked via the fast gradient sign method (Goodfellow et al., 2015). We compared LIDE with gold captions to the ablated models using the image representations and evaluated their performance with the noisy images in the test phase.

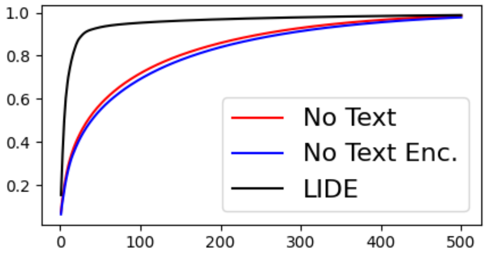

Figure 4: Cumulative contribution rates for PCA of each representations.

	Original	Grayscale	Adversarial
No Text	62.22 ±0.92	38.04 ±0.78	33.09 ±0.69
No Text Enc.	63.10 ±0.90	38.55 ±0.80	31.30 ±0.65
LIDE	78.09 ±0.79	59.81 ±0.97	56.31 ±1.01

Table 7: Performance in noisy settings.

Table 7 lists the result. When a caption was not provided, the classification accuracy dropped greatly in both settings. However, LIDE reduced the decline by virtue of the textual information. These results indicate that the text representation may be useful for classifying certain ill-conditioned images, such as an image in which the bird is extremely small.

What information do text representations have? Finally, we performed a probing test for each modality of representation, as in previous natural language processing (NLP) studies that discovered linguistic properties (Conneau et al., 2018; Hupkes and Zuidema, 2018) in the text representations. The CUB dataset has annotations of the birds' attributions, and we recover the attribution labels from h_{img} and h_{text}. Each image has $\{0, 1\}$ labels for 312 attributions.

We used our trained model to obtain h_{img} and h_{text} for all images and captions. Then, we used linear classifiers $W_{img,attr} \in \mathbb{R}^{1600\times312}$ and $W_{lang,attr} \in \mathbb{R}^{768\times312}$, which were trained the linear classifiers with binary-cross-entropy loss in the training split. Next, we determined the thresholds in the development split and obtained prediction results in the test split. Finally, we performed a Wilcoxon signed-rank test between the image re-

sults and the text results.

Table 8 lists the numbers of attributions having significance at a p-value of 0.05. Among the 68 attributions, 60 were recovered more easily from one modality than from the other modality. In other words, the image and text representations complemented each other. Most of the attributes favored the image representation, but 17 of them favored the text representation. Table 9 lists those 17 attributes, and we can observe two main characteristics among them. First, the colors black and white were recovered from the text representation. These attributes may be difficult to recover from an image because of light and shadow. The second characteristic was a spotted pattern, which is obscure in an image with 84 × 84 pixels.

5 Related Work

Image classification with language Several studies have provides gold language information in the test phase. For zero-shot learning or few-shot learning, class-label words are used as additional information (Frome et al., 2013; Socher et al., 2013; Xing et al., 2019). Moreover, He and Peng (2017); Liang et al. (2020) used language descriptions for the standard image classification problem, in which the classes in the training and test phases are the same. The few-shot image classification is a more challenging problem that requires the capability of learning novel concepts from language descriptions.

Textual explanation of image representation Explainability of artificial intelligence (XAI) has attracted much attention (Bastings et al., 2021). Papers have proposed methods to generate an image description for XAI in the image classification task and visual question answering (VQA) task (Hendricks et al., 2016, 2018; Li et al., 2018). In contrast to those studies, the motivation of this paper is to decode and encode such descriptions to improve the few-shot image classification performance. We could integrate the findings of XAI studies into LIDE.

Analysis of image and text representations Previous papers have investigated why language information is useful in vision and language tasks. Collell Talleda and Moens (2016) also found that the image and text representations complemented each other; for example, taxonomic attributes are captured well in the language. Li et al. (2020) observed that the attention heads of the multi-modal pre-trained models ground elements of language to image regions.

6 Conclusion

We tackled the few-shot image classification task through learning of novel concepts from language descriptions of images. We observed that machine- and user-generated descriptions improved the few-shot image classification performance. We also found that the generated captions explained the input image and were consistent with the prediction performance.

Our experiments also revealed four reasons why the text representation improved the performance: the inner-class distances of the multi-modal representations are smaller and the inter-class distances are larger than those of image representations; multi-modal representations are embedded in a space with a smaller latent dimension; multi-modal representations are robust for noisy images; and certain types of knowledge are easily recovered from text representations.

Humans can learn concepts from language and explain them with language, but this is still difficult for machine learning models. This study sheds light on the importance of interactivity in explanating with language in machine learning.

A Experimental Setup

We trained all the models on an NVIDIA Quadro RTX 8000 (48GB), and each experiment took almost one day. The hyperparameter settings are listed in Table 10. We used the Adam optimizer (Kingma and Ba, 2014), PyTorch (Paszke et al., 2017), and transformers (Wolf et al., 2020). Stop words were implemented with NLTK (Bird et al., 2009), and "bird" was added to the stop words. The training of the "No Image" ablated model was unstable due to the transformer architecture, so we used greedy decoding in the test phase to reduce the discrepancy between the train and test phases.

	Pre-Training	Fine-Tuning
Batch size	128	100
# Epochs	100	1500
Learning rate for main model	1e-3	1e-3
Learning rate for text encoder	1e-3	1e-4
Learning rate for text decoder	1e-5	1e-5
λ_{text}	—	10
λ_{cntr}	—	0.1
τ	—	0.05

Table 10: Hyperparameters.

For the experiments on recovering attributions (Section 4.8), we used sigmoid activation and determined the thresholds for each attribution. We sampled one caption for each image in the development and test splits. When an attribution was not described in a caption even though the label was 1, the example was ignored. We also removed attributions when the number of correct predictions was less than 20 or the number of positive examples was less than 20. Here, a positive example means one for which the label is 1 and the attribution is described in the caption. As a result, 68 attributions remained.

All Information is Valuable: Question Matching over Full Information Transmission Network

Abstract

Question matching is the task of identifying whether two questions have the same intent. For better reasoning the relationship between questions, existing studies adopt multiple interaction modules and perform multi-round reasoning via deep neural networks. In this process, there are two kinds of critical information that are commonly employed: the representation information of original questions and the interactive information between pairs of questions. However, previous studies tend to transmit only one kind of information, while failing to utilize both kinds of information simultaneously. To address this problem, in this paper, we propose a Full Information Transmission Network (FITN) that can transmit both representation and interactive information together in a simultaneous fashion. More specifically, we employ a novel memory-based attention for keeping and transmitting the interactive information through a global interaction matrix. Besides, we apply an original-average mixed connection method to effectively transmit the representation information between different reasoning rounds, which helps to preserve the original representation features of questions along with the historical hidden features. Experiments on two standard benchmarks demonstrate that our approach outperforms strong baseline models.

1 Introduction

Question Matching (QM) aims to identify whether two questions have the same intent, which is widely applied in Question Answering (QA) applications such as community QA and intelligent customer services. Typically, QM is regarded as a semantic matching task (Hu et al., 2021). To correctly infer the relationship of a given question pair, there are two kinds of information that should be considered: the representation information of questions that captures the semantics of the texts, and the interactive information between questions that contains critical hints for relationship reasoning.

For better detecting the relationship between question pairs, it's far from being enough to conduct only one single round of reasoning. Existing methods commonly resort to multiple interaction modules to do deep reasoning, where each module is generally composed of an encoding layer (can be omitted (Gong et al., 2018)) to update the representation information of questions and an interaction layer for capturing the interactive information between questions (Kim et al., 2019; Hu et al., 2021). In such a multi-round reasoning procedure, both the representation and interactive information in history rounds play a vital role in guiding the future inference. However, previous studies either only transmit the representation information (Kim et al., 2019) or only the interactive information (Gong et al., 2018), while failing to utilize both kinds of information simultaneously.

As shown in Figure 1 (i), when performing multi-round reasoning, if a model only transmits the representation information, the interactive information between questions will then be simply utilized to generate the representation of questions for future rounds. Consequently, the critical hints for relationship reasoning conveyed by interactive information are abandoned and cannot be directly used for future inferences. On the other side, if a model only transmits the interactive information, it is equivalent to conduct multi-round reasoning with only one single pass on question pairs, as shown in Figure 1 (ii). Admittedly, missing the representation information of original questions may lead to understanding deviation and thus bring cascading errors. Therefore, as shown in Figure 1 (iii), to better perform reasoning between question pairs, a desirable solution should be able to transmit both the representation and interactive information from historical rounds to the current round simultaneously.

To address the aforementioned problems, in this

(i) Transmit only the representation information

(ii) Transmit only the interactive information

(iii) Transmit both the representation and the interactive information

Figure 1: Comparison between different reasoning process of the relationship between questions S and T when transmitting different kinds of information.

paper, we propose a **F**ull **I**nformation **T**ransmission **N**etwork (FITN) that learns to transmit both the representation and interactive information between each round of reasoning. In particular, we propose a novel **Mem**ory-based **Att**ention (Mem-Att) to transmit the interactive information between question pairs. In the Mem-Att, we maintain a global interaction matrix as a memory for keeping the interactive information and do inference on top of it. Compared with traditional attentions that calculate the alignment score directly, the proposed interaction matrix keeps rich interactive information and is more stable in the update process due to its redundancy. Thanks to the global interaction matrix, each round of inference could benefit from the historical interactive information and the whole reasoning procedure is progressive.

Meanwhile, to effectively transmit the representation information of questions, we introduce an interesting connection method, namely the **O**riginal-**A**verage **Mixed Connection** (OA-mixed Connection). Instead of feeding only the hidden features from the last reasoning round, when performing reasoning at the current round, we regard both the hidden features and the original representation embeddings of questions as the input. Such a connection method enables our model an ability to explicitly utilize the entire rich information of original texts when inference. In addition, the OA-mixed Connection employs the average operation over hidden features from the last two rounds to build the input hidden feature for the current reasoning round. Compared with the residual connection (He et al., 2016) that treats the information in each round equally, the average connection pays more attention to the information in the nearer rounds, and thus brings better discrimination ability.

We evaluate our proposed method on the Quora and LCQMC benchmarks. Experimental results show that FITN outperforms the non-pretrained baselines with considerable margins. Furthermore, compared with pre-trained models (small ones with comparable parameter sizes as FITN), our FITN also achieves better performance, which reveals the advantage of proposed method under resource-constrained conditions. All these illustrates the effectiveness of our method.

In sum, our major contributions are three-fold:

- We propose the Full Information Transmission Network (FITN) that can better utilize the historical information, capturing both the representation and interactive information of questions for question matching.
- We propose the memory-based attention for keeping and transmitting the interactive information and the original-average mixed connection to fully utilize the original embedding features of texts and historical hidden features.
- We evaluate the proposed FITN on two benchmark datasets, where considerable improvements are gained over strong baseline models.

2 Methodology

In this section, we introduce our proposed full information transmission network (FITN) in detail. As shown in Figure 2, FITN comprises three modules: the embedding module, the interaction module and the prediction module. In FITN, we first embed each question in the embedding module, then do inference in the interaction module and finally predict their relationship in the prediction module.

We denote two input questions as $S = \{s_1, s_2, ..., s_m\}$ and $T = \{t_1, t_2, ..., t_n\}$ where s_i/t_j is the i^{th}/j^{th} token of question S/T and m/n is the token length of S/T.

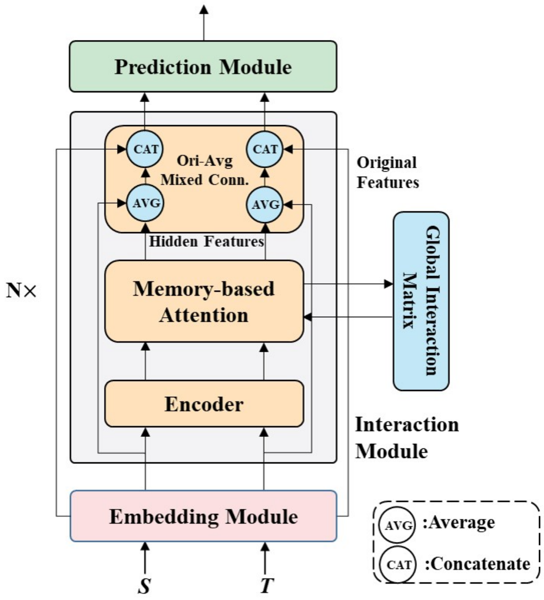

Figure 2: Architecture of the FITN model.

2.1 Embedding Module

In the embedding module, we apply the word embedding along with the character embedding to embed tokens in each question. The character embedding is randomly initialized and then processed by a convolutional neural network (CNN) with a max-pooling operation. Formally, the final representation e_{s_i} of token s_i is calculated as follows:

$$e_{s_i} = [\mathrm{Emb}(s_i); \mathrm{ChConv}(s_i)] \tag{1}$$

where $[;]$ denotes the concatenation operation, Emb is the word embedding and ChConv is the character-level CNN. Each word in S and T is treated in the same procedure and then S and T can be represented as $E_S \in \mathbb{R}^{m \times d_e}$ and $E_T \in \mathbb{R}^{n \times d_e}$.

2.2 Interaction Module

The interaction module is the core of our FITN, composed of N same-structured blocks for doing N rounds of inference. Each block contains 3 components: the encoding layer, the memory-based attention layer and the original-average mixed connection layer. We denote I_S^l and I_T^l as the inputs of the l^{th} block, where $I_S^0 = E_S$ and $I_T^0 = E_T$.

2.2.1 Encoding Layer

We encode two questions through a Bi-LSTM encoder to extract the contextual representation of each token in questions, shown as:

$$H_S^l = \mathrm{BiLSTM}^l(I_S^l) \tag{2}$$

$$H_T^l = \mathrm{BiLSTM}^l(I_T^l) \tag{3}$$

where $H_S^l \in \mathbb{R}^{m \times d_h}$ and $H_T^l \in \mathbb{R}^{m \times d_h}$ are the hidden representations of I_S^l and I_T^l in the l^{th} round, respectively.

2.2.2 Memory-based Attention Layer

As shown in Figure 3, we maintain a global interaction matrix for keeping and transmitting the interactive information in the memory-based attention (Mem-Att) layer. The global interaction matrix is treated as a memory, which keeps all the historical interactive information and will be updated when getting the new one. For each pair of tokens, we keep an interactive vector instead of an attention score in the global interaction matrix. The interactive vector keeps richer information and is more stable in the update process due to its redundancy.

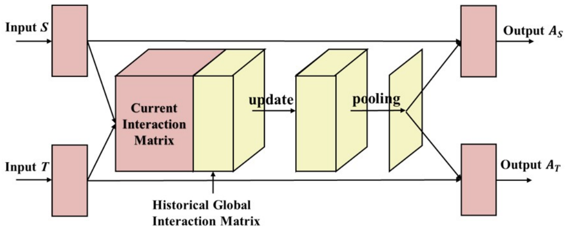

Figure 3: Architecture of the Mem-Att.

In each round, we firstly update the global interaction matrix and then do attention based on this matrix. In this way, the interactive information in history can be transmitted into the current round and provides assistance on the soft-alignment and inference between the two questions.

Global Interaction Matrix Update The global interaction matrix is updated through two steps: current interaction matrix calculation and global interaction matrix combination.

Current Interaction Matrix Calculation The current interaction matrix in the l^{th} round $M^l \in \mathbb{R}^{n \times m \times d_h}$ is calculated as follows:

$$M^l = H_S^l \odot H_T^l \tag{4}$$

For each pair of tokens s_i and t_j in the question S and T, the interaction vector $M_{i,j}^l \in \mathbb{R}^{d_h}$ in M^l is calculated through the element-wise multiplication operation, shown as:

$$M_{i,j}^l = H_{s_i}^l \circ H_{t_j}^l \tag{5}$$

where $\circ$ is the element-wise multiplication.

Global Interaction Matrix Combination After that, we combine the current interaction matrix M^l and the global interaction matrix $\bar{M}^{l-1}$ in the previous round and feed the concatenation result of them into a fully-connected layer with a non-linear activation function as the global interaction matrix $\bar{M}^l \in \mathbb{R}^{n \times m \times d_m}$ in the l^{th} round:

$$\bar{M}^l = \begin{cases} F(M^l) & l = 0 \\ F([M^l; \bar{M}^{l-1}]) & l > 0 \end{cases} \tag{6}$$

where $\bar{M}^l_{i,j} \in \mathbb{R}^{d_m}$ in $\bar{M}$ is calculated as:

$$\bar{M}^l_{i,j} = f(w^l_m[\bar{M}^{l-1}_{i,j}; M^l_{i,j}] + b^l_m) \tag{7}$$

where $[;]$ is vector concatenation across row, $w^l_m \in \mathbb{R}^{(d_h+d_m) \times d_m}$ and $b^l_m \in \mathbb{R}^{d_m}$ correspond to the weight and bias respectively.

Attention over Interaction Matrix Next, we do inference and alignment through the global interaction matrix. We firstly adopt a dense-pooling method to extract an attention map from the global interaction matrix. More specifically, we utilize a fully-connected layer with a nonlinear function to convert each vector into the attention value. Each element $Att^l_{i,j}$ in the attention map $Att^l \in \mathbb{R}^{m \times n}$ is calculated as:

$$Att^l_{i,j} = f(w^l_p \bar{M}^l_{i,j} + b^l_p) \tag{8}$$

where $w^l_p \in \mathbb{R}^{d_m \times 1}$ and $b^l_p \in \mathbb{R}$ correspond to the weight and bias, respectively. Then, the attentive representation $A^l_{s_i}$ of s_i in the l^{th} round is weighted summed by $H^l_{t_j}$, where the weights are calculated by the softmax operation over $Att^l_{i,j}$:

$$A^l_{s_i} = \sum_{j=1}^{n} \mathrm{softmax}(Att^l_{i,j}) H^l_{t_j} \tag{9}$$

Finally, we calculate the average and the difference between the attentive representation $A_{S/T}$ and the contextual representation $H_{S/T}$, concatenate the results with themselves together, and then feed the concatenation result into a fully-connected layer to get the outputs of the block.

$$U^l_S = [H^l_S; A^l_S; (H^l_S + A^l_S)/2; H^l_S - A^l_S] \tag{10}$$

$$U^l_T = [H^l_T; A^l_T; (H^l_T + A^l_T)/2; H^l_T - A^l_T] \tag{11}$$

$$O^l_S = f(w^l_f U^l_S + b^l_f) \tag{12}$$

$$O^l_T = f(w^l_f U^l_T + b^l_f) \tag{13}$$

where $O^l_S \in \mathbb{R}^{m \times d_h}$, $O^l_T \in \mathbb{R}^{n \times d_h}$, $w^l_f \in \mathbb{R}^{4d_h \times d_h}$, and $b^l_f \in \mathbb{R}^{d_h}$ are the weight and bias respectively.

2.2.3 Original-Average Mixed Connection Layer

Finally, we transmit the representation information through the original-average mixed connectivity pattern (OA-mixed connection) in this layer. The question representation input to each round of inference can be divided into two parts: the original features from the initial embedding of questions and the hidden features extracted from previous inference rounds. Both of them play a vital role in each round of inference, where the original features can lead the model to make inference in the right direction, and the hidden features contain deeper contextual and interactive information. Besides, the hidden features can be seen as the information enhancement of the original features. Formally, the whole process can be shown as:

$$I^l = \begin{cases} I_E & l = 0 \\ [I_E; I^l_H] & l > 0 \end{cases} \tag{14}$$

where $I^l \in \mathbb{R}^{m \times (d_e + d_h)}$ $(l > 0)$ is the l-th round input, I_E is the initial embedding, and I^l_H is the l-th round hidden input, calculated as:

$$I^l_H = \begin{cases} O^0 & l = 1 \\ (O^{l-1} + I^{l-1}_H)/2 & l > 1 \\ = \frac{O^{l-1}}{2} + \cdots + \frac{O^1}{2^{l-1}} + \frac{O^0}{2^{l-1}} & \end{cases} \tag{15}$$

where O^l are the hidden outputs of the interaction module before the average connection.

Here, instead of the residual connection, we apply the average connection to capture the hidden features. Compared with the residual connection that treats the information in each round equally, the average connection pay more attention to the information in the nearer rounds. Besides, the residual connection's summation operation may cause the variance of the vectors in the hidden part to go larger as the layers deepen. In comparison, the average connection can balance the variance between the two parts of the question representation.

2.3 Prediction Module

The final representations of the two questions in the interaction module are the last block's next inputs I^{N+1}_S and I^{N+1}_T. To extract a proper representation for each question, we apply the max-pooling operation over them, i.e.:

$$V_S = max(I^{N+1}_S) \tag{16}$$

$$V_T = max(I^{N+1}_T) \tag{17}$$

Table 1: Experimental results on the Quora and LCQMC datasets. Para. denotes the number of parameters. The evaluation metric of Quora is accuracy (%), and that of LCQMC is accuracy (%) and F1. The results are average scores using 5 different seeds along with the standard deviation.

Type	**Model**	**Para.**	**Quora**	**LCQMC**
Non-pretrained	BiMPM(Wang et al., 2017)	1.6m	88.2	83.3/84.9
	DIIN (Gong et al., 2018)	4.4m	89.1	-/-
	CSRAN (Tay et al., 2018)	-	89.2	-/-
	RE2 (Yang et al., 2019)	2.8m	89.4	-/ -
	Enhanced-RCNN (Peng et al., 2020)	7.3m	89.5	-/-
	TIM-W (Zhou et al., 2020)	-	89.6	-/-
	DRCN (Kim et al., 2019)	6.7m	90.2	-/-
	GMN (Chen et al., 2020)	-	-	84.6/86.0
	LET (Lyu et al., 2021)	-	-	84.8/86.1
	COIN (Hu et al., 2021)	6.5m	89.4	85.6/86.5

	BERT-tiny (Turc et al., 2019)	4.4m	87.2	-/-
	BERT-mini (Turc et al., 2019)	11.3m	88.8	-/-
	AlBERT-base (Lan et al., 2020)	11.7m	90.0	86.3/87.0
Ours	**FITN**	**2.5m**	**90.6±0.1**	**86.0±0.5/87.1±0.4**

where $V_S, V_T \in \mathbb{R}^{d_h+d_e}$ and max extracts the maximum value in each column of the inputs.

Finally, we concatenate V_S and V_T to get the feature vector V and feed the feature vector V into a two-layer feed-forward network with one hidden layer and one softmax layer to make the prediction.

3 Experiments

We evaluate our FITN on two QM benchmarks: the Quora (English dataset) (Iyer et al., 2017) and LCQMC (Chinese dataset) (Liu et al., 2018). The Quora dataset contains over 400k question pairs collecting from Quora, an English community question answering (cQA) website, and the data splits (380K/10K/10K) are provided in BIMPM (Wang et al., 2017). The LCQMC collects over 260k question pairs from a Chinese cQA website called BaiduKnows (240K/8K/12K).

3.1 Implementation Details

In the original FITN, we initialize the word embedding with 300d Fasttext vectors (Bojanowski et al., 2017) for the English task and 300d Word2Vec vectors trained in Baidu Encyclopedia (Qiu et al., 2018) for the Chinese task, respectively. We randomly initialize the character embedding with a 25d vector and extract a 50d character representation by CNN. Then, we conduct three rounds of inference and set the hidden size of each layer to 100d in the interaction module. Finally, we set 500 hidden units for the 2-layer FFN in the prediction module. We apply an Adam (Kingma and Ba, 2015) optimizer with a learning rate of 1e-3. We train 100 epochs on the Quora dataset and 20 epochs on the LCQMC dataset. We run 5 times with 5 different randomly selected seeds and report the mean value with the standard deviation selected according to the best performance in the development set.

3.2 Experimental Results

The main experimental results are shown in Table 1. We compare our FITN with non-pretrained models at first. In particular, we employ the baselines including: 1) DIIN(Gong et al., 2018): a CNN-based model that employs a DenseNet on the interaction matrix; 2) RE2 (Yang et al., 2019): a CNN-based model with the augmented residual connection; 3) Enhanced RCNN (Peng et al., 2020): a model that encodes sentences by multi-layer CNNs and adopts the attention-based RNNs for relationship inference; 4) TIM-W (Zhou et al., 2020): a model based on deep mutual information estimation; 5) DRCN (Kim et al., 2019): a co-attention BiLSTM model with dense-connection; 6) GMN (Zhou et al., 2020): a neural graph matching model; 7) LET (Lyu et al., 2021): a transformer-based model that employs the external linguistic knowledge derived from Graph Attention Networks; and 8) COIN (Hu et al., 2021): A CNN-based model with a deep context-aware cross-attention based interaction module.

We can see that our model outperforms all these baselines on the two benchmarks. More specifically, our model beats DIIN because we can keep updating the representation information based on the historical representation information during iterations. Compared with DRCN, our FITN utilizes the historical interactive information for inference and in return acquires performance improvements with fewer inference rounds. Besides, the historical interactive information can also benefit our model on deeper inference. Therefore, the performance of our model is unsurprisingly better than RE2.

In addition, to further verify the effectiveness of our FITN under restricted computing resources, we compare our FITN with 4 publicly available tiny pre-trained models, which are distilled from large pre-trained models (BERT-tiny and BERT-mini (Turc et al., 2019) that are distilled from BERT-base (Devlin et al., 2019)) or directly pre-trained by large-scale datasets (AlBERT-tiny and AlBERT-base (Lan et al., 2020)). As shown in Table 1, our model can achieve competitive or even better performance than pre-trained models with similar model size. It demonstrates that our FITN can be a desirable choice compared with pre-trained models in resource-constrained scenarios.

3.3 Analysis

In this subsection, we firstly verify the effectiveness of our proposed Mem-Att and OA-mixed connection, then show the impact of inference rounds on model performance, and finally further analyze the Mem-Att by a statistical analysis and a case study.

3.3.1 Effectiveness of the Mem-Att

We compare Mem-Att with three attention mechanisms to verify the ability of Mem-Att to maintain richer interactive information and leverage historical interactive information to aid future inference, containing 1) the scaled dot product attention (Dot-Att); 2) the scaled weighted dot product attention (wDot-Att); and 3) the interactive attention (Inter-Att), a variance of Mem-Att, which is only based on the current interaction matrix. The functions of these attentions are shown as following:

$$Att = \begin{cases} Pool_{att}(F(M^c)) & \text{Inter-Att} \\ \frac{ST^T}{\sqrt{d}} & \text{Dot-Att} \\ \frac{SWT^T}{\sqrt{d}} & \text{wDot-Att} \end{cases} \quad (18)$$

Table 2: Comparison experiments about different attention mechanisms on the Quora dataset.

Attentions	**Dev Acc.**	**Test Acc.**
Dot-Att	88.4	88.0
wDot-Att	88.8	88.3
Inter-Att	90.4	90.1
Mem-Att	**90.8**	**90.6**

Table 3: Comparison experiments about different connectivity patterns on the Quora dataset.

Patterns	**Dev Acc.**	**Test Acc.**
Direct	90.3	90.0
Dense	90.4	90.3
Residual	90.5	90.2
OA-mixed	**90.8**	**90.6**

where d is the dimension of the question representation, $S \in \mathbb{R}^{d \times m}$, $T \in \mathbb{R}^{d \times n}$ and $W \in \mathbb{R}^{d \times d}$.

The comparison results are shown in Table 2. With an intuition that the 3D interaction matrix can keep richer interactive information than the 2D attention map, the performance of the Int-Att is unsurprisingly better than those of the wDot-Att and the Dot-Att, which demonstrates that richer interactive information can bring benefit to the model on conducting more proper inference. Furthermore, the performance of the Mem-Att is better than that of the Int-Att, which reflects that the historical interactive information can provide assistance on the current and the future inference.

3.3.2 Effectiveness of the OA-mixed Connection

To illustrate the advantage of the OA-mixed connection, we compare our method with the following connective patterns: 1) residual connection (He et al., 2016); 2) dense connection (Huang et al., 2017), and 3) direct connection that directly treats the output of the previous round as the input.

As shown in Table 3, the direct connection unsurprisingly performs worst. These results show that the historical representation information provides benefits for the current round of inference and it is critical to design advanced connectivity patterns to effectively transmit important information between different reasoning rounds. Moreover, our OA-mixed connection beats both the residual connection and the dense connection. We attribute it to the fact that our method can preserve the entire information of original texts. Meanwhile, the average connection we proposed can help the model to focus more on the information conveyed by the surrounding reasoning rounds. All these bring rich information and helpful hints to determine the relationships between the question pair.

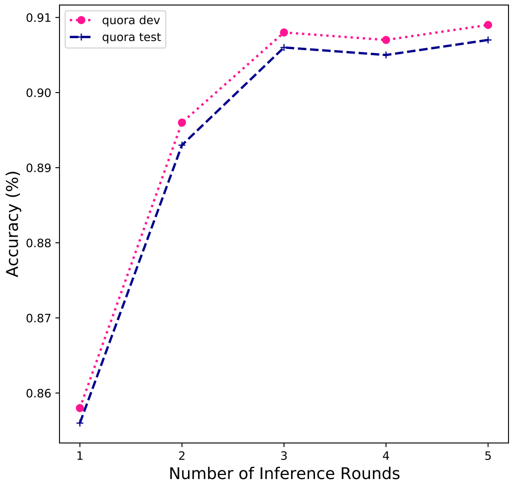

Figure 4: The accuracy curve for different rounds of inference on the Quora dataset.

3.3.3 Impact of the Inference Rounds

In this part, we design a comparison experiment to demonstrate the impact of the inference rounds. We set the inference round in our FITN from 1 to 5 and compare their performance on Quora's development and test set. The comparison result is shown in Figure 4. Obviously, as the number of the inference round increases, our model's accuracy increases, verifying the utility of the multi-round inference. However, the increasing trend of the accuracy gradually slows down as the number of inference rounds grows. Continue stacking layers may not bring further significant improvements. We attribute this to the model capturing enough information from a limited multi-round inference under the assistance of our proposed Mem-Att and OA-mixed connection. There is no need to stack too many inference modules.

3.3.4 Analysis of the Mem-Att

In order to further analyze how the Mem-Att works, we compare our Mem-Att with the Dot-Att and conduct a statistical analysis along with a case study to verify that the Mem-Att can pay higher attention to the critical word pairs and the inference round in the Mem-Att is progressive.

Table 4: Statistical analysis on the Quora dataset. "Mean±std" denotes the mean value and the standard deviation of the attention distribution. R1., R2., and R3. denote the attention in the round 1, 2, and 3 respectively.

Metric	**Mem-Att**	**Dot-Att**
R1. Mean±std	0.0967±0.0026	0.0967±0.0017
R2. Mean±std	0.0967±0.0028	0.0967±0.0003
R3. Mean±std	0.0967±0.0029	0.0967±0.0013
Pearson(R2,R1)	0.7327	0.5456

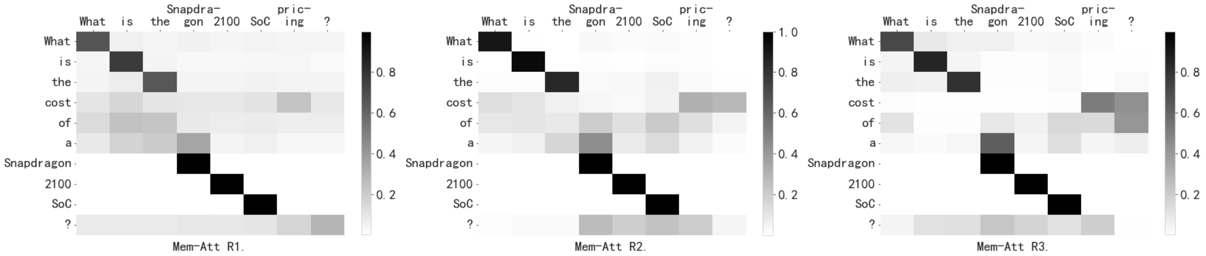
Statistical Analysis We conduct the statistical analysis on the development set of Quora and compare our Mem-Att with the Dot-Att. We calculate the mean value and the standard deviation of the attention distributions in each inference round to observe the distribution characteristics. Then, we calculate the Pearson correlation coefficient (Benesty et al., 2009) to quantify the relevance between two attention distributions in adjacent rounds. We take the average of the above metrics among all samples as the final metrics.

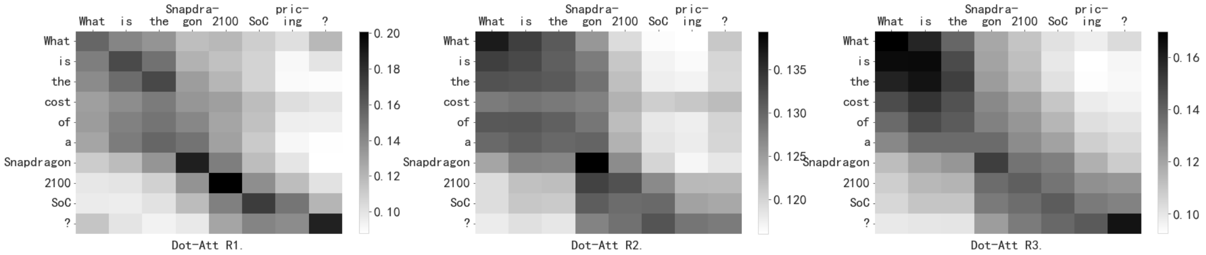
As shown in Table 4, the standard deviation of the attention distributions in the Mem-Att is larger than that in the Dot-Att and the distribution of the Dot-Att tends to be uniform. It demonstrates that our Mem-Att is more discrete and pays more attention to the specific token pairs. Besides, the Pearson correlation coefficient between the attention distributions of the Mem-Att in adjacent rounds is higher than that in the Dot-Att, which denotes that the inference between adjacent rounds has more relevance in the Mem-Att. The inference procedure in the Mem-Att is progressive.

Case Study Then, we take a pair of similar questions "What is the cost of a Snapdragon 2100 SoC ?" and "What is the Snapdragon 2100 SoC pricing ?" as an example and visualize the attention distributions of the Mem-Att and the Dot-Att in each round of inference. Here, the Mem-Att predicts right and the Dot-Att predicts wrong.

As shown in Figure 5, both the Dot-Att and the Mem-Att can align all pairs of the same word in the first inference round, where the Mem-Att focuses more on these word pairs than the Dot-Att. The distribution of the Mem-Att is more concentrated than that of the Dot-Att, which denotes that



(a) The heat maps of Mem-Att.



(b) The heat maps of Dot-Att.

Figure 5: The heat maps of Mem-Att and Dot-Att. Take "What is the cost of a Snapdragon 2100 SoC ?" and "What is the Snapdragon 2100 SoC pricing ?" as an example.

the Mem-Att has obvious tendency to pay attention. With the increase in the number of inference rounds, the Mem-Att's distribution does not tend to be uniform. Furthermore, the change of the Mem-Att's distribution is continuous, where the Mem-Att gradually deepens its focus on "cost" and "pricing". It demonstrates that the inference in the Mem-Att is progressive. The Mem-Att can gradually align word pairs with similar semantics.

4 Related Work

Question Matching can be regarded as a semantic matching task, which core lies in how to model the vector representation of texts (Shen et al., 2018; Reimers and Gurevych, 2019; Gao et al., 2021) and reason about the semantic relationship between text pairs. ESIM (Chen et al., 2017) encodes texts through BiLSTM or TreeLSTM (Socher et al., 2013) and applies the co-attention to extract fine-grained alignment information for inference. BiMPM (Wang et al., 2017) matches texts from multiple perspectives by multiple kinds of attentions. For better inference, many studies tend to employ deeper models. DIIN (Gong et al., 2018) applies a dense-net on the interaction matrix extracted from two texts for deep inference. DRCN (Kim et al., 2019) iterates one same block multiple times for multi-turn inference. TIM-W (Zhou et al., 2020) is based on deep mutual information estimation. ADIN (Liang et al., 2019) performs multiple rounds of asynchronous reasoning for the NLI task. In comparison, our FITN performs better due to the better utilization of historical information.

Thanks to the knowledge obtained from massive data, pre-trained models can greatly improve the performance of semantic matching, such as BERT (Devlin et al., 2019) AlBERT (Lan et al., 2020). However, the complexity of the model and the time consumption of reasoning are greatly increased, making them not suitable to resource-constrained scenarios. Enhanced-RCNN (Peng et al., 2020) compares itself with BERT in inference speed and accuracy. Although the performance is relative low, its inference speed is 10 times faster than BERT-base. Under the resource-constrained condition, directly using publicly available tiny pre-trained models is another solution. These models are commonly pre-trained with large-scale corpus (like AlBERT-tiny and AlBERT-base (Lan et al., 2020)) or distilled from large pre-trained models (like BERT-tiny (Turc et al., 2019)). Compared with these tiny pre-trained models, our FITN achieves better performance.

5 Conclusion

In this paper, we study the task of question matching and propose a Full Information Transmission

Network (FITN) that can utilize both the historical representation and the historical interactive information together in a simultaneous fashion. Specifically, the FITN employs a memory-based attention to keep and transmit the historical interactive information and an original-average mixed connectivity pattern to transmit the representation information. Experimental results on two benchmarks show that our FITN takes advantage of both kinds of information and outperforms strong baselines with considerable margin.

Ethical Considerations

This paper proposes a general model for question matching. This paper neither introduces any social/ethical bias to the model nor amplify any bias in the data. In all the experiments, we use public datasets and consist their intended use. We build our algorithms using public code bases (PyTorch). We do not foresee any direct social consequences or ethical issues.

Abstract

Biomedical pathways have been extensively used to characterize the mechanism of complex diseases. One essential step in biomedical pathway analysis is to curate the description of a pathway based on its graph structure and node features. Neural text generation could be a plausible technique to circumvent the tedious manual curation. In this paper, we propose a new dataset Pathway2Text, which contains 2,367 pairs of biomedical pathways and textual descriptions. All pathway graphs are experimentally derived or manually curated. All textual descriptions are written by domain experts. We form this problem as a Graph2Text task and propose a novel graph-based text generation approach kNN-Graph2Text, which explicitly exploited descriptions of similar graphs to generate new descriptions. We observed substantial improvement of our method on both Graph2Text and the reverse task of Text2Graph. We further illustrated how our dataset can be used as a novel benchmark for biomedical named entity recognition. Collectively, we envision our method will become an important benchmark for evaluating Graph2Text methods and advance biomedical research for complex diseases.[1]

1 Introduction

Many complex diseases, such as cancer and neurodegenerative disorders, are driven by reactions among a combination of genes and metabolites instead of one single gene (Manolio et al., 2009). These reactions, which are formally referred to as pathways (Kanehisa et al., 2017; DS et al., 2020; Gillespie et al., 2022), are represented as a heterogeneous graph (**Figure** 1). Each node in this graph is a biomedical entity, such as gene, chemical or metabolite. Each edge is a specific biomedical reaction. Using natural language to describe this pathway graph is of great importance for scientific communication and further promotes applications in complex disease research (Whirl-Carrillo et al., 2012, 2021). To date, these descriptions are almost entirely curated manually by domain experts, thus substantially slowing down downstream biomedical applications (Naithani et al., 2019). Neural text generation has shown promising results in many applications (Bowman et al., 2016; Sutskever et al., 2014; Song et al., 2020; Brown et al., 2020; Raffel et al., 2020; Lewis et al., 2020). Among them, Graph-to-Text (Graph2Text) generation, such as AMR-to-Text (Song et al., 2018; Marcheggiani and Perez-Beltrachini, 2018; Fan and Gardent, 2020), and Knowledge-Graph-to-Text (Colas et al., 2021; Wang et al., 2021), is most similar to pathway description generation. Therefore, we hypothesize that neural text generation could also be a solution here. To fill in the gap, we first propose a novel biomedical pathway description dataset Pathway2Text, which contains 2,367 pairs of pathway and description. Each description is written by domain experts, describing the function and property of this pathway. In contrast to many other Graph2Text datasets (Banarescu et al., 2013; Colas et al., 2021) that use automatic approach to extract the graph from the text, pathways in our dataset are all experimentally measured or manually curated, presenting a high-quality structured data corresponding to the textual description. To the best of our knowledge, Pathway2Text is the first large-scale dataset studying the problem of biomedical pathway description generation.

One unique feature of our dataset is the rich textual information on each node in the graph. Specif-

Macromolecule
...	...	...

Output: description

Succinic acid, or its anion succinate, can leave the mitochondria and can directly inhibit the prolyl 4-hydroxylase subunit alpha-3 protein, which then allows for additional activation of the hypoxia-inducible factor 1-alpha (HF-1α). The higher levels of HF-1α enhance the expression of genes, including those for interleukin-1 beta (IL-1β). Succinic acid is also necessary for the succinylation of proteins, leading to changes in their structure and function.

Figure 1: An example of a pathway and its description in our dataset. Each pathway is a heterogeneous graph containing different node types and edge types. Each node has three features: textual label, textual description and node type. For Graph2Text task, the input is the graph and the output is the graph description.

ically, each node is associated with a node type, a concise textual label and a detailed textual description. In contrast, many other Graph2Text datasets only have a short textual label or a fixed-size feature vector on each node (Belz et al., 2011; Banarescu et al., 2013; Gardent et al., 2017; Jin et al., 2020; Wang et al., 2021). We found that conventional graph neural network architectures were unable to fully exploited these rich node features, resulting in less accurate graph description generation. And the advantages of exploiting similar input data have been demonstrated in many related works (Baran et al., 2019; Khandelwal et al., 2020; Wang et al., 2022). We therefore propose kNN-Graph2Text, which explicitly incorporates descriptions of similar graphs into the definition generation process. In particular, our method first calculates a description-guided graph embedding and then finds similar graphs for a test graph based on these embeddings. After that, the new description is generated by jointly considering the description of neighbors and the graph structure using a multi-head attention framework (Vaswani et al., 2017).

We evaluated kNN-Graph2Text on our dataset and observed substantial improvement over conventional graph neural network architectures as well as methods that do not fully utilize the heterogeneous node features. We next demonstrated that our dataset can be used to study the reverse task of Text2Graph. In particular, we investigated how graph description can enhance the performance of link prediction and node classification, and obtained accuracy of 0.781 in link prediction and accuracy of 0.352 in node classification. Moreover, our dataset can be used as a novel benchmark for biomedical named entity recognition by extracting the ground truth entity types according to the annotated node types. Collectively, our dataset and our method present the first study in automatic biomedical pathway description generation. We envision Pathway2Text to be an important benchmark for general Graph2Text methods and facilitate downstream biomedical applications.

2 Pathway2Text Dataset

2.1 Data processing

Our dataset was synthesized from five biomedical databases: Reactome (Gillespie et al., 2022), KEGG (Kanehisa et al., 2017), Pathbank (DS et al., 2020), UniProt (Consortium, 2020) and ChEBI (Hastings et al., 2015). We collected biomedical pathways and their associated textual descriptions from Reactome, KEGG, and Pathbank, and aligned nodes in pathways to entities in UniProt and ChEBI for retrieving missing node descriptions. Specifically, the raw data was processed as follows:

Data format definition. We firstly modified SBGN (Le Novère et al., 2009) , a standard export format for biology graphical notation, to organize multiple components in pathway. We followed most of the original definitions in SBGN (e.g., reaction representing format), but we (1) omitted nodes that are not involved in any reaction (e.g., Compartment nodes), (2) reconstructed each Complex node (a container for other nodes) into a tree structure, by adding additional edges between nodes and their container, (3) merged different nodes referring to the same entity into a single node for each pathway, and (4) rewrote the entire dataset into more readable JSON file (cf. Appendix B for more intuitive explanation of our data format).

Format translation. Reactome and Pathbank already provide SBGN files, making it straightforward to adapt pathways in both database into our data format. But KEGG only provides KGML (Kanehisa et al., 2017) file, a specific representation of KEGG pathways. So we applied additional modifications to translate KGML file into our data format: we (1) used Process node to represent a reaction instead of directly adding edges between substrates and products, (2) treated a Group of proteins acting on the same reaction as a Complex node, and (3) adjusted node types to match our definition. We refer readers to Appendix A for an illustration for these operations.

Node description gathering. Neither SBGN nor KGML file contains detailed node descriptions. SBGN file provides node label (a short text for display), and KGML file provides a KEGG identifier for each node. (1) For Pathbank database, each pathway is also recorded in PWML (DS et al., 2020) format, which contains textual node labels and descriptions. We therefore used node labels given by SBGN file to retrieve node descriptions from PWML file. (2) For Reactome database, each pathway is also stored in BioPAX (Demir et al., 2010) format. 49.2% nodes in BioPAX file have long descriptions while most of the others are only linked to identifiers in external biological entity databases. Among these databases, the Function attribute in UniProt and the Definition attribute in ChEBI are appropriate to be utilized as complements to node descriptions. So we aligned each node in SBGN file to node in corresponding BioPAX file using node label. And then extracted node descriptions from the union of BioPAX file, UniProt and ChEBI. (3) For KEGG database, each KEGG identifier indicates particular information (stored in a TXT file) of a specific entity. We parsed this file to pick entity name, textual Comment and external database identifiers. We used entity names as node labels, used Comments as node descriptions for entities having this attribute (3.7%), and used identifiers of UniProt and ChEBI to retrieve node descriptions for others.

2.2 Dataset description

After excluding duplicate pathways and pathways that do not have textual description, we finally obtained 2,367 pairs of pathway and description. An example is shown in **Figure** 1. Each textual description is a few sentences describing functions and structures of the pathway. The textual description has on average 129.5±101.4 words and 7.6±5.3 sentences. Each pathway can be viewed as a heterogeneous graph that contains different types of edges and nodes. There are 7 edge types and 7 node types in the entire dataset, where each pathway has on average 3.5±1.4 edge types and 4.5±1.4 node types. Each node type (e.g., chemical) has a large number of specific classes (e.g., succinic acid). Each class is associated with a concise textual label and a detailed textual description. The average length of the textual description is 114.8 words. We refer to the class description as the node description and the pathway description as the graph description throughout the paper. Each pathway has on average 61±52 nodes and 75±80 edges. In summary, there are four data fields for each pathway description pair: graph description, graph structure, node description and node label.

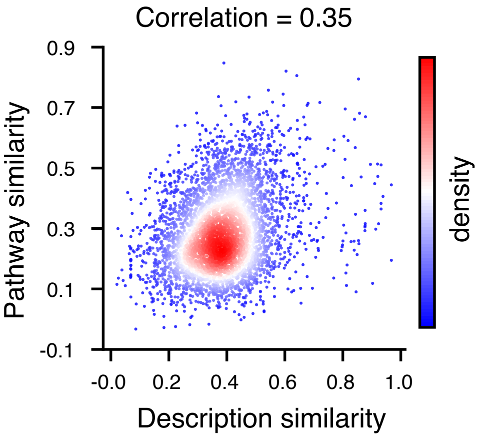

Figure 2: Scatter plot showing the consistency between graph-based representation similarity and description-based representation similarity. Each dot is a pair of graphs.

To examine the feasibility of conducting Graph2Text and Text2Graph tasks using our dataset, we examined the consistency between graph similarity and description similarity (**Figure 2**). We used GAT (Veličković et al., 2018) to embed each graph into a dense representation. We also obtained a dense representation for each graph description using BioBERT (Lee et al., 2020). For every two graphs, we calculated one similarity score based on their graph-based representations and another similarity score based on their description-based representations. We observed a Pearson correlation 0.35 between these two similarity scores, reflecting a substantial consistency between these two similarity metrics. This indicates that graphs with similar structure tend to have similar textual descriptions, suggesting the possibility to generate textual description using the graph structure and vice versa.

3 Task Description

We aim to generate the textual description for a given biomedical pathway graph and generate the biomedical pathway graph from a given textual description. Let $\mathbf{D} = \{\mathbf{D}_{\mathcal{G}}, \mathbf{D}_{\mathcal{S}}\} = \{(G_i, S_i)\}_{i=1}^{N} \overset{dist}{\sim} \mathbb{P}(\mathcal{G}, \mathcal{S})$ be a dataset of paired pathway and its textual description. Each pathway is a directed graph $G = (V, E, F)$, where V represents the set of nodes, $E \subseteq V \times V$ represents the set of edges, and F represents node features. Since each pathway is a heterogeneous graph, we refer to pathway as graph in this paper.

One unique property of the graphs in our dataset is the rich node features $F = \{g, t, d\}$. In particular, each node v is associated with three features $\boldsymbol{g}_v$, t_v, and d_v. $\boldsymbol{g}_v \in \{0, 1\}^{n_c}$ is a one-hot vector representing the node type of v. $\boldsymbol{g}_v^i = 1$ if node v is type i. $t_v \triangleq \left\langle t_v^1, t_v^2, \ldots, t_v^{|t_v|} \right\rangle$ is the textual label of node v. $d_v \triangleq \left\langle d_v^1, d_v^2, \ldots, d_v^{|d_v|} \right\rangle$ is the textual description of node v. $t_v^i \in \mathrm{C}$ and $d_v^i \in \mathrm{C}$, where C is the vocabulary. In practice, the textual label is often a phrase and the textual definition is a few sentences. As a result, $|d_v|$ is often much larger than $|t_v|$. Each edge is associated with an edge type $r \in \mathrm{R}$, where R is the set of edge types in the dataset. Each graph description is a token sequence defined as $S \triangleq \langle S^1, S^2, \ldots, S^{|S|} \rangle$, where $S^i \in \mathrm{C}$.

We use an inductive learning framework in our experiment. The whole dataset $\mathbf{D}$ is randomly divided into $\mathbf{D}_{train} = \{(G_i, S_i)\}_{i=1}^{|\mathbf{D}_{train}|}$ and $\mathbf{D}_{test} = \{(G_i, S_i)\}_{i=|\mathbf{D}_{train}|+1}^{N}$. For each task, we train our model on $\mathbf{D}_{train}$ and evaluate its performance on $\mathbf{D}_{test}$. Graph G and textual description S are always observed for the training data. We define three tasks based on the unobserved information in the test data as follows:

Graph2Text. The input of this task is a graph G. All node features are observed on this graph. The output is the description text S for this graph.

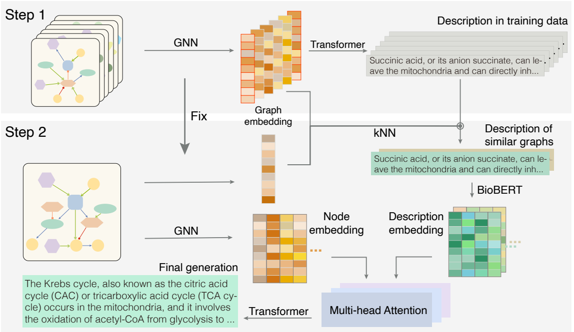

Figure 3: Flow chart of our two-step approach kNN-Graph2Text. In the first step, we learnt a representation for each graph by projecting graphs to descriptions. In the second step, we find similar graphs for a test graph and jointly use descriptions of similar graphs and node embeddings of the test graph to generate the final description.

Text2Graph link prediction. This task aims to predict missing links in a test graph. The inputs are graph description S, all node features F and a subset of edges $\{e\}$ in the graph G. For a test edge $e_{u,v} \in V \times V - \{e\}$, our goal is to classify $e_{u,v}$ into a specific edge type $r \in \mathrm{R}$.

Text2Graph node classification. This task aims to classify each test node into a specific node type in graph G. We split nodes in G into training nodes and test nodes. For training nodes, we observed all node features F, including textual label, textual description and node type, whereas none of these features is observed for the test node. We also observed the graph description S for G. Instead of predicting the node type, we aim at predicting the specific textual label, which is a more challenging task. We form this problem as a node classification task instead of textual generation.

4 Methods

4.1 Graph2Text

The overall framework of our method is shown in **Figure** 3. We propose a two-step approach. In the first step, we embed each graph into a dense representation through jointly considering its graph structure and node features. In the second step, we use the learnt graph embeddings to find similar graphs for each test graph and then leverage the description of these similar graphs to help the generation.

4.1.1 Description guided graph embedding

One unique property of our dataset is the rich textual features on each node. We hypothesize that unsupervised graph embedding methods might be unable to fully exploit these textual features. Therefore, we first use a supervised approach to obtain graph embeddings. Since we don't have any class label for each graph, we treat the graph description as the pseudo label in the supervised learning framework to embed graphs.

In particular, we learn an encoder Enc that projects the graph G into a dense representation $\boldsymbol{h}_G$, and then a decoder Dec that maps this representation into the textual description S. The decoder will be discarded in the second step, while the encoder will be used to obtain the representation of an input graph.

Our encoder could be any existing graph neural network architectures (Kipf and Welling, 2017; Veličković et al., 2018; Xu et al., 2019). We first use a pretrained language model BioBERT to encode the textual label t_v and the description d_v of each node v into a dense vector $\boldsymbol{t}_v$ and a dense vector $\boldsymbol{d}_v$, and fuse them to get the initial node embedding for node v:

$$\boldsymbol{h}_v^0 = \mathrm{RELU}([\boldsymbol{t}_v || \boldsymbol{d}_v]\mathbf{W}), \tag{1}$$

where $\mathbf{W}$ represents a trainable parameter matrix and $||$ is the concatenation operation.

We then propagate this embedding on the graph using a chosen graph neural network architecture, which learns representation of node v through iteratively updating it with neighbors' information $\boldsymbol{h}^l_{\mathcal{N}(v)}$ as:

$$\begin{aligned} \boldsymbol{h}^l_{\mathcal{N}(v)} &= \mathrm{AGG}(\{(\boldsymbol{h}_u^{l-1}, e_{u,v}) | u \in \mathcal{N}(v)\}), \\ \boldsymbol{h}_v^l &= \mathrm{UPDATE}(\boldsymbol{h}_v^{l-1}, \boldsymbol{h}^l_{\mathcal{N}(v)}), \end{aligned} \tag{2}$$

where $\mathcal{N}_v$ denotes the set of neighbors for v. AGG and UPDATE are the aggregation and the update function of the specific graph neural network architecture. We studied the performance of using GIN, GCN and GAT as the neural network architecture in our experiments.

After L iterations, the final embedding $\boldsymbol{h}_v^L$ can be used to represent the local subgraph comprising node v's L-hop neighbors. Next, for each node, we concatenate its node embeddings from all layers to fuse the information from different ranges of neighbors. We then calculate the graph-level representation by applying a READOUT function to the concatenated node embedding:

$$\begin{aligned} \boldsymbol{h}_v &= [\boldsymbol{h}_v^1 || \boldsymbol{h}_v^2 || \cdots || \boldsymbol{h}_v^L]\mathbf{W}, \\ \boldsymbol{h}_G &= \mathrm{READOUT}(\{\boldsymbol{h}_v\}_{v \in V}). \end{aligned} \tag{3}$$

Our decoder is a Transformer based on the pretrained BioBERT. It generates textual description conditioned on $\boldsymbol{h}_G$:

$$P(\hat{S}^i | \boldsymbol{h}_G) = \mathrm{Dec}(\boldsymbol{h}_G, S^{1,\ldots,i-1}). \tag{4}$$

Finally, the decoder Dec and the encoder Enc are trained jointly using the following loss function:

$$\mathcal{L}_1 = -\frac{1}{|\mathbf{D}_{train}|} \sum_{(G,S) \in \mathbf{D}_{train}} \sum_{S^i \in S} \frac{\log P(S^i | \boldsymbol{h}_G)}{|S|}. \tag{5}$$

4.1.2 Exploiting descriptions of similar graphs in generation

The above encoder-decoder framework could already be used to generate the description for a given test graph. However, we observed that such generations were not of great quality in our experiment, partially due to the poor utilization of the node textual features. We thus propose to train a new decoder by leveraging the descriptions of similar graphs.

We first use $\boldsymbol{h}_{G_i}$ to find k similar graphs in the training data:

$$\begin{aligned} \mathrm{dis}_{ij} &= \|\boldsymbol{h}_{G_i} - \boldsymbol{h}_{G_j}\|_{\mathrm{F}}^2, \\ \bar{S}_i &= \mathop{\|}_{G_j \in k\mathrm{NN}(G_i)} (S_j), \end{aligned} \tag{6}$$

where S_j is the description for k nearest graphs measured by dis_{ij}. We then embed neighbor's description $\bar{S}_i$ into a dense representation $\bar{\boldsymbol{s}}_i$ using BioBERT:

$$\begin{aligned} \langle \bar{\boldsymbol{s}}_i^j \rangle &= \mathrm{BioBERT}(\bar{S}_i)\mathbf{W}, \\ \bar{\boldsymbol{s}}_i &= \mathrm{Maxpooling}(\langle \bar{\boldsymbol{s}}_i^j \rangle). \end{aligned} \tag{7}$$

Next, we use multi-head attention framework to calculate a new dense representation $\boldsymbol{v}_s^a$ based on description embedding $\bar{\boldsymbol{s}}_i$ and $\langle \bar{\boldsymbol{s}}_i^j \rangle$, and a new dense representation $\boldsymbol{v}_g^a$ based on graph embedding $\boldsymbol{h}_G$ and $\{\boldsymbol{h}_v\}$as:

$$\begin{aligned} \mathrm{s}^a(\boldsymbol{u}, \boldsymbol{v}_i, V) &= \frac{\exp(\mathcal{Q}^a(\boldsymbol{u})^{\mathrm{T}} \mathcal{K}^a(\boldsymbol{v}_i))}{\sum_{\boldsymbol{v}_j \in V} \exp(\mathcal{Q}^a(\boldsymbol{u})^{\mathrm{T}} \mathcal{K}^a(\boldsymbol{v}_j))}, \\ \mathrm{Attention}^a(\boldsymbol{u}, V) &= \mathrm{LeakyReLU}(\textstyle\sum_{\boldsymbol{v}_i \in V} \mathrm{s}^a(\boldsymbol{u}, \boldsymbol{v}_i, V)\boldsymbol{v}_i), \\ \boldsymbol{v}_g^a &= \mathrm{Attention}^a(\boldsymbol{h}_G, \{\boldsymbol{h}_v\}), \\ \boldsymbol{v}_s^a &= \mathrm{Attention}^a(\bar{\boldsymbol{s}}_i, \langle \bar{\boldsymbol{s}}_i^j \rangle), \end{aligned} \tag{8}$$

where $a \in \{1, \ldots, A\}$ indicates the attention head number. $\mathcal{Q}^a$ is a projection function mapping a vector to the query space, which is defined as $\mathcal{Q}^a(\boldsymbol{v}) = \tanh(\boldsymbol{v}\mathbf{Q}^a)$, where $\mathbf{Q}^a$ represents a trainable parameter matrix. Similarly, we use $\mathcal{K}^a$ to map a vector to the key space.

Finally, we concatenate the new graph embedding $\boldsymbol{v}_g^a$ and new description embedding $\boldsymbol{v}_s^a$, and use a pretrained Transformer as the decoder to generate textual content:

$$\begin{aligned}\mathbf{V} &= [\boldsymbol{v}_g^1 || \cdots || \boldsymbol{v}_g^A || \boldsymbol{v}_s^1 || \cdots || \boldsymbol{v}_s^A], \\ P(\hat{S}^i | \mathbf{V}) &= \mathrm{Dec}(\mathbf{V}, S^{1,\ldots,i-1}).\end{aligned} \tag{9}$$

Since we didn't use the position embedding in the input of the Transformer encoder, it implicitly performs cross attention between graph and description. The loss function is finally defined as:

$$\mathcal{L}_2 = -\frac{1}{|\mathbf{D}_{train}|} \sum_{(D,S)\in\mathbf{D}_{train}} \sum_{S^i \in S} \frac{\log P(S^i|\mathbf{V})}{|S|}. \tag{10}$$

4.2 Text2Graph

For Text2Graph, we studied link prediction and node classification.

4.2.1 Link prediction

To predict the edge type between node u and node v on graph G, we used the node embedding $\boldsymbol{h}_u$, node embedding $\boldsymbol{h}_v$ and the graph description S as the input features. We first define the edge feature $\boldsymbol{w}_{u,v}$ and the graph description feature $\langle \boldsymbol{s}_i^j \rangle$ as:

$$\begin{aligned}\langle \boldsymbol{s}_i^j \rangle &= \mathrm{BioBERT}(S_i)\mathbf{W}, \\ \boldsymbol{w}_{u,v} &= [\boldsymbol{h}_u || \boldsymbol{h}_v].\end{aligned} \tag{11}$$

Then we use the same attention mechanism as in Equation. 8 to obtain a new embedding $\boldsymbol{h}$ from these two features and define the predicted distribution $P(\hat{r}_{u,v}|e_{u,v})$ for edge type r as:

$$\begin{aligned}\boldsymbol{h} &= \mathrm{Attention}(\boldsymbol{w}_{u,v}, \langle \boldsymbol{s}_i^j \rangle), \\ P(\hat{r}_{u,v}|S) &= \mathrm{softmax}(\mathrm{MLP}([\boldsymbol{h}_u || \boldsymbol{h}_v || \boldsymbol{h}])).\end{aligned} \tag{12}$$

Here, MLP is a multi-layer perceptron. The final training loss is defined as:

$$\mathcal{L}_3 = -\frac{1}{|\mathbf{D}_{train}|} \sum_{(G,S)\in\mathbf{D}_{train}} \sum_{e_{u,v}} \frac{P(r_{u,v}|S)}{|\{e_{u,v}\}|}. \tag{13}$$

4.2.2 Node classification

To classify a test node v, we applied a similar attention mechanism on its node embedding $\boldsymbol{h}_v$ and graph description feature $\langle \boldsymbol{s}_i^j \rangle$ as:

$$\begin{aligned}\langle \boldsymbol{s}_i^j \rangle &= \mathrm{BioBERT}(S_i)\mathbf{W}, \\ \boldsymbol{h} &= \mathrm{Attention}(\boldsymbol{h}_v, \langle \boldsymbol{s}_i^j \rangle).\end{aligned} \tag{14}$$

We then define the predicted label distribution and loss function accordingly as:

$$\begin{aligned}P(\hat{t}_v|S) &= \mathrm{softmax}(\mathrm{MLP}([\boldsymbol{h}_v || \boldsymbol{h}])), \\ \mathcal{L}_4 &= -\frac{1}{|\mathbf{D}_{train}|} \sum_{(G,S)\in\mathbf{D}_{train}} \sum_{v} \frac{P(t_v|S)}{|\{v\}|}.\end{aligned} \tag{15}$$

5 Results

5.1 Experimental setup

We exclude any pathway that is a subgraph of another pathway in all experiments to avoid data leakage. For Graph2Text, we randomly split the graph description pairs into 75% training pairs and 25% test pairs. We used a fixed Transformer encoder in BioBERT and initialized the GNN with xavier initialization. We used a learning rate 5e-5. We found that this method performed better than using a fixed Transformer and warming GNN before the training. We used GAT (Veličković et al., 2018), GCN (Kipf and Welling, 2017) and GIN (Xu et al., 2019) as different graph encoders. The hidden state embedding dimension was set to 128 for GAT and 512 for others. The number of heads of GAT was set as 4. AGG and UPDATE functions were implemented according to the original papers. Global mean pooling was used as the READOUT function. Since Transformer can hardly generate more than 512 tokens, we calculated the loss functions and evaluated the generation only on the first 3 sentences, which have an average token length 69±23 (maximum token length is 471). However, the entire text was used as the input in all tasks through the attention mechanism, and we set the attention head number $A = 128$. We set k to 1 in the kNN framework. We focused on the 1,173 pathway from Pathbank (DS et al., 2020) in our experiments.

For Text2Graph node classification, we randomly split the graph and description pairs into 75% training pairs and 25% test pairs. We sampled 10% nodes as the test node in each graph. In Text2Graph link prediction task, we varied the proportion of the test set (10%, 30%, 50%, 70%, 90%). We sampled 40% edges for each graph and the same number of edges from the complementary graph as the test edge. In link prediction and node classification, we only used GAT since it obtained the best performance in Graph2Text. We set the learning rate to 5e-4. We used Adam optimizer for all optimizations.

In Graph2Text task, we compared our methods to supervised graph neural network which jointly trains a graph neural network and a transformer. We denote them as **GNN (des.)**, **GNN (label)**,**GNN (des. + label)** and **GNN(structure only)** based on the node features used. In particular, **GNN (des.)** uses textual description as node feature. **GNN (label)** uses textual label as the node feature. **GNN (des. + label)** uses both textual label

and description as the node feature. We also compared to a k**NN-Transformer** model which trained a transformer using descriptions of similar graphs to the final description. Different GNN architectures are used to identify nearest neighbors in kNN based on the graph information.

5.2 Graph2Text

We sought to evaluate the performance of our method on the task of Graph2Text (**Figure 4a**, **Table 1**). Overall, we found that our method achieves the best performance on all metrics (0.296 BLEU-1 score, 0.230 METEOR, 2.2 NIST, and 0.244 ROGUE-L), demonstrating the effectiveness of jointly modeling graph structure, node description and node label. We first compared our method to graph neural network, which performed the first step of our framework and used concatenated node embeddings instead of single graph embedding as the input to Transformer. We observed substantial improvement over it on all three kinds of graph neural networks, indicating the importance of retraining using descriptions of similar graphs. We also observed that our method was better than kNN-Transformer, reflecting how our description-guided graph embeddings enhance the description generation.

To further understand the importance of each type of node feature, we evaluate the variants that only consider node description or node textual label (**Figure 4a**). We found that the performance of both variants dropped substantially, demonstrating the importance of both node textual label and node description. We further observed that the improvement of our method was consistent when using other graph neural network architectures, including GIN and GCN, demonstrating the robustness of our method. When replacing GAT to a multi-layer perception that cannot model the graph structure, the BLEU score of our method dropped substantially from 0.296 to 0.187, again confirming the necessity of considering the graph structure in this task.

5.3 Text2Graph

We next investigated the performance on the task of Text2Graph. Here, we studied two classic graph prediction tasks: link prediction and node classification. We summarized the performance of link prediction in **Figure 5a**. We obtained an average of 0.781 accuracy score across 8 different edge types, demonstrating an accurate prediction of the graph structure using the graph description. We further examined the effect of using the graph description in **Figure 4c** and observed that all 8 edge types had better F1 score when the graph description was used. We observed the same improvement of using the graph description when evaluated using the accuracy. We also performed the ablation study for the graph structure and observed similar improvement **Figure 4b**. These results collectively confirm that our method can generate the graph structure based on the graph description, offering biologists novel insights in pathway analysis.

We then studied the performance of node classification. We considered three most frequent node types in our dataset: macromolecule, multimer

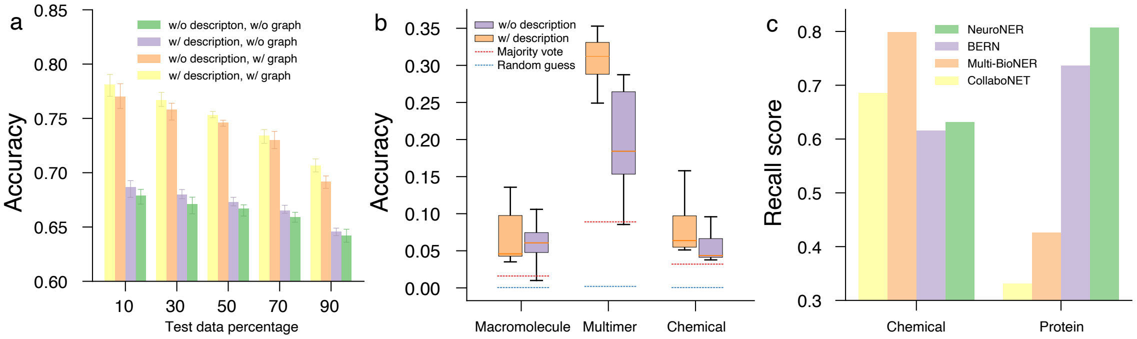

Figure 5: **Performance on Text2Graph link prediction, node classification and named entity recognition.** **a**, Bar plot showing the ablation studies on using the graph description and using the graph structure on link prediction. **b**, Box plot showing the comparison between using the graph description and without using the graph description on node classification. **c**, Bar plot showing the performance of named entity recognition on chemical and protein on our dataset.

and chemical. For each node type, we formed the node classification task as a multi-class classification problem, where each test node is classified into a specific class defined by the textual label. We noticed that each node type has a large number of classes. Therefore, we first evaluated two naive baselines: random guess and majority vote. Random guess obtained 0.0009 average accuracy, while majority vote obtained 0.046 average accuracy, suggesting a challenging classification task. Our method obtained a desirable classification performance, which was substantially higher than the performance of the variant that does not consider the graph description (**Figure 5b**). The improvement of using graph description on both node classification and link prediction further confirm that our dataset could be a promising benchmark for Text2Graph task.

6 Application to Named Entity Recognition

Named entity recognition (NER) is essential in detecting chemicals, genes, and diseases from biomedical text (Leaman et al., 2016; Luo et al., 2018; Kim et al., 2019; Yoon et al., 2019), and further facilitating downstream bioNLP applications, such as relation extraction(Xing et al., 2020). A major bottleneck in NER is the lack of curated benchmarks since such curation often requires substantial domain expertise. Our dataset Path2wayText can be used as a novel curated benchmark for NER.

Specifically, we used the graph description as the sentences that one wants to perform NER. We then obtained the ground truth entity type of phrases in these sentences according to their curated node types in the graph. Since the graphs, including all node types, are curated by domain experts, such node types can be used as the ground truth entity types for NER. Here, we focused on two most frequent entity types in our dataset: protein and chemical. We noticed that some phrases in the graph description sentences might also be a protein or chemical, even though they were not curated in the graph. We excluded such phrases in the evaluation in order to maintain the quality of our NER benchmark.

To this end, we obtained the graph-based curation of 8,779 protein entities and 1,621 chemical entities, offering a good complementary to existing biomedical NER datasets (Kim et al., 2003; Smith et al., 2008; Doğan et al., 2014; Krallinger et al., 2015; Li et al., 2016; Wei et al., 2018). To further investigate the performance of our novel NER datasets, we tested a few state-of-the-art biomedical NER methods, including BERN (Kim et al., 2019), CollaboNet (Yoon et al., 2019), Multi-BioNER (Wang et al., 2019), and NeuroNER (Dernoncourt et al., 2017). We observed that NeuroNER obtained the best performance on protein and Multi-BioNER achieved the best performance on Chemical (**Figure 5c**). Moreover, existing approaches only consider the graph description sentences when labelling entity types. In addition to graph description, our dataset also contains the corresponding graph structure, which has been shown to be critical in graph description generation in our experiments. Therefore, we hypothesize that graph structure might be also helpful in NER, and envision our dataset to be an important resource for benchmarking graph-based NER methods (Radford et al., 2015; Rijhwani et al., 2020; He et al., 2020; Nie et al., 2021).

7 Related Work

Graph2Text, which aims at generating a textual description for a structured graph, has attracted attentions in different applications. Existing Graph2Text datasets aims to generate text from RDF data (Gardent et al., 2017), knowledge graph (Koncel-Kedziorski et al., 2019; Jin et al., 2020; Cheng et al., 2020; Colas et al., 2021; Wang et al., 2021), street view map (Schumann and Riezler, 2021), Abstract Meaning Representation (AMR) (Banarescu et al., 2013; Marcheggiani and Perez-Beltrachini, 2018; Song et al., 2018; Ribeiro et al., 2019; Zhu et al., 2019; Hajdik et al., 2019; Damonte and Cohen, 2019; Mager et al., 2020; Zhang et al., 2020; Zhao et al., 2020; Fan and Gardent, 2020; Wang et al., 2020), terminology ontology (Liu et al., 2021) and graph-transduction grammars (Belz et al., 2011; Mille et al., 2019, 2020). Our dataset is the first Graph2Text dataset that focuses on biomedical pathway generation. In addition, our dataset has more complicated node features than many existing Graph2Text datasets, where each node in our dataset has a node type, a concise textual label and a detailed textual description.

Text2Graph can be viewed as an information extraction task, which aims at mining structured knowledge from free text. The datasets that are more relevant to our task could be generating a knowledge graph from long document (Kertkeidkachorn and Ichise, 2017; Bosselut et al., 2019; Kannan et al., 2020; Wu et al., 2020). Many of these existing datasets use automatic annotation to extract the graph information from corpus (Kertkeidkachorn and Ichise, 2017; Bosselut et al., 2019), which might introduce bias from the extraction method. In contrast, graphs in our dataset are either experimentally derived or manually curated, presenting a high-quality complementary to existing Text2Graph datasets.

8 Conclusion and Future work

We have presented a novel dataset Pathway2Text for biomedical pathway description generation. Our dataset contains 2,367 pairs of curated pathway and its associated description. To generated description for biomedical pathways, we have proposed a kNN-Graph2Text approach, which utilizes neighbor's description to enhance the text generation. We have extensively evaluated our method and observed substantial improvement in comparison to conventional graph neural network architectures. Furthermore, we have investigated the reverse task of Text2Graph and illustrated how our dataset can serve as a novel benchmark for biomedical NER.

In addition to Graph2Text, Text2Graph and NER, our dataset can also be used to investigate other important applications. For example, our dataset can be used as a relation extraction benchmark by regarding graph descriptions as sentences and graph edge types as the ground truth relation type. We can also use our dataset to study other graph-based tasks, such as generating node description given the graph structure and the graph description. Another interesting application is to identify the importance of each node in the graph, which has important applications in recommender system and social media. The order of mentions of each node in the graph description can be used to evaluate the node importance since the graph description often starts from the most important node.

From a methodological perspective, we plan to develop semi-supervised approaches to leverage many other biomedical pathways that currently do not have curated description. For example, we can train a Graph Transformer (Cai and Lam, 2020) on these unlabelled pathways and then fine-tune the model on pathways with graph description. We also want to explore other geometric embedding methods, such as hyperbolic embedding (Cvetkovski and Crovella, 2009) and spherical embedding (Meng et al., 2019, 2020), since biomedical pathways often form a hierarchical structure.

More importantly, our dataset could also open up new venues in biomedical research. Any computational biology tools that utilize biomedical pathways as features in their pipeline can exploit the graph description as additional features. For biomedical pathways that do not have the corresponding description, one can use the description generated by our kNN-Graph2Text as the feature. We envision this will substantially advance a wide range of biomedical research that involves pathway analysis, and our dataset will introduce other new text generation tools developed in the NLP community to broader audience in biomedicine.

A KGML Translation

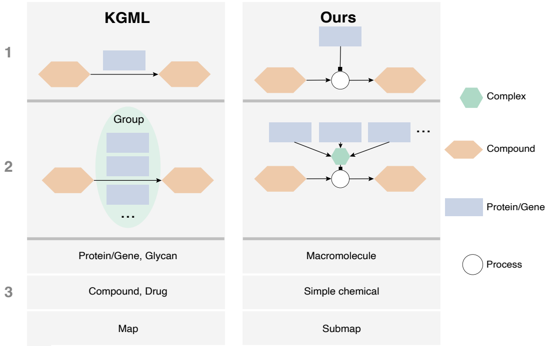

Figure 6: An illustration of KGML translation mentioned in Section 2.1. The first and second operations aim to unify the expression of reaction. The third operation aims to eliminate inconsistencies between node types. The Orthology nodes in KGML file are omitted during this translation.

B Data Format

Our dataset is stored in a JSON file. And the hierarchy structure is organized as follows:

```
{
    Graph identifier: {
        ”Name”: ,
        ”Graph_description”: ,
        ”Node_dict”: {
            Node identifier: {
                ”type”: ,
                ”label”: ,
                ”description”: .
            },
            ...
        },
        ”Arc_list”: [
            {
                ”arc_sourse”: ,
                ”arc_target”: ,
                ”arc_type”: .
            },
            ...
        ]
    },
    ...
}.
```

The node types include Submap, Macromolecule, Process, Complex, Multimer, Simple Chemical and Others. The Others is the union of several types occurring only in a single database (e.g., Unspecified Entity, Association in Reactome and Transport in Pathbank). Nodes in this type account for 7% over the whole dataset. The edge types include Catalysis, Consumption, Stimulation, Inhibition, Production, Logic Arc and Belong To, where the Belong To represents edges that were added for Complex node reconstruction mentioned in Section 2.1.

Exploring Neural Models for Query-Focused Summarization

Abstract

Query-focused summarization (QFS) aims to produce summaries that answer particular questions of interest, enabling greater user control and personalization. While recently released datasets, such as QMSum or AQuaMuSe, facilitate research efforts in QFS, the field lacks a comprehensive study of the broad space of applicable modeling methods. In this paper we conduct a systematic exploration of neural approaches to QFS, considering two general classes of methods: two-stage extractive-abstractive solutions and end-to-end models. Within those categories, we investigate existing models and explore strategies for transfer learning. We also present two modeling extensions that achieve state-of-the-art performance on the QMSum dataset, up to a margin of 3.38 ROUGE-1, 3.72 ROUGE-2, and 3.28 ROUGE-L when combined with transfer learning strategies. Results from human evaluation suggest that the best models produce more comprehensive and factually-consistent summaries compared to a baseline model. Code and checkpoints are made publicly available: `https://github.com/salesforce/query-focused-sum`.

1 Introduction

Text summarization aims at transforming long documents into short snippets that contain only the most important information from the source document. The field has seen substantial progress driven by the availability of large-scale models pre-trained on vast amounts of data (Devlin et al., 2019; Lewis et al., 2020), the development of summarization-specific pre-training strategies (Zhang et al., 2020; Zhao et al., 2020), and computationally efficient neural architectures (Zaheer et al., 2020).

The majority of recent research efforts in text summarization assume an unconstrained setting in which models are given only a source document as input and are expected to generate a general summary covering the salient aspects from the source. The performance of such models has been evaluated on benchmark datasets spanning various domains: news articles (Nallapati et al., 2016; Narayan et al., 2018; Fabbri et al., 2019a), legal documents (Sharma et al., 2019), scientific writing (Cohan et al., 2018), or creative writing (Kryściński et al., 2021; Chen et al., 2021). However, it has been shown that summarization in an unconstrained setting is an ill-defined task where multiple generated summaries are equally relevant (Kryscinski et al., 2019). This in turn hinders the ability to evaluate and understand the models' content selection capacity. In addition, such generic summarization models lack control mechanisms that would allow end users to customize summaries to their particular needs and expectations.

Query-focused summarization (QFS) is a subtask within text summarization that focuses on generating summaries where the summary content is tailored to a user-specified query that is passed alongside the source document as input to the model. Each source document can be associated with multiple unique queries inquiring about different information from that document. In this setting, end users are enabled to explicitly specify their preferences for the summary, and the relevance of the output summary may be evaluated more precisely with respect to the input query. Research on this task has been accelerated by the recently introduced high-quality datasets, such as QMSum (Zhong et al., 2021b) and AQuaMuSe (Kulkarni et al., 2020).

In this work we conduct a systematic, exploratory study of different approaches to query-focused text summarization, considering both two-step and end-to-end neural methods. We present two models, RELREG and SEGENC, which achieve state-of-the-art ROUGE scores on the QMSum dataset, up to a margin of 3.38 R-1, 3.72 R-2, and

---

3.28 R-L when combined with transfer learning methods. The RELREG model uses a two-step approach to solving the problem, where the first step extracts content relevant to the given query and the next step synthesizes the extracted fragments into a coherent summary. The SEGENC method follows an end-to-end framework in which individual document segments are separately encoded to avoid the computational bottleneck of long input documents, and the decoder jointly attends to all encoded segments when producing the summary. Through quantitative studies, we compare our models with other baselines and discuss the trade-offs of the end-to-end methods and pipelined approaches. We also perform human evaluation to understand the qualitative differences between the models. Together with this manuscript, we share the code base and model checkpoints to enable future research in this area.

2 Related Work

2.1 Query-Focused Summarization

Query-focused summarization aims to generate a summary of a given text conditioned upon a query. Initial work in this area centered around unsupervised extractive approaches (Wan et al., 2007; Litvak and Vanetik, 2017) due to the limited availability of task-specific training data (Dang, 2005). More recent work has taken advantage of the relationship between query-focused summarization and the more data-rich task of question answering for extractive summarization (Egonmwan et al., 2019), reranking documents within a retrieval pipeline (Su et al., 2020), and abstractive summarization (Su et al., 2021; Baumel et al., 2018; Xie et al., 2020). Xu and Lapata (2020) introduce a pipeline consisting of a relevance estimator filter followed by query-focused evidence and centrality estimators, while other work converts generic summarization dataset to query-focused training data (Xu and Lapata, 2021a) or performs latent query modeling (Xu and Lapata, 2021b).

Recently, several query-focused summarization datasets have been introduced, which can be further divided into short-document datasets, whose source document length does not exceed the input limits of standard pretrained models, and long-document datasets. Within short-document, query-focused summarization, AnswerSumm (Fabbri et al., 2021c) is composed of summaries of answers to queries from StackExchange forums, while WikiHowQA (Deng et al., 2020) proposes the task of answer selection followed by the summarization of individual response articles to queries from the how-to site WikiHow. Within long-document summarization, WikiSum (Liu et al., 2018a) consists of Wikipedia article titles as queries, the first paragraph of the article as the summary, and documents referenced by the article as the input. AQuaMuSe (Kulkarni et al., 2020) is a query-focused multi-document summarization dataset with user-written queries and human-verified long-answer summaries from the Natural Questions dataset (Kwiatkowski et al., 2019), and QMSum (Zhong et al., 2021b) is a manually-curated dataset for query-focused dialog summarization. QMSum and AQuaMuSe are of particular interest to our study due to the combined challenges of query-focused and long-document summarization and the presence of high-quality, curated query-summary pairs.

Recent work on QMSum has introduced task-specific denoising objectives for meeting summarization (Zhong et al., 2021a), generated final fine-grained summaries based on multiple coarse-grained steps (Zhang et al., 2021a), and treated the extractive text of an extractive-abstractive model as a latent variable (Mao et al., 2021). Zhang et al. (2021b) analyze the challenges of long dialogue summarization such as the input length, the role of queries, and domain adaptation. Our work builds on QA-motivated methods and presents two approaches yet to be applied in query-focused summarization that each achieve state-of-the-art results, including a two-step model and an end-to-end model.

2.2 Long Document Summarization

Long document summarization addresses the setting where source document length exceeds the input limits of standard pre-trained models. Approaches to this task can largely be divided into two categories: two-step extractive-abstractive frameworks, which first extract a subset of the text as input to an abstractive model, and end-to-end models, which process the input within a single model. The two-step pipeline has been applied to topic-focused Wikipedia summarization (Liu et al., 2018b; Liu and Lapata, 2019; Perez-Beltrachini et al., 2019), low-resource summarization (Bajaj et al., 2021), and single-document summarization Chen and Bansal (2018). End-to-end approaches address the input-length problem using sparse-attention models. Beltagy et al. (2020) introduce the Longformer, consisting of local attention as well as global attention between select input tokens. Other approaches make use of dynamic attention mechanisms (Zhao et al., 2020; Manakul and Gales, 2021; Cui and Hu, 2021), sliding window strategies (Liu and Chen, 2021), and other mechanisms to introduce sparsity into the model (Huang et al., 2021; Liu et al., 2021). Izacard and Grave (2021) concatenate the outputs of multiple encoders as input to a generator component for the task of open domain question answering. In our work we build on these models for query-focused summarization and perform extensive hyperparameter ablations, achieving state-of-the-art results over other two-step and end-to-end models.

3 Methodology

We present existing methods and propose modeling extensions to address the challenges of query-focused summarization.

3.1 Two-Step Approaches

Two-step approaches consist of an *extractor* model, which extracts parts of the source document relevant to the input query, and an *abstractor* model, which synthesizes the extracted segments into a final summary. We consider *score-and-rank* extractor models, which first score each source passage for relevance to the query and then rank the passages in descending order of relevance, with the concatenated and truncated results passed to the abstractor. In this work we present two types of scoring models: *single-encoder* models and *dual-encoder* models, which we describe below. All two-step approaches share the same abstractor, a BART-large model.

3.1.1 Single-Encoder Models

Single encoder models concatenate a query and source passage as input to the scoring function that produces the similarity score. Those models benefit from full cross-attention between query and passage, resulting in richer data representations.

MARGE (Xu and Lapata, 2021a) is a single-encoder, **Ma**sked **ROUGE** extractor that aims to improve upon low-resource query-focused summarization by synthesizing query-focused data from more resource rich, generic summarization datasets. This model is trained to predict the relevance of each passage in the source document with respect to a query, where the proxy for relevance is the ROUGE overlap between the passage and the reference summary. For training on generic summarization datasets, MARGE uses pseudo-queries that are created by masking content words in the reference summaries.

When performing inference using real queries, certain query words (e.g., wh-words) are masked to better align the queries to the pseudo-queries from the training process. Following Xu and Lapata (2021a), we apply MARGE trained for masked relevance prediction on Multi-News (Fabbri et al., 2019b) without training on our target dataset.

RELREG Motivated by the retrieval component of MARGE, we propose the RELREG (RELevance REGression) model, which trains a relevance prediction model directly on QFS data using the *original, non-masked* query. Like MARGE, this model is trained to predict the ROUGE overlap between a source passage and the reference summary, using only the passage and query as input. A single-encoder model jointly encodes the delimiter-separated query and passage, and the final layer of the model outputs the predicted relevance value.

3.1.2 Dual-Encoder Models

Dual-encoder models separately encode a query and source passage before calculating the cosine similarity between the embeddings to compute the relevance score. This class of models offers computational benefits, as passage embeddings may be precomputed and stored for a given input, while the single-encoder model must be run over all passages should a new query be introduced.

DPR (Karpukhin et al., 2020) is a dual-encoder model that separately encodes queries and passages into an embedding space optimized for calculating semantic similarity between the two, showing improved results over traditional vector-space models. We fine-tune a DPR extractor model directly on the target dataset. As opposed to other locators that optimize with respect to the continuous ROUGE overlap, DPR uses the ROUGE score between the passage and reference summary to identify binary positive and negative passages and optimizes the negative log likelihood of the positive passages.

RELREGTT (RELevance REGression Two Tower) is a more computationally-efficient version of RELREG that uses a dual-encoder architecture to predict ROUGE-based relevance scores. This model is implemented with a backbone architecture of Sentence-BERT (Reimers and Gurevych, 2019), using a shared-parameter encoder for each of the query and passage and a special token appended to each input that identifies it is as either query or passage, following the suggested best practices of Reimers and Gurevych (2019). The final output for the model is based on the inner product of the pooled embeddings for the query and passage.

3.2 End-to-End Approaches

Two-step pipelines depend on the strength of the retrieval component, and may still fail to capture all relevant content despite an ideal retriever, due to length limitations of the generation component. This motivates our experiments on end-to-end models that can incorporate longer input texts.

BART (Lewis et al., 2020) As a baseline end-to-end model, we consider BART, an encoder-decoder Transformer model pre-trained using a denoising objective. BART is composed of a bidirectional encoder module and an autoregressive decoder model that attends to the encoder's final layer outputs. Due to the quadratic memory complexity of the encoder's full self-attention mechanism, the model input size is limited to 1024 tokens. In our experiments, we prepare the input to BART by concatenating the query, a delimiter token, and the source document, and then truncating the combined text to the model's input size.

LED To circumvent the input size limitations of the BART model, we include the Longformer Encoder-Decoder (Beltagy et al., 2020) (LED) in our study LED replaces the quadratic self-attention mechanism of traditional Transformers with a memory-efficient version that combines local attention with sparse global attention. The architecture allowed us to run experiments with input sizes up to 16384 tokens. Based on insights from the original work on tuning the model to the QA task, we configure the global attention mechanism to span the entire query.

SEGENC We also consider a simpler form of sparse attention in the encoder based solely on windowed local attention, combining elements of LED with Fusion-in-Decoder (FiD) (Izacard and Grave, 2021), a model for open-domain question answering. In our Segment Encoder (SEGENC) model, the source document is split into fixed-length overlapping[1] segments, each of which is separately appended to the query and encoded using a standard Transformer model. Similar to FiD, these encodings are then concatenated into a single embedding sequence and passed to a decoder model that generates the summary. Since there is no cross-attention between the encoded segments, the attention mechanism scales linearly in the number of segments and hence the length of the source document. Nonetheless, the decoder can attend to all encoded segments jointly, enabling the encoder-decoder architecture to operate in an end-to-end fashion. This model is motivated by two hypotheses: 1) query-relevant sections within a source document are often small enough to be processed by standard Transformer models (e.g. 1024 tokens), and 2) each query-relevant section may be understood independently of other sections, removing the need for cross-attention between the segments.

3.3 Data

We analyze our methods on two high-quality query-focused, long-document datasets.

QMSum (Zhong et al., 2021b) is a query-focused dialogue summarization dataset consisting of 1,808 query-summary pairs over 232 meetings from product design, academic, and political committee meetings, all conducted in English. QMSum also includes additional annotations such as topic segmentations and highlighted text spans associated with reference summaries. We leverage the provided span annotations to run oracle experiments. We focus our analysis on QMSum due to the availability of prior work as points of comparison.

AQuaMuSe (Kulkarni et al., 2020) is a query-focused multi-document summarization dataset consisting of 5,519 query-long answer summary pairs from the Natural Questions question-answering dataset (Kwiatkowski et al., 2019) and associated input documents from the Common Crawl[2]. Input documents for the original dataset were selected based on embedding similarity with respect to the summary, and hyperparameters can be chosen to control the level of semantic overlap between the input document set and the summary. Data replication details are found in the Appendix. We use AQuaMuSe to examine the generalizability of our QMSum results.

---

[1] We use segments that are 50% overlapping, though other configurations may be considered.

3.4 Experiment Setup

Implementation Models were implemented using the PyTorch (Li et al., 2020) and Huggingface (Wolf et al., 2019) libraries. Model weights were initialized from pre-trained checkpoints available through the Huggingface Model Hub[3]. All BART models were based on the `facebook/bart-large` checkpoint, the LED-model was based on the `allenai/led-large-16384` checkpoint, which itself is based on `BART-large`.

Training & Inference Models were trained for 10 epochs with final checkpoints selected based on the average of ROUGE-$\{1, 2, L\}$ (*R-1*, *R-2*, *R-L*) scores achieved on the validation set. Gradient checkpointing (Chen et al., 2016) was used for the LED and SEGENC models to reduce the memory footprint. Model outputs were decoded using beam search with 4 beams. To ensure high consistency of results, all experiments in §4 were repeated 5 times with results averaged across runs.

Evaluation Models were automatically evaluated using the ROUGE-$\{1, 2, L\}$ metrics (Lin, 2004) included in the SummEval toolkit (Fabbri et al., 2021b). Models were also manually evaluated by hired human annotators. Annotators were hired through the Amazon Mechanical Turk platform. Workers were selected from English speaking countries and offered an hourly rate of approximately 12 USD. The study was conducted on 50 model generated examples chosen at random from the test set of QMSum.

4 Model Exploration

In this section, we first analyze the effects of model-specific architectural and hyperparameter choices on the performance of two-stage (§4.1) and end-to-end models (§4.2). Next, we study the task-specific knowledge transfer capabilities of different pre-training strategies in §4.3. Lastly, we conduct a final evaluation and comparison of all discussed models in §4.4. All experiments and analyses presented in this section were conducted on QMSum.

4.1 Two-Stage Approaches

For two-stage models, we first focus on evaluating the extractor component and comparing performance to baseline heuristics. We quantify extractor performance using two metrics: 1) lexical overlap between the extracted utterances and reference summaries, computed using R-1, R-2, and R-L metrics, 2) span overlap between the extracted and golden spans included with QMSum represented by Precision and Recall scores, with results shown in Table 1. In both cases, we first order utterances of the conversation according to the scores assigned by the extractor models, then concatenate the utterances and finally truncate the result to 1024 tokens (excluding the space reserved for the query) to mimic the input length limits of downstream abstractor models; we present those numbers as the *All* columns in the table. For the lexical overlap, we also show the scores for the best 1 (*Top-1*), 5 (*Top-5*), and 15 (*Top-15*) utterances.

The results show that the best-performing extractor model is RELREG closely followed by RELREGTT in the *Top-1* evaluation and DPR in the *Top-5*, *Top-15*, and *All* cases. We note that both the RELREG and RELREGTT models tend to select longer utterances than the other extractors; the regression-based training mirrors the ROUGE overlap score which favors longer, more informative utterances. However, despite their strong performance in extracting top-matching utterances, the results also expose a considerable gap between model-based approaches and human annotations when considering the entirety of extracted spans. This shows a promising topic for future work in this matter. We also notice that despite the simplicity of the LEAD heuristic, which extracts the first k utterances in their original order, it remains competitive with the data-driven extractor models when we consider the *All* case. An extended version of this study, which includes the lexical overlap between extracted spans and input queries is presented in Table 8 in the Appendix.

Next, we analyze how the performance of the extractor components carries over to the final summarization task. For the best-performing model, we additionally test the effect of varying the input segment size used during training and inference between 256 and 512 tokens. Validation-set results for all models are reported in Table 2.

We find that DPR slightly outperforms RELREGTT for dual-encoder models. Among single-encoder models, RELREG outperforms MARGE by over a full R-1 point, which may explained by RELREG using more direct supervision based on an in-domain query, rather than creating

---

Table 1: Performance of extractor models on the QMSum validation set. The left section presents the lexical overlap between the utterances retrieved by extractor models and the reference summaries, evaluated by means of ROUGE-1 (*R-1*), ROUGE-2 (*R-2*), and ROUGE-L (*R-L*) metrics. Segments of the section focus on the lexical overlap between the highest ranked 1 (Top-1), 5 (Top-5), 15 (Top-15) utterances, and all utterances truncated to a 1024 token limit (All). The table also includes the average word counts of all extracted utterances, denoted as $\bar{x}$. The right section shows the span overlap between the utterance spans retrieved by the extractor models and those collected from human annotators by the authors of QMSum. The performance is evaluated by means of *Precision* and *Recall* scores and uses the highest ranked utterances truncated to the limit of 1024 tokens.

Model	R-1	R-2	R-L

	16384	256	37.21	12.14	32.67
		512	**37.47**	**12.47**	**32.95**
		1024	36.30	11.71	32.01
SEGENC-D	16384	512	36.68	11.97	32.35

Table 3: Performance of end-to-end models on the QMSum validation set, across varying input and attention window sizes (in number of tokens). SEGENC-D is a variant of SEGENC in which the segments are *disjoint* rather than overlapping; this ablation was evaluated on the best-performing SEGENC hyperparameters.

synthetic queries from an external dataset using masking. We find that the single-encoder RELREG outperforms the best dual-encoder model; the cross-attention term in the single-encoder RELREG model allows it to better attend to the query when determining relevance. Intuitively, the ordering of results corresponds to the span overlap recall with the gold spans; the ability of the extractor to select produce high-recall rankings directly affects abstractor performance. We see that increasing the input segment length used in training and inference for RELREG improves at 256 tokens but decreases at 512 tokens, suggesting that a balance is found between including additional context for ranking versus enabling a greater number of shorter segments that may capture more diverse content from the source.

4.2 End-to-End Approaches

We explore hyperparameter choices for two end-to-end architectures described in §3.2: the Longformer Encoder-Decoder (LED) and Segment Encoder (SEGENC). For both models, we consider different choices for input size (4096, 8192, or 16384 tokens) and attention window size[4] (256, 512, or 1024 tokens). For SEGENC, we also consider two different segmentation strategies: overlapping segments (50% overlap) and disjoint segments. Validation set results for both models and a baseline BART model are reported in Table 3.

We notice that both the LED and SEGENC benefit from increasing the input size and perform best with the input limit set to 16,384 tokens. The optimal attention window for LED is 1024, while SEGENC performs best with an attention window

---

[4] For SEGENC, attention window size is equivalent to segment size.

Model	R-1	R-2	R-L
No Transfer	32.42	9.62	28.37
AnswerSumm	34.36	9.64	30.22
AQuaMuse	34.57	9.78	30.42
WikiHowQA	33.08	9.03	28.48
CNNDM	33.87	9.36	28.48
WikiSum	**34.73**	**9.80**	**30.54**

Table 4: QMSum validation-set performance of the end-to-end BART models first fine-tuned on related summarization tasks and then further fine-tuned on QMSum data. The model indicates the task first fine-tuned on, and input is truncated to 1024 tokens.

of 512 tokens. For SEGENC, using overlapping segments improves performance compared to using disjoint segments, suggesting that the additional context provided by the former approach is helpful for locating relevant content. The SEGENC model achieves the highest performance out of the end-to-end architectures with ROUGE scores of 37.47 *R-1*, 12.47 *R-2*, and 32.95 *R-L* on the validation set.

The results also highlight that while the LED model matches or slightly outperforms the BART baseline for higher maximum input and window sizes, it performs substantially worse than SEGENC. This observation is consistent with prior findings on the QMSum dataset (Zhang et al., 2021b). One possible explanation for the lower performance of LED relative to SEGENC is that LED must adapt its parameters for a global attention mechanism that is absent from the backbone BART encoder model, whereas SEGENC relies solely on local self-attention that is aligned with the backbone model. This may be particularly relevant to QMSum given its relatively small size.

Practitioners may wish to consider the computational cost and efficiency of various hyperparameter settings. Computational complexity increases with both input length and attention window size (since attention grows quadratically in attention-window size). Complexity is also greater with the overlapping segment strategy compared to the disjoint segment strategy for the SEGENC model, due to the greater number of resulting segments that are passed through the encoder and decoder modules.

4.3 Task-Specific Transfer

Having determined the best-performing models, we examine whether performance can be further improved by fine-tuning a model that has already been fine-tuned for a different summarization task. We conduct this study using the end-to-end BART on 1024 tokens, as this model is the backbone, albeit in varying ways, of both our two-step and end-to-end models. We test the transferring capabilities of models trained on the news summarization task from CNN/DailyMail (Nallapati et al., 2016), which performed best among non query-focused datasets in Zhang et al. (2021b). We also explore transferring from the previously-mentioned query- and topic-focused summarization tasks: AnswerSumm, AQuaMuSe, WikiHowQA, and WikiSum. We compare to fine-tuning from the original BART checkpoint, with results shown in Table 4.

Model	R-1	R-2	R-L
Baselines			
DYLE	*34.42*	*9.71*	*30.10*
SUMM^N	*34.03*	*9.28*	*29.48*
BART	31.87	9.08	27.50
BART-W	32.68	8.97	28.74
BART-W (Gold)	39.54	15.65	35.17
Two-stage			
DPR	32.28	9.73	28.34
RELREGTT	33.02	10.17	28.90
MARGE	31.99	8.97	27.93
RELREG	34.91	11.91	30.73
RELREG-W	**36.45**	**12.81**	**32.28**
End-to-end			
LED	34.18	10.32	29.95
SEGENC	37.05	13.03	32.62
SEGENC-W	**37.80**	**13.43**	**33.38**

Table 5: QMSum test-set performance of two-stage and end-to-end models that performed best on the validation set (Tables 2 and 3), including versions fine-tuned from the WikiSum-finetuned checkpoint (denoted by -*W*). Results reported in prior work are *italicized*. Also included is an extractive-oracle model that takes the gold spans (§3.3) as input.

We find that transferring from any of the tasks improves over no transfer in R-1 and R-L. Transferring from any of the constrained, query-focused tasks outperforms transferring from unconstrained news summarization. Furthermore, transferring from WikiSum outperforms transfer from other datasets, which aligns with other work that shows the generalizability of Wikipedia as a source of data for task transfer (Fabbri et al., 2021a).

4.4 Final Results
