Prompt and Pivot task based learning has emerged as a candidate solution for data-scarcity problems (Le Scao and Rush, 2021; Min et al., 2021; Liu et al., 2021a). The use of discrete (Gao et al., 2021; Schick and Schütze, 2021a,b,c) or continuous (Liu et al., 2021b) prompts allowed language models to perform significantly better on many text classification tasks. Closely related to our approach, several works make use of a high-resource supervised task such as Question Answering or entailment as pivot tasks (Yin et al., 2019, 2020; Wang et al., 2021; Sainz and Rigau, 2021; McCann et al., 2018). In the case of entailment, Dagan et al. (2006) converted QA data to entailment manually and Demszky et al. (2018) did it automatically. Other semantic tasks such as Named Entity Recognition, Relation Extraction and Semantic Role Labelling have also been reformulated as entailment by automatically converting data into the entailment format (White et al., 2017; Poliak et al., 2018a; Levy et al., 2017; Sainz et al., 2021).

Multi-task learning reformulates multiple tasks to a single and common task via prompting large pre-trained language models, leveraging multiple data sources to improve each task of interest. Such approaches have shown improvements in supervised (Subramanian et al., 2018; Raffel et al., 2020; Aribandi et al., 2022) and zero-shot scenarios (Sanh et al., 2022; Wei et al., 2021a). While using the language modelling task as a pivot shows strong performance with very large language models, it is not clear that smaller models can benefit from this strategy in the same way. Wei et al. (2021a) and Mishra et al. (2022) obtained contradictory results. In a similar way, Question Answering has been proposed as a pivot task for multi-task learning but without promising results (McCann et al., 2018). In this work, we explore multi-source learning, where datasets from different or similar tasks are used to build a model for the target task.

Event Argument Extraction is a sub-task of Event Extraction. The goal is to identify arguments or fillers for a specific slot (a.k.a., role) in an event template. This task has been largely explored on the Message Understanding Conference (MUC, Grishman and Sundheim (1996)) and later on Automatic Content Evaluation (ACE). ACE focused mainly on sentence level evaluation due to the difficulty of the task at the time. Recently, new benchmarks such as RAMS (Ebner et al., 2020) and WikiEvents have emerged with the aim of addressing document level information extraction similar to MUC. However, most of the interest is still focused on the sentence level.

EAE has been recently addressed by end-to-end event extraction models (Wadden et al., 2019; Lin et al., 2020; Li et al., 2021a), instead of treating it as an independent task (Du and Cardie, 2020a), as we do, or as a subtask in a pipeline (Lyu et al., 2021). Lately, with the recent paradigm shift **to prompt design learning** (Min et al., 2021), several works reformulated the task as a Question Answering problem (Li et al., 2020; Feng et al., 2020; Du and Cardie, 2020b; Liu et al., 2020; Wei et al., 2021b; Lyu et al., 2021; Sulem et al., 2022) or as a Constrained Text Generation problem (Chen et al., 2020; Du et al., 2021; Li et al., 2021b) using predefined prompts, questions or templates. We instead reformulate the task as a textual entailment problem.

3 Approach

In order to cast EAE as an entailment task, we verbalize event argument instances using a set of intuitive and linguistically motivated templates to capture the event argument roles, and then per-

---

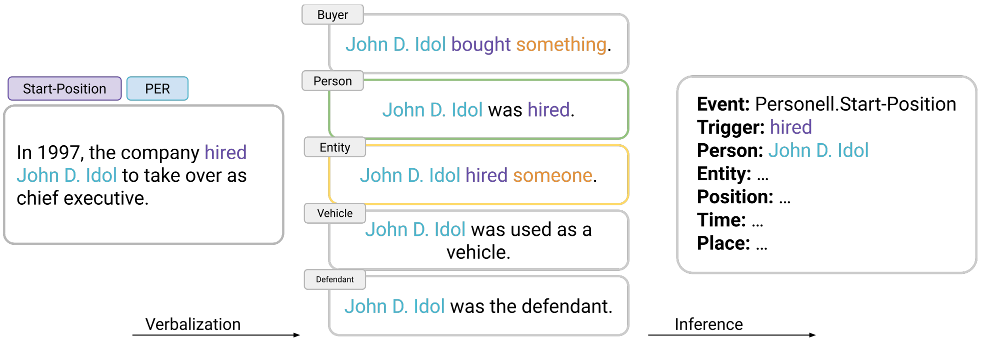

Figure 1: Entailment-based Event Argument Extraction. On the left, input information: the context, the event trigger (*hired*) and the argument candidate (*John D. Idol*), alongside the types of both. On the middle, some hypothesis verbalized using the templates: the green box is entailed, the yellow box matches the type constraint but it is not entailed, and the rest do not satisfy type constraints. On the right, the output with the inferred role (Person).

form inferences with entailment models. The entailment model can be additionally trained with EAE training data converted into the entailment format, similar to Sainz et al. (2021). Figure 1 shows the general workflow of the method. First, the possible roles are verbalized by means of predefined templates and the input, which comprises the context, trigger and argument candidate. Then, an entailment model is used to generate the entailment probability for each verbalization. To predict the role, the most probable hypothesis (verbalization) is chosen among the roles that satisfy the event-entity[3] constraints. A more detailed description of each component follows.

Label verbalization is attained using templates that combine the information of the instance and express a specific label. Different role verbalizations are shown in Figure 1. A verbalization is generated using templates that have been manually written based on the task guidelines of each dataset. The templates involve the candidate argument, and optionally the event trigger. In some cases, in order to produce a grammatical hypothesis, placeholders corresponding to the agent or theme are also introduced, which can be generic, e.g. *someone*, or dependent of the argument role, e.g. *defendant*. We defined several template types (see Table 1) to guide the creation of templates more systematically. In Section 5.1 we describe the process to create templates, and in Section 7 we analyse the differences between independent template developers and how this did not affect performance. The templates created for the ACE dataset are listed in Appendix C.

Entailment model. Given a premise and hypothesis, the model returns the probabilities of the hypothesis being entailed by, contradicted to or neutral to the premise. In principle, any model trained on the NLI task can be used.

Inference takes into account three key factors to output the role label for an argument candidate: the entailment probabilities of each verbalization, the type constraints of the specific role, and a threshold. Argument candidates which do not match the type constraints are discarded. From the rest, we return the role of the verbalized hypothesis with highest entailment probability, unless the probability is lower than the threshold, in which case we return the negative class.[4]

Training. Our entailment-based model can be applied without any training on the EAE task, in a zero-shot fashion, or, alternatively, the entailment model can be finetuned using training data from the EAE dataset. For this purpose, we convert the EAE training dataset into a NLI format, i.e we generate entailment, neutral and contradiction hypotheses heuristically from the data using the templates themselves. For each positive labeled example (a candidate that is an argument) we sample N_E entailment hypotheses using the templates that correspond to the correct label and N_N neutral hypotheses using templates from different roles. For each negative example (the candidate is not an argument of the event) we create N_C contradiction hypotheses using any template at random. N_E, N_N and N_C are considered hyperparameters of the training phase along with the hyperparameters of the neural network model such as learning-rate and

---

[3] In this context, entities also include values such as time or amounts.

[4] The class that represents that the argument candidate takes no part on the event.

Template type	Description	Example
{arg}	Templates with **implicit** information about the event. {arg} variable is the placeholder for the argument candidate.	The victim was {arg}.
{trg} → {arg}	Templates with **explicit** information about the event. The {trg} variable is the placeholder for the event trigger.	The {trg} occurred in {arg}.
{canonical(trg)} → {arg}	Templates with predefined canonical values for the {trg} variable.	{arg} was jailed.
{canonical(trg)}, placeholder → {arg}	Templates that makes use of agent or patient dummy placeholders in order to produce grammatical sentences.	The {arg} inspected something.

Table 1: The four main template categories used to create the role verbalizations.

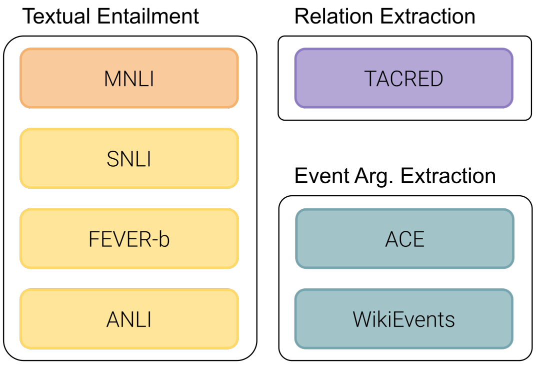

Figure 2: Datasets used by task category.

batch-size. In order to create challenging training examples for the negative class, we propose to use **constrained sampling**, based on the trigger-entity type constraints, where we create negative examples from candidates that satisfy the constraints. Preliminary experiments showed slight improvements with respect to regular sampling.

4 Entailment for Multi-source Learning

We hypothesize that two similar IE tasks can benefit from each other even if they do not share the same schema or domain. Although this hypothesis is very intuitive and it has been demonstrated on several works for tasks other than IE (see Multitask learning on Section 2), actual IE models are limited by schema dependency, which makes it almost impossible to learn from datasets annotated with different IE schemas. One option is to perform a manual mapping between schemas, which is costly and often inaccurate (Kalfoglou and Schorlemmer, 2003). Our approach instead is domain and schema agnostic, and therefore allows to learning from multiple sources seamlessly. Given that the sources are recast into a single format in a common entailment formulation, it suffices to fine-tune the model in sequence across the sources.

To check our hypothesis we split tasks according to the following criteria: (1) IE sources like Relation Extraction that are different from EAE (e.g. TACRED), and (2) EAE sources using different schemas (e.g. WikiEvents and ACE). Figure 2 summarizes the tasks and datasets used in this work, including the four natural language understanding datasets.

5 Experimental Setup

In this section, we describe the methodology for template development, evaluation setting, the baselines used in our experiments, and the computation infrastructure specifications.

5.1 Methodology for verbalization

The templates used to generate the verbalizations were created based on the annotation guidelines of each dataset. During the creation, the template developers had access to the guidelines that describe each of the roles (which can include one or two examples) and a NLI model that the developer could use to verify whether the generated verbalizations of these examples were entailed by the model. The developer was allowed a maximum of 15 minutes per role, and spent 5 and 12 hours[5] to create the templates for ACE and WikiEvents respectively.

5.2 Evaluation

Datasets. We carried out our evaluation on two different EAE datasets: ACE (Walker et al., 2006) and WikiEvents (Li et al., 2021b). The ACE2005 dataset is a sentence-level Event Extraction dataset that contains entities, relations, event-triggers and arguments annotations on English, Chinese and

---

[5] Given that there is a total of 22 and 59 role types respectively, this is equivalent to an average of 13 and 12 minutes per role.

	ACE		WikiEvents	
Train split	# Pos	Total	# Pos	Total
0%	-	-	-	-
1%	2.05	173	0.86	195
5%	11.36	843	4.09	966
10%	23.86	1736	8.26	1903
20%	45.00	3302	15.84	3578
100%	220.86	16502	79.68	18532

Table 2: Mean examples per role (pos) and total number of examples (positive and negative) across different training data splits and datasets.

Arabic texts. We worked only on the English EAE task. The WikiEvents dataset is instead more focused on document-level argument extraction task. Although the last is intended to be use as a document-level benchmark we focused on the sentence-level extraction[6] for two reasons: to maintain consistency with ACE dataset and because the nearest occurrence of the arguments are inside the sentence of the event trigger in almost all examples. For both ACE and WikiEvents, we split the training data into different amounts (0%, 1%, 5%, 10%, 20% and 100%) following Liu et al. (2020) to also evaluate our system on extreme data scarcity scenarios. Table 2 shows the amount of examples per split. The total amount refers to the addition of all positives and negatives trigger-candidate pairs.

Metrics. We have used the standard F1-Score, which is a common metric on IE tasks. Along with that, we propose the use of the Area Under the Curve (AUC) for better model comparison across all scenarios. The reported AUC scores are computed with all splits for the main results and just with 0%, 5% and 100% for the multi-source results, and therefore, they are not comparable.

5.3 Baselines and Models

Baselines. Our main point of comparison is our re-implementation of EM (Baldini Soares et al., 2019), as we can run it on the same few-shot splits as our system and allow for head-to-head comparison. EM is a state-of-the-art (Zhou and Chen, 2021) model that uses RoBERTa$_{\text{LARGE}}$ as a backbone. In addition we also report results of the state-of-the-art models that have been run on our same experimental setup, having access to gold event-trigger and entity annotations. On ACE, we report the results of BERTEE and RCEE_ER, both reported at (Liu et al., 2020), which correspond to a BERT (Devlin et al., 2019) based baseline and a QA based pivot approach that leverages SQuAD (Rajpurkar et al., 2016) data. Unfortunately the data splits used by (Liu et al., 2020) are not available[7] and thus, only the results for zero-shot (i.e. 0% training data) and full training (i.e. 100% training data) are directly comparable. Regarding WikiEvents Gen-Arg (Li et al., 2021b) uses gold triggers, but not gold entity information, so we decided to report Coref-F1[8] which refers to the F1-Score of predicting at least one of the gold entity coreferential chain as argument.

NLI models used in this work are based on the RoBERTa$_{\text{large}}$ (Liu et al., 2019) checkpoint, and are available via HuggingFace Transformer's model repository (Wolf et al., 2020). The main results use a model trained on all MNLI, SNLI, FEVER and ANLI, and in the analysis we also report the results of a model using just MNLI (see Appendix A for more information, including hyperparameters used).

5.4 Infrastructure

All the experiments were done in a **single** RTX 2080ti (11Gb) with a 250W power consumption. The average training times are:[9] 0.36h/epoch for ACE, 0.52h/epoch for WikiEvents and 2.86 h/epoch for TACRED. In total, 464.56 hours (154.86 if only a single run is done) of computation time are required to reproduce **all** the experiments, that in our setting corresponds to 21.36 kgCO$_2$eq carbon footprint[10] (roughly equivalent to the CO$_2$ emitted by 88.2 km driven by an average car).

6 Results

Main results. Table 3 reports our NLI system, including the median F1-Score and the standard deviation across 3 different runs of our implementations NLI and EM. On ACE our system is best on all comparable results and overall as shown by the AUC score. On the case of WikiEvents, our

system is the best in all cases. In both datasets the EM baseline is outperformed by the NLI system.

Multi-source results. Table 4 describes our multi-source learning results, where we use NLI+ to indicate systems that use additional sources for training. We report the median F1-Score across 3 runs for 0%, 5% and 100% scenarios and the corresponding AUC score on ACE and WikiEvents. The rows show the impact of transferring knowledge from the training part of different tasks (for more detailed per role analysis see Appendix B). The results show that the signal between EAE datasets (i.e. WikiEvents and ACE) is strong, yielding significant improvements in all scenarios. For instance, on zero-shot evaluation, the systems obtain the impressive scores of 62.7 and 57.3, close to 20 points of improvement.

Sequentially fine-tuning our NLI model in TACRED and then in our target task shows small improvements on low-resource scenarios (0% split for ACE, 0% and 5% splits for WikiEvents). Training on the three sources sequentially does not seem to yield further improvements.

Figure 3 shows the performance of our NLI and multi-source enhanced NLI+ systems along with the EM baseline (data from Tables 3 and 4). The curves show that our NLI+ systems only need 10% and 5% of the data (on ACE and WikiEvents, respectively) to outperform the EM baseline that uses 100% of the training data.

7 Analysis

After performing the main experiments we did some additional analysis.

The importance of using several NLI datasets. A perfect NLI model should, in theory, solve any task that is framed correctly as entailment. Of course, there is not "perfect" NLI model. In fact, current state-of-the-art NLI models tend to learn artifacts and lexical patterns (Gururangan et al., 2018; Poliak et al., 2018b; Tsuchiya, 2018; Glockner et al., 2018; Geva et al., 2019; McCoy et al.,

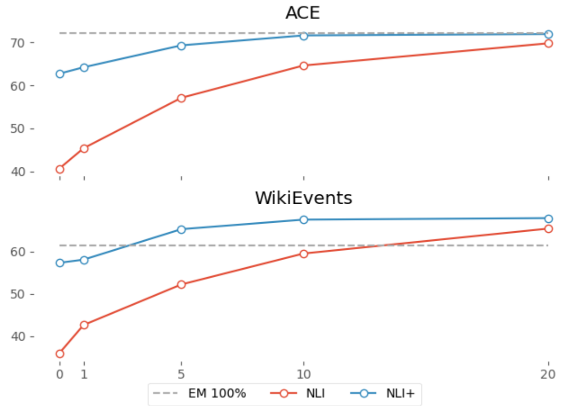

Figure 3: Comparison between the baseline EM model trained on 100% training, and our NLI and multi-source enhanced NLI+ models (NLI$_{+\text{ WikiEvents}}$ and NLI$_{+\text{ ACE}}$) with different training subsets.

Model $_{\text{source}}$	0%	5%	100%	AUC
		ACE		
NLI $_{\text{MNLI only}}$	31.4	46.0 ±0.55	62.8 ±2.83	53.6
NLI	**40.6**	**57.1** ±0.93	**74.6** ±0.88	**65.0**
		WikiEvents		
NLI $_{\text{MNLI only}}$	29.5	49.3 ±0.32	59.9 ±0.99	53.8
NLI	**35.9**	**52.2** ±1.40	**69.9** ±0.70	**60.2**
		TACRED		
NLI $_{\text{MNLI only}}$	55.6	64.1±0.20	71.0	67.2
NLI	**56.8**	**70.5**±0.62	**73.2**±0.65	**71.4**

Table 5: Ablation on NLI datasets used to-pretrain our NLI model on three datasets. NLI for our system using MNLI, FEVER, SNLI and ANLI (taken Table 3) and NLI $_{\text{MNLI only}}$ for our system when using MNLI only.

2019) instead of the task itself. Motivated by these issues, datasets like ANLI (Nie et al., 2020) were adversarially created to alleviate them. The lack of robustness of NLI models gets amplified when it comes to a cross-task evaluation. For instance, the model trained on MNLI achieves 90.2 accuracy on MNLI and 31.4, 29.5 and 55.6 F1-Score on ACE, WikiEvents and TACRED respectively (cf. Table 5). Adding FEVER, SNLI and ANLI to the training improves MNLI accuracy only 0.8 points to 91.0, but zero-shot scores on ACE, WikiEvents and TACRED improve +9.2, +6.4 and +1.2 respectively. In few-shot and full-training scenarios, the results also improve when using several NLI datasets. Our results suggest that new, more challenging NLI datasets, as well as NLI datasets automatically generated from other sources (as done in this work with WikiEvents and ACE) will yield more robust entailment models, and could further increase the performance of entailment-based EAE and IE.

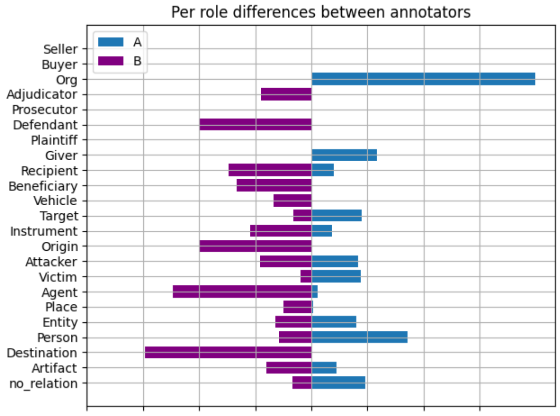

Figure 4: Recall differences between the main developer (A, right) and the linguist (B, left).

The impact of different template developers. In order to test the robustness of the templates, we enrolled a linguist with experience in NLP annotation but no prior contact with the project nor access to the original templates from the main developer. Under the same time and resource conditions, she was asked to write templates for the ACE dataset. The templates written by the main developer and the linguist vary in different ways: (1) the number of created templates per role and (2) the verbalization style, as the main developer tended to use finite and conjugated verbs while the linguist tended to use infinitives and lemmas. The templates of both are available in Appendix C.

To study the performance of the templates of each developer per role, Figure 4 shows the instances that a system correctly classified and the other system did not, and vice versa. The bars display the recall, as they are normalized by the frequencies of the roles. Missing bars on a row means that both performed the same on that role (e.g. Seller). When only a blue bar is shown (e.g. Org) it means that the main developer recovered arguments which the linguist did not, **and** there were no examples where the linguist recovered arguments that the developer did not. The same applies to situations where there is only purple bars. Roles with mixed results include examples where one or the other succeeded. As we can see, the approaches seem to be complementary, with the linguist having a higher recall with the roles that are more associated with classical semantic roles. Table 6 shows that in general, the templates of the linguist perform similarly to those of the main developer, except for 100% of the data, where the templates of the main developer were slightly better.

Developer	0%	1%	5%	10%	20%	100%
(A) Main	40.3	46.2	56.3	63.8	69.6	76.4
(B) Linguist	40.4	44.9	57.3	64.2	70.1	73.3
Δ F1	-0.1	+1.3	-1.0	-0.4	-0.5	+3.1

Table 6: Results for templates from two developers. Median F1 on the development set are reported.

Verbalizations vs. annotations Finally, we carried out an experiment to compare the time and effort requirements of annotation vs. writing the templates. To that end, the linguist re-annotated a small portion of ACE with the same information she had as she was creating the templates. That is, given the argument candidates for each event trigger in the document, she needs to decide whether the candidate was an argument and the type of the argument. She has access to the guidelines (similar to creating the templates), though she did not study them beforehand. Note also that she did the annotations **after** writing the templates, so she was already familiar with the slots. Under these conditions, she annotated 46 pairs (event trigger, potential argument candidate) in 30 minutes. Taking into account that ACE has 16.5000 such pairs, it would take approximately 180 hours to annotate ACE training part. Note that in practice, ACE requires much more time than our estimate to achieve the desired level of quality: the ACE annotation procedure involved double annotation and a second pass with a senior annotator (Doddington et al., 2004). For an analysis of the annotation procedure the interested reader is referred to Min and Grishman (2012).

Based on our estimation, 9 hours would allow an annotator to annotate 5% of the dataset which yields a 37.5 F1 (Figure 5), while 5 hours of template building yields 40.6 F1-Score in the zero-shot setting. With 18 hours 10% would be annotated and the F1-Score will be 50.9, while 5 hours of template building and 9 hours of annotations would yield 57. Figure 5 plots the performance according to manual hours on ACE, showing the huge gains provided by the initial 5 hours writing templates, plus the reuse of WikiEvents annotations. According to our experience, more hours on template building does not necessarily lead to improvements (contrary to annotation), so a **sweet spot for time investment** seems to be to firstly create templates, and then spend the remaining budget on annotating examples.

On another note, the linguist mentioned that writing templates is more natural and rewarding than annotating examples, which is more repetitive, stressful and tiresome. When writing templates, she was thinking in an abstract manner, trying to find generalizations, while she was paying attention to concrete cases when doing annotation.

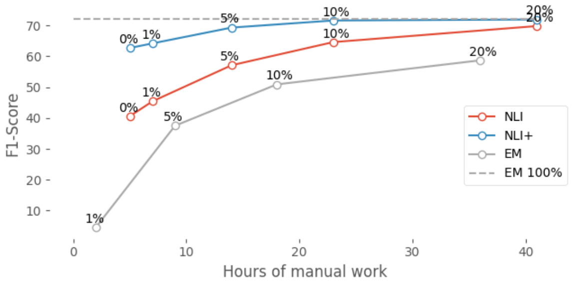

Figure 5: Performance on ACE according to our estimations of manual work in hours. We also indicate the percentage of training data used.

8 Conclusions

This paper shows the entailment-based approach for event argument extraction is extremely effective in zero-shot, few-shot and full train scenarios both on ACE and WikiEvents, outperforming previous methods. First of all, recasting EAE as an entailment task allows it to reuse annotations from different event schemas, achieving large gains when transferring annotations between ACE and WikiEvents, and also some gains in the zero-shot performance when transferring annotations from a relation extraction model such as TACRED. Secondly, we show that using additional training entailment datasets improves results significantly over just using MNLI, not only on EAE but also on TACRED. Thirdly, we show that the relatively short time spent writing manual templates is much more effective than the time spent on doing annotations, with a sweet spot where the annotation effort is split between the two, with large savings in manual labour. Lastly, we show that an independent linguist is able to write templates with comparable performance without any special training. We think that our results and analysis support the potential of entailment models for other NLP tasks.

Our work paves the way for a new paradigm for IE, where the expert defines the schema using natural language and directly runs those specifications, annotating a handful of examples in the process, and allowing for quick trial-and-error iterations. Sainz et al. (2022) propose a user interface alongside this paradigm. More generally, inference capability could be extended, acquired and applied from other tasks, in a research avenue where entailment and task performance improve in tandem.

Hyperparameter	EM	NLI	$\text{NLI}_{\text{MNLI only}}$
N_E / N_N / N_C	-	2 / 5 / 5	2 / 5 / 5
Batch size		32	
Learning rate	1×10^{-5}	4×10^{-6}	1×10^{-5}
Seeds		{0, 24, 42}	
Epochs		25 (*50)	
Weight decay		0.01	

Table 7: Hyperparameters of the trained systems. * indicates the difference between full-train and few-shot scenarios.

A Hyperparameters

On this section we describe the hyperparameters we have used on our experiments. All the hyperparameters optimized on this work were optimized for the 100% split with the batch-size fixed to 32, and used on the rest. The Table 7 describes the hyperparameters used on EM, NLI and $\text{NLI}_{\text{MNLI only}}$ variants, for the NLI+ the same hyperparameters as NLI were used. We have found that the same exact hyperparameters were the best on ACE, WikiEvents and TACRED datasets. For the future, we plan to test new hyperparameter sets that uses bigger batch-sizes, as recent works (Aribandi et al., 2022) suggest to be optimal for multi-task and -source learning experiments.

The pre-trained NLI models used on this work can be downloaded from the HuggingFace Models repository: NLI $_{\text{MNLI only}}$ (`roberta-large-mnli`) and NLI (`ynie/roberta-large-snli_mnli_fever_anli_R1_R2_R3-nli`).

The fine-tuned models derived from this work will be uploaded to HuggingFace Models repository. Check the GitHub repository for updated information.

B Multi-task in-depth analysis

The Figure 6 shows the per role absolute improvement obtained by training on different tasks over the 0% NLI system. Overall, we can see that training on ACE or WikiEvents improves almost all the roles and training on TACRED improves some and some others do not. A result that was unexpected is that there are few roles on WikiEvents that after training on WikiEvents become worse in contrary to training on ACE. This could be explained by the differences among the frequency distributions that the train, development and test sets of WikiEvents has. Moreover, there are some roles on WikiEvents that decreases in all training scenarios, this suggests us that sequential fine-tuning might be not the best option for this type of multi-source learning and therefore further ways should be explored.

C ACE templates from both developers

The next table contains the templates written by both developers for the ACE arguments. We follow the notation introduced in Section 5.1. In addition, we also consider information from the event, such as the type on different granularity levels, including `{trg_type}` for the trigger type (e.g. *Movement* from *Movement.Transport*) and `{trg_subtype}` for the subtype of the trigger, e.g. *Transport* from *Movement.Transport*).

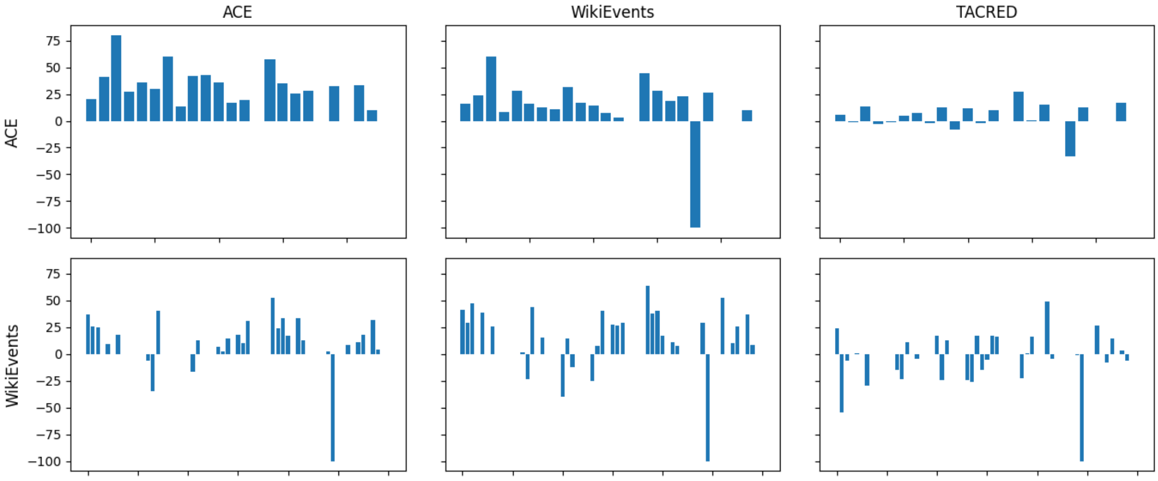

Figure 6: Absolute improvements over the NLI baseline using different tasks and sources. Rows indicates the testing data and columns the training data. Each bar indicates the F1-Score difference between the trained NLI system vs 0% NLI for a specific role.

RCL: Relation Contrastive Learning for Zero-Shot Relation Extraction

Shusen Wang, Bosen Zhang, Yajing Xu,[*] Yanan Wu, Bo Xiao
Pattern Recognition & Intelligent System Laboratory,

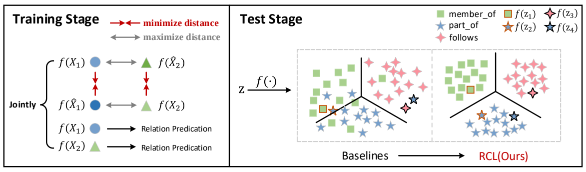
`{shusenw,zhangbosen,xyj,yanan.wu,xiaobo}@bupt.edu.cn`

Abstract

Zero-shot relation extraction aims to identify novel relations which cannot be observed at the training stage. However, it still faces some challenges since the unseen relations of instances are similar or the input sentences have similar entities, the unseen relation representations from different categories tend to overlap and lead to errors. In this paper, we propose a novel Relation Contrastive Learning framework (RCL) to mitigate above two types of similar problems: Similar Relations and Similar Entities. By jointly optimizing a contrastive instance loss with a relation classification loss on seen relations, RCL can learn subtle difference between instances and achieve better separation between different relation categories in the representation space simultaneously. Especially in contrastive instance learning, the dropout noise as data augmentation is adopted to amplify the semantic difference between similar instances without breaking relation representation, so as to promote model to learn more effective representations. Experiments conducted on two well-known datasets show that RCL can significantly outperform previous state-of-the-art methods. Moreover, if the seen relations are insufficient, RCL can also obtain comparable results with the model trained on the full training set, showing the robustness of our approach[1]

1 Introduction

Relation extraction is a fundamental problem in natural language processing, which aims to identify the semantic relation between a pair of entities mentioned in the text. Recent progress in supervised relation extraction has achieved great successes (Zeng et al., 2014; Zhou et al., 2016; Soares et al., 2019), but these approaches usually require large-scale labeled data. While in practice, human annotation is time-consuming and labor-intensive. To alleviate the human annotation efforts in relation extraction, some recent studies use distant supervision to generate labeled data for training (Mintz et al., 2009; Lin et al., 2016). However, in the real-world setting, the relations of instances are not always included in the training data, and existing supervised methods cannot well recognize unobserved relations due to weak generalization ability.



Error Type	Input Sentence	Ground Truth	Baseline Pred	RCL Pred(Ours)
Similar Relation	z_1 : In 1978, he replaced Thomas Erdelyi in the Ramones, assuming the name Marky Ramone.	member_of	member_of	member_of
	z_2 : The Doctor tries to restore the universe with the help of River and the alternative universe ve-rsions of his companions Amy Pond(Karen Gillan) and Rory Williams(Arthur Darvill).	part_of	member_of	part_of
Similar Entity	z_3 : In May 2015, Vienna hosted the Eurovision Song Contest following Austria 's victory in the 2014 contest.	follows	follows	follows
	z_4 : Thus, the song was succeeded as Romanian repre-sentative at the 2002 Contest by Monica Anghel & Marcel Pavel with "Tell Me Why".	part_of	follows	part_of

Figure 1: **Top:** Overview of the proposed RCL at the training and test stage. $f(\cdot)$ is a learnable projection function that projects the input sentence X_i to its corresponding relation representation $f(X_i)$. $f(\hat{X}_i)$ is the augmented view of $f(X_i)$ and Z is the whole test set. **Bottom:** Four examples at the test stage and their corresponding relation representations are shown in the right of Top. The entities are marked in orange.

To address the aforementioned limitations, zero-shot relation extraction has been proposed to extract relational facts where the target relations cannot be observed at the training stage. The challenge of zero-shot relation extraction models is how to learn effective representations based on seen relations at the training stage and well generalize to unseen relations at the test stage. Two studies (Levy et al., 2017; Obamuyide and Vlachos, 2018) treat zero-shot relation extraction as a different task (i.e., question answering and textual entailment), but they both need human annotation auxiliary information for input, i.e., pre-defining question templates and relation descriptions. ZS-BERT (Chen

and Li, 2021) predicts unseen relations with attribute representation learning. Despite promising improvements on directly predicting unseen relations, ZS-BERT still makes wrong predictions due to similar relations or similar entities. The same problem arises in supervised methods under the zero-shot settings.

As shown in Figure 1, there are two types of similar errors: **Similar Relations** and **Similar Entities**. For similar relations (see Z_1 and Z_2), existing methods predict wrongly results because the unseen relations possess similar semantics and data points belong to two relations in the representation space are overlapped. For similar entities (i.e., *2014 contest* and *2002 Contest*), since entities are the context of relation and relation representations are derived from entities, the relation representations containing similar entities are close (see $f(Z_3)$ and $f(Z_4)$) and baselines wrongly consider $f(Z_4)$ belongs to *follows* in the representation space, even if two unseen relations are not related. Recently, Instance-wise Contrastive Learning (Instance-CL) (He et al., 2020; Chen et al., 2020; Yan et al., 2021; Gao et al., 2021; Zhang et al., 2021) has achieved remarkable success in representation learning. Instance-CL is used to learn an effective representation by pulling together the instances from the same class, while pushing apart instances from different classes. Inspired by Instance-CL, we attempt to use Instance-CL on seen relations to learn the difference between similar relations and the divergence of relation representations derived from similar entities.

In this paper, we propose a novel Relation Contrastive Learning framework (RCL) to solve the above-mentioned problems. Figure 1 depicts the overview of the proposed model, which consists of four steps: (i) The input for RCL is a batch of sentences containing the pair of target entities and each sentence is sent into input sentence encoder to generate the contextual sentence embeddings[2]. (ii) Taking the sentence embeddings as input, relation augmentation layer is designed to obtain the relation representations $f(X_i)$ and their corresponding augmented views $f(\hat{X}_i)$. (iii) By jointly optimizing a contrastive loss and a relation classification loss on seen relations, RCL can learn subtle difference between instances and achieve better separation between relations in the representation space simultaneously to obtain an effective projection function f. (iv) With the learned f, the whole test set Z can be projected for unseen relation representations in the representation space and zero-shot prediction is performed on unseen relation representations by K-Means.

To summarize, the major contributions of our work are as follows: (i) We propose a novel framework based on contrastive learning for zero-shot relation extraction. It effectively mitigates two types of similar problems: similar relations and similar entities by learning representations jointly optimized with contrastive loss and classification loss. (ii) We explore various data augmentation strategies in relation augmentation to minimize semantic impact for contrastive instance learning and experimental results show dropout noise as minimal data augmentation can help RCL learn the difference between similar instances better. (iii) We conduct experiments on two well-known datasets. Experimental results show that RCL can advance state-of-the-art performance by a large margin. Besides, even if the number of seen relations is insufficient, RCL can also achieve comparable results with the model trained on the full training set.

2 Related Work

Relation Extraction. Relation extraction aims at extracting relation between entities within a given sentence. Many relation extraction methods (Qian et al., 2008; Zeng et al., 2014; Zhou et al., 2016) are supervised model. Recently, some studies focus on pre-training language model (Devlin et al., 2019; Liu et al., 2019; Lan et al., 2020) because of its powerful capability of semantic representation. Wu and He (2019) propose R-BERT that uses BERT to extract relation features and incorporates entity information to perform relation extraction. Soares et al. (2019) propose a relation representation learning method based on BERT and have shown promising results. However, these models require labeled data. Unsupervised relation extraction (Yu et al., 2017; Saha and Mausam, 2018; Stanovsky et al., 2018) can discover semantic relation feature from data without human annotations. One representative work is Open relation extraction. Wu et al. (2019) propose a novel model to learn a similarity metric of relations from labeled data, and identify unseen relations by transferring knowledge learned from seen relations. While OpenRE method can identify novel relation without annotations and external resources, it cannot effectively

---

[2] The words, "embeddings", and "representations", are used interchangeably throughout this paper.

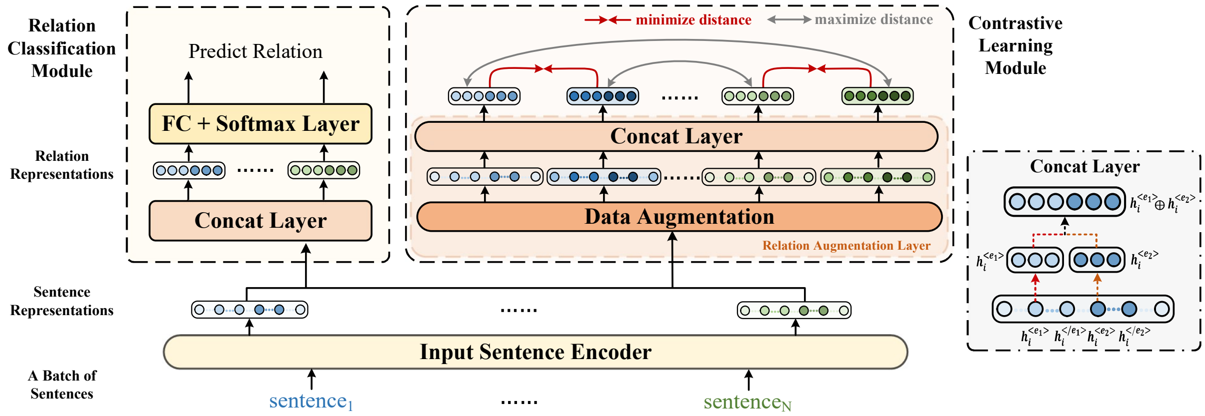

Figure 2: Architecture of the RCL, which consists of three components, and the details are introduced in Section 3. Note that relation augmentation layer contains data augmentation and a concat layer.

discard irrelevant information and severely suffers from the instability.

Zero-shot Relation Extraction. Zero-shot relation extraction aims to identify novel relation without training instances. Existing zero-shot relation extraction methods are few and most rely on human annotation auxiliary information for input. Levy et al. (2017) reduce zero-shot relation extraction to a question answering task. They use 10 predefining question templates to represent relations, and then train a reading comprehension model to infer which relation satisfies the given sentence and question. Obamuyide and Vlachos (2018) treat zero-shot relation extraction as a textual entailment task, which requires the model to input descriptions of relations. They train a textual entailment model to predict whether the input sentence containing two entities matches the description of a given relation, identifying novel relations by generalizing from the descriptions of seen relations at the training stage to those of unseen relations at test time. Chen and Li (2021) propose ZS-BERT to tackle zero-shot relation extraction task with attribute representation learning. ZS-BERT learns the representations of relations based on their descriptions during the training time, and generates the prediction of unseen relation for new sentence by nearest neighbor search. However, ZS-BERT suffers from similar relation error and similar entity error, and it needs human annotation auxiliary information for input, i.e., relation descriptions. In this paper, we do not require any human annotation auxiliary information for input.

Contrastive Learning. In the field of image and natural language processing, many recent successes are inspired by contrastive learning (He et al., 2020; Chen et al., 2020; Yan et al., 2021; Gao et al., 2021). Contrastive learning regards the input data and corresponding augmented views as an independent class. The goal of contrastive learning is to pull together representations from the same class, while keeping representations from different classes away. Therefore, the representations learned from contrastive learning are better separated and good for clustering. Gao et al. (2021) propose a novel sentence embeddings learning framework based on contrastive learning to produce superior sentence embeddings and show that dropout is an effective data augmentation. SCCL (Zhang et al., 2021) jointly optimizes a contrastive loss and a clustering loss to disperse overlap categories in the representation space. Inspired by contrastive learning, we leverage contrastive learning to help the model learn an effective representation.

3 Proposed Model

3.1 Model Overview

As illustrated in Figure 2, the proposed model RCL consists of three components: input sentence encoder, contrastive learning module and relation classification module. Given a batch of sentences containing two entities, the sentence representations are generated by input sentence encoder and then are sent to relation classification module and contrastive learning module. For contrastive learning module, the relation representations and their corresponding augmented views generated by a relation augmentation layer are used to perform contrastive instance learning to learn the difference between instances. For relation classification module, the relation representations generated by the concat layer are used to identify seen relations to achieve better separation between relations. We train RCL under a multi-task learning structure with contrastive learning module and relation classification module to learn effective representations for unseen relations. At the test stage, we obtain the unseen relation representations by the input sentence encoder and concat layer, and then send them into K-Means to predict the unseen relations.

3.2 Input Sentence Encoder

Input Sentence Encoder aims to generate the contextual representation of each token. In this work, we assume entities contained in the sentence have been recognized before input. For a sentence $X_i = [x_i^1, .., x_i^L]$ where two entities e_1 and e_2 are mentioned, we use the ENTITY MARKERS (Soares et al., 2019) to augment X_i to better extract relation features from context. Specifically, we introduce four special tokens to mark the beginning and the end of each entity mentioned in the sentence. The input token sequence X_i for input sentence encoder is as follows:

$$\begin{aligned} X_i = [x_i^1, \ldots, < e_1 >, x_i^k, \ldots, x_i^{l-1}, < /e_1 >, \\ \ldots, < e_2 >, x_i^p, \ldots, x_i^{z-1}, < /e_2 >, \ldots, x_i^L] \end{aligned} \tag{1}$$

where $< e_1 >, < /e_1 >, < e_2 >, < /e_2 >$ are four special tokens to mark the beginning and the end of each entity mentioned in the sentence, L is the length of sentence. Then we use BERT (Devlin et al., 2019) to obtain the sentence embeddings $\boldsymbol{h}_i \in \mathbb{R}^{L \times d}$:

$$\begin{aligned} \mathbf{h_i} = [\mathbf{h_i^1}, \ldots, \mathbf{h_i^{<e_1>}}, \ldots, \mathbf{h_i^{</e_1>}}, \\ \ldots, \mathbf{h_i^{<e_2>}}, \ldots, \mathbf{h_i^{</e_2>}}, \ldots, \mathbf{h_i^L}] \end{aligned} \tag{2}$$

where d is the hidden dimension.

3.3 Contrastive Learning Module

Contrastive Learning Module aims at learning the difference between a batch of instances to better represent relations.

Contrastive Instance Learning. After we obtained $\boldsymbol{H} = \{\boldsymbol{h}_1, \ldots, \boldsymbol{h}_N\}$ from N input sentences using input sentence encoder, relation augmentation layer is used to generate relation representations and their augmented views. More specifically, the relation augmentation layer consists of data augmentation and a concat layer. For each sentence embeddings $\boldsymbol{h}_i$, a transformation $T(\cdot)$ is applied to generate its augmented view: $\boldsymbol{\hat{h}_i} = T(\boldsymbol{h_i})$, where $\boldsymbol{\hat{h}_i} \in \mathbb{R}^{L \times d}$.

After obtaining sentence embeddings $\boldsymbol{h_i}$ and its augmentation $\boldsymbol{\hat{h}_i}$, we obtain relation representations and its augmentation by a concat layer. Specifically, we use the token embeddings corresponding to $< e_1 >, < e_2 >$ positions as the entity representation and concatenate them to derive a contextualized relation representation and its augmented view $\boldsymbol{r_i}, \boldsymbol{\hat{r}_i} \in \mathbb{R}^{2 \cdot d}$:

$$\begin{aligned} \mathbf{r_i} &= \mathbf{h_i^{<e_1>}} \oplus \mathbf{h_i^{<e_2>}} \\ \mathbf{\hat{r}_i} &= \mathbf{\hat{h}_i^{<e_1>}} \oplus \mathbf{\hat{h}_i^{<e_2>}} \end{aligned} \tag{3}$$

where $\oplus$ is the concatenation operator and $\boldsymbol{r_i}, \boldsymbol{\hat{r}_i}$ are both fixed-length vector.

To better learn effective relation representations, we optimizes a contrastive objective, which disperses different relation of instances apart while implicitly bringing the same relation of instances together. Let $\boldsymbol{R} = \{\boldsymbol{r_1}, \ldots, \boldsymbol{r_N}\}$ and $\boldsymbol{\hat{R}} = \{\boldsymbol{\hat{r}_1}, \ldots, \boldsymbol{\hat{r}_N}\}$ denote a mini-batch of relation representations and its augmented views respectively. We regard $(\boldsymbol{r_i}, \boldsymbol{\hat{r}_i})$ as a positive pair and other $N-1$ augmented views as negative instances. For a mini-batch with N pairs, we follow the contrastive framework in SimCSE (Gao et al., 2021) and take a cross-entropy objective with in-batch negatives (Chen et al., 2017). The training objective for $(\boldsymbol{r_i}, \boldsymbol{\hat{r}_i})$ is:

$$\ell_i^{cl} = -\log \frac{e^{\mathrm{sim}(\mathbf{r_i}, \mathbf{\hat{r}_i})/\tau}}{\sum_{j=1}^{N} e^{\mathrm{sim}\left(\mathbf{r_i}, \mathbf{\hat{r}_j}\right)/\tau}} \tag{4}$$

where $\boldsymbol{r_i} \in \boldsymbol{R}, \boldsymbol{\hat{r}_i} \in \boldsymbol{\hat{R}}$, $\mathrm{sim}\left(\mathbf{r_1}, \mathbf{r_2}\right)$ is the cosine similarity $\frac{\mathbf{r_1^\top r_2}}{\|\mathbf{r_1}\| \cdot \|\mathbf{r_2}\|}$,and τ is a temperature hyperparameter.

Data Augmentation Strategies. To amplify the semantic difference between similar instances without breaking the semantic of relation representations, we explore five different data augmentations $T(\cdot)$ for contrastive instance learning, including feature cutoff (Shen et al., 2020), random mask (Hinton et al., 2012), dropout (Gao et al., 2021), composition of dropout and feature cutoff and composition of dropout and random mask.

Feature cutoff is a simple and efficient data augmentation strategy to introduce minimal semantic impact for relation instances. Specifically, we randomly erase some feature dimensions in the sentence embeddings produced by input sentence encoder.

Random mask is proved its effectiveness as an augmentation strategy (Yan et al., 2021). In our experiments, we randomly drop elements in the sentence embeddings by a specific probability and sets their values to zero.

Dropout has been shown its effectiveness as minimal data augmentation by SimCSE (Gao et al., 2021). Thus, similar to SimCSE, we augment sentence embeddings by feeding the same input sentence to BERT again.

Composition of augmentations is an effective strategy in image domain (Chen et al., 2020). Based on dropout, we explore two strategies of composition of data augmentations. Composition of dropout and feature cutoff is a strategy that we first use dropout to obtain augmented view and then send it into feature cutoff to obtain the final augmented view. Similarly, composition of dropout and random mask is a strategy that dropout first and then random mask. We present the experimental results of these strategies and analyze their effects for contrastive learning in Section 4.4.

3.4 Relation Classification Module

Relation Classification Module aims to identify seen relations. With sentence embeddings $\boldsymbol{h_i}$ from input sentence encoder, we obtain relation representation $\boldsymbol{r_i}$ by the concat layer, following the way same as Equation (3). Let n denotes the number of seen relations and Y_s denotes the set of seen relations. By transforming the relation representation $\boldsymbol{r_i}$, along with a softmax layer, we generate the n-dimensional classification probability distribution of the i-th sample over seen relations:

$$p\left(y_i \mid X_i, \theta\right) = \operatorname{softmax}\left(W\left(\tanh\left(\mathbf{r_i}\right)\right) + b\right) \tag{5}$$

where X_i is the i-th input sentence containing two entities, $y_i \in Y_s$ is the seen relation, θ is the model parameter, $W \in \mathbb{R}^{n \times 2 \cdot d}$, and $b \in \mathbb{R}^n$. Note that we use the relation representation $\boldsymbol{r_i}$ produced intermediately for predicting unseen relations under the zero-shot settings instead of the probability distribution. For each data point X_i, we use cross-entropy to calculate classification loss:

$$\ell_i^{rc} = CrossEntropy(p(y_i \mid X_i, \theta), \hat{y}_i) \tag{6}$$

where $\hat{y}_i$ is the ground-truth label of the i-th sample.

3.5 Train and Test

At the training stage, We train the model with two objectives under the multi-task learning structure. The first is to minimize the distance between the relation representation and its augmented view, while keeping the relation representation distant from other augmented relation representations in a mini-batch. The second objective is to bring high prediction accuracy of seen relations. For a mini-batch of input sentences, the training objective of RCL is as follows:

$$\begin{aligned} &\mathcal{L}_{\text{CL}} = -\frac{1}{N}\sum_{i=1}^{N} \ell_i^{cl}, \mathcal{L}_{\text{RC}} = -\frac{1}{N}\sum_{i=1}^{N} \ell_i^{rc} \\ &\mathcal{L}_{\text{joint}} = \mathcal{L}_{\text{RC}} + \alpha \mathcal{L}_{\text{CL}} \end{aligned} \tag{7}$$

where N is the number of input sentences, α is a hyper-parameter to balance two objectives.

At the test stage, we send the new-coming sentences into the input sentence encoder and concat layer to generate unseen relation representations, and the prediction on unseen relations can be achieved by K-Means.

4 Experiments

4.1 Datasets

Two datasets are used to evaluate our model: SemEval2010 Task8 (Hendrickx et al., 2010) and FewRel (Han et al., 2018). **SemEval2010 Task8** has been widely used in relation extraction task, which contains 9 relations and an Other relation. There are 10,717 instances in the dataset and the number of instances of each relation is not equal. Each relation has direction in the dataset, but in our experiments, we do not consider the direction of 9 relations and not use the Other relation. For each relation, we combine the instances of training set with instances of test set to obtain overall instances of each relation. **FewRel** is a public dataset based on Wikipedia, and it contains 80 types of relations, each with 700 instances. Although FewRel is widely used in few-shot learning setting, it is also suitable for zero-shot learning as long as we disjoint the relation labels within training and test data. The statistics of the two datasets are shown in Appendix A.

4.2 Evaluation Settings

Zero-shot Learning Settings. Let m denotes the number of unseen relations, and Y_u denotes the set of unseen relations. We randomly select m relations as unseen relations and the rest of relations n as seen relations. Note that $Y_s \cap Y_u = \emptyset$. Then we split the whole dataset into training and test data. The training data only contains the instances of seen relations, in contrast to test data only with the instances of unseen relations. We repeat experiments 5 times on SemEval2010 Task8 and FewRel, and then report the average results. As for implementation details for RCL, we implement our model based on `Transformers` package[3] (Wolf et al., 2020). And we use an Adam optimizer (Kingma and Ba, 2014), in which the learning rate is 5e-5. Please refer to the Appendix B for more implementation details.

Evaluation Metrics. We follow the setting in the previous work (Simon et al., 2019) to convert pseudo labels predicted by clustering to relation labels. In each cluster, the relation label with the largest proportion among the cluster is assigned to all samples as the prediction label. For evaluation metrics, we adopt three commonly-used metrics (Wu et al., 2019; Hu et al., 2020; Zhang et al., 2021) to measure the effectiveness of clustering : B^3 (Bagga and Baldwin, 1998), Normalized Mutual Information (NMI) and Adjusted Rand Index (ARI). For B^3, B^3 precision and recall correspondingly measure the correct rate of putting each sentence in its cluster or clustering all samples into a single class. Then B^3 F_1 is computed as the harmonic mean of the B^3 precision and recall:

$$\mathrm{B}^3\text{precision} = \underset{X,Y}{\mathbb{E}} P(g(X) = g(Y) \mid c(X) = c(Y))$$
$$\mathrm{B}^3\text{recall} = \underset{X,Y}{\mathbb{E}} P(c(X) = c(Y) \mid g(X) = g(Y))$$

NMI measures the information shared between the predicted label and the ground truth. When data are partitioned perfectly, the NMI score is 1, while it becomes 0 when prediction and ground truth are independent. ARI is a metric to measure the degree of agreement between the cluster and golden distribution, which ranges in [-1,1]. The more consistent two distributions, the higher the score.

Baselines. We compare RCL to previous methods consisting of CNN (Zeng et al., 2014), Attention BiLSTM (Zhou et al., 2016), RSNs (Wu et al., 2019), MTB (Soares et al., 2019), ZS-BERT (Chen and Li, 2021). For CNN, Attention BiLSTM and MTB, these methods have great success in supervised relation extraction (SRE) but fail to perform zero-shot prediction. Specifically, we consider two variations of MTB which only differ in the backbone (MTB-BERT and MTB-RoBERTa). For fair comparison and zero-shot prediction, we make the relation representation from encoder become the output of the SRE model, instead of originally outputting a probability vector whose dimension is equal to the seen relations. The dimension of output vector is same as RCL. The K-Means is applied over output vector to generate zero-shot prediction. Although RSNs is a open relation extraction method, its Supervised RSN model also meets the setting of zero-shot. For ZS-BERT, the original relation descriptions are used for FewRel and we collect the descriptions of relations for SemEval2010 Task8 from open resources. Then we use the sentence embeddings for K-Means to predict unseen relations. Note that we set the dimension of sentence embeddings same as RCL for fair comparison.

4.3 Experimental Results

Results on SemEval2010 Task8. Table 1 show the comparison results on SemEval2010 Task8. RCL achieves the best performance, significantly outperforming the previous state-of-the-art with 22.31% F1, 27.79% NMI and 31.02% ARI improvements. Due to the relations of SemEval2010 Task8 dataset with high similarity, baseline models severely suffer from similar errors and the performances of baselines are poor. Another reason why baselines perform poorly is that small number of seen relations and class imbalance are more challenging for model. Moreover, SemEval2010 Task8 is much less related to the general domains on which the transformers are pretrained. However, comparing with baselines, experimental results show RCL can effectively mitigates similar problems and better use the general knowledge of the pre-training language model.

Results on FewRel. For FewRel, the experimental results are shown in Table 2. From the results, we observe that our model RCL outperforms existing baselines on FewRel when targeting at different numbers of unseen relations m. Specifically, RCL achieves an average of 2.87% F1, 1.98% NMI and 2.98% ARI improvements compared to previous best results. Since relations on FewRel are class balance and sufficient, MTB-BERT and MTB-

Table 2: Experimental results(%) produced by the baseline models and the proposed model RCL on FewRel dataset in terms of B^3 F-score, NMI, ARI. m is the number of unseen relations, and we vary m in [5, 10, 15, 30, 40] to examine how performance is affected. RCL w/o RC means RCL without relation classification module. In addition, we also report the standard F1 score results in Table 6.

RoBERTa perform well among competing models but their performance is still lower than RCL. The reason is that their approaches cannot well deal with similar problems. ZS-BERT performs worse than most competing models because ZS-BERT severely relies on the unseen relation descriptions for prediction, while our approach can perform well without external resources. In addition, we find that the improvement of RCL gets larger when m is larger, especially when $m = 40$. It is obvious that it becomes more difficult for prediction since the number of unseen relations increases leading to more seriously similar problems.

Ablation Study. To better validate our model, we conduct an ablation study on each module by correspondingly ablating one. Note that MTB-BERT is the version of RCL without contrastive learning module. From Table 1 and Table 2, we can see that combining these two modules can result in a noticeable performance gain over two datasets. Especially in SemEval2010 Task8, RCL w/o RC outperforms existing baselines by all evaluation metrics, which prove the effectiveness of contrastive learning. However, our proposed RCL significantly outperforms RCL w/o RC with 15.57% F1, 21.36% NMI and 25.74% ARI improvements. It demonstrates that these two modules are complementary on relation representation learning: contrastive learning focuses on learning the difference between instances and implicitly obtaining some knowledge about the difference between relations while relation classification can explicitly learn the difference between relations by identifying the relations but cannot learn the difference between similar instances and suffers from similar problems. When the number of unseen relations increases on FewRel, RCL w/o RC performs worse than competing methods due to without effectively learning relation difference, which also shows that both two modules are important to final model performance.

4.4 Qualitative Analysis

Effect of Data Augmentations. To study the effect of data augmentations, we consider six different data augmentation strategies for contrastive learning in our experiments, including None (i.e. doing nothing), Random Mask, Feature Cutoff, Dropout, Composition of Dropout and Feature Cutoff (Dropout+Feature Cutoff) and Composition of Dropout and Random Mask (Dropout+Random Mask).

The results are shown in Table 3. We can make the following observations: (a) Dropout is the most effective strategy, outperforming all competing strategies. It demonstrate that Dropout essentially acts as minimal data augmentation (Gao et al., 2021) and the noise produced by Dropout can make model learn the difference between similar instances better. (b) When compared with None, Random Mask and Feature Cutoff also improve performance across two datasets. Moreover, Dropout+Random Mask and Dropout+Feature Cutoff significantly outperform Random Mask and Feature Cutoff with roughly 6 and 2 points gain respectively while Dropout still outperforms these two composition of augmentations. It shows that different from the image domain (Chen et al., 2020), composition of augmentations is not always effective for the text domain. (c) We find that our model can improve performance on two datasets

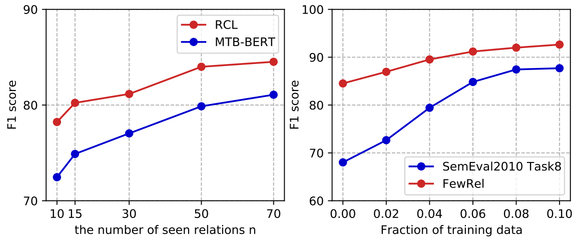

Figure 3: Left: The results of RCL and MTB-BERT with different numbers of seen relations. Right: The performance of RCL with different fractions of unseen instances available for training. The number of unseen relations is set to 10 on FewRel.

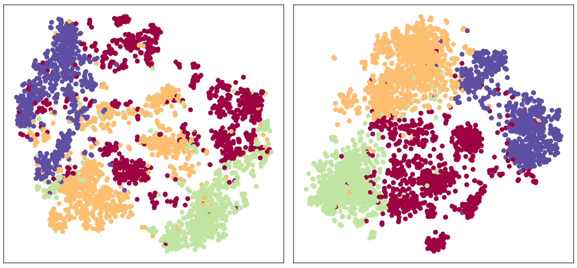
even without any data augmentation (None), especially for SemEval2010 Task8 (from 45.71 to 58.14). This is because None tunes the representation space by keeping each representation away from others, even if it has no effect on minimizing the distance between instance and its augmented view since the embeddings of augmented view are same with original instance. It also demonstrates that the effectiveness of the contrastive learning without external resources.

Effect of Number of Seen Relations. In this section, we study the effect of the number of seen relations on FewRel which contains sufficient relations. In our experiment, we vary the number of seen relations n from 10 (insufficient) to 70 (sufficient) and consistently set the number of unseen relations m to 10. Experimental results are presented in Figure 3. As the number of seen relations increases, RCL continuously outperforms MTB-BERT, which shows the effectiveness of our approach. More specifically, when n is set to 10, RCL can achieve 90% F1 score of the model trained on the full seen relations. In addition, the performance of RCL declines more slighter and smoother than MTB-BERT when seen relations gradually become insufficient (from 30 to 10), showing the robustness of our approach.

Capability under Few-shot Settings. In this section, we conduct the experiment of few-shot prediction by following the setting of Chen and Li (2021) to understand the capability of RCL. We move a small fraction of sentences of each unseen relation from test data to training data. Experimental results are shown in Figure 3. As expected on two datasets, RCL achieves more F1 score improvement with more unseen relation instances available at the training stage. When the fraction is set to 4%, RCL can achieve 90% F1 score on FewRel and 80% F1 score on SemEval2010 Task8. It shows the capability of few-shot learning for RCL.



(a) MTB-BERT

(b) RCL (ours)

Figure 4: t-SNE visualization of unseen relation representations learned by MTB-BERT and RCL on SemEval2010 Task8 dataset.

Visualization of Relation Representations. To intuitively show how our approach helps to learn better relation representations on seen relations, we visualize the representations of unseen relations by using t-SNE (Van der Maaten and Hinton, 2008) to reduce the dimension to 2. We randomly choose 4 relations as unseen relation from SemEval2010 Task8 and the visualization results are shown in Figure 4. In each figure, relation instances are colored according to their ground-truth labels.

As we can see from Figure 4(a), the data points from MTB-BERT are mingled with different clusters, especially for red points. The reason is these instances possess similar relations or similar entities, and MTB-BERT has not learned the corresponding knowledge to deal with similar problems. However, as illustrated in Figure 4(b), RCL effectively mitigates these two types of similar problems since our approach can learn the difference between instances and the difference between seen relations. It again exhibits the effectiveness of the contrastive loss and multi-task learning structure. We also provide a case study in the Appendix F.

5 Conclusion

In this paper, we propose a jointly framework for zero-shot relation extraction to mitigate two types of similar errors: Similar Relations and Similar Entities. Different from conventional zero-shot relation extraction models which require external resources for training and test, our model does not require external resources. We demonstrate the effectiveness of our framework on two datasets, and our method achieves new state-of-the-art performance. Furthermore, we compare various data augmentation strategies for contrastive learning and provide fine-grained analysis for interpreting how our approach works.

A Statistics of Datasets

The statistics of SemEval2010 Task8 and FewRel are shown in Table 4. For SemEval2010 Task8, we use 9 relations except the Other relaiton. Because of small number of relations, class imbalance and relations with high similarity, the experiment on SemEval2010 Task8 is more challenging and close to real world setting. For FewRel, we use the train and valid split but not test split, because the test split is not publicly available.

	#Instances	#Entities	#Relations	Avg.Len.
SemEval2010 Task8	10,717	7,984	10	18.84
FewRel	56,000	72,954	80	24.95

Table 4: Statistics of two datasets. "Avg.Len." means the average length of sentences.

B Implementation Details

We implement RCL based on `Transformers` package[4] (Wolf et al., 2020), where we use *Bert-base-uncased* as backbone. We set the maximum input length to 96 for SemEval2010 Task8 and 80 for FewRel. The epoch is set to 6 for training and we use an Adam optimizer (Kingma and Ba, 2014) with a batch size of 32. The learning rate is set to 5e-5 and the weight decay is set to 0.1. Same as SimCSE (Gao et al., 2021), the dropout probability of data augmentation is set to 0.1. The temperature τ is set to 0.05 across two datasets and we set α to 0.4 and 0.6 on SemEval2010 Task8 and FewRel respectively. The hidden size of fully-connected layer is set to 1536. All experiments are conducted by using a GeForce RTX 3090Ti with 24 GB memory.

C Standard F1 score Results on Two Datasets

To comprehensively compare the performance of baselines and our method, we report the standard F1 score results in Table 5 and Table 6. We follow the setting in the previous work (Simon et al., 2019) to convert pseudo labels predicted by clustering to relation labels. In each cluster, the relation label with the largest proportion among the cluster is assigned to all samples as the prediction label. From the standard F1 score results, we can see that the performance of our method is much better than the baselines, especially in SemEval2010 Task8. For FewRel, we find that the improvement of RCL gets larger when m is larger, especially when $m = 40$. It is obvious that it becomes more difficult for prediction since the number of unseen relations increases leading to more seriously similar problems. It proves that our method can effectively mitigates two types of similar problems.

SemEval2010 Task8			
Model	**P**	**R**	**F1**
CNN	46.83	48.53	47.52
Att-BiLSTM	47.46	51.87	49.41
Supervised RSN	32.87	40.12	36.07

D More Ablation Studies

The effects of hyper-parameters are shown in Table 7 and Table 8. For hyper-parameter α, we vary α in the list of [0.0, 0.2, 0.4, 0.6, 0.8, 1.0] and find RCL can achieve the best performance when α is set to 0.4 on SemEval2010 Task8 or 0.6 on Fewrel. For temperature hyper-parameter τ, we vary τ in the list of [0.001, 0.01, 0.05, 0.1, 1.0] and find $\tau = 0.05$ can achieve the best performance across two datasets.

E Different Clustering methods for Zero-shot Prediction

Figure 5 shows the results of different clustering methods for RCL, including Mini-Batch K-Means (Sculley, 2010), Gaussian Mixture Model

(GMM), Hierarchical Agglomerative Clustering (HAC), Birch (Zhang et al., 1996), K-Means. We can find that the performance of K-Means is much better than other clustering methods on two datasets. Moreover, Mini-Batch K-Means still outperforms MTB-BERT on SemEval2010 Task8, even its performance is worse than other clustering methods, showing the effectiveness of our model.

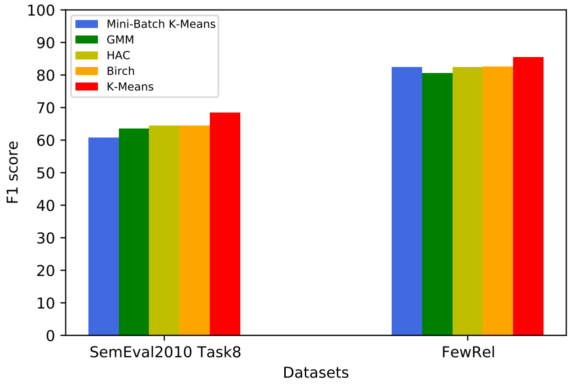

Figure 5: Different clustering methods for our proposed RCL model on two datasets. For FewRel, the number of unseen relations is set to 10.

F Case Study

To intuitively show how RCL helps to solve two types of similar problems (similar relations and similar entities), we conduct some case studies on two datasets. As shown in Figure 6, it is clear to see that RCL effectively solves these two problems under the multi-task learning structure. Specifically, RCL can better represent two sentences which have similar relations or similar entities, and then make their euclidean distance closer to the cluster corresponding to their ground truth.

Abstract

Multidomain and multilingual machine translation often rely on parameter sharing strategies, where large portions of the network are meant to capture the commonalities of the tasks at hand, while smaller parts are reserved to model the peculiarities of a language or a domain. In adapter-based approaches, these strategies are hardcoded in the network architecture, independent of the similarities between tasks. In this work, we propose a new method to better take advantage of these similarities, using a latent-variable model. We also develop new techniques to train this model end-to-end and report experimental results showing that the learned patterns are both meaningful and yield improved translation performance without any increase of the model size.

1 Introduction

Multidomain and multilingual machine translation aim to develop one single model to perform translation for multiple domains and multiple language pairs, respectively.[1] These paradigms are motivated by the compactness of the resulting translation system (Chu and Dabre, 2018; Dabre et al., 2020), the hypothetical positive knowledge transfer between similar domains (Pham et al., 2021) or between languages in the same family (Tan et al., 2019). However, having all the tasks use exactly the same model parameters can cause negative interference between unrelated tasks (Conneau et al., 2020; Wang et al., 2020b). Hence, the recent development of approaches relying on a partial sharing of the parameters, eg. using adapter layers as studied in (Houlsby et al., 2019; Bapna and Firat, 2019; Pham et al., 2020; Philip et al., 2020). If these techniques have proven effective for building strong baselines, they fail to fully take advantage of the similarities that exist between domains and tasks, as documented eg. in (Pham et al., 2021). This is because the partition of the parameter space between generic or task-specific subparts, and their allocation to each task, is hard-coded in the network, irrespective of the actual commonalties and differences in the data space.

In this work, we study and develop a new method, *multi-task group dropout*, aimed to take into account the similarity between tasks in a more effective way, by *learning the network organization from the data*. To this end, we introduce a set of latent variables in the model, to account for the unseen association between tasks and regions of the representation space and show how training can still be performed end-to-end using a variational surrogate of the log-likelihood loss function. Our experiments with multilingual and multidomain machine translation confirm that this method can automatically detect similarities in the data, meaning that related tasks use the same subparts of the network. Our results also show that this method is comparable to using adapter layers in a number of empirical comparisons; however, contrarily to adapters, these performance are obtained without any increase of the model size. Our contributions are primarily methodological and can be summarized as follows:

1. We introduce a novel, sound mathematical formulation to the problem of jointly learning task-dependent sub-networks and the parameters of the underlying models using variational probabilistic modeling techniques;
2. We present algorithms to train this model end-to-end with very little extra parameters;
3. We report, using an extensive set of experiments, gains for multidomain MT and very low-resourced languages in multilingual MT;
4. We study how this method can actually exploit the similarities between tasks to learn

---

[∗] Now Research Scientist at Zoom Video Communications

[1] We will refer to these two situations as 'multi-task MT' and refer to individual domains and languages as 'tasks'.

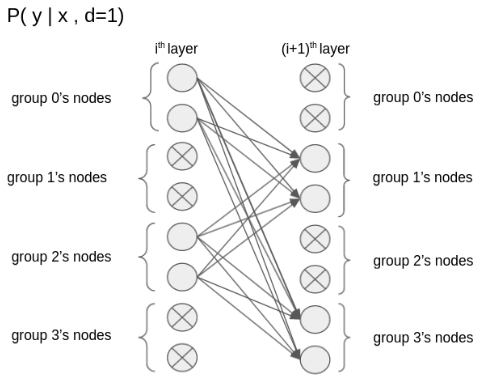

Figure 1: Latent group dropout. The set of nodes in each layer is divided into equal-sized groups. For each task, we only keep a fixed number of active groups of nodes and nullify all the other nodes.

interpretable sub-networks.

2 Multi-task group dropout

2.1 Network architecture, groups and layers

Many architectures for multitask learning are based on a matching of subset of model parameters with tasks. Given the task and the input instance, only a subpart of the network will be involved in the computation of the output value, based on a predefined association between subnetworks and tasks. The adapter architecture of (Bapna and Firat, 2019) illustrates this strategy, where a task-dependent set of layers is activated for each task.

In our approach, we also require to know the task $d \in [0 \dots n_d - 1]$ for each training and test instance. The structure of our Transformer networks (Vaswani et al., 2017) is however based on the notion of *groups of nodes in the computation graph*. At the input of each Transformer layer $l \in [1 \dots L]$, we partition all input state vectors into n_p groups of nodes, and zero-out a task-dependent subset of these groups. The assignment of tasks to groups will be learned from the data, under the constraint that each task only activates exactly k groups of *active nodes*, while the all the other values are nullified, akin to a dropout process (see Figure 1). Formally, a *group dropout mask* m_l^d is a n_p-dimensional binary vector containing exactly k ones: group p ($\in [0, \dots, n_p$-1]) is retained for task d if $m_l^d(p) = 1$ and is dropped if $m_l^d(p) = 0$. We denote $\Delta_k^{n_p} = \{m \in \{0,1\}^{n_p}$ such that $\mid m \mid_{L_1} = k\}$ the set of all admissible masks, with $\mid m \mid_{L_1}$ the L_1 norm of vector m; $\#\Delta_k^{n_p}$ is the cardinal of Δ^{n_p}.

Given m_l^d, the mask r_l^d for task d in layer l is then derived as:

$$r_l^d(i) = m_l^d(p) \quad \text{if} \quad p \times \frac{d_k}{n_p} \leqslant i < (p+1) \times \frac{d_k}{n_p},$$

where d_k is the dimension of the hidden state. The propagation of information within the network then depends on the current task value as follows:

$$\forall l \in [0, \cdots, L-1] : \tilde{h}^l = h^l \odot r_l^d,$$
$$h^{l+1} = \text{LAYER}^{l+1}(\tilde{h}^l),$$

where $\text{LAYER}^l()$ represents all the computations in Transformer layer l, $\odot$ is element-wise product. It is applied at all positions of each layer in the encoder and in the decoder.

2.2 Training with latent dropout masks

Assuming standard notation for our translation model $P(y|x,d;\theta)$ where x, y and θ respectively refer to the input, output, and parameter vector, the latent variables $m_l^d, l \in [0, \dots, L], d \in [0, \dots, n_d - 1]$ are introduced as follows. We chose the prior distribution for m_l^d as the uniform distribution over $\Delta_k^{n_p}$: $P(m_l^d|x,d;\theta) = \text{Unif}(\Delta_k^{n_p})$; variables for each layer are independent and collectively refered to as m^d. For any (variational) distribution $Q(m^1 \dots m^{n_d}; \Phi)$ with parameters $\Phi = \{\phi_l^1, ..., \phi_L^{n_d}\}$, it is well-known that the log-likelihood is lower-bounded by the so-called ELBO function (hereafter denoted ℓ), made of a summation of two terms: the *distortion* D and the *rate* R defined as follows:

$$\begin{aligned} \log P(y|x,d;\theta) \geq & \ell(x,y,d;\theta,\Phi) \\ \ell(x,y,d;\theta,\Phi) = & D(x,y,d;\theta,\Phi) - R(x,y,d;\theta,\Phi) \end{aligned} \tag{1}$$

$$\begin{aligned} D(x,y,d;\theta,\phi) = & \mathbb{E}_{m^d \sim Q(m^d|d,\Phi)} \log P(y|m^d,x,d;\theta) \\ R(x,y,d;\theta,\phi) = & \text{KL}(Q(m^d|d,\Phi)||P(m^d|x,d;\theta)), \end{aligned}$$

where KL is the Kullback-Leibler divergence. We use $-\ell(x,y,d;\theta,\Phi)$ as our surrogate training loss, as a tractable approximation of the likelihood, and try to minimize this function in θ and Φ.

The variational distribution Q of m^d is defined independently on a layerwise basis; this means that each layer only involves a subset Φ_l^d of variational parameters. Q is computed as follows:

$$\text{Ind}^d = \{i_1, \cdots, i_k\} \sim \text{SRS}(\text{softmax}(\Phi_l^d), k)$$
$$m_l^d(i) = \mathbb{I}(i \in \text{Ind}^d),$$

where $\text{SRS}(\pi, k)$ denotes the process of sampling k times without replacement from the distribution π, and $\mathbb{I}$ is the indicator function. This modeling choice for the latent vector m_l^d is motivated by the Gumbel Top-K trick of Kool et al. (2019) that we use below. Given our choices for the prior and the variational distributions, the two terms in Eq. (1) can be computed as:

$$\begin{aligned}D(\dots) &= \mathbb{E}_{m^d \sim Q(m^d|d;\Phi)} \log P(y|m^d, x, d, \theta) \\ &= \mathbb{E}_{g^d \sim^{\text{i.i.d}} G(0,1)} \left[\log P(y|\tilde{m}^d, x, d, \theta,)\right]\end{aligned}$$

where the generation process $G(0,1)$ is a product of independent Gumbel distributions, yielding:

$$\begin{aligned} \forall d, g^d &= [g_1^d, \dots, g_L^d], \text{ with } g_l^d \in \mathbb{R}^{n_p} \\ \forall p, g_l^d(p) &\overset{\text{i.i.d}}{\sim} \text{Gumbel}(0,1) \\ \text{Ind}^d = \{i_1, \cdots, i_k\} &= \text{Top-k} \, \{ \, g_l^d(0) + \Phi_l^d(0), \cdots, \\ &\quad g_l^d(n_p\text{-}1) + \Phi_l^d(n_p\text{-}1) \, \} \end{aligned} \tag{2}$$

$$\tilde{m}_l^d(p) = \mathbb{I}(p \in Ind^d).$$

For the second term, the derivation is the following:

$$\begin{aligned} R &= \text{KL}(Q(m^d|d,\Phi)||P(m^d|x,d;\theta)), \\ &= -\sum_{l=1}^{L} \left(\mathbb{H}\left[Q(m_l^d|d,\Phi)\right] - \log(\#\Delta_k^{n_p})\right) \\ &= -\sum_{l=1}^{L} \left(\mathbb{H}\left[Q(i_1,\cdots,i_k|d,\Phi)\right] - \log(\#\Delta_k^{n_p})\right) \\ &\leqslant -\sum_{l=1}^{L} \left(\mathbb{H}\left[Q(i_1|d,\Phi_l^d)\right] - \log(\#\Delta_k^{n_p})\right). \end{aligned} \tag{3}$$

We prove inequality (3) in Appendix B. This inequality shows that an upperbound of R is $\sum_{l=1}^{L}(\log(\#\Delta_k^{n_p}) - \mathbb{H}(\text{softmax}(\Phi_l^d)))$ since $i_1|\Phi_l^d \sim \text{softmax}(\Phi_l^d)$. During training, we thus maximize a sum over layers of the entropy $\mathbb{H}(\text{softmax}(\Phi_l^d))$ which performs a regularization over the parameters Φ^d of the variational distribution.

Thanks to the Gumbel Top-K trick, we can move the parameters Φ into the objective function and get rid of policy gradients, which have been reported to be very unstable (Kingma and Welling, 2014). However, the operator Top-k, which serves to define $\tilde{m}_l^d$ in Equation (2), is not differentiable. Therefore, we approximate this function by the Soft-Top-K function defined as follows:

$$\hat{m}_l^d(\tau) = \underset{\substack{0 \leqslant m_i \leqslant 1 \\ \forall 0 \leqslant i \leqslant n_d\text{-}1 \\ 1^T.m = k}}{argmin} \; -(g_l^d + \Phi_l^d)^T.m - \tau H_b(m) \tag{4}$$

in which

$$H_b(m) = -\sum_i m_i \log(m_i) + (1 - m_i)\log(1 - m_i).$$

In Appendix A, we prove that $\lim_{\tau \to 0} \hat{m}_l^d(\tau) = \tilde{m}_l^d$. Furthermore, we also provide the computation of $\hat{m}_l^d(\tau)$ and prove that $\hat{m}_l^d(\tau)$ is a differentiable function w.r.t Φ_l^d and that its gradients can be computed using the implicit differentiation theorem. During training, we approximate $\tilde{m}_l^d$ by $\hat{m}_l^d(\tau)$ by gradually decaying the hyper-parameter τ to 0.2. The gradient of D w.r.t Φ_l^d is computed using the chain rule as follows:

$$\frac{\partial D}{\partial \Phi_l^d} = \frac{\partial D}{\partial \hat{m}_l^d(\tau)} \times \frac{\partial \hat{m}_l^d(\tau)}{\partial \Phi_l^d}$$

The gradient $\frac{\partial D}{\partial \hat{m}_l^d(\tau)}$ is computed via autograd algorithm while $\frac{\partial \hat{m}_l^d(\tau)}{\partial \Phi_l^d}$ is computed via implicit differentiation, as explained in Appendix A.

We jointly train the Transformer parameters θ and the parameters of the variational distribution Φ using the following multi-task loss.

$$\mathscr{L}(\theta, \Phi) = \sum_{d=1}^{n_d} \mathbb{E}_{x \sim \mathscr{D}_s^d, y \sim MT^d(x)} \left[-\ell(x, y, d; \theta, \Phi)\right]$$

in which $\mathscr{D}_s^d$ is distribution of task d over the input space Ω_s^d; $\text{MT}^d : \Omega_s^d \to \Omega_t^d$ is the translation function for task d, which our multi-task model needs to learn; $-\ell(x, y, d, \theta, \Phi)$ is the ELBO loss, defined in Equation 1.

Finally, during inference, we define the dropout mask for layer l and task d as follows:

$$\begin{aligned} Ind_l^d &= \text{Top-k}(\Phi_l^d) \\ m_l^d &= \mathbb{I}(i \in Ind_l^d) \end{aligned}$$

meaning that we simply pick the k most likely parameter groups for the task at hand, and define the state dropout mask accordingly.

3 Experimental settings

3.1 System design and configuration

3.1.1 Multidomain translation systems

Our systems for the multidomain experiments are designed as follows:

- Transformer: The embedding dimension for both encoder and decoder is set as 512, and the feedforward dimension is 2048; the multi-head attention mechanism contains 8 heads; 6 layers in the encoder; 6 layers in the decoder.
- Adapter-based Transformer: the intermediate feedforward dimension is set to 2048, as in Pham et al. (2021).
- Transformer using Latent multi-task group dropout (`LaMGD` Transformers): There is no change in the architecture. We group the 512 nodes in each layer into 16 groups of 32 consecutive nodes. For each domain, only 12 out of the 16 groups are selected. The number

of parameters of the variational distribution is $L \times k \times L \times n_d$, which is negligible in comparison to the size of the Transformer model.

- Transformer using heuristic multi-task group dropout (`HMGD` Transformer): we share 320 nodes for every task, and reserve 32 nodes for each task (totalling $320 + 32 * 6 = 512$ nodes).

We set the dropout probability to 0.1. We train the multidomain Transformer model for 200k iterations with a batch size of 12k tokens using 4 V100 GPUs. The convergence of the standard Transformer is before 200K as its validation curve became flat near the 200K-th iteration. The `LaMGD` Transformer converged after 300k iterations with the same batch size. The convergence of `LaMGD` is controlled by its validation curve. Finally, we plug adapters to the multidomain Transformer model and finetune them for 25k iterations using the same batch size as the baseline.

3.1.2 Multilingual translation systems

The systems used in our multilingual experiments are implemented as follows:

- Multilingual Transformer: the embedding dimension for both encoder and decoder is set as 512, and the feedforward dimension is 1024, each multi-head attentions contains 8 heads as in (Wang et al., 2020a).
- Adapter based Transformer: the intermediate feedforward dimension is set as 128. We follow here the parameter setting of (Gong et al., 2021a).
- `LaMGD` Transformer: There is no change in the architecture. We group 512 nodes in each layer into 16 groups of 32 consecutive nodes. For each language, we select 12 groups.

We set the dropout probability to 0.3. We train the multilingual Transformer model for 40k iterations with a batch size of 9600 tokens on 16 V100 GPUs as in Gong et al. (2021a). We train `LaMGD` Transformer for 50k iterations with the same batch size. The convergence of the models are controlled via their validation curves. Finally, we finetune the language-specific Adapters for 5k iterations.

All the translation systems are implemented with OpenNMT-tf [2] (Klein et al., 2017).

3.1.3 Hyper-parameters

We choose $n_d = 16$ so that the size of the dropout group is neither too small nor too large. The second important hyper-parameter in `LaMGD` is the number of selected groups in each layer, k, which we set to 12 in every experiments. By retaining 12/16 groups, we share on average 75% active groups between two domains or languages. This design ensures that the percentage of sharing is in the same ballpark as what we obtain with adapter modules. In our future work, we intend to analyze how these choices affect the final performance of the model.

The temperature parameter τ for the Soft-Top-K operator is gradually decreased from 0.5 to 0.2 according to the following policy:

$$\tau = \min\{0.2, 0.5 * \exp^{-r*step}\},$$

in which $r = 0.0001$. While Gong et al. (2021b,a) fixed τ to be 0.2, we select an anneal policy for τ proposed by previous studies (Jang et al., 2017). Finally, we set the weight of the entropy term to 0.0001 in the training loss in every experiments.

3.1.4 Latent variables initialization

We initialize the distribution of the latent variables uniformly. More precisely, we set Φ_l^d, which generates the probability of the masks via the softmax activation function, to 0^{n_d}.

3.2 Datasets and metrics

3.2.1 Multidomain translation

We use the same data as in the recent work of Pham et al. (2021) on multidomain translation. The datasets [3] for the multidomain translation experiments are detailed in Table 1. For each domain, the size of the dev set and the test set is 1 K.

3.2.2 Multilingual translation

We evaluate our model on both one-to-many (O2M) and many-to-one (M2O) translation tasks borrowing the multilingual translation datasets from past studies. More precisely, we used:

- TED8-Related. Following the setting of Wang et al. (2020a), we use a subset of translations from Qi et al. (2018) between English and eight *related languages*.
- TED8-Diverse. The dataset consists of parallel sentences between English and eight *diverse languages* as in Wang et al. (2020a).

The languages used in the multilingual experiments are as follows (see statistics in Table 2):

- **Diverse set**: bos (Bosnian), Bulgarian (bul), French (fra), ell (Greek), hin (Hindi), Korean (kor) mkd (Macedonian), mar (Marathi);

For all experiments, we report the BLEU score of Papineni et al. (2002) computed with SacreBleu (Post, 2018). Statistical significance is computed with compare-mt[4] (Neubig et al., 2019). We report significant differences at the level of $p = 0.05$.

4 Results and analyses

4.1 Multidomain translation

For these experiments, our main results are in Table 3, where we observe that the LaMGD Transformer achieves a significant improvement (+2.78) over the generic Transformer system with zero extra parameters. Moreover, LaMGD Transformer achieves performance that are equivalent on average to that of the Adapter sytems, which is fine-tuned and contains approximately 25M additional parameters per domain. Variational mask learned from data by LaMGD also outperforms heuristic dropout mask HMGD by 0.5 in average.

4.1.1 Fuzzy domain separation

For this experiment, we reuse proposal of Pham et al. (2021), who measure the efficiency of a multidomain NMT system exploiting the proximity between domains. It uses the same data as in the previous experiment; however, the domain LAW is now randomly split into two pseudo-domains LAW_1 and LAW_2 of equal size. A truly multidomain system should be able to automatically detect the proximity between LAW_1 and LAW_2, and there should be no significant difference between the performance of a system trained with the six original domains (including LAW) or with the seven domains (including LAW by LAW_1 and LAW_2). Pham et al. (2021) reported a large gap between the two settings when using residual adapters. We replicated this setting and report the results obtained with the LaMGD Transformer system in Table 4.

The results in Table 4 show a performance decrease for the adapter-based system when training with two pseudo-domains LAW_1 and LAW_2. In contrast, the LaMGD model obtains very stable results. In Section 4.3, we show that our algorithm in fact computes the same sub-network for LAW_1 and LAW_2, that allows a full sharing of information between these two pseudo-domains.

4.2 Multilingual translation

Results for the multilingual experiments are in Table 5. The LaMGD Transformer achieves an improvement of 0.42, 0.33, 0.32 in average over the multilingual Transformer in the O2M-related, M2O-related, M2O-diverse conditions, respectively. Significant gains are observed for languages BEL, GLG (both direction), HIN and BOS (O2M direction) which are very low-resource languages in our sets. However, LaMGD Transformer is outperformed by the multilingual Transformer and language Adapters for the O2M-diverse condition.

4.3 Similarity between dropping masks

This section compares the sub-networks learnt for each domain or language pair by computing the average similarity between the corresponding dropout masks concatenated for all the layers of the underlying model. For the multidomain experiment, we analyze the case of pseud-domain separation reported in Section 4.1.1 in Figure 2a. We see that the sub-networks for LAW_1 and LAW_2 are identical, yielding a full sharing between the corresponding training sets. Furthermore, we observe a large distance between REL and the other domains, which is expected given that REL is quite distinct from the other domains. REL only share around 75% its active groups with other domains, as would be obtained by chance in our setting (see Section 3.1.3). In Figure 4, we visualize the domains using their dropping masks concatenated and mapped to a 2d

agonal in every column or every row.

We also plot the languages based on their dropout masks in Figure 3 using a 2d PCA projection.

4.4 Ablation study

We discuss here the choice of the hyper-parameters k, the number of activated nodes in each layer, and its impact on the sharing level between the tasks. Table 7 shows the variance of performance when the number of activated nodes is changed, and the sharing level between tasks decreases in consequence. In addition, we also report in this section the effect of not choosing the number of groups n_p, which is assigned to 16 in the comparison of `LaMGD` and the contrasting methods. We show that setting n_p to the layer's size, which means the group size is 1, has a very similar performance as choosing n_p heuristically.

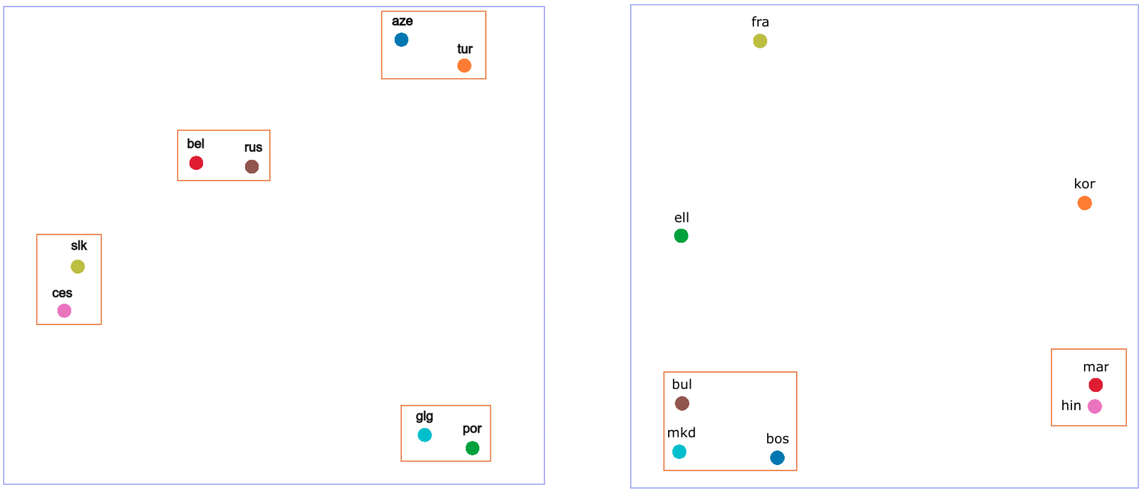
5 Related work

Multidomain and multilingual translation systems have received considerable attention in the recent years, and a exhaustive survey is beyond the goal of this paper. Domain adaptation for neural MT is surveyed in (Chu et al., 2017), while multidomain MT systems are notably studied in (Saunders, 2021; Pham et al., 2021); for multilingual MT, the reader is referred eg. to (Chu and Dabre, 2018; Dabre et al., 2020). We focus on the most relevant subset of this literature below.

Language similarity The methods developed by (Sen et al., 2019; Kong et al., 2021) use language proximity to design parameter sharing strategies. The authors propose a multi-decoder model sharing the same encoder among languages and routing languages in different families to different decoders. These approaches share the same interest in expressing the proximity between tasks in the selection of task-specific parameters as our approach. However, our method learn the selection from a latent commonality in data instead of using a predefined selection such as "One language family per decoder" in (Kong et al., 2021).

Language-specific sub-networks. Frankle and Carbin (2019); Liu et al. (2019) study techniques to identify the most important parameters for the current task, so that masking the less important parameters during training does not hurt performance. Lin et al. (2021) adapts this idea for multilingual NMT, trying to identify language dependent subsets of parameters by pruning a fine-tuned model. Our approach also aims to map sub-networks to tasks: we do so by masking the output of each layer, rather than masking parameters. Furthermore, Lin et al. (2021) computes the masks via a heuristic selection; while our approach learns the masks with variational techniques.

Sparse Transformer The idea of adaptive sparsity is studied in several works. For instance, Li et al. (2020) propose to use a variable depth for dif-



(a) TED-Related

(b) TED-Diverse

Figure 3: Visualization of languages according to their dropout masks (a large vector concatenating the dropping masks of all the layers of the model) constructed by PCA.

ferent tasks. The authors aimed to match the depth of the sub-network to the complexity of the task. Gong et al. (2021b,a) also take an interest in the adaptive sparse Transformers, in which differ each task triggers the selection of specific heads in multi-head attention, layers, and blocks in feedforward matrices. Mixture-of-experts (MoE) constitute another effective approach to achieve sparsity. Using the Transformer architecture, the GShard model replaces a single feedforward (FFN) sub-layer with an MoE module consisting of multiple FFN sub-layers (Lepikhin et al., 2021; Fedus et al., 2021).

Adapter modules Adapters have proven to be very efficient for multi-task NLP (Houlsby et al., 2019; Bapna and Firat, 2019; Pham et al., 2020; Pfeiffer et al., 2020). In a nutshell, this technique consists in plugging several so-called adapter modules to the intermediate layers of a pretrained Transformer and finetuning these adapters on the downstream tasks. Adapters can also be trained without supervision for multilingual translation (Philip et al., 2020). However, the hard-coded separation between the domains of different tasks may lead to a catastrophic forgetting effect (Pfeiffer et al., 2021), which is a common problem in multi-task modeling using neural networks (McCloskey and Cohen, 1989). In multidomain translation, Pham et al. (2021) recently demonstrated the brittleness of adapters against fuzzy domain separations, out-of-domain distributions, and erroneous domain tags. Several subsequent studies have aimed to mitigate this weakness through a mixture of expert mechanism (e.g. (Pfeiffer et al., 2021)).

Zhang et al. (2021) propose to learn to route between shared and language-specific representations with a conditional language-specific routing while training the parameters of the underlying Transformer. This method is related to the Fusion-Adapters of Pfeiffer et al. (2021). Both approaches aim to select between shared and task-specific representations. The proximity between tasks is not taken into account in the routing mechanism. We propose a different approach to the problem of multi-task routing in the underlying network.

6 Conclusions and outlook

In this work, we have presented a novel method for multdomain and multilingual translation. It allows us to jointly search for an optimal assignment of sub-networks to tasks and to learn the parameters of the underlying network. Our method relies on a sound mathematical framework and an end-to-end optimization procedure; it only adds a small number of extra parameters. The additional training cost is also reasonable, amounting to 100k iterations in the multidomain setting, given the observed gains in performance. Experimentally, we achieve a large improvement over a Transformer baseline; our performance are also comparable to that of a strong a multi-task baseline using residual adapter modules which rely on a large number of extra parameters. For multilingual translation, our model outperforms multilingual Transformer and Language Adapters in 3 our of 4 settings. LAMGD seems specially beneficial for training languages with little parallel data, which can take advantage of the resources that are available for related languages. Besides, we provided an thorough analysis of the similarities between learned sub-networks and demonstrate a strong correlation between the learned similarities and the proximity of the corresponding tasks (domain or language).

There are several ways in which our methodology can be improved. In future work, we would first like to provide an complete variational framework to model both the number of groups, k and the selection of the dropout masks. Second, we also intend to dispense with the domain information during inference: this would mean replacing the dependency on d in the variational distribution by a dependency on the input x. Another interesting direction will be to consider adapting the size and capacity allocated to each domain / language, depending on the difficulty of the associated translation task. Addressing these questions will allow to us replace heuristic choices in the architecture design with an increased dependency on the training data.

7 Ethical Considerations

MT technologies are generally intended to facilitate cross-lingual as well as cross-cultural communications. The methods presented here are notably interesting in the view to improve MT from and into English for low-resource languages, subject to the availability of data for a related language. We acknowledge that (a) our results should ultimately be backed-up large scale experiments involving much more languages – even though this goes against the idea of limiting the computing cost our experiments; (b) better architectures and training regimes can improve the translation quality for low-resource languages, yet will not solve the problem entirely. This means that additional work focusing specifically on developing resources for these languages should remain an important objective for future work.

A Appendix A

This section explains how to compute $\hat{m}_l^d(\tau)$ by solving the optimization problem (4) and then how to compute the gradients $\frac{\partial \hat{m}_l^d(\tau)}{\partial \Phi_l^d}$.

First, to solve (4) we follow the same approach as in (Amos et al., 2019; Amos and Yarats, 2020) by applying the Karush–Kuhn–Tucker (KKT) conditions to (4). The solution of (4) will have the following form:

$$\hat{m}_l^d(\tau) = \sigma\left(\frac{g_l^d + \Phi_l^d + \bar{v}}{\tau}\right) \tag{5}$$

in which $\sigma(.)$ is the sigmoid function and $\bar{v}$ is the solution of the following equation:

$$\sum_{i=1}^{n_p} \sigma\left(\frac{g_l^d(i) + \Phi_l^d(i) + v}{\tau}\right) = k \tag{6}$$

Because sigmoid is monotonically increasing, equation (6) has a unique solution. Furthermore, because of the smoothness of $g(v, \Phi_l^d) = \sum_{i=1}^{n_p} \sigma\left(\frac{g_l^d(i) + \Phi_l^d(i) + v}{\tau}\right)$ w.r.t v and Φ_l^d, we can perform the implicit differentiation of its solution $\bar{v}$ w.r.t Φ_l^d as below, even though the solution of (6) does not have an explicit form.

$$\frac{\partial g}{\partial \bar{v}} \times \frac{\partial \bar{v}}{\partial \Phi_l^d} + \frac{\partial g}{\partial \Phi_l^d} = 0$$
$$\Rightarrow \frac{\partial \bar{v}}{\partial \Phi_l^d} = -\left(\frac{\partial g}{\partial \bar{v}}\right)^{-1} \times \frac{\partial g}{\partial \Phi_l^d}$$

Because the differentiation of sigmoid has exact forms, $\frac{\partial g}{\partial v}$ and $\frac{\partial g}{\partial \Phi_l^d}$ also have exact form. Therefore, we do not need autograd to compute the implicit gradient $\frac{\partial v}{\partial \Phi_l^d}$. The gradient of $\hat{m}_l^d(\tau)$ w.r.t Φ_l^d is computed as follows:

$$\frac{\partial \hat{m}_l^d(\tau)}{\partial \Phi_l^d} = \frac{\partial \hat{m}_l^d(\tau)}{\partial v} \times \frac{\partial v}{\partial \Phi_l^d} + \frac{1}{\tau} \frac{exp\left(\frac{g_l^d(i)+\Phi_l^d(i)+v}{\tau}\right)}{\left(1+exp\left(\frac{g_l^d(i)+\Phi_l^d(i)+v}{\tau}\right)\right)^2} \tag{7}$$

In our algorithm, we solve (6) by binary search. The convergence of binary search is extremely fast and assured by the monotonicity of $g(v, \Phi_l^d)$. In our experiments, we set the search range to $[-100, 100]$.

Finally, we need prove that $\lim_{\tau \to 0} \hat{m}_l^d(\tau) = \tilde{m}_l^d$.

We assume $g_l^d(i_1)+\Phi_l^d(i_1) > g_l^d(i_2)+\Phi_l^d(i_2) > \cdots > g_l^d(i_{n_p})+\Phi_l^d(i_{n_p})$.

Because:

$$\lim_{\tau\to 0}\sigma(\frac{g_l^d(i)+\Phi_l^d(i)+\nu}{\tau}) = \\ = \begin{cases} 1, & \text{if } \tau > -(g_l^d(i)+\Phi_l^d(i)), \\ 0, & \text{if } \tau < -(g_l^d(i)+\Phi_l^d(i)), \\ \frac{1}{2} & \text{otherwise} \end{cases}$$

and

$$\sum_{i=1}^{n_p}\sigma(\frac{g_l^d(i)+\Phi_l^d(i)+\nu}{\tau}) = k$$

there exist ε such that $\forall\tau<\varepsilon$, the solution $\bar{\nu}$ of (6) satisfies $-(g_l^d(i_{k+1})+\Phi_l^d(i_{k+1})) > \bar{\nu} > -(g_l^d(i_k)+\Phi_l^d(i_k))$. Furthermore, because sigmoid is monotonically increasing,

$$\sigma(\frac{g_l^d(i)+\Phi_l^d(i)-(g_l^d(i_k)+\Phi_l^d(i_k))}{\tau}) < \hat{m}_l^d(\tau)(i) \\ < \sigma(\frac{g_l^d(i)+\Phi_l^d(i)-(g_l^d(i_{k+1})+\Phi_l^d(i_{k+1}))}{\tau})$$

By taking the limit on both sides, we get the following results:

$$\lim_{\tau\to 0}\hat{m}_l^d(\tau)(i_u) = \begin{cases} 1, & \text{if } u > k \\ 0, & \text{if } u < k \end{cases}$$

And, because $\sum_{u=1}^{n_p}\hat{m}_l^d(\tau)(i_u) = k$, by taking the limit on both sides, we will have $\lim_{\tau\to 0}\hat{m}_l^d(\tau)(i_k) = 1$. Finally, we have

$$\lim_{\tau\to 0}\hat{m}_l^d(\tau)(i_u) = \begin{cases} 1, & \text{if } u \geqslant k \\ 0, & \text{if } u < k \end{cases}$$

which is equivalent to $\lim_{\tau\to 0}\hat{m}_l^d(\tau) = \tilde{m}_l^d$.

B Appendix B

In this section, we give a simple proof of inequality (3). In fact, we only need to prove $\mathbb{H}\big[P(i_1,\cdots,i_k|\Phi_l^d)\big] \geqslant \mathbb{H}\big[P(i_1|\Phi_l^d)\big]$. The proof is as follows:

$$\mathbb{H}\big[P(i_1,\cdots,i_k|\Phi_l^d)\big] = -\mathop{\mathbb{E}}_{i_1,\cdots,i_k|\Phi_l^d}\big[\log P(i_1,\cdots,i_k|\Phi_l^d)\big]$$

$$= -\mathop{\mathbb{E}}_{i_1,\cdots,i_k|\Phi_l^d}\big[\sum_{j=2}^{k}\log P(i_j|i_1,\cdots,j_{j-1},\Phi_l^d)+\log P(i_1|\Phi_l^d)\big]$$

$$\geqslant -\mathop{\mathbb{E}}_{i_1,\cdots,i_k|\Phi_l^d}\big[\log P(i_1|\Phi_l^d)\big]$$

$$= -\mathop{\mathbb{E}}_{i_1|\Phi_l^d}\big[\log P(i_1|\Phi_l^d)\big] = \mathbb{H}\big[P(i_1|\Phi_l^d)\big]$$

Abstract

As Abstract Meaning Representation (AMR) implicitly involves compound semantic annotations, we hypothesize auxiliary tasks which are semantically or formally related can better enhance AMR parsing. We find that 1) Semantic role labeling (SRL) and dependency parsing (DP), would bring more performance gain than other tasks e.g. MT and summarization in the text-to-AMR transition even with much less data. 2) To make a better fit for AMR, data from auxiliary tasks should be properly "AMRized" to PseudoAMR before training. Knowledge from shallow level parsing tasks can be better transferred to AMR Parsing with structure transform. 3) Intermediate-task learning is a better paradigm to introduce auxiliary tasks to AMR parsing, compared to multitask learning. From an empirical perspective, we propose a principled method to involve auxiliary tasks to boost AMR parsing. Extensive experiments show that our method achieves new state-of-the-art performance on different benchmarks especially in topology-related scores. Code and models are released at `https://github.com/PKUnlp-icler/ATP`.

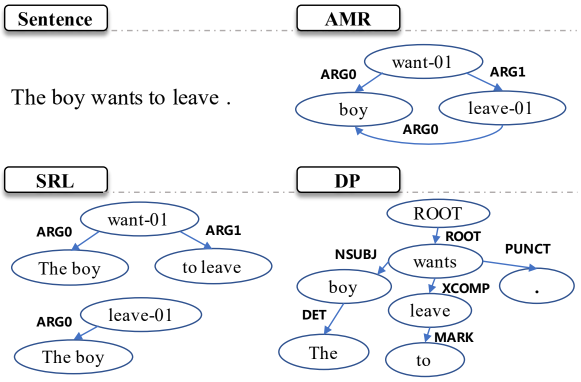

Figure 1: The Abstract Meaning Representation (AMR), Semantic Role Labeling (SRL), and Dependency Parsing (DP) structure of the sentence "The boy wants to leave."

1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) parsing aims to translate a sentence to a directed acyclic graph, which represents the relations among abstract concepts as shown in Figure 1. AMR can be applied to many downstream tasks, such as information extraction (Rao et al., 2017; Wang et al., 2017; Zhang and Ji, 2021), text summarization, (Liao et al., 2018; Hardy and Vlachos, 2018) question answering (Mitra and Baral, 2016; Sachan and Xing, 2016) and dialogue modeling (Bonial et al., 2020).

Recently, AMR Parsing with the sequence-to-sequence framework achieves most promising results (Xu et al., 2020; Bevilacqua et al., 2021). Comparing with transition-based or graph-based methods, sequence-to-sequence models do not require tedious data processing and is naturally compatible with auxiliary tasks (Xu et al., 2020) and powerful pretrained encoder-decoder models (Bevilacqua et al., 2021). Previous work (Xu et al., 2020; Wu et al., 2021) has shown that the performance of AMR parser can be effectively boosted through co-training with certain auxiliary tasks, e.g. Machine Translation or Dependency Parsing.

However, when introducing auxiliary tasks to enhance AMR parsing, we argue that three important issues still remain under-explored in the previous work. **1) How to choose auxiliary task?** The task selection is important since loosely related tasks may even impede the AMR parsing according to Damonte and Monti (2021). However, in literature there are no principles or consensus on how to choose the proper auxiliary tasks for AMR parsing. Though previous work achieves noticeable performance gain through multi-task learning, they do not provide explainable insights on why certain task outperforms others or in which aspects the auxiliary tasks benefit the AMR parser.

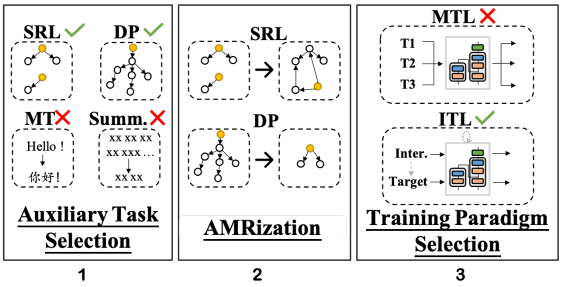

Figure 2: Illustration of methodology in this paper. We proposed a principled method to select, transform and train the auxiliary tasks.

2) How to bridge the gap between tasks ? The gaps between AMR parsing and auxiliary tasks are non-negligible. For example, Machine Translation generates text sequence while Dependency Parsing (DP) and Semantic Role Labeling (SRL) produces dependency trees and semantic role forests respectively as shown in Figure 1. Prior studies (Xu et al., 2020; Wu et al., 2021; Damonte and Monti, 2021) do not attach particular importance to the gap, which might lead the auxiliary tasks to *outlier-task* (Zhang and Yang, 2021; Cai et al., 2017) in the Multitask Learning, deteriorating the performance of AMR parsing. **3) How to introduce auxiliary tasks more effectively?** After investigating different training paradigms to combine the auxiliary task training with the major objective (AMR parsing), we figure out that, although all baseline models (Xu et al., 2020; Wu et al., 2021; Damonte and Monti, 2021) choose to jointly train the auxiliary tasks and AMR parsing with Multitask Learning (MTL), Intermediate-task Learning (ITL) is a more effective way to introduce the auxiliary tasks for pretrained models. Our observation is also consistent with (Pruksachatkun et al., 2020; Poth et al., 2021), which improve other NLP tasks with enhanced pretrained models.

In response to the above three issues, we summarize a principled method to select, transform and train the auxiliary tasks (Figure 2) to enhance AMR parsing from extensive experiments. **1) Auxiliary Task Selection**. We choose auxiliary tasks by estimating their similarities with AMR from the semantics and formality perspectives. AMR is recognized as a deep semantic parsing task which encompasses multiple semantic annotations, e.g. semantic roles, name entities and co-references. As a direct semantic-level sub-task of AMR parsing, we select SRL as one auxiliary task. Traditionally, formal semantics views syntactic parsing a precursor to semantic parsing, leading to the mapping between syntactic and semantic relations. Hence we introduce dependency parsing, a syntactic parsing task as another auxiliary task. **2) AMRization.** Despite being highly related, the output formats of SRL, DP and AMR are distinct from each other. To this end, we introduce transformation rules to "AMRize" SRL and DP to PseudoAMR, intimating the feature of AMR. Specifically, through *Reentrancy Restoration* we transform the structure of SRL to a graph and restore the reentrancy within arguments, which mimics AMR structure. Through *Redundant Relation Removal* we conduct transformation in dependency trees and remove relations that are far from semantic relations in AMR graph. **3) Training Paradigm Selection.** We find that ITL makes a better fit for AMR parsing than MTL since it allows model progressively transit to the target task instead of learning all tasks simultaneously, which benefits knowledge transfer (Zhang and Yang, 2021).

We summarize our contributions as follows:

1. Semantically or formally related tasks, e.g., SRL and DP, are better auxiliary tasks for AMR parsing compared with distantly related tasks, e.g. machine translation and machine reading comprehension.

2. We propose task-specific rules to AMRize the structured data to PseudoAMR. SRL and DP with properly transformed output format further improve AMR parsing.

3. ITL outperforms classic MTL methods when introducing auxiliary tasks to AMR Parsing. We show that ITL derives a steadier and better converging process during training.

Extensive experiments show that our method (PseudoAMR + ITL) achieves the new state-of-the-art of single model on in-distribution (85.2 Smatch score on AMR 2.0, 83.9 on AMR 3.0), out-of-distribution benchmarks. Specifically we observe that AMR parser gains larger improvement on the SRL(+3.3), Reentrancy(+3.1) and NER(+2.0) metrics*, due to higher resemblance with the selected auxiliary tasks.

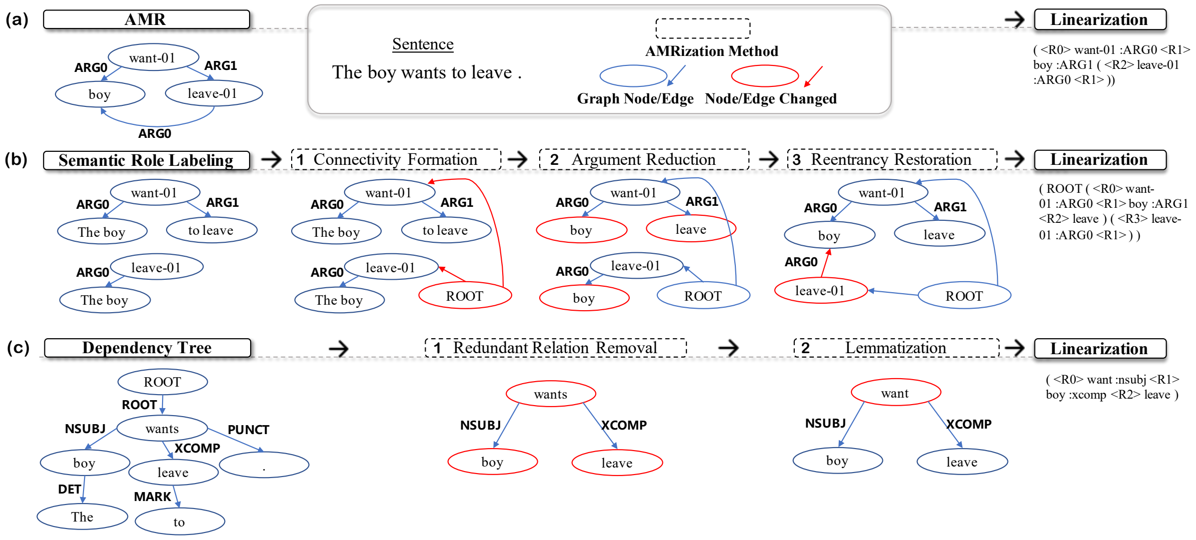

Figure 3: Illustration of AMRization methods and Graph Linearization. The source sentence is “The boy wants to leave."

2 Methodology

As shown in Figure 2, in this paper, we propose a principled method to select auxiliary tasks (Section 2.1), AMRize them into PseudoAMR (Section 2.2) and train PseudoAMR and AMR effectively (Section 2.3) to boost AMR parsing. We formulate both PseudoAMR and AMR parsing as the sequence-to-sequence generation problem. Given a sentence $x = [x_i]_{1 \leq i \leq N}$, the model aims to generate a linearized PseudoAMR or AMR graph $y = [y_i]_{1 \leq i \leq M}$ (the right part of Figure 3) with a product of conditional probability:

$$P(y|x) = \prod_{i=1}^{M} p(y_i|(y_1, y_2, ..., y_{i-1}), x)$$

2.1 Auxiliary Task Selection

When introducing auxiliary tasks for AMR parsing, the selected tasks should be formally or semantically related to AMR, thus the knowledge contained in them can be transferred to AMR parsing. Based on this principle of relevance, we choose semantic role labeling (SRL) and dependency parsing (DP) as our auxiliary tasks. We involve Translation and Summarization tasks for comparison.

Semantic Role Labeling SRL aims to recover the predicate-argument structure of a sentence, which can enhance AMR parsing, because: (1) Recovering the predicate-argument structure is also a sub-task of AMR parsing. As illustrated in Figure 3(a,b), both AMR and SRL locate the predicates (“want”, “leave”) of the sentence and conduct word-sense disambiguation. Then they both capture the multiple arguments of center predicate. (2) SRL and AMR are known as shallow and deep semantic parsing, respectively. It is reasonable to think that the shallow level of semantic knowledge in SRL is useful for deep semantic parsing.

Dependency Parsing DP aims to parse a sentence into a tree structure, which represents the dependency relation among tokens. The knowledge of DP is useful for AMR parsing, since: (1) Linguistically, DP (syntax parsing task) can be the precursor task of AMR (semantic parsing). (2) The dependency relation of DP is also related to semantic relation of AMR, e.g., as illustrated in Figure 1(c), “NSUBJ” in DP usually represents “:ARG0” in AMR. Actually, they both correspond to the agent-patient relations in the sentence. (3) DP is similar to AMR parsing from the perspective of edge prediction, because both of them need to capture the relation of nodes (tokens/concepts) in the sentence.

2.2 AMRization

Although SRL and DP are highly related to AMR parsing, there still exists gaps between them, e.g., SRL annotations may be disconnected, while AMR is always a connected graph. To bridge these gaps, we transform them into PseudoAMR, which we call AMRization.

---

*Computed on AMR 2.0 and 3.0 dataset.

2.2.1 Transform SRL to PseudoAMR

We summarize typical gaps between SRL and AMR as: (1) *Connectivity*. AMR is a connected directed graph while the structure of SRL is a forest. (2) *Span-Concept Gap*. Nodes in AMR graph represent concepts (e.g., “boy”) while that of SRL are token spans (e.g., “the boy”, “that boy”). Actually all the mentioned token spans correspond to the same concept. (3) *Reentrancy*. Reentrancy is an important feature of AMR as shown in Figure 3(a), the instance boy is referenced twice as ARG0. The feature can be applied to conduct coreference resolution. However, there is no reentrancy in SRL. To bridge such gaps, we propose **Connectivity Formation**, **Argument Reduction** and **Reentrancy Restoration** to transform SRL into PseudoAMR.

Connectivity Formation To address the connectivity gap, we need to merge all SRL trees into a connective graph. Note that the merging doesn’t guarantee correctness in semantic level. As shown in Figure 3(b-1), we first add a virtual root node, then generating a directed edge from the virtual root to each root of SRL trees, thus the SRL annotation becomes a connected graph.

Argument Reduction To address the Span-Concept Gap, as shown in Figure 3(b-2), if the argument of current predicate is a span with more than one token, we will replace this span with its head token in its dependency structure. Thus token spans “the boy”, “that boy” will be transformed to “boy”, more similar to the corresponding concept. Similar method has been to applied by (Zhang et al., 2021) to find the head of token spans of argument.

Reentrancy Restoration For the reentrancy gap, we design a heuristic algorithm based on DFS to restore reentrancy in SRL. As shown in Figure 3(b-3), the core idea of the restoration is that we create a variable when the algorithm first sees a node. If the DFS procedure meets node with the same name, the destination of current edge will be redirected to the variable we have created at first. Please refer to Appendix A for the pseudo code of the reentrancy restoration.

Dependency Guided Restoration The previous restoration algorithm can not guarantee the merging of nodes agrees to the meaning of reentrancy in AMR since it merges concept according to their appearance order in the SRL structure. And it does not handle the merging of predicates. As shown in Figure 3(b-3), the node “leave” and “leave-01” should be merged, however we can’t get this information directly from the SRL annotations. We therefore propose another restoration method based on the dependency structure of the corresponding sentence of the SRL as illustrated in Figure 4

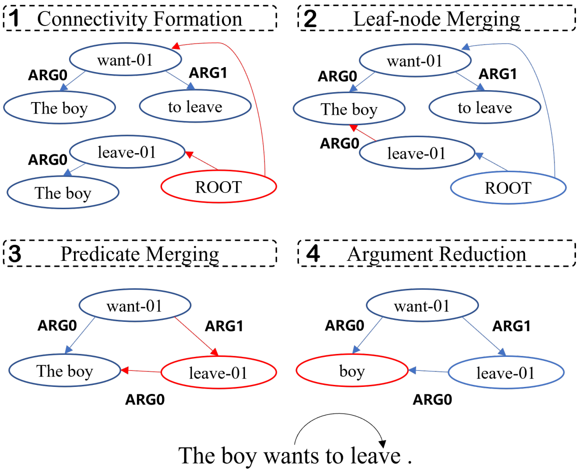

Figure 4: Illustration of Dependency Guided Restoration. In step 2, leaf-nodes “The boy” are merged. In step 3, none-leaf node “leave-01” is merged with leaf-node “to leave” since “leave-01” appears in word span “to leave” and word “leave” depends on word “want”.

This restoration algorithm takes the result of previous Connectivity Formation as input. It first merges the leaf-nodes corresponding to the same token. This step is accurate since leaf-nodes’ merging will not bring divergence. The second step is to merge predicate nodes. For all sub-trees of the root node, it first check whether one predicate appear in others’ argument span and whether the predicate directly depend on the span’s predicate. If both two conditions are satisfied, the algorithm will merge the predicate and the span to one node. Last, it removes the root node and root-edges if the graph remains connected after removing.

2.2.2 Transform Dependency Structure to PseudoAMR

We summarize the gaps between Dependency Tree and AMR as: (1) *Redundant Relation*. Some relations in dependency parsing focus on syntax, e.g., “:PUNCT” and “:DET”, which are far from semantic relations in AMR. (2) *Token-Concept Gap*. The basic element of dependency structure is token while that of AMR is the concept, which captures deeper syntax-independent semantics. We use **Redundant Relation Removal** and **Token Lemmatization** to transform the dependency structure to

PseudoAMR to handle the gaps.

Redundant Relation Removal For the Redundant Relation Gap, we remove some relations which are far from the sentence's semantics most of the time, such as "PUNCT" and "DET". As illustrated in Figure 3(c-1), by removing some relations of the dependence, the parsing result become more compact compared with original DP tree, forcing the model to ignore some semantics-unrelated tokens during seq2seq training.

Token Lemmatization As shown in Figure 3(c-2), for Token-Concept Gap, we conduct lemmatization on the node of dependency tree based on the observation that the affixes of single word do not affect the concept it corresponds to. Together with the smart-initialization (Bevilacqua et al., 2021) by setting the concept token's embedding as the average of the subword constituents, the embedding vector of lemmatized token ('want') becomes closer to the vector concept ('want-01') in the embedding matrix, therefore requiring the model to capture deeper semantic when conducting DP task.

2.2.3 Linearization

After all AMRization steps, the graph structure of SRL/DP also should be linearized before doing seq2seq training. As depicted in the right part of Figure 3, we linearize the graph by the DFS-based travel, and use special tokens *<R0>, ..., <Rk>* to indicate variables, and parentheses to mark the depth, which is the best AMR linearization method of Bevilacqua et al. (2021).

2.3 Training Paradigm Selection

After task selection and AMRization, we still need to choose an appropriate training paradigm to train PseudoAMR and AMR effectively. We explore three training paradigms as follows:

Multitask training Following Xu et al. (2020); Damonte and Monti (2021), we use classic schema in sequence-to-sequence multitask training by adding special task tag at the beginning of input sentence and training all tasks simultaneously. The validation of best model is conducted only on the AMR parsing sub-task.

Intermediate training Similar to Pruksachatkun et al. (2020), we first fine-tune the pretrained model on the intermediate task (PseudoAMR parsing), followed by fine-tuning on the target AMR parsing task under same training setting.

Multitask & Intermediate training We apply a joint paradigm to further explore how different paradigms affect AMR parsing. We first conduct multitask training, followed by fine-tuning on AMR parsing. Under this circumstance, Multitask training plays the role as the intermediate task.

3 Experiments

3.1 Datasets

AMR Datasets We conducted out experiment on two AMR benchmark datasets, AMR 2.0 and AMR 3.0. AMR2.0 contains 36521, 1368 and 1371 sentence-AMR pairs in training, validation and testing sets, respectively. AMR 3.0 has 55635, 1722 and 1898 sentence-AMR pairs for training validation and testing set, respectively. We also conducted experiments in out-of-distribution datasets (BIO,TLP,News3) and low-resources setting.

Auxiliary Task Datasets Apart from DP/SRL, we choose NLG tasks including summarization and translation to evaluate the contributions of auxiliary tasks. Description of datasets is listed Appendix C.

3.2 Evaluation Metrics

We use the Smatch scores (Cai and Knight, 2013) and further the break down scores (Damonte et al., 2017) to evaluate the performance.

To fully understand the aspects where auxiliary tasks improve AMR parsing, we divide the fine-grained scores to two categories: **1) Concept-Related** including Concept, NER and Negation scores, which care more about concept centered prediction. **2) Topology-Related** including Unlabeled, Reentrancy and SRL scores, which focus on edge and relation prediction. NoWSD and Wikification are listed as isolated scores because NoWSD is highly correlated with Smatch score and wikification relies on external entity linker system.

3.3 Experiment Setups

Model Setting We use current state-of-the-art Seq2Seq AMR Paring model SPRING (Bevilacqua et al., 2021) as our main baseline model and apply BART-Large (Lewis et al., 2020) as our pretrained model. Blink (Li et al., 2020) is used to add wiki tags to the predicted AMR graphs. We do not apply re-category methods and other post-processing methods are the same with Bevilacqua et al. (2021) to restore AMR from token sequence. Please refer to Section E from appendix for more training details.

	Model	Extra Data	SMATCH	NoWSD	Wiki	Concept-related			Topology-related

Table 1: SMATCH and fine-grained F1 scores on AMR 2.0 and 3.0. ^{D} denotes model using Dependency Guided Restoration. ^{E} denotes result with model ensemble (the details of the ensembling models are described in Appendix B). We conduct ensembling by averaging the models from three random seeds following Zhou et al. (2021b).

AMRization Setting For SRL, we explore four AMRization settings. 1) Trivial. Concept :multi-sentence and relation :snt are used to represent the virtual root and its edges to each of the SRL trees. 2) With Argument Reduction. We use dependency parser from Stanford CoreNLP Toolkit (Manning et al., 2014) to do the argument reduction. 3) With Reentrancy Restoration 4) All techniques.

For DP, we apply four AMRization settings 1) Trivial. Extra relations in dependency tree are added to the vocabulary of BART 2) With Lemmatization. We use NLTK (Bird, 2006) to conduct token lemmatization 3) With Redundant Relation Removal. We remove PUNCT, DET, MARK and ROOT relations. 4) All techniques.

3.4 Main Results

We report the result (ITL + All AMRization Techniques) on benchmark AMR 2.0 and 3.0 in Table 1. On AMR 2.0, our models with DP or SRL as intermediate task gains consistent improvement over the SPRING model by a large margin (1.2 Smatch) and reach new state-of-the-art for single model (85.2 Smatch). Compared with SPRING with 200k extra data, our models achieve higher performance with much less extra data (40k v.s. 200k), suggesting the effectiveness of our intermediate tasks. We also compare our models with contemporary work (Lam et al., 2021; Zhou et al., 2021b). It turns out that our ensemble model beats its counterpart with less extra data, reaching a higher performance (85.3 Smatch). In fact, even without ensembling, our model still performs better than those ensembling models and the model using Dependency Guided Restoration method achieves higher performance than the trivial one, showing the effectiveness of our methods.

On AMR 3.0, Our models consistently outperform other models under both single model (83.9 Smatch) and ensembling setting (84.0 Smatch). Same as AMR 2.0, our single model reaches higher Smatch score than those ensembling models, revealing the effectiveness of our proposed methods.

Fine-grained Performance To better analyse how the AMR parser benefits from the intermediate training and how different intermediate tasks affect the overall performance. We report the fine-grained score as shown in Table 1. We can tell that by incorporating intermediate tasks, considerable increases on most sub-metrics, especially on the Topology-related terms, are observed. On both AMR 2.0 and 3.0 our single model with SRL as intermediate task achieves the highest score in Unlabeled, Reentrancy and SRL metrics, suggesting that SRL intermediate task improves our parser's capability in Coreference and SRL.

DP leads to consistent improvement in topology-related metrics, which also derives better result on NER sub-task (92.5 on AMR 2.0, 89.2 on AMR 3.0). We suppose that the ":nn" relation which signifies multi-word name entities in dependency parsing helps the AMR parser recognize multi-word

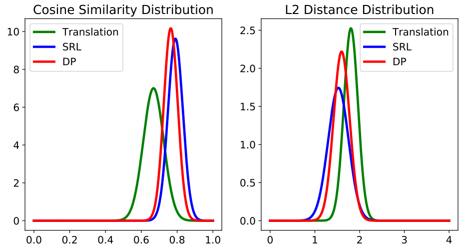
name entities. Generally speaking, AMR parser gains large improvement in Topology-related subtasks and NER by incorporating our intermediate tasks in terms of the Smatch scores.

3.5 Exploration in Auxiliary Task Selection

We explore how different tasks affect AMR parsing apart from DP and SRL. We involve two classic conditional NLG tasks, Summarization and Translation for comparison as shown in Table 2.

The comparison implies that SRL and DP are better auxiliary tasks for AMR Parsing even under the circumstance where their counterparts exploit far more data (40k v.s. 400k). In fact, the performance of MT drops while introducing more data, which contradicts with Xu et al. (2020) 's findings that more MT data can lead to better result when pretraining the *raw Transformer model*. However, this is not surprising under the background of Intermediate-task Learning where we already have a pretrained model with large-scale pretraining. Whether the intermediate tasks' form fits for the target task is far more important than the amount of data in the intermediate-task as also revealed by Poth et al. (2021). According to their observation, tasks with the most data (QQP 363k, MNLI 392k) perform far worse (-97.4% relative performance degradation at most) on some target tasks compared with tasks having much smaller datasets (CommonsenseQA 9k, SciTail 23k) which on the contrary give a positive influence.

In conclusion, our findings suggest that the selection of intermediate task is important and should be closely related to AMR parsing in form, otherwise it would even lead to a performance drop for AMR parsing.



Cosine Similarity Distribution

L2 Distance Distribution

Figure 5: The distance distribution of sentences representation. SRL and DP consistently provide more similar sentence representation to AMR than Translation. The computation is illustrated in Figure 7 in appendix.

4 Analysis

4.1 More Similar Sentence Representation

To examine how different auxiliary tasks affect AMR parsing, we collect the sentences' representation from different tasks' trained encoders[2]. We use the average hidden state of the encoder's output as the sentence representation. We compute the Cosine Similarity and L2 distance between auxiliary tasks' representation and AMR's representation for same sentence. The test split of AMR 2.0 is used for evaluation. Finally, We apply Gaussian distribution to fit the distribution of distances and draw the probability distribution function curves as shown in Figure 5. It turns out that under both distance metrics, SRL/DP consistently provide more similar sentence representation to AMR than Translation and SRL/DP are more similar to AMR parsing. It empirically justifies our hypothesis that semantically or formally related tasks can lead to a better initialization for AMR parsing.

4.2 Ablation Study on AMRization Methods

As shown in Table 3, we conduct ablation study on how different AMRization methods affect the performance AMR parsing. For both SRL and DP, jointly adopting our AMRization techniques can further improve the performance of AMR parsing significantly, comparing to trivial linearization. The imperfect reentrancy restoration method leads to a significant improvement in terms of both the Topology and Concept related scores. It reveals that transformation of structure to mimic the feature of AMR can better the knowledge transfer between shallow and deep semantics.

As shown in Table 8, compared with jointly using the two techniques, it is worth noting that model

Table 4: Analysis on Training Paradigms. Intermediate-task training is more suitable for AMR parsing than Multitask training

with solely Reentrancy Restoration reaches highest fine-grained scores in especially on Reentrancy and SRL scores. To explore the reason why it surpasses adopting both techniques, we analyse the number of restored reentrancy. The result shows that about 10k more reentrancies are added when Argument Reduction (AR) is previously executed. It's expected since AR replaces the token span to the root token. Compared with token span, single token is more likely to be recognized as the correference variable according to the Reentrancy Restoration (RR) algorithm, thus generating more reentrancy, which might include bias to the model. This explains why solely using RR can lead to better results on SRL and Reen.

4.3 ITL Outweighs MTL

We report the result of different fine-tuning paradigms in Table 4. It justifies our assumption that classic multitask learning with task tag as previously applied in Xu et al. (2020); Damonte and Monti (2021) does not compare with intermediate training paradigm for AMR Parsing task.

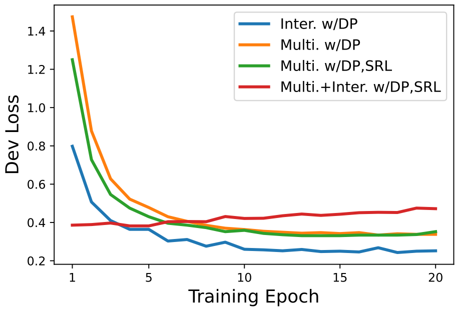

Figure 6: The loss curve on development set of AMR 2.0 for different training paradigms.

Model	BIO	TLP	News3
SPRING	59.7	77.3	73.7
SPRING + silver	59.5	77.5	71.8
SPRING^E	60.5	77.9	74.7
Ours	**61.2**	**78.9**	**75.4**

Table 5: Analysis on OOD data. ^{E} denotes result given by the ensembling of models. Our model exploits SRL as the intermediate task.

As shown in Figure 6, Intermediate-task training provides a faster and better converging process than MTL. We assume this is due to the huge gap between AMR parsing and auxiliary tasks which may harm the optimization process of MTL. The process of optimizing all auxiliary tasks simultaneously may introduce noise to AMR Parsing.

We also find that under the setting of ITL, sequentially training SRL and DP tasks did not bring further improvement to AMR parsing. We guess this is due to the catastrophic forgetting problem. Further regularization during training might help the model progressively learn from different auxiliary tasks and relieve catastrophic forgetting.

4.4 Exploration in Out-of-Distribution Generalization

Following Bevilacqua et al. (2021); Lam et al. (2021), we assess the performance of our models when trained on out-of-distribution (OOD) data. The models trained solely on AMR 2.0 training data are used to evaluate out-of-distribution performance on the BIO, the TLP and the News3 dataset.

Table 7 shows the result of our out-of-distribution experiments. Our model surpass other models even the ensembled one(Lam et al., 2021), creating new state-of-the-art for single model.

	Model	BOLT	LORELEI	DFA
Dev	SPRING	30.8	72.3	73.5
	Ours	**56.0**	**73.9**	**76.1**
Test	SPRING	34.6	73.8	71.1
	Ours	**59.4**	**74.5**	**74.3**

Table 6: Model Smatch scores in the low-resource setting. There are 1061, 4441, 6455 examples in the training set of BOLT, LORELEI and DFA, respectively. The model exploits SRL as the intermediate task.

4.5 Exploration in Low Resources Setting

Since the annotation of AMR is both time and labor consuming, it raises our interests if we can improve the learning ability of AMR Parser under low resources setting.

We set three low resources benchmarks **BOLT, LORELEI, DFA** for AMR parsing based on the different sufficient degree of training examples. Detail of the datasets is described in Appendix D . Compared with the AMR2.0 dataset which has 36521 training samples, the number of training samples in **BOLT, LORELEI, DFA** are 2.9%, 12.2% and 17.7% of the number of AMR2.0. Table 6 reports the result. Our model surpasses the SPRING model by a real large margin (about 25 Smatch) in the BOLT dataset which is the most insufficient in data and gains a consistent improvement on all datasets, suggesting that our pretraining method is effective under low resources conditions.

5 Related Work

AMR Parsing AMR parsing is a challenging semantic parsing task, since AMR is a deep semantic representation and consists of many separate annotations (Banarescu et al., 2013) (e.g., semantic relations, named entities, co-reference and so on). There are four major methods to do AMR Parsing currently, sequence-to-sequence approaches (Ge et al., 2019; Xu et al., 2020; Bevilacqua et al., 2021; Wang et al., 2022), tree-based approaches (Zhang et al., 2019b,a), graph-based approaches (Lyu and Titov, 2018; Cai and Lam, 2020) and transition-based approaches (Naseem et al., 2019; Lee et al., 2020; Zhou et al., 2021a).

There are two ways to incorporate other tasks to AMR Parsing. Goodman et al. (2016) builds AMR graph directly from dependency trees while (Ge et al., 2019) parse directly from linearized syntactic tree. Xu et al. (2020) introduces Machine Translation, Constituency Parsing as pretraining tasks for Seq2Seq AMR parsing and Wu et al. (2021) introduces Dependency Parsing for transition-based AMR parsing. However all of them do not take care of the semantic and formal gap between the auxiliary tasks and AMR parsing.

Multitask & Intermediate-task Learning Multi-task Learning (MTL) (Caruana, 1997) aims to jointly train multiple related tasks to improve the performance of all tasks. Different from MTL, Intermediate-task Learning (ITL) is proposed to enhance pretrained models e.g. BERT by training on intermediate task before fine-tuning on the target task. Recent studies(Pruksachatkun et al., 2020; Poth et al., 2021) on ITL expose that choosing right intermediate tasks is important. Tasks that don't match might even bring negative effect to the target even if it has far more data.

Xu et al. (2020); Damonte and Monti (2021); Procopio et al. (2021) utilize auxiliary tasks in a MTL fashion with specific task tags. Bevilacqua et al. (2021); Zhou et al. (2021b) adopt sliver training data in a ITL paradigm. However, there is no work comparing ITL and MTL when introducing auxiliary tasks to enhance PTM-based AMR parser.

6 Conclusion

In this paper, We find that semantically or formally related tasks, e.g. SRL and DP are better auxiliary tasks for AMR parsing and can further improve the performance by proper AMRization methods to bridge the gap between tasks. And Intermediate-task Learning is more effective in introducing auxiliary tasks compared with Multitask Learning. Extensive experiments and analyses show the effectiveness and priority of our proposed methods.

A Algorithms

Algorithm 1 Reentrancy Restoration for SRL

Input: Treenode:T

Output: Graph:G

Description: T is root node of the original SRL after node ROOT is added to form tree structure. G is the output graph with possible reentrancy restored.

Global Variables: Dict: V={}. Here Dict is the official data structure of Python's dictionary.

```
for predicate in T.sons do
    for son in predicate.sons() do
        if son.name in V.keys() then
            son = V[son.name]
            # restore reentrancy
        else
            V[son.name] = son
return T
```

B Ensemble Models' Methods

Graphene-4S^E Lam et al. (2021) make use of 4 SPRING models from different random seeds and their proposed graph ensemble algorithm to do the ensembling. They also include another ensemble model named Graphene All which includes four checkpoints from models of different architectures, SPRING(Bevilacqua et al., 2021), APT(Zhou et al., 2021a), T5, and Cai&Lam(Cai and Lam, 2020). We do not report the score of Graphene All since it aggregates models with different inductive bias while our ensemble model only use models from one structure. It is out of the scope for fair comparison.

Structure-aware^E Zhou et al. (2021b) use ensemble results from 3 models' combination to generate the ensemble model.

Ours (w/ SRL)^E We use the setting the same as Zhou et al. (2021b), we use the average of three models' parameters as the ensemble model.

C Auxiliary Datasets Description

C.1 Summarization

CNN/DM(Hermann et al., 2015) The CNN / DailyMail Dataset is an English-language dataset containing news articles as written by journalists at CNN and the Daily Mail. The dataset is widely accepted as benchmark to test models' performance of summarizing .

DIALOGSUM(Chen et al., 2021) The Real-Life Scenario Dialogue Summarization (DIALOGSUM), is a large-scale summarization dataset for dialogues. Unlike CNN/DM which focuses on monologue news summarization, DIALOGSUM covers a wide range of daily-life topics in the form of spoken dialogue. We use all the training data (13k) to conduct the intermediate training.

C.2 Translation

WMT14 EN-DE We select the first 40k,80k,200k and 400k training examples from WMT14 EN-DE training set to form EN-DE translation intermediate tasks.

C.3 Dependency Parsing

PENN TREEBANK(Marcus et al., 1999) The Penn Treebank (PTB) project selected 2,499 stories from a three year Wall Street Journal (WSJ) collection of 98,732 stories for syntactic annotation. We only utilize the dependency structure annotations to form our intermediate dependency parsing task. There are 39,832 (~40k) sentences.

C.4 Semantic Role Labeling

ONTONOTES(Weischedel et al., 2017) The OntoNotes project is built on two resources, following the PENN TREEBANK(Marcus et al., 1999) for syntax and the PENN PROPBANK for predicate-argument structure. We select 40k sentences with SRL annotations to form intermediate task.

D Low-resource Datasets Description

We set three Low-resource Learning benchmark for AMR parsing:

1. **BOLT** Using only the BOLT split of AMR data of AMR2.0 dataset. The training, validation and test data each has 1061, 133 and 133 amrs respectively.

2. **LORELEI** Using only the LORELEI split of AMR data of AMR3.0 dataset. The training,validation and test data each has 4441, 354 and 527 amrs respectively.

3. **DFA** Using only the DFA split of AMR data of AMR2.0 dataset. The training, validation and test data each has 6455, 210 and 229 amrs respectively.

Compared with the AMR2.0 dataset which has 36521 training samples, the number of training samples in **BOLT, LORELEI, DFA** are 2.9%, 12.2% and 17.7% of the number of AMR2.0.

E Training Details

We tune the hyper-parameters on the SPRING baseline, and then adding the auxiliary data using just those hyper-parameters without any changing.

We use RAdam (Liu et al., 2019) as our optimizer, and the learning rate is $3e^{-5}$. Batch-size is set to 2048 tokens with 10 steps accumulation. The dropout rate is set to 0.3.

Parameter	Searching Space
Learning rate	1e-5, 3e-5, 5e-5, 1e-4
Batch-size	256, 512, 1024, 2048, 4096
Grad. accu.	10
Dropout	0.1, 0.2, 0.3

Table 7: Hyper-parameters searching space

Abstract

Masked language models (MLMs) such as BERT have revolutionized the field of Natural Language Understanding in the past few years. However, existing pre-trained MLMs often output an anisotropic distribution of token representations that occupies a narrow subset of the entire representation space. Such token representations are not ideal, especially for tasks that demand discriminative semantic meanings of distinct tokens. In this work, we propose **TaCL** (**T**oken-**a**ware **C**ontrastive **L**earning), a novel continual pre-training approach that encourages BERT to learn an isotropic and discriminative distribution of token representations. TaCL is fully unsupervised and requires no additional data. We extensively test our approach on a wide range of English and Chinese benchmarks. The results show that TaCL brings consistent and notable improvements over the original BERT model. Furthermore, we conduct detailed analysis to reveal the merits and inner-workings of our approach.[1]

1 Introduction

Since the rising of BERT (Devlin et al., 2019), masked language models (MLMs) have become the de facto backbone for almost all natural language understanding (NLU) tasks. Despite their clear success, many existing language models pre-trained with MLM objective suffer from the *anisotropic problem* (Ethayarajh, 2019). That is, their token representations reside in a narrow subset of the representation space, therefore being less discriminative and less powerful in capturing the semantic differences of distinct tokens.

Recently, great advancement has been made in continually training MLMs with unsupervised sentence-level contrastive learning, aiming at creating more discriminative sentence-level representations (Giorgi et al., 2021; Carlsson et al., 2021; Yan et al., 2021; Kim et al., 2021; Liu et al., 2021b; Gao et al., 2021). However, such representations are only evaluated as sentence embeddings and there is no evidence that they will benefit other well-established NLU tasks. We show that these approaches hardly bring any benefit to challenging tasks like SQuAD (Rajpurkar et al., 2016, 2018).

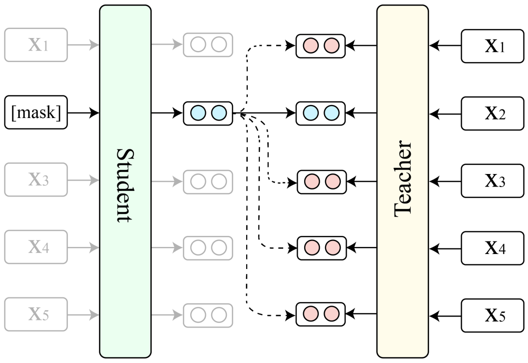

Figure 1: An overview of TaCL. The student learns to make the representation of a masked token closer to its "reference" representation produced by the teacher (solid arrow) and away from the representations of other tokens in the same sequence (dashed arrows).

In this paper, we argue that the key of obtaining more discriminative and transferrable representations lies in learning contrastive and isotropic token-level representations. To this end, we propose TaCL (**T**oken-**a**ware **C**ontrastive **L**earning), a new continual pre-training approach that encourages BERT to learn discriminative token representations. Specifically, our approach involves two models (a student and a teacher) that are both initialized from the same pre-trained BERT. During the learning stage, we freeze the parameters of the teacher and continually optimize the student model with (1) the original BERT pre-training objectives (masked language modelling and next sentence prediction) and (2) a newly proposed TaCL objective. The TaCL loss is obtained by contrasting the student representations of masked tokens against the "reference" representations produced by the teacher

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2497 - 2507
July 10-15, 2022

without masking the input tokens. In Figure 1, we provide an overview of our approach.

We extensively test our approach on a wide range of English and Chinese benchmarks and illustrate that TaCL brings notable performance improvements on most evaluated datasets (§3.1.1). These results validate that more discriminative and isotropic token representations lead to better model performances. Additionally, we highlight the benefits of using our token-level method compared to current state-of-the-art sentence-level contrastive learning techniques on NLU tasks (§3.2.1). We further analyze the inner workings of TaCL and its impact on the token representation space (§3.2.2).

Our work, to the best of our knowledge, is the first effort on applying contrastive learning to improve token representations of Transformer models. We hope the findings of this work could facilitate further development of methods on the intersection of contrastive learning and representation learning at a more fine-grained granularities.

2 Token-aware Contrastive Learning

Our approach contains two models, i.e., a student S and a teacher T, both of which are initialized from the same pre-trained BERT. During learning, we freeze T and only optimize the parameters of S. Given an input sequence $x = [x_1, ..., x_n]$, we randomly mask x with the same procedure as in Devlin et al. (2019) and feed the masked sequence $\tilde{x}$ into the student model to produce the contextual representation $\tilde{h} = [\tilde{h}_1, ..., \tilde{h}_n]$. Meanwhile, the teacher model takes the original sequence x as input and produces the representation $h = [h_1, ..., h_n]$ (see Figure 1). The proposed token-aware contrastive learning objective $\mathcal{L}_{\text{TaCL}}$ is then defined as

$$-\sum_{i=1}^{n} \mathbb{1}(\tilde{x}_i) \log \frac{\exp(\text{sim}(\tilde{h}_i, h_i)/\tau)}{\sum_{j=1}^{n} \exp(\text{sim}(\tilde{h}_i, h_j)/\tau)}, \quad (1)$$

where $\mathbb{1}(\tilde{x}_i) = 1$ if $\tilde{x}_i$ is a masked token, otherwise $\mathbb{1}(\tilde{x}_i) = 0$. τ is a temperature hyper-parameter and $\text{sim}(\cdot, \cdot)$ computes the cosine similarity. Intuitively, the student learns to make the representation of a masked token closer to its "reference" representation produced by the teacher and away from other tokens in the same sequence. As a result, the token representations learnt by the student are more discriminative with respect to distinct tokens, therefore better following an isotropic distribution. Similar to Devlin et al. (2019), we also adopt the masked language modelling $\mathcal{L}_{\text{MLM}}$ and next sentence prediction $\mathcal{L}_{\text{NSP}}$ objectives. The overall learning objective $\mathcal{L}$ of the student model during the continual pre-training stage is defined as

$$\mathcal{L} = \mathcal{L}_{\text{TaCL}} + \mathcal{L}_{\text{MLM}} + \mathcal{L}_{\text{NSP}}. \quad (2)$$

Note that the learning of the student is fully unsupervised and can be realized using the original pre-training corpus. After the learning is completed, we fine-tune the student model on downstream tasks.

3 Experiment

We test our approach on a wide range of benchmarks in two languages. For English benchmarks, we evaluate the $\text{BERT}_{\text{base}}$ and $\text{BERT}_{\text{large}}$ models. For Chinese benchmarks, we test the $\text{BERT}_{\text{base}}$ model.[2] After initializing the student and teacher, we continually pre-train the student on the same Wikipedia corpus as in Devlin et al. (2019) for 150k steps. The training samples are truncated with a maximum length of 256 and the batch size is set as 256. The temperature τ in Eq. (1) is set as 0.01. Same as Devlin et al. (2019), we optimize the model with Adam optimizer (Kingma and Ba, 2015) with weighted decay, and an initial learning rate of 1e-4 (with warm-up ratio of 10%).

3.1 Evaluation Benchmarks

For English benchmarks, we use the GLUE dataset (Wang et al., 2019) which contains a variety of sentence-level classification tasks covering textual entailment (RTE and MNLI), question-answer entailment (QNLI), paraphrase (MRPC), question paraphrase (QQP), textual similarity (STS-B), sentiment (SST-2), and linguistic acceptability (CoLA). Our evaluation metrics are Spearman correlation for STS-B, Matthews correlation for CoLA, and accuracy for the other tasks; the macro average score is also reported. Additionally, we conduct experiments on SQuAD 1.1 (Rajpurkar et al., 2016) and 2.0 (Rajpurkar et al., 2018) datasets that evaluate the model's performance on the token-level answer-extraction task. The dev set results of Exact-Match (EM) and F1 scores are reported.

For Chinese benchmarks, we evaluate our model on two token-level labelling tasks, including name entity recognition (NER) and Chinese word segmentation (CWS). For NER, we use the Ontonotes (Weischedel et al., 2011), MSRA (Levow, 2006), Resume (Zhang and Yang, 2018), and Weibo (He and Sun, 2017) datasets. For CWS, we use the

Table 1: Benchmark Results. ‖: published in Devlin et al. (2019); and ‡: models from our implementations.

PKU, CityU, and AS datasets from SIGHAN 2005 (Emerson, 2005) for evaluation. The standard F1 score is used for evaluation.

Baselines: We compare against two baselines: (1) the original BERT used to initialize the student and teacher; (2) BERT+*MT* (BERT with more training) which is acquired by continually pre-training the original BERT on Wikipedia for 150k steps[3] using the original BERT pre-training objectives.

3.1.1 Benchmark Results

Table 1 reports the results on English and Chinese benchmarks.[4] We observe that, on most sequence-level classification tasks in GLUE, TaCL outperforms BERT and BERT+*MT*. Additionally, on all token-level benchmarks (SQuAD, NER, and CWS), TaCL consistently and notably surpasses other baselines. These results indicate that the learning of an isotropic token representation space is beneficial for the model's performance, especially on the token-centric tasks.

3.2 Analysis

In this section, we present further comparisons and in-depth analysis of the proposed approach.

3.2.1 Sentence-Level vs. Token-Level CL

We compare TaCL against existing sentence-level contrastive learning methods, including DeCLUTR (Giorgi et al., 2021), SimCSE (Gao et al., 2021), and MirrorBERT (Liu et al., 2021b). We also include two ablated models to study the effect of different combinations of pre-training objectives. Specifically, the ablated model-1 is initialized with BERT and trained with the original BERT objectives ($\mathcal{L}_{\text{MLM}}$ and $\mathcal{L}_{\text{NSP}}$) **plus** the sentence-level contrastive objective as proposed in Liu et al. (2021b). The ablated model-2 is initialized with BERT and trained **only** with the proposed token-aware contrastive objective of Eq. (1). Note that all compared models have the same size as the BERT$_{\text{base}}$ model.

Model	$\mathcal{L}_{\text{MLM}} + \mathcal{L}_{\text{NSP}}$	CL	SQuAD 1.1	SQuAD 2.0
BERT	✓	×	80.8/88.5	73.4/76.8
		Sentence-Level Contrastive Methods		
DeCLUTR	×	Sen.	79.9/87.6	72.1/75.4
SimCSE	×	Sen.	80.2/88.0	72.5/75.7
MirrorBERT	×	Sen.	80.3/88.1	72.7/75.9
		Ablated Models		
model-1	✓	Sen.	80.5/88.3	73.1/76.5
model-2	×	Tok.	81.3/88.7	73.8/77.1
TaCL	✓	Tok.	**81.6/89.0**	**74.4/77.5**

Table 2: Comparison of various sentence- and token-level contrastive learning methods. "Sen." or "Tok." denotes training with sentence- or token-level contrastive objectives. Scores of (EM/F1) are reported.

Table 2 shows the performance of different models on SQuAD. We observe decreased performance of existing sentence-level contrastive methods compared with the original BERT. This could be attributed to the fact that such methods only focus on learning sentence-level representations while ignoring the learning of individual tokens. This be-

---

[3] The number of steps is set the same as our TaCL training.

[4] For all tasks, the average results over five runs are reported.

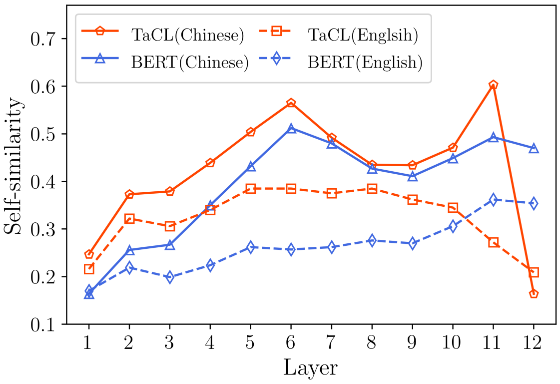

Figure 2: Layer-wise representation self-similarity.

haviour is undesired for tasks like SQuAD that demands informative token representations. Nonetheless, the ablated model-1 shows that the original BERT pre-training objective ($\mathcal{L}_{\text{MLM}}$ and $\mathcal{L}_{\text{NSP}}$) remedies, to some extent, the performance degeneration caused by the sentence-level contrastive methods. On the other hand, the ablated model-2 demonstrates that our token-aware contrastive objective helps the model to achieve improved results by learning better token representations.

3.2.2 Token Representation Self-similarity

To analyze the token representations learnt by TaCL and BERT, we follow Ethayarajh (2019) and define the averaged self-similarity of the token representations within one sequence $x = [x_1, ..., x_n]$ as,

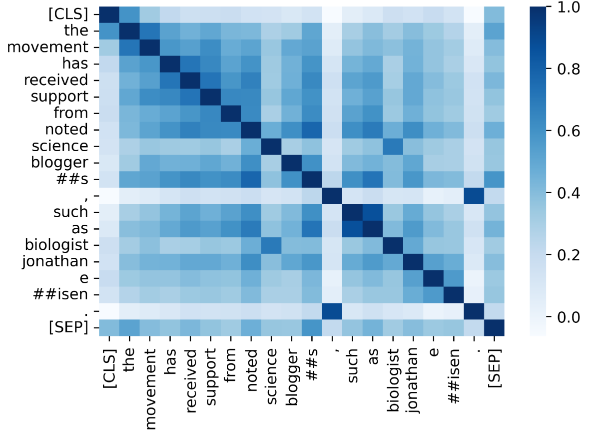
$$s(x) = \frac{1}{n(n-1)} \sum_{i=1}^{n} \sum_{j=1, j\neq i}^{n} \text{cosine}(h_i, h_j), \quad (3)$$

where h_i and h_j are the token representations of x_i and x_j produced by the model. Intuitively, a lower $s(x)$ indicates that the representations of tokens within the sequence x are less similar to each other, therefore being more discriminative.

We sample 50k sentences from both Chinese and English Wikipedia and compute the self-similarity of representations over different layers. Figure 2 plots the results of TaCL$_{\text{base}}$ and BERT$_{\text{base}}$ averaged over all sentences. We see that, in the intermediate layers, the self-similarity of TaCL is higher than BERT's. In contrast, at the top layer (layer 12), TaCL's self-similarity becomes notably lower than BERT's, demonstrating that the final output token representations of TaCL are more discriminative.

Qualitative Analysis. We sample one sentence from Wikipedia and visualize the self-similarity matrix M (where $M_{i,j} = \text{cosine}(h_i, h_j)$) produced by BERT$_{\text{base}}$ and TaCL$_{\text{base}}$. The results are shown

(a) Self-similarity Visualization of BERT



(b) Self-similarity Visualization of TaCL

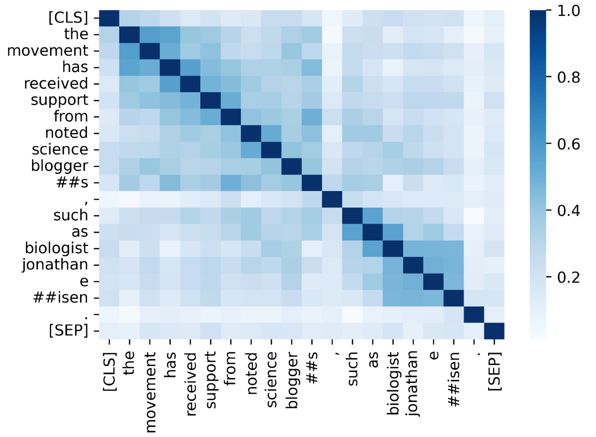


Figure 3: Self-similarity Matrix Visualization: (a) BERT and (b) TaCL. (best viewed in color)

in Figure 3, where a darker color denotes a higher self-similarity score.[5] We see that, as compared with BERT (Fig. 3(a)), the self-similarities of TaCL (Fig. 3(b)) are much lower in the off-diagonal entries. This further highlights that the individual token representations of TaCL are more discriminative, which in return leads to improved model performances as demonstrated (§3.1.1, §3.2.1).

4 Conclusion

In this work, we proposed TaCL, a novel approach that applies token-aware contrastive learning for the continual pre-training of BERT. Extensive experiments are conducted on a wide range of English and Chinese benchmarks. The results show that our approach leads to notable performance improvement across all evaluated benchmarks. We then delve into the inner-working of TaCL and demonstrate that our performance gain comes from a more discriminative distribution of token representations.

---

[5] The entries $M_{i,i}$ in the diagonal have a 1.0 self-similarity by definition, as $\text{cosine}(h_i, h_i) = 1.0$.

Acknowledgments

The first author would like to thank Jialu Xu and Piji Li for the insightful discussions and support. Many thanks to our anonymous reviewers and area chairs for their suggestions and comments.

Ethical Statement

We honor and support the ACL code of Ethics. Language model pre-training aims to improve the system's performance on downstream NLU tasks. All pre-training corpora and pre-trained models used in this work are publically available. In addition, all evaluated datasets are from previously published works, and in our view, do not have any attached privacy or ethical issues.

B Related Work

Pre-trained Language Models. Since the introduction of BERT (Devlin et al., 2019), the research community has witnessed remarkable progress in the field of language model pre-training on a large amount of free text. Such advancements have led to significant progresses in a wide range of natural language understanding (NLU) tasks (Liu et al., 2019; Yang et al., 2019; Clark et al., 2020; Lan et al., 2021) and text generation tasks (Radford et al., 2019; Lewis et al., 2020; Raffel et al., 2020; Su et al., 2021a,e,g,d,f,c; Zhong et al., 2021)

Contrastive Learning. Generally, contrastive learning methods distinguish observed data points from fictitious negative samples. They have been widely applied to various computer vision areas, including image (Chopra et al., 2005; Oord et al., 2018) and video (Wang and Gupta, 2015; Sermanet et al., 2018). Recently, Chen et al. (2020) proposed a simple framework for contrastive learning of visual representations (SimCLR) based on multiclass N-pair loss. Radford et al. (2021); Jia et al. (2021) applied the contrastive learning approach for language-image pretraining. Xu et al. (2021); Yang et al. (2021) proposed a contrastive pre-training approach for video-text alignment.

In the field of NLP, numerous approaches have been proposed to learn better sentence-level (Reimers and Gurevych, 2019; Wu et al., 2020; Meng et al., 2021a; Liu et al., 2021b; Gao et al., 2021; Su et al., 2021b) and lexical-level (Liu et al., 2021a; Vulić et al., 2021; Liu et al., 2021c; Wang et al., 2021) representations using contrastive learning. Different from our work, none of these studies specifically investigates how to utilize contrastive learning for improving general-purpose token-level representations. Beyond representation learning, contrastive learning has also been applied to other NLP applications such as NER (Das et al., 2021) and summarisation (Liu and Liu, 2021), knowledge probing for pre-trained language models (Meng et al., 2021b), and open-ended text generation (Su et al., 2022).

Continual Pre-training. Many researchers (Xu et al., 2019; Gururangan et al., 2020; Pan et al., 2021) have investigated how to continually pretrain the model to alleviate the task- and domain-discrepancy between the pre-trained models and the specific target task. In contrast, our proposed approach studies how to apply continual pre-training to directly improve the quality of model representations which is transferable and beneficial to a wide range of benchmark tasks.

C More Self-similarity Visualizations

In Figure 4, 5, and 6, we provide three more comparisons between the self-similarity matrix produced by TaCL and BERT (the example sentences are randomly sampled from Wikipedia).[6] From the figures, we can draw the same conclusion as in section §3.2.2, that the token representations of BERT follow an anisotropic distribution and are less discriminative. On the other hand, the token representations of TaCL better follow an isotropic distribution, therefore different tokens become more

Abstract

We introduce MTG, a new benchmark suite for training and evaluating multilingual text generation. It is the first-proposed multilingual multiway text generation dataset with the largest human-annotated data (400k). It includes four generation tasks (story generation, question generation, title generation and text summarization) across five languages (English, German, French, Spanish and Chinese). The multiway setup enables testing knowledge transfer capabilities for a model across languages and tasks. Using MTG, we train and analyze several popular multilingual generation models from different aspects. Our benchmark suite fosters model performance enhancement with more human-annotated parallel data. It provides comprehensive evaluations with diverse generation scenarios. Code and data are available at `https://github.com/zide05/MTG`.

1 Introduction

Natural language generation (NLG) aims to automatically generate meaningful texts with the input in different formats, such as images (Anderson et al., 2018), tables (Ye et al., 2020) or texts (Guan et al., 2019). The generated texts generally target at realizing an underlying communicative goal while remaining coherent with the input information and keeping grammatically correct. Multilingual text generation extends the natural language generation task to produce texts in multiple languages, which is important to overcome language barriers and enable universal information access for the world's citizens (Artetxe et al., 2020; Arivazhagan et al., 2019; Pan et al., 2021).

To achieve this goal, various multilingual text generation datasets have been proposed. Some of them do not incorporate cross-lingual pairs (Liang et al., 2020; Ladhak et al., 2020). This limits the knowledge transfer from one language to another. Others involve cross-lingual pairs while English is included on either source or target side in most cases (Zhu et al., 2019; Ladhak et al., 2020), leading to difficult transfer between low-resource or distant language pairs. Constructing a multilingual text generation dataset that can directly transfer knowledge between any two languages is still under-explored.

To this end, we propose MTG, a human-annotated multilingual multiway dataset. Multiway means that the same sample is expressed in multiple languages. It covers four generation tasks (story generation, question generation, title generation and text summarization) across five languages (English, German, French, Spanish and Chinese). We do not include multilingual machine translation because MT itself is a standard task. The multiway parallel feature enables cross-lingual data construction between arbitrary language pairs. Such direct parallel signal promotes knowledge transfer and cross-lingual generation between any language pairs (even distant pairs such as Spanish-Chinese) without involving an intermediate language such as English (Leng et al., 2019).

The multilingual multiway feature also enables various training and test scenarios. In this paper, we design four scenarios to verify the advantages of our MTG from different aspects. Several representative pretrained multilingual models are employed to test these scenarios, including multilingual BERT (M-BERT) (Devlin et al., 2019), XLM (Lample and Conneau, 2019), mBART (Liu et al., 2020) and mT5 (Xue et al., 2020). We leverage various metrics to assess the coherence and diversity of the outputs generated by these models. Besides, we also propose an ensemble metric, which mainly focuses on relevance, measuring to what degree is the generated text close to human-level. Human evaluation is also conducted to validate models' performances.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2508 - 2527
July 10-15, 2022

In summary, the contributions of this paper are listed as follows:
(i) We propose a new human-annotated multilingual multiway text generation benchmark suite MTG.
(ii) We design a new evaluation metric measuring how a text resembles human writing and prove that it has higher correlation scores with human scores compared with other automatic relevance metrics.
(iii) We evaluate several representative pretrained multilingual models on our proposed MTG and make a rigorous analysis to verify its advantages.

2 Related Work

A significant body of works have been committed to the construction of multilingual datasets covering diverse tasks (Hu et al., 2020; Jiang et al., 2020; Longpre et al., 2020). XTREME (Hu et al., 2020) is a multilingual understanding benchmark across 40 languages and 9 tasks, but it does not cover any generation task. Jiang et al. (2020) propose X-FACTR, which is a cross-lingual factual retrieval benchmark. Longpre et al. (2020) propose MKQA, an open-domain question answering evaluation dataset covering 26 diverse languages. Ladhak et al. (2020) present WikiLingua, which is a large-scale, multilingual dataset for cross-lingual abstractive summarization systems. MLSUM (Wang et al., 2021) is a dataset for text summarization in 12 languages. Wiki-40B (Guo et al., 2020) is a multilingual language model dataset across 40+ languages. Although these datasets cover multiple languages, they either belong to natural language understanding tasks or a single, specific generation task, which limits researchers to obtain general findings incorporating a set of generation tasks.

XGLUE (Liang et al., 2020) is a cross-lingual benchmark dataset for nine understanding tasks and two generation tasks. GEM (Gehrmann et al., 2021) is a newly-presented vision-language dataset covering 11 image-language and video-language tasks and 32 languages. These two datasets encompass multiple tasks and languages. However, a remarkable difference of our MTG from XGLUE and GEM is that MTG focuses on text-to-text generation tasks and is parallel across all languages, which facilitates easier knowledge transfer.

3 Dataset Collection and Methodology

This section will introduce how to create the benchmark suite for multilingual text generation (MTG). In order to construct multiway parallel dataset, the initial dataset is translated into other languages by an off-the-shelf translation model. Part of the translated data is randomly selected for further human annotation to increase data quality. The selection of tasks, initial datasets and languages are based on several principles as described below.

3.1 Task and Dataset Selection

It is important to select suitable tasks for our MTG benchmark to make it diverse and challenging. Thus, we define several criteria during the task selection procedure:

Task Definition Tasks should be well-defined, which means that humans can easily determine whether the generated results meet the task requirements.

Task Difficulty Tasks should be solvable by most college-educated speakers. In the meantime, they should be challenging to current models, the performance of which in various test scenarios falls short of human performance.

Task Diversity Tasks should cover a wide range of generation challenges that allow for findings to be as general as possible.

Input Format The input format of the tasks needs to be as simple as possible to reduce the difficulty of data processing. Besides, it should not contain anything but text (e.g., without any images or videos).

In order to meet the above criteria, 8 domain experts are asked to vote from 10 typical generation tasks[1]. Finally, four generation tasks are selected for MTG, which are story generation, question generation, title generation and text summarization. **Story generation** (SG) aims to generate the end of a given story context, which requires the model to understand the story context and generate a reasonable and fluent ending (Guan et al., 2019). **Question generation** (QG) targets at generating a correct question for a given passage and its answer (Duan et al., 2017). For the same passage with different answers, the system should be able to generate different questions. **Title generation** (TG) converts a given article into a condensed sentence while preserving its main idea (Jin and Hauptmann, 2002). The title should be faithful to the original document and encourage users to read the news

---

[1] These generation tasks are story generation, commonsense generation, style transfer, question generation, question answering, dialogue generation, title generation, text summarization, image caption, and data-to-text generation.

Task	Corpus	Domain	Format	Goal
Story Generation	ROCStories	Daily life	<story>	Generate the end of the story
Question Generation	SQUAD 1.0	Wikipedia	<passage,answer, question>	Generate the question of the answer
Title Generation	ByteCup	News	<article, title>	Generate the title of the document
Text Summarization	CNN/DailyMail	News	<article, summary>	Generate the summary of the document

Table 1: The description of tasks and English datasets included in MTG. For story generation, we use the last sentence as story end to be generated and the rest as input.

at the same time. **Text summarization** (Summ) aims to condense the source document into a coherent, concise, and fluent summary (Mani, 2001). It is similar to title generation but the output of text summarization is relatively longer. These four tasks focus on different generative abilities and realize different goals.

After confirming the tasks, the next step is to choose the dataset for each task. The two selection principles are listed as follows:(1) **License:** Task data must be available under licenses that allow using and redistributing for research purposes. The dataset should be free and available for download. (2) **Quality:** The dataset size should be as large as possible and the quality should be checked.

English datasets are chosen as the initial datasets because they are more accessible in all four tasks and have relatively larger size compared with datasets in other languages. We choose ROCStories (Mostafazadeh et al., 2016) for story generation, SQUAD 1.0 (Rajpurkar et al., 2016) for question generation, ByteCup [2] for title generation and CNN/DailyMail (Nallapati et al., 2016) for text summarization. These datasets are popular in the corresponding fields and have been verified to be high-quality by many works. Moreover, they are all under a permissive license. An overview of all task datasets is shown in Table 1.

3.2 Language Selection

The original datasets are in **English** (en) only and we want to extend them into a multiway parallel form. This means that all English texts should be translated into other languages, which will lead to high annotation costs. Thus, a state-of-the-art translator is leveraged to do the translation and then annotators are asked to correct the translated text. Considering this construction method, MTG should contain languages that (1) have good English-to-X translators and (2) are diverse in language family. Finally, **German** (de), **French** (fr), **Spanish** (es) and **Chinese** (zh) are chosen. German is from the same language branch as English while French and Spanish are from different ones. Chinese is more distant from the rest of languages in the language family tree.

Task	SG, QG, TG, Summ
For each language	
Rough training size	76k/61k/270k/164k
Annotated training size	15k/15k/15k/15k
Annotated development size	2k/2k/2k/2k
Annotated test size	3k/3k/3k/3k
For five languages (en, de, fr, es, zh)	
Total Annotated size	400k
Total dataset size	6.9m

Table 2: The number of samples in MTG. MTG consists of four subsets: *rough training*, *annotated training*, *development* and *test* set. The rough training set is filtered by back translating across five languages. The annotated training, development and test sets are corrected by human experts.

3.3 Data Collection

After determining the tasks and languages, we introduce the data collection process to get the MTG. The Google Translate[3] is used to translate the English datasets to the selected languages. To control the quality of translated texts, we back translate the text to English and filter the samples whose n-gram overlap ratios with the original English texts are lower than a certain threshold. Different threshold values (from 0.3 to 0.6 with 0.1 as step length) are tested and if it is set to 0.6, the training data size of QG will drop more than 60%. Thus we decide to use 0.5 as the threshold number to improve the quality of the filtered data while still maintaining more than 70% of the original training data.[4] Samples in four languages are aligned to ensure that the dataset is multiway parallel.

$20,000$ samples of each task and language are randomly selected for annotation under the premise

[4] The detailed sizes of the filtered datasets with respect to different thresholds are included in appendix A.

Correlation	AdaBoost	DecisionTree	ExtraTree	GradientBoosting	Kneighbors	Linear	RandomForest	SVR	Bagging
Pearson	0.100	0.133	0.190	0.215	0.192	0.173	0.208	0.113	**0.240**
Correlation	BLEU	ROUGE-1	ROUGE-2	ROUGE-L	METEOR	BERTScore-P	BERTScore-R	BERTScore-F1	Bagging
Pearson	0.180	0.142	0.163	0.144	0.122	0.142	0.176	0.162	**0.344**

Table 3: The correlation scores between automatic metric scores and human-annotated scores (the average scores of grammar, fluency and relevance). Upper part of the table shows the correlation scores of different regression algorithms in test set of all languages. The lower part demonstrates correlation scores of our ensemble score (the bagging regressor) and other classic automatic scores in test set without Chinese results because Meteor does not support Chinese.

of ensuring inter-language alignment. The annotators are required to further check the translated results based on the following rules: (1) **Semantic aligned** Whether the target text is meaningful and is fully semantic aligned with the source text. (2) **Fluency** Whether the translated text is grammatically correct. (3) **Style** Whether the translation follows the norms of local culture, language conventions, and gender-related words. If the translated text contradicts any of the above rules, annotators will correct it accordingly. The annotated data is then split to 15k/2k/3k as training/development/test subsets.

A team of 10 full-time experts[5] are hired to do the annotation, who are paid daily. Some part-time workers[6] are also employed to increase the annotation throughput, who are paid by the number of annotations. Each annotator is an expert in at least two languages (English and another target language). They are trained to correct translation errors according to the above rules, first a small number of samples for trial, these annotation results are re-checked by us and feedback is given to the annotators to help them understand the tasks better. After this annotation training process, the annotators start to annotate the dataset. For quality control, we sample 2% from the annotations and arrange for 9 experts to double-check them. Each example is assigned to two other experts and the data is qualified only if both of them agree on the annotation[7]. If more than 5% of the annotations fail, then all the data of that annotator for that day will be re-checked.

Then the multiway parallel generation benchmark MTG is finally completed. It contains four different generation tasks in five languages and its quality is improved by the incorporation of human annotation. However, the number of human-annotated data is still small due to cost concerns. Introducing more human-annotated data or carrying out extra filtering for machine-translated data can be future directions to further improve the quality of MTG. The statistics of MTG is shown in Table 2.

4 Experiments

In this section, we conduct extensive experiments to benchmark the difficulty of our proposed MTG via several state-of-the-art multilingual models under different scenarios.

4.1 Baseline Models

The performance of the following four popular multilingual pretrained models is explored[8]:

M-BERT Multilingual BERT (M-BERT) (Devlin et al., 2019) is a language model pretrained from monolingual corpora in 104 languages using Masked Language Modeling (MLM) task.

XLM The Cross-Lingual Language Model (XLM) (Lample and Conneau, 2019) is pretrained with Masked Language Modeling (MLM) task using monolingual data and Translation Language Modeling (TLM) task using parallel data.

mBART Multilingual BART (mBART) (Liu et al., 2020) is a pretrained encoder-decoder model using denoising auto-encoding objective on monolingual data over 25 languages.

mT5 Multilingual T5 (mT5) (Xue et al., 2020) is a multilingual variant of T5 (Raffel et al., 2020) formatting all tasks as text-to-text generation problems. mT5 is pretrained on a span-corruption version of Masked Language Modeling objective over 101 languages.

---

[5] There are 3 language experts for German, 3 for French, 4 for Spanish and 4 for Chinese

[6] There are 16 part-time workers who are participated in the German annotation, 39 for French, 4 for Spanish and 15 for Chinese.

[7] The grammar, expressions, and punctuation of the annotated text are completely correct and the expressions are in accordance with the foreign language.

[8] Detailed descriptions for models are included in Appendix B.

Figure 1: The cross-lingual ensemble metric results for four models in four tasks. Every cell of row lang1 and column lang2 means the result when the languages of input and output are lang1 and lang2 respectively. Deeper red represents better cross-lingual performance while deeper gray indicates worse performance.

4.2 Evaluation Metrics

In order to fully understand the model performance, the quality of generated texts is evaluated from different aspects, including metrics measuring the relevance between outputs and references (e.g., BLEU, ROUGE, and BERTScore) and metrics measuring the diversity of the generated texts (e.g., Distinct). Moreover, we propose a new ensemble metric leveraging relevance metrics to measure how close the generated text is to human writing. It not only has higher correlation scores with human judgments but also is capable of measuring model performances fairly between languages.

N-gram based Metrics N-gram based metrics evaluate the text-overlapping scores between the outputs and references. The following three metrics are used: (1) **BLEU** (Papineni et al., 2002) is a popular metric that calculates the word-overlap scores between the generated texts and gold-standard ones. We use the BLEU-4, which is the average score for unigram, bigram, trigram, and 4-gram. (2) **ROUGE** (Lin, 2004) is a recall-oriented metric that counts the number of overlapping units such as n-gram and word sequences between the produced texts and gold-standard ones. (3) **METEOR** (Banerjee and Lavie, 2005) relies on semantic features to predict the similarity scores between system hypotheses and human references.

Embedding based Metrics The embedding-based metrics can, to a large extent, capture the semantic-level similarity between the generated text and the ground truth. **BERTScore** (Zhang et al., 2019) computes the similarity of candidate and reference as a sum of cosine similarities of tokens using BERT contextual embeddings.

Diversity Metrics We also employ the distinct metric (Li et al., 2016), which calculates the proportion of the distinct n-grams in all the system hypotheses and can be used to evaluate the diversity of the generated texts.

Human Evaluation Human evaluation is also leveraged to better estimate the quality of model outputs. Specifically, 30 cases are randomly sampled from the test set for each task and language while ensuring all 30 cases are aligned among five languages, and then they are presented to human annotators with the model outputs. The generated texts are evaluated under task-agnostic and task-specific aspects. Task-agnostic aspects include **Grammar**, **Fluency**, **Relevance** and **Language**

Task	Model	BLEU		ROUGE-L		METEOR		BERTScore		Distinct-1		Ensemble

Table 4: Automatic scores averaged across five languages for four models on four tasks. Mono and multi mean models are trained in monolingual and multilingual setting respectively. Higher scores between monolingual and multilingual results are bolded.

Fusion. The former three aspects are scored from 1 to 5 while the language fusion score is set to 1 if all tokens of a model-generated text are in the target language and 0 otherwise.

Besides task-agnostic aspects, the generated text is also evaluated under task-specific aspects. For title generation and summarization, coverage measures the degree to which the generated text covers the main content of the document. Correspondence for question generation measures the extent to which the generated question is matched with both document and answer. For story generation, we further evaluate whether the generated story is logically feasible. All task-specific aspects are scored from 1 to 5.

Ensemble Metric Some N-gram based metrics such as BLEU and ROUGE largely depend on the tokenizer for specific languages. For example, BLEU scores for Chinese outputs are relatively high because it simply uses a character-level tokenizer. This causes unfair comparison between different languages. To this end, we propose an ensemble metric that evaluates the degree to which a piece of text resembles manual writing. It not only enables fair comparison between languages but is also proved to have a better correlation with human-annotated scores at the end of this subsection. We first average the grammar, fluency and relevance scores as targets, then normalize the automatic metrics and human scores among every language to eliminate the score discrepancy between languages. Three relevance metrics (BLEU, ROUGE-L, and BERTScore-F1) are gathered as features. The samples are split into training, development and test sets.

After comparing different regression models' performance as shown in the upper part of Table 3 , we finally choose bagging regression model (Breiman, 1996) as the ensemble metric. Moreover, the bagging ensemble metric shows a higher correlation with human-annotated scores compared with other relevance automatic metrics as shown in the lower part of Table 3.

4.3 Evaluation Scenarios

To validate the effect of different experimental settings on model performance, several state-of-the-art multilingual models are studied under four evaluation scenarios.

Monolingual fine-tuning The pretrained model is tuned for a downstream task using the training data for a specific language and evaluated on the test set for the same language.

Multilingual fine-tuning The pretrained model is jointly fine-tuned with data in all languages for a specific task. Different from the monolingual fine-tuning setting, there is only one model for each downstream task, which can serve all languages.

Cross-lingual generation Since MTG is multiway parallel, it can be reorganized to create input-output pairs that belong to different languages. In this paper, we make use of the multiway parallel data to do the supervised cross-lingual training, e.g., for English centric cross-lingual training, we take the English source as the input and the parallel German, French, Spanish, Chinese target as the output. Then we evaluate the model on same setting (en->de, en->es, en->fr, en->zh). The cross-lingual generation performances on all $5 * 4$ directions are evaluated.

Zero-shot transfer We also try to explore the zero-shot ability of multilingual pretrained models on the four tasks. The model is fine-tuned on a specific task with English input and output. Then it is used to generate output in other languages with a given language tag.

5 Results

5.1 Monolingual and Cross-lingual

This section displays the monolingual and cross-lingual model comparison to explore their performances in different tasks and languages. Figure 1 contains the five language-centric cross-lingual and monolingual results. Several conclusions can be drawn from the results:

The performance of Cross-lingual is better than monolingual in some cases. As shown in Figure 1, model performances on ensemble scores in cross-lingual setting exceed those in monolingual setting frequently (e.g., the monolingual result of French underperforms the English to French cross-lingual result in Figure 1(b)). This is because the cross-lingual models are trained with more data (e.g., the English centric cross-lingual model is trained with en->de, en->fr, en->es, en->zh data), and the data from different cross-lingual directions can sometimes benefit from each other thus improving the model performance.

Chinese text generation is challenging in cross-lingual setting. As illustrated in Figure 1, nearly all models obtain inferior scores when generating Chinese text. Also, model results on Chinese inputs are usually worse than results on inputs in other languages. The wide discrepancies in grammar and vocabulary between Chinese and other languages lead to the poor performance of cross-lingual generation when either the target language or source language is Chinese.

Multilingual pretrained models obtain lower scores on the Summarization task. Compared with other tasks, summarization task requires longer output, which increases the difficulty of text generation, thus causing poor performance both in cross-lingual and monolingual settings.

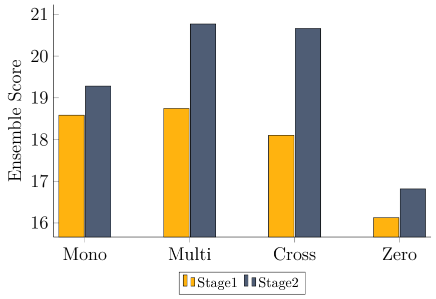

Figure 2: The different stage performances averaged across five languages of XLM in summarization under various settings. Here stage1 represents models trained only on rough training data while stage2 represents models further trained on human-annotated training data based on models in stage1.

5.2 Monolingual and Multilingual

In addition to cross-lingual analysis, we also explore the performance difference between models trained in monolingual and multilingual settings. Table 4 displays the monolingual and multilingual training results for four models in four tasks.

In most cases, multilingual training can improve model performance on relevance. As shown in Table 4, 75 out of 96 multilingual results outperform the monolingual counterparts on various relevance metrics in different tasks. The reason is that the multilingual data in MTG is fully parallel across all five languages and every sample has semantically aligned counterparts in other languages. It makes better semantic fusion among different languages, thus boosting the multilingual training performance.

The advantages of multilingual training are not obvious on diversity measured by distinct-1. Especially in the story generation task, 3 out of 4 models obtain better distinct-1 scores in monolingual setting than in multilingual one. Diversity can not be improved by semantic sharing across languages especially when the samples of them are multiway parallel. This is because the multiway parallel dataset with the semantic aligned samples repeating in different languages encourages models to generate similar texts to some extent.

5.3 Zero-shot results

To test the cross-lingual generation ability of multilingual pretrained models when no direct cross-lingual training data are provided, we evaluate the zero-shot cross-lingual generation performance.

Table 5 presents the zero-shot results for XLM in four tasks. It demonstrates that the multilin-

Table 5: English centric zero-shot and cross-lingual results for XLM on four tasks. Scores on the left and right side of each cell represent the zero-shot and cross-lingual results respectively.

gual pretrained model XLM still lacks the ability to generate high-quality cross-lingual output in zero-shot scenario. **Moreover, English to Chinese and French zero-shot generation shows inferior performance.**[9] The performance decline is rather salient when generating Chinese text. This is because Chinese and French (especially Chinese) are distant from English in the language family tree. **On the other hand, zero-shot results underperform cross-lingual results** which further emphasizes the importance of direct cross-lingual training data for cross-lingual text generation.

5.4 Pseudo and Annotated Data

To answer the question "Does the 400k annotated training data help the model generate better? ", we use the rough training data filtered by back translation for the first stage fine-tuning and the annotated training data for the second stage. The ablation study results on the two-step fine-tuning in summarization under all evaluation scenarios with XLM are illustrated in Figure 2.

The extra human-annotated data boost model performance by at least 3.8% on the ensemble metric. We also make a T-test and prove that the improvement of annotated training data is significant in all settings.[10] **It demonstrates that although the number of annotated data is small, it can significantly improve the performance.** It also highlights the necessity of human-annotated multilingual data compared with pseudo-parallel data via machine translation.

Setting	Model	Gram.	Flu.	Rel.	lang fuse	task spec.

	zero	1.57	1.54	1.58	0.03	1.59

Table 6: Human evaluation scores averaged on five languages for mBART on four tasks. 'Gram.', 'Flu.', 'Rel.', 'Lang Fu.', 'Task Spec.' indicates **Grammar**, **Fluency**, **Relevance**, **Language Fusion** and **Task Specific** scores respectively.

5.5 Human evaluation

Table 6 presents the human evaluation scores for mBART in four tasks. Multilingual training results can surpass the monolingual results in QG, TG and Summ on relevance. In terms of task-specific score, multilingual results are also superior in SG and QG. This is consistent with the conclusion in Sec. 5.2. On the other hand, language fusion scores in zero-shot setting are extremely low, indicating the pretrained models still lack the ability to generate texts in correct language in zero-shot setting.

6 Leaderboard

We build a leaderboard for MTG[11]. It provides an overall evaluation of models in two scores:

MTGScore MTGScore is designed to evaluate the multilingual model. It is the average of ensem-

---

[9] Zero-shot results show the same trend as shown in Table 18 in Appendix.

[10] The t-test details are shown in Appendix C.

[11] The address of MTG leaderboard is `https://mtg-benchmark.netlify.app/`

Models	MTGScore	MTGScore-XL
M-BERT	28.24	27.72
XLM	27.07	26.99
mBART	29.37	25.63
mT5	29.07	28.63

Table 7: MTGScore and MTGScore-XL for the four multilingual pretrained models.

ble scores over all languages and tasks.

MTGScore-XL MTGScore-XL is a special score for MTG. It enbales better evaluation of cross-lingual generation ability by testing model in 25 cross-lingual directions. It is the average of ensemble scores over all tasks and all cross-lingual language directions.

The MTGScore and MTGScore-XL for the four multilingual pretrained models are shown in Table 7.

7 Discussions

Considering the annotation cost, it is not realistic to construct a multiway text generation dataset with all data annotated by human. As a consequence, most of the non-English data in MTG are automatically translated from their English counterparts. Although the n-gram consistency check when round-trip translating the data can guarantee the quality of them to some extent, some translation errors are inevitable. MTG with more annotated data and with data filtered by more reliable methods will be explored in the future.

On the other hand, human often gives an overall evaluation of a generated text rather than measuring it in fine-grained aspects of grammar, fluency and relevance. Thus we try to propose a metric measuring how a text resembles human writing and consider grammar, fluency and relevance as a whole. This metric may not be perfect, but it is a promising direction as there does not exist a really reliable text generation metric nowadays.

8 Conclusion

In this paper, we propose a multilingual multiway benchmark MTG for text generation. It contains four typical generation tasks: story, question, title generation and text summarization. The key feature of MTG is that it has multiway parallel data across five diverse languages: English, German, French, Spanish and Chinese. It provides the benchmark with the ability to create cross-lingual data between any two languages and makes the semantic fusion between languages easier. On the other hand, it provides more evaluation scenarios, such as multilingual training, cross-lingual generation and zero-shot transfer. We also benchmark state-of-the-art multilingual pretrained models on our MTG from different metrics (including a newly proposed ensemble metric) to explore its features and promote research in multilingual text generation.

9 Ethics Consideration

Since we propose a new multilingual text generation benchmark MTG, we solve some possible ethic considerations in this section.

English dataset We choose ROCStories, SQUAD 1.0, ByteCup and CNN/DailyMail as the English datasets for story, question, title generation and text summarization tasks. All of them are available for research use under their licenses. They can be downloaded free from their websites[12]. We ensure that these datasets are only used for academic research and the dataset construction process complies with the intellectual property and privacy rights of the original authors. Also, our proposed benchmark suite MTG should only be used for academic research purposes.

Annotation process As described in Sec. 3.3, we hire some full-time and part-time language experts to do the annotation. Full-time experts are paid \$40 per day and part-time annotators are paid \$0.2 per example[13]. Their salary is higher than the local average hourly minimum wage. All annotators are aware of any risk of harm associated with their participation. The annotation process is in compliance with the intellectual property and privacy rights of the recruited annotators. The annotation protocol is proved by the legal department inside the company.

Risk Concern In this paper we propose a new ensemble metric measuring to what degree is the generated text close to human-level. The further pursue for more human-like multilingual generation will possibly raise safety concerns.

---

[12] ROCStories requires for some necessary contact information

[13] Full-time employees work at most 8 hours per day, and the local minimum hourly wage is \$3.7. The part-time annotators can produce at least 20 examples per hour.

A Back Translation Threshold Testing

The detailed data sizes of back translation filtered datasets for different tasks are presented in Table 8.

B Experimental settings

The overall statistics for multilingual pretrained models are presented in Table 9 and the detailed descriptions for them are as follows:

1**M-BERT** Multilingual BERT (M-BERT) (Devlin et al., 2019) is a single language model pretrained from monolingual corpora in 104 languages using Masked Language Modeling (MLM) task. M-BERT leverages a shared vocabulary of 110k WordPiece tokens and has 12 layers with 172M parameters totally.

XLM The Cross-Lingual Language Model (XLM) (Lample and Conneau, 2019) is pre-trained simultaneously with Masked Language Model (MLM) task using monolingual data and Translation Language Model (TLM) task using parallel data. XLM has a shared vocabulary of 200k byte-pair encoded (BPE) subwords (Sennrich et al., 2016) and 16 layers totaling 570M parameters.

1**mBART** Multilingual BART (mBART) (Liu et al., 2020) is a pre-trained encoder-decoder model using denoising auto-encoding objective on monolingual data over 25 languages. mBART has a shared vocabulary of 250k tokens leveraging Sentence Piece tokenization scheme. mBART consists of 12-layer encoder and 12-layer decoder with a total of 680M parameters.

mT5 Multilingual T5 (mT5) (Xue et al., 2020) is a multilingual variant of T5 (Raffel et al., 2020) leveraging a text-to-text format. mT5 is pre-trained on a span-corruption version of Masked Language Modeling objective over 101 languages. It is composed of 24-encoder layers and 24 decoder layers with 13B parameters.

We use the encoder-decoder architecture for our generation tasks. Among the models described above, mBART and mT5 have been pretrained for generation tasks, but M-BERT and XLM are only pretrained for encoder representations. Therefore, we initialize the decoder with the encoder parameters for M-BERT and XLM. During the pretraining phase, there are no language tags in M-BERT and mT5. Thus we manually add the language tag at the beginning of the source and target for M-BERT and add the target language tag to the beginning of source for mT5.

We adjust the input format for each task. For QG, we append the answer to the passage and insert a special token to separate them. For SG, we take the beginning four sentences as the source and make the last sentence as the target.

We take a two-step finetuning to make full use of our MTG benchmark. We first use the large rough parallel training data to train our models on the downstream tasks for 20 epochs, and then finetune the models on the small annotated training data to further improve the generation performance for 10 epochs. We evaluate the model for every 2000 steps and use the loss on development to choose the best model. The batch size is 32. The learning rate and optimizer parameters are set to the default parameters for each model. All models are trained with 32GB Tesla-V100.

Threshold	QG	TG	SG	Summ
0	82306	393792	88161	287083
0.3	80836	355034	88158	243698
0.4	79390	333461	88077	217777
0.5	71819	280376	87003	164355
0.6	32261	144109	75892	58060

Table 8: The data sizes of datasets filtered by back translation with respect to different thresholds.

Models	Arch	# langs	# vocab	# layers	# params
M-BERT	enc	104	110k	12	172M
XLM	enc	17	200k	16	570M
mBART	enc-dec	25	250k	12	680M
mT5	enc-dec	101	250k	24	13B

Table 9: The overall statistics for multilingual pretrained models. Arch means the architectures of models. # vocab means the vocabulary sizes of models. # langs, # layers and # params mean the number of languages, layers and parameters respectively.

C Significant Test Results

The average ensemble metric scores for stage1 and stage2 in four tasks and the corresponding significant test p-values are displayed in Table 10. As it shows, adding human-annotated training data can always improve the model performance under different settings. The improvements are significant in all settings.

Tasks		Mono	Multi	Cross	Zero
SG	stage1	0.268	0.270	0.258	0.125
	stage2	**0.284**	**0.284**	**0.289**	**0.167**
	p-value	0.000	0.000	0.000	0.000
QG	stage1	0.286	0.287	0.279	0.235
	stage2	**0.301**	**0.300**	**0.295**	**0.258**
	p-value	0.000	0.000	0.000	0.000
TG	stage1	0.257	0.270	0.268	0.223
	stage2	**0.288**	**0.291**	**0.289**	**0.232**
	p-value	0.000	0.000	0.000	0.003
Summ	stage1	0.186	0.187	0.181	0.161
	stage2	**0.193**	**0.208**	**0.207**	**0.168**
	p-value	0.001	0.000	0.000	0.004

Table 10: The average ensemble metric scores for XLM for stage1 and stage2 in four tasks in four settings and the corresponding t test p-values. Here stage1 represents models trained only on rouge training data while stage2 represents models further trained on human-annotated training data based on models in stage1. The bold cell means the significantly higher score between stage1 and stage2 scores.

D Experimental Results

We present detailed experimental results of our four baseline models under four different evaluation settings here.

Abstract

Text-to-SQL parsers are crucial in enabling non-experts to effortlessly query relational data. Training such parsers, by contrast, generally requires expertise in annotating natural language (NL) utterances with corresponding SQL queries. In this work, we propose a *weak supervision* approach for training text-to-SQL parsers. We take advantage of the recently proposed question meaning representation called QDMR, an intermediate between NL and formal query languages. Given questions, their QDMR structures (annotated by non-experts or automatically predicted), and the answers, we are able to automatically synthesize SQL queries that are used to train text-to-SQL models. We test our approach by experimenting on five benchmark datasets. Our results show that the weakly supervised models perform competitively with those trained on annotated NL-SQL data. Overall, we effectively train text-to-SQL parsers, while using zero SQL annotations.

1 Introduction

The development of natural language interfaces to databases has been extensively studied in recent years (Affolter et al., 2019; Kim et al., 2020; Thorne et al., 2021). The current standard is Machine Learning (ML) models which map utterances in natural language (NL) to executable SQL queries (Wang et al., 2020; Rubin and Berant, 2021). These models rely on supervised training examples of NL questions labeled with their corresponding SQL queries. Labeling copious amounts of data is cost-prohibitive as it requires experts that are familiar both with SQL and with the underlying database structure (Yu et al., 2018). Furthermore, it is often difficult to re-use existing training data in one domain in order to generalize to new ones (Suhr et al., 2020). Adapting the model to a new domain requires new NL-SQL training examples, which results in yet another costly round of annotation.

In this paper we propose a *weak supervision* approach for training text-to-SQL parsers. We avoid the use of manually labeled NL-SQL examples and rely instead on data provided by non-expert users. Fig. 1 presents a high-level view of our approach. The input (left corner, in red) is used to automatically synthesize SQL queries (step 3, in green) which, in turn, are used to train a text-to-SQL model. The supervision signal consists of the question's answer and uniquely, a structured representation of the *question decomposition*, called QDMR. The annotation of both these supervision sources can be effectively crowdsourced to non-experts (Berant et al., 2013; Pasupat and Liang, 2015; Wolfson et al., 2020). In a nutshell, QDMR is a series of computational steps, expressed by semi-structured utterances, that together match the semantics of the original question. The bottom left corner of Fig. 1 shows an example QDMR of the question *"Which authors have more than 10 papers in the PVLDB journal?"*. The question is broken into five steps, where each step expresses a single logical operation (e.g., select papers, filter those in PVLDB) and may refer to previous steps. As QDMR is derived entirely from its question, it is agnostic to the underlying form of knowledge representation and has been used for questions on images, text and databases (Subramanian et al., 2020; Geva et al., 2021; Saparina and Osokin, 2021). In our work, we use QDMR as an intermediate representation for SQL synthesis. Namely, we implement an automatic procedure that given an input QDMR, maps it to SQL. The QDMR can either be manually annotated or effectively predicted by a trained model, as shown in our experiments.

We continue to describe the main components of our system, using the aforementioned supervision (Fig. 1). The *SQL Synthesis* component (step 1) attempts to convert the input QDMR into a corresponding SQL query. To this end, *Phrase DB linking* matches phrases in the QDMR with rele-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2528 - 2542

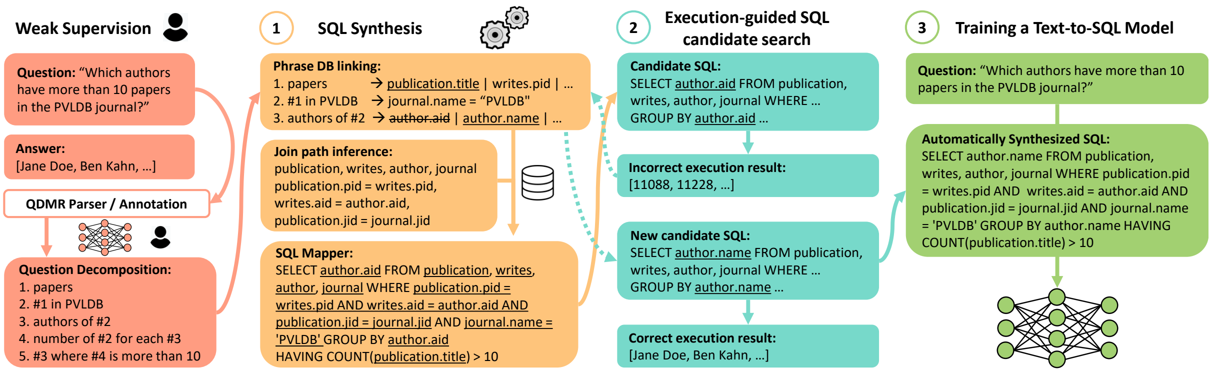

Figure 1: Our pipeline for training a Text-to-SQL model on data synthesized using weak supervision.

vant columns and values in the database. Next, SQL *join paths* are automatically inferred given the database schema structure. Last, the QDMR, DB-linked columns and inferred join paths are converted to SQL by the *SQL Mapper*. In step 2, we rely on question-answer supervision to filter out incorrect candidate SQL. Thus, our *Execution-guided SQL Search* returns the first candidate query which executes to the correct answer.

Given our synthesis procedure, we evaluate its ability to produce accurate SQL, using weak supervision. To this end, we run our synthesis on 9,313 examples of questions, answers and QDMRs from five standard text-to-SQL benchmarks (Zelle and Mooney, 1996; Li and Jagadish, 2014; Yaghmazadeh et al., 2017; Yu et al., 2018). Overall, our solution successfully synthesizes SQL queries for 77.8% of examples, thereby demonstrating its applicability to a broad range of target databases.

Next, we show our synthesized queries to be an effective alternative to training on expert annotated SQL. We compare a text-to-SQL model, trained on the queries synthesized from questions, answers and QDMRs, to one trained using gold SQL. As our model of choice we use T5-large, which is widely used for sequence-to-sequence modeling tasks (Raffel et al., 2020). Following past work (Shaw et al., 2021; Herzig et al., 2021), we fine-tune T5 to map text to SQL. We experiment with the SPIDER and GEO880 datasets (Yu et al., 2018; Zelle and Mooney, 1996) and compare model performance based on the training supervision. When training on manually *annotated QDMRs*, the weakly supervised models achieve 91% to 97% of the accuracy of models trained on gold SQL. We further extend our approach to use automatically *predicted QDMRs*, requiring zero annotation of in-domain QDMRs. Notably, when training on predicted QDMRs models still reach 86% to 93% of the fully supervised versions accuracy. In addition, we evaluate cross-database generalization of models trained on SPIDER (Suhr et al., 2020). We test our models on four additional datasets and show that the weakly supervised models are generally better than the fully supervised ones in terms of cross-database generalization. Overall, our findings show that weak supervision, in the form of question, answers and QDMRs (annotated or predicted) is nearly as effective as gold SQL when training text-to-SQL parsers.

Our codebase and data are publicly available.[1]

2 Background

Weakly Supervised ML The performance of supervised ML models hinges on the quantity and quality of their training data. In practice, labeling large-scale datasets for new tasks is often cost-prohibitive. This problem is further exacerbated in semantic parsing tasks (Zettlemoyer and Collins, 2005), as utterances need to be labeled with formal queries. *Weak supervision* is a broad class of methods aimed at reducing the need to manually label large training sets (Hoffmann et al., 2011; Ratner et al., 2017; Zhang et al., 2019). An influential line of work has been dedicated to weakly supervised semantic parsing, using question-answer pairs, referred to as *learning from denotations* (Clarke et al., 2010; Liang et al., 2011). Past work has shown that non-experts are capable of annotating answers over knowledge graphs (Berant et al., 2013) and tabular data (Pasupat and Liang, 2015). This approach could potentially be extended to databases by sampling subsets of its tables, such that question-answer examples can be manually annotated. A key issue in learning text-to-SQL parsers from denotations is the vast search space of potential candidate

---

[1] `https://github.com/tomerwolgithub/question-decomposition-to-sql`

queries. Therefore, past work has focused on constraining the search space, which limited applicability to simpler questions over single tables (Wang et al., 2019). Here, we handle arbitrary SQL by using QDMR to constrain the search space.

Question Decomposition QDMR expresses the meaning of a question by breaking it down into simpler sub-questions. Given a question x, its QDMR s is a sequence of reasoning steps $s^1, ..., s^{|s|}$ required to answer x. Each step s^k is an intermediate question which represents a relational operation, such as projection or aggregation. Steps may contain phrases from x, tokens signifying a query operation (e.g., *"for each"*) and references to previous steps. Operation tokens indicate the structure of a step, while its arguments are the references and question phrases. A key advantage of QDMR is that it can be annotated by non-experts and at scale (Wolfson et al., 2020). Moreover, unlike SQL, annotating QDMR requires zero domain expertise as it is derived entirely from the original question.

3 Weakly Supervised SQL Synthesis

Our input data contains examples of question x_i, database D_i, the answer a_i, and s_i, which is the QDMR of x_i. The QDMR is either annotated or predicted by a trained model f, such that $f(x_i) = s_i$. For each example, we attempt to synthesize a SQL query $\hat{Q}_i$, that matches the intent of x_i and executes to its answer, $\hat{Q}_i(D_i) = a_i$. The successfully synthesized examples $\langle x_i, \hat{Q}_i \rangle$ are then used to train a text-to-SQL model.

3.1 Synthesizing SQL from QDMR

Given QDMR s_i and database D_i, we automatically map s_i to SQL. Alg. 1 describes the synthesis process, where candidate query $\hat{Q}_i$ is incrementally synthesized by iterating over the QDMR steps. Given step s_i^k, its phrases are automatically linked to columns and values in D_i. Then, relevant join paths are inferred between the columns. Last, each step is automatically mapped to SQL based on its QDMR operator and its arguments (see Table 1).

3.1.1 Phrase DB Linking

As discussed in §2, a QDMR step may have a phrase from x_i as its argument. When mapping QDMR to SQL these phrases are linked to corresponding columns or values in D_i. For example, in Table 1 the two phrases *"ships"* and *"injuries"* are linked to columns `ship.id` and `death.injured` respectively. We perform phrase-column linking automatically by ranking all columns in D_i and returning the top one. The ranked list of columns is later used in §3.2 when searching for a correct assignment to all phrases in the QDMR. To compute phrase-column similarity, we tokenize both the phrase and column, then lemmatize their tokens using the WordNet lemmatizer.[2] The similarity score is the average GloVe word embeddings similarity (Pennington et al., 2014) between the phrase and column tokens. All columns in D_i are then ranked based on their word overlap and similarity with the phrase: (1) we return columns whose lemmatized tokens are identical to those in the phrase; (2) we return columns who share (non stop-word) tokens with the phrase, ordered by phrase-column similarity; (3) we return the remaining columns, ordered by similarity.

Algorithm 1 SQL Synthesis

```
procedure SQLSYNTH($\mathbf{s}$: QDMR, $D$: database)
    mapped ← []
    for $s^k$ in $\mathbf{s} = \langle s^1, ..., s^n \rangle$ do
        cols ← PHRASECOLUMNLINK($D$, $s^k$)
        refs ← REFERENCEDSTEPS($s^k$)
        join ← []
        for $s^j$ in refs do
            other_cols ← mapped[$j$].cols
            join ← join + JOINP($D$, cols, other_cols)
        op ← OPTYPE($s^k$)
        $\hat{Q}$ ← MAPSQL(op, cols, join, refs, mapped)
        mapped[$k$] ← $\langle s^k$, cols, $\hat{Q} \rangle$
    return mapped[$n$].$\hat{Q}$
```

We assume that literal values in D_i, such as strings or dates, appear verbatim in the database as they do in the question. Therefore, using string matching, we can identify the columns containing all literal values mentioned in s_i. If a literal value appears in multiple columns, they are all returned as potential links. This assumption may not always hold in practice due to DB-specific language, e.g., the phrase *"women"* may correspond to the condition `gender = 'F'`. Consequently, we measure the effect of DB-specific language in §4.2.

3.1.2 Join Path Inference

In order to synthesize SQL (Codd, 1970), we infer join paths between the linked columns returned in §3.1.1. Following past work (Guo et al., 2019; Suhr et al., 2020), we implement a heuristic returning the shortest join path connecting two sets of columns. To compute join paths, we convert D_i into a graph where the nodes are its tables and edges exist for every foreign-key constraint connecting two tables.

---

[2] `https://www.nltk.org/`

QDMR Step	Phrase-DB Linking	SQL
1. ships	1. `SELECT(ship.id)`	`SELECT ship.id FROM ship;`
2. injuries	2. `SELECT(death.injured)`	`SELECT death.injured FROM death;`
3. number of #2 for each #1	3. `GROUP(count, #2, #1)`	`SELECT COUNT(death.injured) FROM ship, death WHERE death.caused_by_ship_id = ship.id GROUP BY ship.id;`
4. #1 where #3 is highest	4. `SUPER.(max, #1, #3)`	`SELECT ship.id FROM ship, death WHERE death.caused_by_ship_id = ship.id GROUP BY ship.id ORDER BY COUNT(death.injured) DESC LIMIT 1;`
5. the name of #4	5. `PROJECT(ship.name, #4)`	`SELECT ship.name FROM ship, death WHERE death.caused_by_ship_id = ship.id AND ship.id IN (#4);`

Table 1: Mapping the QDMR of the question *"What is the ship name that caused most total injuries?"* to SQL.

x: **"What are the populations of states through which the Mississippi river runs?"**

s: the Mississippi river; states #1 runs through; the populations of #2

```
1. SELECT(river.river_name = 'Mississippi')
2. PROJECT(state.state_name, #1)
3. PROJECT(state.population, #2)
```

```
1. SELECT river.river_name FROM river WHERE
   river.river_name = 'Mississippi';
2. SELECT state.state_name FROM state, river
   WHERE river.traverse = state.state_name AND
   river.river_name IN (#1);
3. SELECT state.population FROM state, river
   WHERE river.traverse = state.state_name AND
   state.state_name IN (#2);
```

Figure 2: Previously mapped QDMR steps (with operations and arguments) used as nested SQL queries.

The JOINP procedure in Alg. 1 joins the tables of columns mentioned in step s^k (*cols*) with those mentioned in the previous steps which s^k refers to (*other_cols*). If multiple shortest paths exist, it returns the first path which contains either $c_i \in$ *cols* as its start node or $c_j \in$ *other_cols* as its end node. Step 3 of Table 1 underlines the join path between the `death` and `ship` tables.

3.1.3 QDMR to SQL Mapper

The MAPSQL procedure in Alg. 1 maps QDMR steps into executable SQL. First, the QDMR operation of each step is inferred from its utterance template using the OPTYPE procedure of Wolfson et al. (2020). Then, following the previous DB linking phase, the arguments of each step are either the linked columns and values or references to previous steps (second column of Table 1). MAPSQL uses the step operation type and arguments to automatically map s^k to a SQL query $\hat{Q}^k$. Each operation has a unique mapping rule to SQL, as shown in Table 2. SQL mapping is performed incrementally for each step. Then, when previous steps are referenced, the process can re-use parts of their previously mapped SQL (stored in the *mapped* array). Furthermore, our mapping procedure is able to handle complex SQL that may involve nested queries (Fig. 2) and self-joins (Fig. 3).

x: **"What papers were written by both H. V. Jagadish and also Yunyao Li?"**

s: papers; #1 by H. V. Jagadish; #2 by Yunyao Li

```
1. SELECT(publication.title)
2. FILTER(#1, author.name = 'H. V. Jagadish')
3. FILTER(#2, author.name = 'Yunyao Li')
```

```
1. SELECT publication.title FROM author, publi-
   cation;
2. SELECT publication.title FROM author, pub-
   lication, writes WHERE publication.pid=
   writes.pid AND writes.aid = author.aid AND
   author.name = 'H. V. Jagadish';
3. SELECT publication.title FROM author, pub-
   lication, writes WHERE publication.pid
   = writes.pid AND writes.aid = author.aid
   AND author.name = 'Yunyao Li' AND publica-
   tion.title IN (#2);
```

Figure 3: Handling Self-joins in QDMR mapping. The two `FILTER` steps have conflicting assignments to the same column and are identified as a self-join. This is resolved by using a nested query in the SQL of step 3.

3.2 Execution-guided SQL Candidate Search

At this point we have $\hat{Q}_i$, which is a potential SQL candidate. However, this candidate may be incorrect due to a wrong phrase-column linking or due to its original QDMR structure. To mitigate these issues, we search for accurate SQL candidates using the answer supervision.

Following phrase DB linking (§3.1.1), each phrase is assigned its top ranked column in D_i. However, this assignment may potentially be wrong. In step 1 of Fig. 1 the phrase *"authors"* is incorrectly linked to `author.aid` instead of `author.name`. Given our weak supervision, we do not have access to the gold phrase-column linking and rely instead on the gold answer a_i. Namely, we iterate over phrase-column assignments and synthesize their corresponding SQL. Once an assignment whose SQL executes to a_i has been found, we return it as our result. We iterate over assignments that cover only the top-k ranked columns for each phrase, shown to work very well in practice (§4.2).

Failing to find a correct candidate SQL may be due to QDMR structure rather than phrase-column linking. As s_i is derived entirely from

QDMR Operation	SQL Mapping
`SELECT(t.col)`	`SELECT t.col FROM t;`
`FILTER(#x, =, val)`	`SELECT #x[SELECT] FROM #x[FROM] WHERE #x[WHERE] AND t.col = val;`
`PROJECT(t.col, #x)`	`SELECT t.col FROM t, #x[FROM] WHERE Join(t, #x[FROM]) AND #x[SELECT] IN (#x);`
`AGGREGATE(count, #x)`	`SELECT COUNT(#x[SELECT]) FROM #x[FROM] WHERE #x[WHERE];`
`GROUP(avg, #x, #y)`	`SELECT AVG(#x[SELECT]) FROM #x[FROM], #y[FROM] WHERE Join(#x[FROM], #y[FROM]) AND #x[WHERE] AND #y[WHERE] GROUP BY #y[SELECT];`
`SUPER.(max, k, #x, #y)`	`SELECT #x[SELECT] FROM #x[FROM], #y[FROM] WHERE Join(#x[FROM], #y[FROM]) AND #x[WHERE] AND #y[WHERE] ORDER BY #y[SELECT] DESC k;`

Table 2: QDMR to SQL mapping rules for six operations. The full set of mapping rules, for all QDMR operations, is provided in the Appendix A. #x denotes a previously mapped SQL query while #x[CLAUSE] denotes its relevant SQL clause. For example, #x[FROM] returns all tables in the FROM clause of SQL query #x.

the question it may fail to capture database-specific language. E.g., in the question *"How many students enrolled during the semester?"* the necessary aggregate operation may change depending on the database structure. If D_i has the column `course.num_enrolled`, the query should *sum* its entries for all courses in the semester. Conversely, if D_i has the column `course.student_id`, the corresponding query would need to *count* the number of enrolled students. We account for these structural mismatches by implementing three additional search heuristics which modify the structure of a candidate $\hat{Q}_i$. If the candidate executes to the correct result following modification, it is returned by the search process. These modifications are described in detail in Appendix B. Namely, they include the addition of a `DISTINCT` clause, converting QDMR `FILTER` steps into `SUPERLATIVE` and switching between the `COUNT` and `SUM` operations.

4 Experiments

Our experiments target two main research questions. First, given access to weak supervision of question-answer pairs and QDMRs, we wish to measure the percentage of SQL queries that can be automatically synthesized. Therefore, in §4.2 we measure SQL synthesis *coverage* using 9,313 examples taken from five benchmark datasets. Second, in §4.3 we use the synthesized SQL to train text-to-SQL models and compare their performance to those trained on gold SQL annotations.

4.1 Setting

Datasets We evaluate both the SQL synthesis coverage and text-to-SQL accuracy using five text-to-SQL datasets (see Table 3). The first four datasets contain questions over a single database: Academic (Li and Jagadish, 2014) has questions over the Microsoft Academic Search database; Geo880 (Zelle and Mooney, 1996) concerns US geography; IMDB and Yelp (Yaghmazadeh et al., 2017) contain complex questions on a film and restaurants database, respectively. The Spider dataset (Yu et al., 2018) measures *domain generalization* between databases, and therefore contains questions over 160 different databases. For QDMR data we use the Break dataset (Wolfson et al., 2020). The only exception is 259 questions of IMDB and Yelp, outside of Break, which we (authors) annotate with corresponding QDMRs and release with our code. See Appendix C for license.

Training We fine-tune the T5-large sequence-to-sequence model (Raffel et al., 2020) for both text-to-SQL and QDMR parsing (§4.2). Namely, for each task we fine-tune the pre-trained model on its specific data. For text-to-SQL, we fine-tune on mapping utterances $x_i; cols(D_i)$ to SQL, where sequence $cols(D_i)$ is a serialization of all columns in database D_i, in an arbitrary order. In QDMR parsing, input questions are mapped to output QDMR strings. We use the T5 implementation by HuggingFace (Wolf et al., 2020) and train using the Adam optimizer (Kingma and Ba, 2014). Following fine-tuning on the dev sets, we adjust the batch size to 128 and the learning rate to $1e$-4 (after experimenting with $1e$-5, $1e$-4 and $1e$-3). All models were trained on an NVIDIA GeForce RTX 3090 GPU.

4.2 SQL Synthesis Coverage

Our first challenge is to measure our ability to synthesize accurate SQL. To evaluate SQL synthesis we define its *coverage* to be the percentage of examples where it successfully produces SQL $\hat{Q}$ which executes to the correct answer. To ensure our procedure is domain independent, we test it on five different datasets, spanning 164 databases (Table 3).

Dataset	DB #	Examples	Synthesized	Coverage %
ACADEMIC	1	195	155	79.5
GEO880	1	877	736	83.9
IMDB	1	131	116	88.5
YELP	1	128	100	78.1
SPIDER dev	20	1,027	793	77.2
SPIDER train	140	6,955	5,349	76.9
Total:	**164**	**9,313**	**7,249**	**77.8**
SPIDER pred.	20	1,027	797	77.6

Table 3: SQL synthesis coverage scores across datasets.

Error	Description	%
Nonstandard QDMR	The annotated QDMR contains a step utterance that does not follow any of the pre-specified operation templates in Wolfson et al. (2020)	42
DB-specific language	Phrase entails an implicit condition, e.g., *"female workers"* → `emp.gender = 'F'`	23
Phrase-column link.	The correct phrase-column assignment falls outside of the top-k candidates (§3.2)	13
Gold SQL	An error due to an incorrectly labeled gold SQL	6

Table 4: SQL synthesis error analysis.

Annotated QDMRs The upper rows of Table 3 list the SQL synthesis coverage when using manually annotated QDMRs from BREAK. Overall, we evaluate on 9,313 QDMR annotated examples, reaching a coverage of 77.8%. Synthesis coverage for single-DB datasets tends to be slightly higher than that of SPIDER, which we attribute to its larger size and diversity. To further ensure the quality of synthesized SQL, we manually validate a random subset of 100 queries out of the 7,249 that were synthesized. Our analysis reveals 95% of the queries to be correct interpretations of their original question. In addition, we evaluate synthesis coverage on a subset of 8,887 examples whose SQL denotations are not the empty set. As SQL synthesis relies on answer supervision, discarding examples with empty denotations eliminates the false positives of spurious SQL which incidentally execute to an empty set. Overall, coverage on examples with non-empty denotations is nearly identical, at 77.6% (see Appendix D). We also perform an error analysis on a random set of 100 failed examples, presented in Table 4. SQL synthesis failures are mostly due to QDMR annotation errors or implicit database-specific conditions. E.g., in GEO880 the phrase *"major river"* should implicitly be mapped to the condition `river.length > 750`. As our SQL synthesis is domain-general, it does not memorize any domain-specific jargon or rules.

Predicted QDMRs While QDMR annotation can be crowdsourced to non-experts (Wolfson et al., 2020), moving to a new domain may incur annotating new in-domain examples. Our first step to address this issue is to evaluate the coverage of SQL synthesis on predicted QDMRs, for out-of-domain questions. As question domains in SPIDER dev differ from those in its training set, it serves as our initial testbed. We further explore this setting in §4.3.4. Our QDMR parser (§4.1) is fine-tuned on BREAK for 10 epochs and we select the model with highest exact string match (EM) on BREAK dev. Evaluating on the hidden test set reveals our model scores 42.3 normalized EM,[3] setting the state-of-the-art on BREAK.[4] The predicted QDMRs, are then used in SQL synthesis together with examples $\langle x_i, a_i, D_i \rangle$. In Table 3, the last row shows that coverage on SPIDER dev is nearly identical to that of manually annotated QDMRs (77.6% to 77.2%).

4.3 Training Text-to-SQL Models

Next, we compare text-to-SQL models trained on our synthesized data to training on expert annotated SQL. Given examples $\langle x_i, D_i \rangle$ we test the following settings: (1) A *fully supervised* training set, that uses gold SQL annotations $\{\langle x_i, Q_i, D_i \rangle\}_{i=1}^{n}$. (2) A *weakly supervised* training set, where given answer a_i and QDMR s_i, we synthesize queries $\hat{Q}_i$. As SQL synthesis coverage is less than 100%, the process returns a subset of $m < n$ examples $\{\langle x_i, \hat{Q}_i, D_i \rangle\}_{i=1}^{m}$ on which the model is trained.[5]

4.3.1 Training Data

We train models on two text-to-SQL datasets: SPIDER (Yu et al., 2018) and GEO880 (Zelle and Mooney, 1996). As our weakly supervised training sets, we use the synthesized examples $\langle x_i, \hat{Q}_i, D_i \rangle$, described in §4.2, (using annotated QDMRs). We successfully synthesized 5,349 training examples for SPIDER and 547 examples for GEO880 train.

4.3.2 Models and Evaluation

Models We fine-tune T5-large for text-to-SQL, using the hyperparameters from §4.1. We choose T5 as it is agnostic to the structure of its input sequences. Namely, it has been shown to perform competitively on different text-to-SQL datasets, regardless of their SQL conventions (Shaw et al., 2021; Herzig et al., 2021). This property is particularly desirable in our cross-database evaluation (§4.3.3), where we test on multiple datasets.

---

[3] The metric is a strict lower bound on performance.

[4] https://leaderboard.allenai.org/break

[5] In practice, we do not train directly on $\hat{Q}_i$ but on s_i following its phrase-column linking. This representation is then automatically mapped to SQL to evaluate its execution.

Model	Supervision	Training set	Exec. %
T5-SQL-G	$\langle x_i, Q_i, D_i \rangle$	7,000	68.0 ± 0.3
T5-SQL-G$_{\text{part}}$	$\langle x_i, Q_i, D_i \rangle$	5,349	66.4 ± 0.8
T5-QDMR-G	$\langle x_i, a_i, s_i, D_i \rangle$	5,349	65.8 ± 0.3
T5-QDMR-P	$\langle x_i, a_i, D_i \rangle$*	5,075	62.9 ± 0.8

Table 5: SPIDER trained model results on the dev set. *Supervision for T5-QDMR-P also includes 700 annotated QDMRs of SPIDER train questions.

Model	ACADEMIC	GEO880	IMDB	YELP
T5-SQL-G	8.2 ± 1.3	33.6 ± 2.5	19.8 ± 3.6	22.7 ± 1.2
T5-SQL-G$_{\text{part}}$	4.9 ± 1.5	32.4 ± 1.3	20.9 ± 0.8	20.7 ± 1.4
T5-QDMR-G	10.7 ± 0.7	40.4 ± 1.8	27.1 ± 3.6	16.2 ± 4.7
T5-QDMR-P	8.2 ± 0.4	39.7 ± 1.4	23.6 ± 5.5	16.7 ± 3.7

Table 6: SPIDER trained models zero-shot performance on cross-database (XSP) examples.

We train and evaluate the following models:

- **T5-SQL-G** trained on $\{\langle x_i, Q_i, D_i \rangle\}_{i=1}^{n}$, using *gold SQL*, annotated by experts
- **T5-QDMR-G** trained on $\{\langle x_i, \hat{Q}_i, D_i \rangle\}_{i=1}^{m}$ with $\hat{Q}_i$ that were synthesized using weak supervision
- **T5-SQL-G$_{\text{part}}$** trained on $\{\langle x_i, Q_i, D_i \rangle\}_{i=1}^{m}$, using gold SQL. This models helps us measure the degree to which the smaller size of the synthesized training data and its different query structure (compared to gold SQL) affects performance

Evaluation Metric Due to our SQL being automatically synthesized, its syntax is often different from that of the gold SQL (see Appendix E.2). As a result, the ESM metric of Yu et al. (2018) does not fit our evaluation setup. Instead, we follow Suhr et al. (2020) and evaluate text-to-SQL models using the *execution accuracy* of output queries. We define execution accuracy as the percentage of output queries which, when executed on the database, result in the same set of tuples (rows) as a_i.

4.3.3 Training on Annotated QDMRs

We begin by comparing the models trained using annotated QDMRs to those trained on gold SQL. Meanwhile, the discussion of T5-QDMR-P, trained using predicted QDMRs, is left for §4.3.4. The results in Tables 5-7 list the average accuracy and standard deviation of three model instances, trained using separate random seeds.

SPIDER & XSP Evaluation Tables 5-6 list the results of the SPIDER trained models. All models were trained for 150 epochs and evaluated on the dev set of 1,034 examples. When comparing T5-QDMR-G to the model trained on gold SQL, it achieves 96.8% of its performance (65.8 to 68.0). The T5-SQL-G$_{\text{part}}$ model, trained on the same 5,349 examples as T5-QDMR-G, performs roughly on par, scoring +0.6 points (66.4 to 65.8).

Model	Supervision	Train. set	Exec. %
T5-SQL-G	$\langle x_i, Q_i, D_i \rangle$	547	82.1 ± 1.9
T5-SQL-G$_{\text{part}}$	$\langle x_i, Q_i, D_i \rangle$	454	79.4 ± 0.4
T5-QDMR-G	$\langle x_i, a_i, s_i, D_i \rangle$	454	74.5 ± 0.2
T5-QDMR-P	$\langle x_i, a_i, D_i \rangle$	432	70.4 ± 0.2

Table 7: GEO880 trained models results on the test set. Supervision for T5-QDMR-P does not include any in-domain annotated QDMRs.

As SPIDER is used to train cross-database models, we further evaluate our models performance on *cross-database semantic parsing* (XSP) (Suhr et al., 2020). In Table 6 we test on four additional text-to-SQL datasets (sizes in parenthesis): ACADEMIC (183), GEO880 (877), IMDB (113) and YELP (66). For ACADEMIC, IMDB and YELP we removed examples whose execution result in an empty set. Otherwise, the significant percentage of such examples would result in false positives of predictions which incidentally execute to an empty set. In practice, evaluation on the full datasets remains mostly unchanged and is provided in Appendix E. Similarly to Suhr et al. (2020), the results in Table 6 show that SPIDER trained models struggle to generalize to XSP examples. However, T5-QDMR-G performance is generally better on XSP examples, which further indicates that QDMR and answer supervision is effective, compared to gold SQL. Example predictions are shown in Appendix E.2.

GEO880 Table 7 lists the execution accuracy of models trained on GEO880. Models were trained for 300 epochs, fine-tuned on the dev set and then evaluated on the 280 test examples. We note that T5-QDMR-G achieves 90.7% of the performance of T5-SQL-G (74.5 to 82.1). The larger performance gap, compared to SPIDER models, may be partly to due to the dataset size. As GEO880 has 547 training examples, fewer synthesized SQL to train T5-QDMR-G on (454) may have had a greater effect on its accuracy.

4.3.4 Training on Predicted QDMRs

We extend our approach by replacing the annotated QDMRs with the predictions of a trained QDMR parser (a T5-large model, see §4.1). In this setting, we now have two sets of questions: (1) questions used to train the QDMR parser; (2) questions used to synthesize NL-SQL data. We want these two sets to be as separate as possible, so that training the QDMR parser would not require new *in-domain* annotations. Namely, the parser must generalize to questions in the NL-SQL domains while being trained on as few of these questions as possible.

Spider Unfortunately, Spider questions make up a large portion of the Break training set, used to train the QDMR parser. We therefore experiment with two alternatives to minimize the in-domain QDMR annotations of NL-SQL questions. First, is to train the parser using few-shot QDMR annotations for Spider. Second, is to split Spider to questions used as the NL-SQL data, while the rest are used to train the QDMR parser.

In Table 5, T5-QDMR-P is trained on 5,075 queries, synthesized using predicted QDMRs (and answer supervision) for Spider train questions. The predictions were generated by a QDMR parser trained on a subset of Break, excluding all Spider questions save 700 (10% of Spider train). Keeping few in-domain examples minimizes additional QDMR annotation while preserving the predictions quality. Training on the predicted QDMRs, instead of the annotated ones, resulted in accuracy being down 2.9 points (65.8 to 62.9) while the model achieves 92.5% of T5-SQL-G performance on Spider dev. On XSP examples, T5-QDMR-P is competitive with T5-QDMR-G (Table 6).

In Table 8, we experiment with training T5-QDMR-P without in-domain QDMR annotations. We avoid any overlap between the questions and domains used to train the QDMR parser and those used for SQL synthesis. We randomly sample 30-40 databases from Spider and use their corresponding questions exclusively as our NL-SQL data. For training the QDMR parser, we use Break while discarding the sampled questions. We experiment with 3 random samples of Spider train, numbering 1,348, 2,028 and 2,076 examples, with synthesized training data of 1,129, 1,440 and 1,552 examples respectively. Results in Table 8 show that, on average, T5-QDMR-P achieves 95.5% of the performance of T5-SQL-G. This indicates that even without any in-domain QDMR annotations, data induced from answer supervision and out-of-domain QDMRs is effective in training text-to-SQL models, compared to gold SQL.

Geo880 For predicted QDMRs on Geo880, we train the QDMR parser on Break while discarding all of its 547 questions. Therefore, the parser was trained without any in-domain QDMR annotations for Geo880. SQL synthesis using the predicted QDMRs resulted in 432 queries. In Table 7, T5-QDMR-P reaches 85.7% of T5-SQL-G performance while being trained using question-answer supervision and no in-domain QDMR annotations.

Model	Supervision	Train. set	DB #	Exec. %
T5-SQL-G	$\langle x_i, Q_i, D_i \rangle$	1,348	30	48.4
T5-SQL-G$_{\text{part}}$	$\langle x_i, Q_i, D_i \rangle$	1,129	30	47.4
T5-QDMR-P	$\langle x_i, a_i, D_i \rangle$	1,129	30	46.2
T5-SQL-G	$\langle x_i, Q_i, D_i \rangle$	2,028	40	54.7
T5-SQL-G$_{\text{part}}$	$\langle x_i, Q_i, D_i \rangle$	1,440	40	51.3
T5-QDMR-P	$\langle x_i, a_i, D_i \rangle$	1,440	40	52.1
T5-SQL-G	$\langle x_i, Q_i, D_i \rangle$	2,076	40	56.2
T5-SQL-G$_{\text{part}}$	$\langle x_i, Q_i, D_i \rangle$	1,552	40	53.7
T5-QDMR-P	$\langle x_i, a_i, D_i \rangle$	1,552	40	53.8

Table 8: Spider models results on the dev set. T5-QDMR-P is trained without using any QDMR annotations for training set questions. We train separate models on the three randomly sampled training sets.

5 Limitations

Our approach uses question decompositions and answers as supervision for text-to-SQL parsing. As annotating SQL requires expertise, our solution serves as a potentially cheaper alternative. Past work has shown that non-experts can provide the answers for questions on knowledge graphs (Berant et al., 2013) and tables (Pasupat and Liang, 2015). However, manually annotating question-answer pairs on large-scale databases may present new challenges which we leave for future work.

During SQL synthesis we assume that literal values (strings or dates) appear verbatim in the database as they do in the question. We observe that, for multiple datasets, this assumption generally holds true (§4.2). Still, for questions with domain-specific jargon (Lee et al., 2021) our approach might require an initial step of named-entity-recognition. Failure to map a QDMR to SQL may be due to a mismatch between a QDMR and its corresponding SQL structure (§3.2). We account for such mismatches by using heuristics to modify the structure of a candidate query (Appendix B). A complementary approach could train a model, mapping QDMR to SQL, to account for cases where our heuristic rules fail. Nevertheless, our SQL synthesis covers a diverse set of databases and query patterns, as shown in our experiments.

6 Related Work

For a thorough review of NL interfaces to databases see Affolter et al. (2019); Kim et al. (2020). Research on parsing text-to-SQL gained significant traction in recent years with the introduction of large supervised datasets for training models and evaluating their performance (Zhong et al., 2017; Yu et al., 2018). Recent approaches relied on specialized architectures combined with pre-trained language models (Guo et al., 2019; Wang et al., 2020; Lin et al., 2020; Yu et al., 2021; Deng et al., 2021; Scholak et al., 2021). As our solution synthesizes NL-SQL pairs (using weak supervision) it can be used to train supervised text-to-SQL models.

Also related is the use of intermediate meaning representations (MRs) in mapping text-to-SQL. In past work MRs were either annotated by experts (Yaghmazadeh et al., 2017; Kapanipathi et al., 2020), or were directly induced from such annotations as a way to simplify the target MR (Dong and Lapata, 2018; Guo et al., 2019; Herzig et al., 2021). Instead, QDMR representations are expressed as NL utterances and can therefore be annotated by non-experts. Similarly to us, Saparina and Osokin (2021) map QDMR to SPARQL. However, our SQL synthesis does not rely on the annotated linking of question phrases to DB elements (Lei et al., 2020). In addition, we train models without gold QDMR annotations and test our models on four datasets in addition to SPIDER.

7 Conclusions

This work presents a weakly supervised approach for generating NL-SQL training data, using answer and QDMR supervision. We implemented an automatic SQL synthesis procedure, capable of generating effective training data for dozens of target databases. Experiments on multiple text-to-SQL benchmarks demonstrate the efficacy of our synthesized training data. Namely, our weakly-supervised models achieve 91%-97% of the performance of fully supervised models trained on annotated SQL. Further constraining our models supervision to few or zero in-domain QDMRs still reaches 86%-93% of the fully supervised models performance. Overall, we provide an effective solution to train text-to-SQL parsers while requiring zero SQL annotations.

A QDMR to SQL Mapping Rules

Table 9 lists all of the QDMR operations along with their mapping rules to SQL. For a thorough description of QDMR semantics please refer to Wolfson et al. (2020).

B SQL Candidate Search Heuristics

We further describe the execution-guided search process for candidate SQL queries, that was introduced in §3.2. Given the search space of candidate queries, we use four heuristics to find candidates $\hat{Q}_i$ which execute to the correct answer, a_i.

1. Phrase linking search: We avoid iterating over each phrase-column assignment by ordering them according to their phrase-column ranking, as described in §3.1.1. The query $\hat{Q}_i^{(1)}$ is induced from the top ranked assignment, where each phrase in s_i is assigned its top ranked column. If $\hat{Q}_i^{(1)}(D_i) \neq a_i$ we continue the candidate search using heuristics 2-4 (described below). Assuming that the additional search heuristics failed to find a candidate $\hat{Q}_i^{(1)'}$ such that $\hat{Q}_i^{(1)'}(D_i) = a_i$, we return to the phrase linking component and resume the process using the candidate SQL induced from the following assignment $\hat{Q}_i^{(2)}$, and so forth. In practice, we limit the number of assignments and review only those covering the top-k most similar columns for each phrase in s_i, where $k = 20$. Our error analysis (Table 4) reveals that only a small fraction of failures are due to limiting k. Step 2 in Fig. 1 represents the iterative process, where $\hat{Q}_i^{(1)}$ executes to an incorrect result while the following candidate $\hat{Q}_i^{(2)}$ correctly links the phrase *"authors"* to column `author.name` and executes to a_i, thereby ending the search.

2. Distinct modification: Given a candidate SQL $\hat{Q}_i$ such that $\hat{Q}_i(D_i) \neq a$, we add `DISTINCT` to its `SELECT` clause. In Table 10 the SQL executes to the correct result, following its modification.

3. Superlative modification: This heuristic automatically corrects semantic mismatches between annotated QDMR structures and the underlying database. Concretely, steps in s_i that represent `PROJECT` and `FILTER` operations may entail an

QDMR Operation	SQL Mapping
`SELECT(t.col)`	`SELECT t.col FROM t;`
`SELECT(val)`	`SELECT t.col FROM t WHERE t.col = val;`
`FILTER(#x, =, val)`	`SELECT #x[SELECT] FROM #x[FROM] WHERE #x[WHERE] AND t.col = val;`
`PROJECT(t.col, #x)`	`SELECT t.col FROM t, #x[FROM] WHERE Join(t, #x[FROM]) AND #x[SELECT] IN (#x);`
`AGGREGATE(count, #x)`	`SELECT COUNT(#x[SELECT]) FROM #x[FROM] WHERE #x[WHERE];`
`GROUP(avg, #x, #y)`	`SELECT AVG(#x[SELECT]) FROM #x[FROM], #y[FROM] WHERE Join(#x[FROM], #y[FROM]) AND #x[WHERE] AND #y[WHERE] GROUP BY #y[SELECT];`
`SUPERLATIVE(max, k, #x, #y)`	`SELECT #x[SELECT] FROM #x[FROM], #y[FROM] WHERE Join(#x[FROM], #y[FROM]) AND #x[WHERE] AND #y[WHERE] ORDER BY #y[SELECT] DESC k;`
`COMPARATIVE(#x, #y, >, val)`	`SELECT #x[SELECT] FROM #x[FROM], #y[FROM] WHERE Join(#x[FROM], #y[FROM]) AND #x[WHERE] AND #y[WHERE] AND #y[SELECT] > val;`
`UNION(#x, #y)`	`SELECT #x[SELECT] FROM #x[FROM], #y[FROM] WHERE Join(#x[FROM], #y[FROM]) AND (#x[WHERE] OR #y[WHERE]);`
`UNION_COLUMN(#x, #y)`	`SELECT #x[SELECT], #y[SELECT] FROM #x[FROM], #y[FROM] WHERE Join(#x[FROM], #y[FROM]) AND #x[WHERE] AND #y[WHERE];`
`INTERSECT(t.col, #x, #y)`	`SELECT t.col FROM t, #x[FROM], #y[FROM] WHERE Join(t, #x[FROM], #y[FROM]) AND #x[WHERE] AND t.col IN ( SELECT t.col FROM t, #x[FROM], #y[FROM] WHERE Join(t, #x[FROM], #y[FROM]) AND #y[WHERE] );`
`SORT(#x, #y, asc)`	`SELECT #x[SELECT] FROM #x[FROM], #y[FROM] WHERE Join(#x[FROM], #y[FROM]) AND #x[WHERE] ORDER BY #y[SELECT] ASC;`
`DISCARD(#x, #y)`	`SELECT #x[SELECT] FROM #x[FROM] WHERE #x[WHERE] AND #x[SELECT] NOT IN ( #y );`
`ARITHMETIC(+, #x, #y)`	`( #x ) + ( #y );`

Table 9: QDMR to SQL mapping rules for all QDMR operations. #x denotes a previously mapped SQL query while #x[CLAUSE] denotes its relevant SQL clause. For example, #x[FROM] returns all tables in the FROM clause of SQL query #x. Join, denotes the inferred join paths between sets of tables (see §3.1.2). Note that `AGGREGATE` and `GROUP` steps may use the operations: min, max, count, sum and avg. `SUPERLATIVE` steps may use min, max operations and `COMPARATIVE` steps use the operations: $>$, $<$, $=$, $\neq$, $\geq$, $\leq$. Last, `SORT` steps sort in either ascending (asc) or descending (desc) order and `ARITHMETIC` steps use one of the following: $+$, $-$, $\times$, $\div$.

implicit `ARGMAX`/`ARGMIN` operation. For example for the question *"What is the size of the largest state in the USA?"* in the third row of Table 10. Step (3) of the question's annotated QDMR is the `PROJECT` operation, "state with the largest #2". While conforming to the `PROJECT` operation template, the step entails an `ARGMAX` operation. Using the NLTK part-of-speech tagger, we automatically identify any superlative tokens in the `PROJECT` and `FILTER` steps of s_i. These steps are then replaced with the appropriate `SUPERLATIVE` type steps. In Table 10, the original step (3) is modified to the step "#1 where #2 is highest".

4. Aggregate modification: This heuristics replaces instances of `COUNT` in QDMR steps with `SUM` operations, and vice-versa. In Table 10, the question *"Find the total student enrollment for different affiliation type schools."*, is incorrectly mapped to a candidate query involving a `COUNT` operation on `university.enrollment`. By modifying the aggregate operation to `SUM`, the new $\hat{Q}_i$ correctly executes to a_i and is therefore returned as the output.

C Data License

We list the license (when publicly available) and the release details of the datasets used in our paper.

The BREAK dataset (Wolfson et al., 2020) is under the MIT License. SPIDER (Yu et al., 2018) is under the CC BY-SA 4.0 License. GEO880 (Zelle and Mooney, 1996) is available under the GNU General Public License 2.0.

The text-to-SQL versions of GEO880 and ACADEMIC (Li and Jagadish, 2014) were made publicly available by Finegan-Dollak et al. (2018) in: `https://github.com/jkkummerfeld/text2sql-data/`.

The IMDB and YELP datasets were publicly released by Yaghmazadeh et al. (2017) in: `goo.gl/DbUBMM`.

D SQL Synthesis Coverage

We provide additional results of SQL synthesis coverage. Table 11 lists the coverage results, per dataset, when discarding all examples whose SQL executes to an empty set. Out of the 9,313 original examples, 8,887 examples have non-empty denotations. Coverage scores per dataset remain generally the same as they do when evaluating on all exam-

Heuristic	Question	Candidate SQL/QDMR	Modified Candidate SQL/QDMR
Phrase linking search	What are the distinct majors that students with treasurer votes are studying?	`SELECT DISTINCT student.major FROM student, voting_record WHERE student.stuid =` **`voting_record.stuid`**	`SELECT DISTINCT student.major FROM student, voting_record WHERE student.stuid =` **`voting_record.treasurer_vote`**
Distinct modification	Find the number of different product types.	`SELECT products.product_type_code FROM products`	`SELECT` **`DISTINCT`** `products.product_type_code FROM products`
Superlative modification	What is the size of the largest state in the USA?	`(1) states in the usa; (2) size of #1;` **`(3) state with the largest #2`**`; (4) size of #3`	`(1) states in the usa; (2) size of #1;` **`(3) #1 where #2 is highest`**`; (4) the size of #3`
Aggregate modification	Find the total student enrollment for different affiliation type schools.	`SELECT university.affiliation,` **`COUNT`**`(university.enrollment) FROM university GROUP BY university.affiliation`	`SELECT university.affiliation,` **`SUM`**`(university.enrollment) FROM university GROUP BY university.affiliation`

Table 10: Examples of the four execution-guided search heuristics used during SQL synthesis.

Dataset	DB #	Examples	Synthesized	Coverage %
Academic	1	183	148	80.9
Geo880	1	846	707	83.6
IMDB	1	113	101	89.4
Yelp	1	66	54	81.8
Spider dev	20	978	745	76.2
Spider train	140	6,701	5,137	76.7
Total:	**164**	**8,887**	**6,892**	**77.6**
Spider pred.	20	978	750	76.7

Table 11: SQL synthesis coverage scores for SQL queries with non-empty denotations. We report the coverage only for non-empty examples to minimize the effect of potentially spurious SQL being synthesized.

ples. These results further indicate the effectiveness of the SQL synthesis procedure. Namely, this ensures the synthesis results in Table 3 are faithful, despite the potential noise introduced by SQL with empty denotations.

E NL to SQL Models Results

E.1 Evaluation on the Full XSP Datasets

We provide additional results of the models trained on Spider. Namely, we evaluate on all examples of the Academic, IMDB and Yelp datasets, including examples whose denotations are empty. Table 12 lists the results of all the models trained on the original training set of Spider. In Table 13 we provide the XSP results of the models trained on the random subsets of Spider train, used in §4.3.4. Similar to our previous experiments, T5-QDMR-P is generally better than T5-SQL-G in terms of its cross-database generalization.

E.2 Qualitative Results

Table 14 includes some example predictions of our Spider trained models from Tables 5-6. For each example we describe its question and target (gold) SQL annotation, followed by each model's result.

Model	Supervision	Training set	SPIDER dev.	ACADEMIC	GEO880	IMDB	YELP
T5-SQL-G	$\langle x_i, Q_i, D_i \rangle$	7,000	68.0 ± 0.3	7.9 ± 1.3	33.6 ± 2.5	19.1 ± 2.9	25.3 ± 1.7
T5-SQL-G$_{\text{part}}$	$\langle x_i, Q_i, D_i \rangle$	5,349	66.4 ± 0.8	4.9 ± 1.7	32.4 ± 1.3	21.1 ± 0.7	26.1 ± 1.0
T5-QDMR-G	$\langle x_i, a_i, s_i, D_i \rangle$	5,349	65.8 ± 0.3	11.2 ± 1.0	40.4 ± 1.8	30.3 ± 3.1	25.8 ± 5.1
T5-QDMR-P	$\langle x_i, a_i, D_i \rangle$	5,075	62.9 ± 0.8	8.4 ± 0.9	39.7 ± 1.4	27.0 ± 5.1	28.2 ± 2.9

Table 12: Model execution accuracy on SPIDER and its performance on cross-database (XSP) examples. Evaluation on ACADEMIC, IMDB and YELP is on the *full datasets*, including examples with empty denotations.

Model	Supervision	Train. set	DB #	SPIDER dev.	ACADEMIC	GEO880	IMDB	YELP
T5-SQL-G	$\langle x_i, Q_i, D_i \rangle$	1,348	30	48.4	2.1	29.6	9.9	22.6
T5-SQL-G$_{\text{part}}$	$\langle x_i, Q_i, D_i \rangle$	1,129	30	47.4	2.6	26.9	14.5	16.9
T5-QDMR-P	$\langle x_i, a_i, D_i \rangle$	1,129	30	46.2	8.4	29.0	16.0	16.9
T5-SQL-G	$\langle x_i, Q_i, D_i \rangle$	2,028	40	54.7	6.3	28.3	18.3	21.0
T5-SQL-G$_{\text{part}}$	$\langle x_i, Q_i, D_i \rangle$	1,440	40	51.3	3.7	21.2	12.2	19.4
T5-QDMR-P	$\langle x_i, a_i, D_i \rangle$	1,440	40	52.1	6.8	27.4	12.2	18.5
T5-SQL-G	$\langle x_i, Q_i, D_i \rangle$	2,076	40	56.2	3.2	25.5	13.0	24.5
T5-SQL-G$_{\text{part}}$	$\langle x_i, Q_i, D_i \rangle$	1,552	40	53.7	2.3	17.8	10.2	22.8
T5-QDMR-P	$\langle x_i, a_i, D_i \rangle$	1,552	40	53.8	6.1	32.3	19.8	21.8

Table 13: Model results on SPIDER dev when trained on predicted QDMRs versus gold SQL. We train separate models on each of the three randomly sampled training sets. Results include the performance on XSP examples where the evaluation on ACADEMIC, IMDB and YELP is on the *full datasets*, including examples with empty denotations.

Question:	Return me the total citations of papers in the VLDB conference in 2005.	
Target SQL:	`select sum ( publication_0.citation_num ) from conference as conference_0, publication as publication_0 where conference_0.name = "VLDB" and publication_0.year = 2005 and conference_0.cid = publication_0.cid;`

Detect Rumors in Microblog Posts for Low-Resource Domains via Adversarial Contrastive Learning

Abstract

Massive false rumors emerging along with breaking news or trending topics severely hinder the truth. Existing rumor detection approaches achieve promising performance on the yesterday's news, since there is enough corpus collected from the same domain for model training. However, they are poor at detecting rumors about unforeseen events especially those propagated in different languages due to the lack of training data and prior knowledge (i.e., low-resource regimes). In this paper, we propose an adversarial contrastive learning framework to detect rumors by adapting the features learned from well-resourced rumor data to that of the low-resourced. Our model explicitly overcomes the restriction of domain and/or language usage via language alignment and a novel supervised contrastive training paradigm. Moreover, we develop an adversarial augmentation mechanism to further enhance the robustness of low-resource rumor representation. Extensive experiments conducted on two low-resource datasets collected from real-world microblog platforms demonstrate that our framework achieves much better performance than state-of-the-art methods and exhibits a superior capacity for detecting rumors at early stages.

1 Introduction

With the proliferation of social media such as Twitter and Weibo, the emergence of breaking events provides opportunities for the spread of rumors, which is difficult to be identified due to limited domain expertise and relevant data. For instance, along with the unprecedented COVID-19 pandemic, a false rumor claimed that "everyone who gets the vaccine will die or suffer from auto-immune diseases"[1] was translated into many languages and spread at lightning speed on social media, which seriously confuses the public and destroys the achievements of epidemic prevention in related countries or regions of the world. Although some recent works focus on collecting microblog posts corresponding to COVID-19 (Chen et al., 2020a; Zarei et al., 2020; Alqurashi et al., 2020), existing rumor detection methods perform poorly without a large-scale qualified training corpus, i.e., in a low-resource scenario (Hedderich et al., 2021). Thus there is an urgent need to develop automatic approaches to identify rumors in such low-resource domains especially amid breaking events.

Social psychology literature defines a rumor as a story or a statement whose truth value is unverified or deliberately false (Allport and Postman, 1947). Recently, techniques using deep neural networks (DNNs) (Ma et al., 2018; Khoo et al., 2020; Bian et al., 2020) have achieved promising results for detecting rumors on microblogging websites by learning rumor-indicative features from sizeable rumor corpus with veracity annotation. However, such DNN-based approaches are purely data-driven and have a major limitation on detecting emerging events concerning about low-resource domains, i.e., the distinctive topic coverage and word distribution (Silva et al., 2021) required for detecting low-resource rumors are often not covered by the public benchmarks (Zubiaga et al., 2016; Ma et al., 2016, 2017). On another hand, for rumors propagated in different languages, existing monolingual approaches are not applicable since there are even no sufficient open domain data for model training in the target language.

In this paper, we assume that the close correlations between the well-resourced rumor data and the low-resourced could break the barriers of domain and language, substantially boosting low-resource rumor detection within a more general framework. Taking the breaking event COVID-19 as an example, we collect corresponding rumorous and non-rumorous claims with propaga-

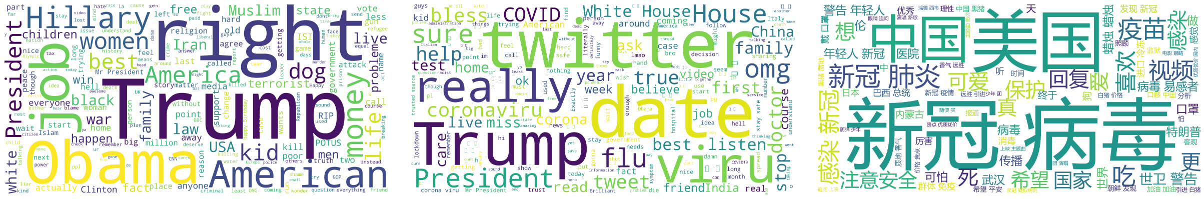
(a) TWITTER (Rumor) (b) Twitter-COVID19 (Rumor) (c) Weibo-COVID19 (Rumor)



(d) TWITTER (Non-rumor) (e) Twitter-COVID19 (Non-rumor) (f) Weibo-COVID19 (Non-rumor)

Figure 1: Word clouds of rumor and non-rumor data generated from TWITTER, Twitter-COVID19, and Weibo-COVID19 datasets, where the size of terms corresponds to the word frequency. Both TWITTER and Twitter-COVID19 are presented in English while Weibo-COVID19 in Chinese.

tion threads from Twitter and Sina Weibo which are the most popular microblogging websites in English and Chinese, respectively. Figure 1 illustrates the word clouds of rumor and non-rumor data from an open domain benchmark (i.e., TWITTER (Ma et al., 2017)) and two COVID-19 datasets (i.e., Twitter-COVID19 and Weibo-COVID19). It can be seen that both TWITTER and Twitter-COVID19 contain denial opinions towards rumors, e.g., “fake", “joke", “stupid" in Figure 1(a) and “wrong symptom", “exactly sick", “health panic" in Figure 1(b). In contrast, supportive opinions towards non-rumors can be drawn from Figure 1(d)–1(e). Moreover, considering that COVID-19 is a global disease, massive misinformation could be widely propagated in different languages such as Arabic (Alam et al., 2020), Indic (Kar et al., 2020), English (Cui and Lee, 2020) and Chinese (Hu et al., 2020). Similar identical patterns can be observed in Chinese on Weibo from Figure 1(c) and Figure 1(f). Although the COVID-19 data tend to use expertise words or language-related slang, we argue that aligning the representation space of identical rumor-indicative patterns of different domains and/or languages could adapt the features captured from well-resourced data to that of the low-resourced.

To this end, inspired by contrastive learning (He et al., 2020; Chen et al., 2020b,c), we propose an Adversarial Contrastive Learning approach for low-resource rumor detection (ACLR), to encourage effective alignment of rumor-indicative features in the well-resourced and low-resource data. More specifically, we first transform each microblog post into a language-independent vector by semantically aligning the source and target language in a shared vector space. As the diffusion of rumors generally follows a propagation tree that provides valuable clues on how a claim is transmitted (Ma et al., 2018), we thus resort to a structure-based neural network (Bian et al., 2020) to catch informative patterns. Then, we propose a novel supervised contrastive learning paradigm to minimize the intra-class variance of source and target instances with same veracity, and maximize inter-class variance of instances with different veracity. To further enhance the feature adaption of contrastive learning, we exploit adversarial attacks (Kurakin et al., 2016) to plenish noise to the original event-level representation by computing adversarial worst-case perturbations, forcing the model to learn non-trivial but effective features. Extensive experiments conducted on two real-world low-resource datasets confirm that (1) our model yields outstanding performances for detecting low-resource rumors over the state-of-the-art baselines with a large margin; and (2) our method performs particularly well on early rumor detection which is crucial for timely intervention and debunking especially for breaking events. The main contributions of this paper are of three-fold:

- To our best knowledge, we are the first to present a radically novel adversarial contrastive learning framework to study the low-resource rumor detection on social media[2].
- We propose supervised contrastive learning

---

[2] Our resources will be available at `https://github.com/DanielLin97/ACLR4RUMOR-NAACL2022`.

for structural feature adaption between different domains and languages, with adversarial attacks employed to enhance the diversity of low-resource data for contrastive paradigm.

- We constructed two low-resource microblog datasets corresponding to COVID-19 with propagation tree structure, respectively gathered from English tweets and Chinese microblog posts. Experimental results show that our model achieves superior performance for both rumor classification and early detection tasks under low-resource settings.

2 Related Work

Pioneer studies for automatic rumor detection focus on learning a supervised classifier utilizing features crafted from post contents, user profiles, and propagation patterns (Castillo et al., 2011; Yang et al., 2012; Liu et al., 2015). Subsequent studies then propose new features such as those representing rumor diffusion and cascades (Kwon et al., 2013; Friggeri et al., 2014; Hannak et al., 2014). Zhao et al. (2015) alleviate the engineering effort by using a set of regular expressions to find questing and denying tweets. DNN-based models such as recurrent neural networks (Ma et al., 2016), convolutional neural networks (Yu et al., 2017), and attention mechanism (Guo et al., 2018) are then employed to learn the features from the stream of social media posts. However, these approaches simply model the post structure as a sequence while ignoring the complex propagation structure.

To extract useful clues jointly from content semantics and propagation structures, some approaches propose kernel-learning models (Wu et al., 2015; Ma et al., 2017) to make a comparison between propagation trees. Tree-structured recursive neural networks (RvNN) (Ma et al., 2018) and transformer-based models (Khoo et al., 2020; Ma and Gao, 2020) are proposed to generate the representation of each post along a propagation tree guided by the tree structure. More recently, graph neural networks (Bian et al., 2020; Lin et al., 2021a) have been exploited to encode the conversation thread for higher-level representations. However, such data-driven approaches fail to detect rumors in low-resource regimes (Janicka et al., 2019) because they often require sizeable training data which is not available for low-resource domains and/or languages. In this paper, we propose a novel framework to adapt existing models with the effective propagation structure for detecting rumors from different domains and/or languages.

To facilitate related fact-checking tasks in low-resource settings, domain adaption techniques are utilized to detect fake news (Wang et al., 2018; Yuan et al., 2021; Zhang et al., 2020; Silva et al., 2021) by learning features from multi-modal data such as texts and images. Lee et al. (2021) proposed a simple way of leveraging the perplexity score obtained from pre-trained language models (LMs) for the few-shot fact-checking task. Different from these works of adaption on multi-modal data and transfer learning of LMs, we focus on language and domain adaptation to detect rumors from low-resource microblog posts corresponding to breaking events.

Contrastive learning (CL) aims to enhance representation learning by maximizing the agreement among the same types of instances and distinguishing from the others with different types (Wang and Isola, 2020). In recent years, CL has achieved great success in unsupervised visual representation learning (Chen et al., 2020b; He et al., 2020; Chen et al., 2020c). Besides computer vision, recent studies suggest that CL is promising in the semantic textual similarity (Gao et al., 2021; Yan et al., 2021), stance detection (Mohtarami et al., 2019), short text clustering (Zhang et al., 2021), unknown intent detection (Lin et al., 2021b), and abstractive summarization (Liu and Liu, 2021), etc. However, the above CL frameworks are specifically proposed to augment unstructured textual data such as sentence and document, which are not suitable for the low-resource rumor detection task considering claims together with more complex propagation structures of community response.

3 Problem Statement

In this work, we define the low-resource rumor detection task as: Given a well-resourced dataset as source, classify each event in the target low-resource dataset as a rumor or not, where the source and target data are from different domains and/or languages. Specifically, we define a well-resourced source dataset for training as a set of events $\mathcal{D}_s = \{C_1^s, C_2^s, \cdots, C_M^s\}$, where M is the number of source events. Each event $C^s = (y, c, \mathcal{T}(c))$ is a tuple representing a given claim c which is associated with a veracity label $y \in \{\text{rumor}, \text{non-rumor}\}$, and ideally all its relevant responsive microblog post in chronolog-

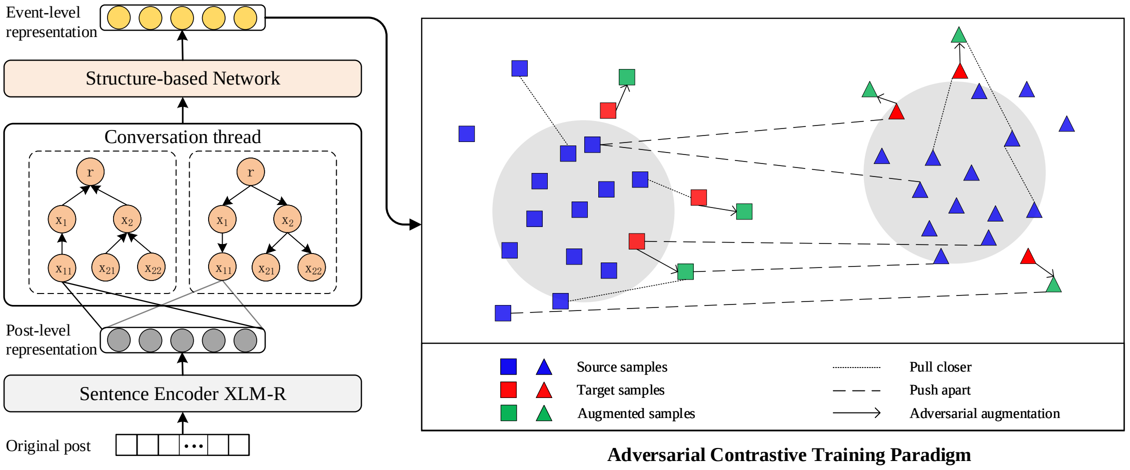


Figure 2: The overall architecture of our proposed method. For source and small target training data, we first obtain post-level representations after cross-lingual sentence encoding, then train the structure-based network with the adversarial contrastive objective. For target test data, we extract the event-level representations to detect rumors.

ical order, i.e., $\mathcal{T}(c) = \{c, x_1^s, x_2^s, \cdots, x_{|C|}^s\}$[3], where $|C|$ is the number of responsive tweets in the conversation thread. For the target dataset with low-resource domains and/or languages, we consider a much smaller dataset for training $\mathcal{D}_t = \{C_1^t, C_2^t, \cdots, C_N^t\}$, where $N (N \ll M)$ is the number of target events and each $C^t = (y, c', \mathcal{T}(c'))$ has the similar composition structure of the source dataset.

We formulate the task of low-resource rumor detection as a supervised classification problem that trains a domain/language-agnostic classifier $f(\cdot)$ adapting the features learned from source datasets to that of the target events, that is, $f(C^t|\mathcal{D}_s) \rightarrow y$. Note that although the tweets are notated sequentially, there are connections among them based on their responsive relationships. So most previous works represent the conversation thread as a tree structure (Ma et al., 2018; Bian et al., 2020).

4 Our Approach

In this section, we introduce our adversarial contrastive learning framework to adapt the features captured from the well-resourced data to detect rumors from low-resource events, which considers cross-lingual and cross-domain alignment. Figure 2 illustrates an overview of our proposed model, which will be depicted in the following subsections.

4.1 Cross-lingual Sentence Encoder

Given a post in an event that could be either from source or target data, to map it into a shared semantic space where the source and target languages are semantically aligned, we utilize XLM-RoBERTa (Conneau et al., 2019) (XLM-R) to model the context interactions among tokens in the sequence for the sentence-level representation:

$$\bar{x} = \mathit{XLM\text{-}R}(\mathbf{x}) \tag{1}$$

where $\mathbf{x}$ is the original post, and we obtain the post-level representation $\bar{x}$ using the output state of the <*s*> token in XLM-R. We thus denote the representation of posts in the source event C^s and the target event C^t as a matrix X^s and X^t respectively: $X^* = [\bar{x}_0^*, \bar{x}_1^*, \bar{x}_2^*, ..., \bar{x}_{|X^*|-1}^*]^\top; * \in \{s, t\}$, where $X^s \in \mathbb{R}^{m \times d}$ and $X^t \in \mathbb{R}^{n \times d}$, d is the dimension of the output state of the sentence encoder.

4.2 Propagation Structure Representation

On top of the sentence encoder, we represent the propagation of each claim with the graph convolutional network (GCN) (Kipf and Welling, 2016), which achieves state-of-the-art performance on capturing both structural and semantic information for rumor classification (Bian et al., 2020). It is worth noting that the choice of propagation structure representation is orthogonal to our proposed framework that can be easily replaced with any existing structure-based models without any other change to our supervised contrastive learning architecture.

Given an event and its initialized embedding matrix $C^*, X^*; * \in \{s, t\}$, We model the conversation thread of the event as a tree structure $\mathcal{T} = \langle V, E \rangle$, where V consists of the event claim and all its relevant responsive posts as nodes and E refers to a set of directed edges corresponding to the response relation among the nodes in V. Inspired by Ma et al.

---

[3] c is equivalent to x_0^s.

(2018), here we consider two different propagation trees with distinct edge directions: (1) *Top-Down tree* where the edge follows the direction of information diffusion. (2) *Bottom-Up tree* where the responsive nodes point to their responded nodes, similar to a citation network.

Top-Down GCN. We treat the Top-Down tree structure as a graph and transform the edge E into an adjacency matrix $\mathbf{A} \in \{0,1\}^{|V|\times|V|}$, where $\mathbf{A}_{i,j} = 1$ if $\mathbf{x}_i$ has a response to $\mathbf{x}_j$ or $i = j$, else $\mathbf{A}_{i,j} = 0$. Then we utilize a layer-wise propagation rule to update the node vector at the l-th layer:

$$H^{(l+1)} = ReLU(\hat{\mathbf{A}} \cdot H^{(l)} \cdot W^{(l)}) \qquad (2)$$

where $\hat{\mathbf{A}} = \mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2}$ is the symmetric normalized adjacency matrix, $\mathbf{D}$ denotes the degree matrix of $\mathbf{A}$. $W^{(l)} \in \mathbb{R}^{d^{(l)}\times d^{(l+1)}}$ is a layer-specific trainable transformation matrix. $H^{(0)}$ is initialized as X^*. For a GCN model with L-layers, we obtain the final node representation H_{TD} w.r.t $H^{(L)}$.

Bottom-Up GCN. We also leverage the structure of Bottom-Up tree to encode the informative posts. Similar to Top-Down GCN, we update the hidden representation of nodes in the same manner as Eq. 2 and finally get the output node states H_{BU} at the L-th graph convolutional layer.

The Overall Model. Finally, we concatenate H_{TD} and H_{BU} via mean-pooling to jointly capture the opinions expressed in both Top-Down and Bottom-Up trees:

$$o = mean\text{-}pooling([H_{TD}; H_{BU}]) \qquad (3)$$

where $o \in \mathbb{R}^{2d^{(L)}}$ is the event-level representation of the entire propagation thread, $d^{(L)}$ is the output dimension of GCN and $[\cdot;\cdot]$ means concatenation.

4.3 Contrastive Training

To align the representation space of rumor-indicative signals from different domains and languages, we present a novel training paradigm to exploit the labeled data including rich sourced data and small-scaled target data to adapt our model on target domains and languages. The core idea is to make the representations of source and target events from the same class closer while keeping representations from different classes far away.

Given an event C_i^s from the source data, we firstly obtain the language-agnostic encoding for all the involved posts (see Eq. 1) as well as the propagation structure representation o_i^s (see Eq. 3) which is then fed into a *softmax* function to make rumor predictions. Then, we learn to minimize the cross-entropy loss between the prediction and the ground-truth label y_i^s:

$$\mathcal{L}_{CE}^s = -\frac{1}{N^s}\sum_{i=1}^{N^s} log(p_i) \qquad (4)$$

where N^s is the total number of source examples in the batch, p_i is the probability of correct prediction. To make rumor representation in the source events be more dicriminative, we propose a supervised contrastive learning objective to cluster the same class and separate different classes of samples:

$$\mathcal{L}_{SCL}^s = -\frac{1}{N^s}\sum_{i=1}^{N^s}\frac{1}{N_{y_i^s}-1}\sum_{j=1}^{N^s}\mathbb{1}_{[i\neq j]}\mathbb{1}_{[y_i^s=y_j^s]} \, log\frac{exp(\mathrm{sim}(o_i^s, o_j^s)/\tau)}{\sum_{k=1}^{N^s}\mathbb{1}_{[i\neq k]}exp(\mathrm{sim}(o_i^s, o_k^s)/\tau)} \qquad (5)$$

where $N_{y_i^s}$ is the number of source examples with the same label y_i^s in the event C_i^s, and $\mathbb{1}$ is the indicator. $\mathrm{sim}(\cdot)$ denotes the cosine similarity function and τ controls the temperature.

For an event C_i^t from the target data, we also compute the classification loss $\mathcal{L}_{CE}^t$ in the same manner as Eq. 4. Although we projected the source and target languages into the same semantic space after sentence encoding, rumor detection not only relies on post-level features, but also on event-level contextual features. Without constraints, the structure-based network can only extract event-level features for all samples based on their final classification signals while these features may not be critical to the target domain and language. We make full use of the minor labels in the low-resource rumor data by parameterizing our model according to the contrastive objective between the source and target instances in the event-level representation space:

$$\mathcal{L}_{SCL}^t = -\frac{1}{N^t}\sum_{i=1}^{N^t}\frac{1}{N_{y_i^t}}\sum_{j=1}^{N^s}\mathbb{1}_{[y_i^t=y_j^s]} \, log\frac{exp(\mathrm{sim}(o_i^t, o_j^s)/\tau)}{\sum_{k=1}^{N^s} exp(\mathrm{sim}(o_i^t, o_k^s)/\tau)} \qquad (6)$$

where N^t is the total number of target examples in the batch and $N_{y_i^t}$ is the number of source examples with the same label y_i^t in the event C_i^t. As a result, we project the source and target samples belonging to the same class closer than that of different categories, for feature alignment with minor

Algorithm 1 **Adversarial Contrastive Learning**

```

```

annotation at the target domain and language.

4.4 Adversarial Data Augmentation

Data augmentation techniques were successfully utilized to enhance contrastive learning models (Chen et al., 2020b). Some simple augmentation strategies are designed based on handcrafted features or rules, but they are not efficient and suitable for the propagation tree structures in rumor detection task. In this section, we introduce adversarial attacks to generate pseudo target samples at the event-level latent space to increase the diversity of views for model robustness in the contrastive learning manner. Specifically, we apply Fast Gradient Value (Miyato et al., 2016; Vedula et al., 2020) to approximate a worst-case perturbation as a noise vector of the event-level representation:

$$\tilde{\boldsymbol{o}}_{noise}^t = \epsilon \frac{g}{||g||}; \text{where } \ g = \nabla_{o^t} \mathcal{L}_{CE}^t \qquad (7)$$

where the gradient is the first-order differential of the classification loss $\mathcal{L}_{CE}^t$ for a target sample, i.e., the direction that rapidly increases the classification loss. We perform normalization and use a small ϵ to ensure the approximate is reasonable. Finally, we can obtain the pseudo augmented sample $o_{adv}^t = o^t + \tilde{\boldsymbol{o}}_{noise}^t$ in the latent space to enhance our model.

4.5 Model Training

We jointly train the model with the cross-entropy and supervised contrastive objectives:

$$\mathcal{L}^* = (1 - \alpha)\mathcal{L}_{CE}^* + \alpha\mathcal{L}_{SCL}^*; * \in \{s, t\} \qquad (8)$$

where α is a trade-off parameter, which is set to 0.5 in our experiments. Algorithm 1 presents the training process of our approach. We set the number L of the graph convolutional layer as 2, the temperature τ as 0.1, and the adversarial perturbation norm ϵ as 1.5. Parameters are updated through back-propagation (Collobert et al., 2011) with the Adam optimizer (Loshchilov and Hutter, 2018). The learning rate is initialized as 0.0001, and the dropout rate is 0.2. Early stopping (Yao et al., 2007) is applied to avoid overfitting.

5 Experiments

5.1 Datasets

To our knowledge, there are no public benchmarks available for detecting low-resource rumors with propagation tree structure in tweets. In this paper, we consider a breaking event COVID-19 as a low-resource domain and collect relevant rumors and non-rumors respectively from Twitter in English and Sina Weibo in Chinese. For Twitter-COVID19, we resort to a COVID-19 rumor dataset (Kar et al., 2020) which only contains textual claims without propagation thread. We extend each claim by collecting its propagation threads via Twitter academic API with a twarc2 package[4]. For Weibo-COVID19, similar to Ma et al. (2016), a set of related rumorous claims are gathered from the Sina community management center[5] and non-rumorous claims by randomly filtering out the posts that are not reported as rumors. Then Weibo API is utilized to collect all the repost/reply messages towards each claim (see Appendix for the dataset statistics).

5.2 Experimental Setup

We compare our model and several state-of-the-art baseline methods described below. 1) **CNN**: A CNN-based model for misinformation identification (Yu et al., 2017) by framing the relevant posts as a fixed-length sequence; 2) **RNN**: A RNN-based rumor detection model (Ma et al., 2016) with GRU for feature learning of relevant posts over time; 3) **RvNN**: A rumor detection approach based on tree-structured recursive neural networks (Ma et al., 2018) that learn rumor representations guided by the propagation structure; 4) **PLAN**: A transformer-based model (Khoo et al., 2020) for rumor detection to capture long-distance interactions between any pair of involved tweets; 5) **BiGCN**: A GCN-based model (Bian et al., 2020) based on directed conversation trees to learn higher-level representations (see Section 4.2); 6) **DANN-***: We employ and extend an existing few-shot learning technique,

domain-adversarial neural network (Ganin et al., 2016), based on the structure-based model where * could be RvNN, PLAN, and BiGCN; 7) **ACLR-***: our proposed adversarial contrastive learning framework on top of RvNN, PLAN, or BiGCN.

In this work, we consider the most challenging setting: to detect events (i.e., target) from a low-resource domain meanwhile in a cross-lingual regime. Note that although English and Chinese in our datasets are not minority languages, the target domain and/or languages can be easily replaced without any change to our ACLR framework. Specifically, we use the well-resourced TWITTER (Ma et al., 2017) (or WEIBO (Ma et al., 2016)) datasets as the source data, and Weibo-COVID19 (or Twitter-COVID19) datasets as the target. We use accuracy and macro-averaged F1, as well as class-specific F1 scores as the evaluation metrics. We conduct 5-fold cross-validation on the target datasets (see more details in Appendix).

5.3 Rumor Detection Performance

Table 1 shows the performance of our proposed method versus all the compared methods on the Weibo-COVID19 and Twitter-COVID19 test sets with pre-determined training datasets. It is observed that the performances of the baselines in the first group are obviously poor due to ignoring intrinsic structural patterns. To make fair comparisons, all baselines are employed with the same cross-lingual sentence encoder of our framework as inputs. Other state-of-the-art baselines exploit the structural property of community wisdom on social media, which confirms the necessity of propagation structure representations in our framework.

Among the structure-based baselines in the second group, due to the representation power of message-passing architectures and tree structures, PLAN and BiGCN outperform RvNN with only limited labeled target data for training. The third group shows the results for DANN-based methods. It improves the performance of structure-based baselines in general since it extracts cross-domain features between source and target datasets via generative adversarial nets (Goodfellow et al., 2014). Different from that, we use the adversarial attacks to improve the robustness of our proposed contrastive training paradigm, which explicitly encourages effective alignment of rumor-indicative features from different domains and languages.

In contrast, our proposed ACLR-based approaches achieve superior performances among all their counterparts ranging from 21.8% (13.4%) to 30.0% (17.7%) in terms of Macro F1 score on Weibo-COVID19 (Twitter-COVID19) datasets, which suggests their strong judgment on low-resource rumors from different domains/languages. ACLR-BiGCN performs the best among the three ACLR-based methods by making full use of the structural property via graph modeling for conversation threads. This also justifies the good performance of DANN-BiGCN and BiGCN. The results also indicate that the adversarial contrastive learning framework can effectively transfer knowledge from the source to target data at the event level, and substantiate our method is model-agnostic for different structure-based networks.

5.4 Ablation Study

We perform ablation studies based on our best-performed approach ACLR-BiGCN. As demonstrated in Table 2, the first group shows the results for the backbone baseline BiGCN. We observe that the model performs best if pre-trained on source

Model	Weibo-COVID19		Twitter-COVID19	
	Acc.	Mac-F_1	Acc.	Mac-F_1
BiGCN(T)	0.569	0.508	0.616	0.415
BiGCN(S)	0.578	0.463	0.611	0.425
BiGCN(S,T)	0.693	0.472	0.617	0.471
DANN-BiGCN	0.629	0.561	0.618	0.510
CLR-BiGCN	0.844	0.804	0.719	0.618
ACLR-BiGCN	0.873	0.861	0.765	0.686

Table 2: Ablation studies on our proposed model.

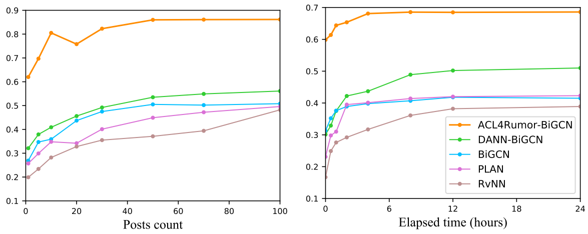

Figure 3: Early detection performance at different checkpoints of posts count (or elapsed time) on Weibo-COVID19 (left) and Twitter-COVID19 (right) datasets.

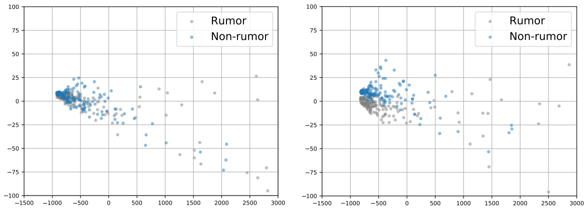

Figure 4: Visualization of target event-level representation distribution.

data and then fine-tuned on target training data (i.e., BiGCN(S,T)), compared with the poor performance when trained on either minor labeled target data only (i.e., BiGCN(T)) or well-resourced source data (i.e., BiGCN(S)). This suggests that our hypothesis of leveraging well-resourced source data to improve the low-resource rumor detection on target data is feasible. In the second group, the DANN-based model makes better use of the source data to extract domain-agnostic features, which further leads to performance improvement. Our proposed contrastive learning approach CLR without adversarial augmentation mechanism, has already achieved outstanding performance compared with other baselines, which illustrates its effectiveness on domain and language adaptation. We further notice that our ACLR-BiGCN consistently outperforms all baselines and improves the prediction performance of CLR-BiGCN, suggesting that training model together with adversarial augmentation on target data provide positive guidance for more accurate rumor predictions, especially in low-resource regimes. More qualitative analyses of hyper-parameters, training data size and alternative source datasets are shown in Appendix.

5.5 Early Detection

Early alerts of rumors is essential to minimize its social harm. By setting detection checkpoints of “delays" that can be either the count of reply posts or the time elapsed since the first posting, only contents posted no later than the checkpoints is available for model evaluation. The performance is evaluated by Macro F1 obtained at each checkpoint. To satisfy each checkpoint, we incrementally scan test data in order of time until the target time delay or post volume is reached.

Figure 3 shows the performances of our approach versus DANN-BiGCN, BiGCN, PLAN, and RvNN at various deadlines. Firstly, we observe that our proposed ACLR-based approach outperforms other counterparts and baselines throughout the whole lifecycle, and reaches a relatively high Macro F1 score at a very early period after the initial broadcast. One interesting phenomenon is that the early performance of some methods may fluctuate more or less. It is because with the propagation of the claim there is more semantic and structural information but the noisy information is increased simultaneously. Our method only needs about 50 posts on Weibo-COVID19 and around 4 hours on Twitter-COVID19, to achieve the saturated performance, indicating the remarkably superior early detection performance of our method.

5.6 Feature Visualization

Figure 4 shows the PCA visualization of learned target event-level features on BiGCN (left) and ACLR-BiGCN (right) for analysis. The left figure represents training with only classification loss, and the right figure uses ACLR for training. We observe that (1) due to the lack of sufficient training data, the features extracted with the traditional training paradigm are entangled, making it difficult to detect rumors in low-resource regimes; and (2) our ACLR-based approach learns more discriminative representations to improve low-resource rumor classification, reaffirming that our training paradigm can effectively transfer knowledge to bridge the gap between source and target data distribution resulting from different domains and languages.

6 Conclusion and Future Work

In this paper, we proposed a novel Adversarial Contrastive Learning framework to bridge low-resource gaps for rumor detection by adapting features learned from well-resourced data to that of the low-resource breaking events. Results on two real-world benchmarks confirm the advantages of our model in low-resource rumor detection task. In our future work, we plan to collect and apply our model on other domains and minority languages.

A Datasets

The focus of this work, as well as in many previous studies (Ma et al., 2017, 2018; Khoo et al., 2020; Bian et al., 2020), is rumors on social media, not just the "fake news" strictly defined as a news article published by a news outlet that is verifiably false (Shu et al., 2017; Zubiaga et al., 2018). To our knowledge, there is no public dataset available for classifying propagation trees in tweets about COVID-19, where we need the tree roots together with the corresponding propagation structure, to be appropriately annotated with ground truth. In this paper, we organize and construct two datasets Weibo-COVID19 and Twitter-COVID19 for experiments. For Twitter-COVID19, the original dataset (Kar et al., 2020) of tweets was released with just the source tweet without its propagation thread. So we collected all the propagation threads using the Twitter academic API with the twarc2 package[6] in python. Finally, we annotated the source tweets by referring to the labels of the events they are from the raw COVID-19 rumor dataset (Kar et al., 2020), where rumors contain fact or misinformation to be verified while non-rumors do not. For Weibo-COVID19, data annotation similar to Ma et al. (2016), a set of rumorous claims is gathered from the Sina community management center[7] and non-rumorous claims by randomly filtering out the posts that are not reported as rumors. Weibo API is utilized to collect all the repost/reply messages towards each claim. Both Weibo-COVID19 and Twitter-COVID19 contain two binary labels: Rumor and Non-rumor. For Weibo-COVID19 as the target dataset, we use the TWITTER dataset (Ma et al., 2017) as the source data in our low-resource (i.e., cross-domain and cross-lingual) settings; In terms of Twitter-COVID19 as the target dataset, we use WEIBO (Ma et al., 2016) as the source data. The statistics of the four datasets are shown in Table 3.

B Implementation Details

We set the number L of the graph convolutional layer as 2, the trade-off parameter α as 0.5, and the adversarial perturbation norm ϵ as 1.5. The temperature τ is set to 0.1. Parameters are updated through back-propagation (Collobert et al., 2011) with the Adam optimizer (Loshchilov and Hutter, 2018). The learning rate is initialized as 0.0001, and the dropout rate is 0.2. Early stopping (Yao et al., 2007) is applied to avoid overfitting. We run all of our experiments on one single NVIDIA Tesla T4 GPU. We set the total batch size to 64, where the batch size of source samples is set to 32, the same as target samples. The hidden and output dimensions of each node in the structure-based network are set to 512 and 128, respectively. Since the focus in this paper is primarily on better leveraging the contrastive learning for domain and language adaptation on top of event-level representations, we choose the XLM-R$_{Base}$ (Layer number = 12, Hidden dimension = 768, Attention head = 12, 270M params) as our sentence encoder for language-agnostic representations at the post level. We use accuracy and macro-averaged F1 score, as well as class-specific F1 score as the evaluation metrics. Unusually, to conduct five-fold cross-validation on the target dataset in our low-resource settings, we use each fold (about 80 claim posts with propagation threads in the target data) in turn for training, and test on the rest of the dataset. The average runtime for our approach on five-fold cross-validation in one iteration is about 3 hours. The number of total trainable parameters is 1,117,954 for our model. We implement our model with pytorch[8].

C Qualitative Analysis

C.1 Effect of Adversarial Perturbation Norm

Figure 5 shows the effect of adversarial perturbation norm on rumor detection performance. The X-axis denotes the value of ϵ, where $\epsilon = 0.0$ in the line means no adversarial augmentation. In general, the adversarial augmentation contributes to the improvements and $\epsilon \in [1.0, 2.0)$ achieves better performances. For the Weibo-COVID19 dataset, our proposed approach ACLR with a smaller adversarial perturbation can still obtain better results but lower than the results with an optimal range of perturbation, while large norms tend to damage the effect of ACLR. In terms of Twitter-COVID19, our method still performs well with a broad range of adversarial perturbations and the performance tends to stabilize as the norm value increases.

Table 3: Statistics of Datasets in Cross-Domain and Cross-Lingual Settings.

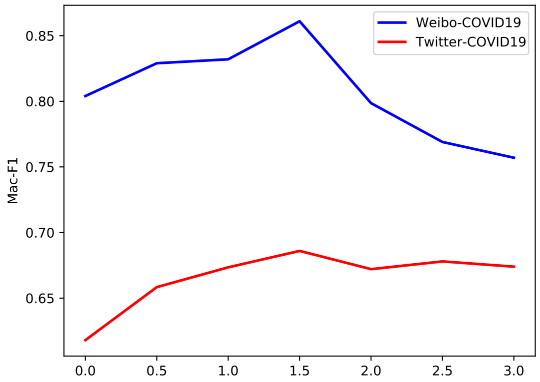

Figure 5: Effect of Adversarial Perturbation Norm ϵ.

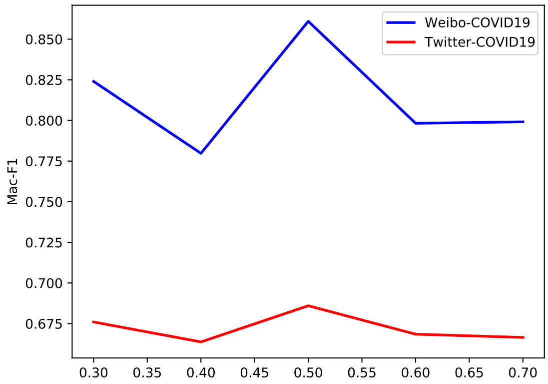

Figure 6: Effect of trade-off parameter α.

C.2 Effect of Trade-off Parameter between Classification and Contrastive Objectives

To study the effects of the trade-off hyper-parameter in our training paradigm, we conduct ablation analysis under ACLR architecture (Figure 6). We can see that $\alpha = 0.5$ achieves the best performance while the point where $\alpha = 0.3$ also has good performance. Looking at the overall trend, the performance fluctuates more or less as the value of α grows. We conjecture that this is because the supervised contrastive objective, while optimizing the representation distribution, compromises the mapping relationship with labels. Multitask means optimizing two losses simultaneously. This setting leads to mutual interference between two tasks, which affects the convergence effect. This phenomenon points out the direction for our further research in the future.

C.3 Effect of Target Training Data Size.

Figure 7 shows the effect of target training data size. We randomly choose training data with a certain proportion from target data and use the rest set for evaluation. We use the cross-domain and cross-lingual settings concurrently for model training, the same as the main experiments. Results show that with the decrease of training data size, the performance gradually decreases. Especially for Weibo-COVID19, it will be greatly affected. However, even when only 20 target data are used for training, our model can still achieve more than approximately 60% and 65% rumor detection performance (Macro F1 score) on two target data sets Weibo-COVID19 and Twitter-COVID19 respectively, which further proves ACLR has strong applicability for improving low-resource rumor detection on social media.

C.4 Discussion about Low-Resource Settings

In this section, we evaluate our proposed framework with different source datasets to discuss the low-resource settings in our experiments. Considering the cross-domain and cross-lingual settings in the main experiments, we also conduct an experiment in cross-domain settings. Specifically, for the Weibo-COVID as the target data, we utilize the WEIBO dataset as the source data with rich annotation. In terms of Twitter-COVID19, we set the TWITTER dataset as the source data. Ta-

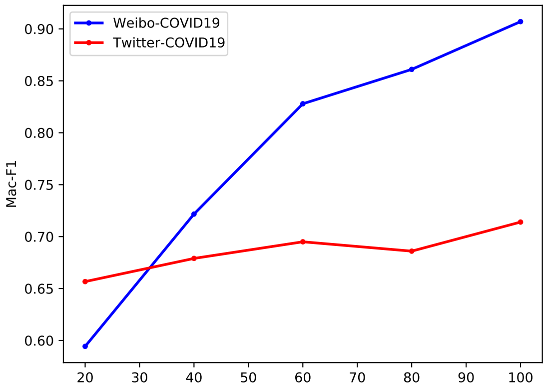

Figure 7: Effect of target training data size.

Target	Weibo-COVID19		Twitter-COVID19	
Settings	Acc.	Mac-F_1	Acc.	Mac-F_1
Cross-D&L	0.873	**0.861**	**0.765**	**0.686**
Cross-D	**0.884**	0.855	0.737	0.623

Table 4: Rumor detection results of our proposed framework in different low-resource settings. Cross-D&L denotes the cross-domain and cross-lingual settings and Cross-D denotes the cross-domain and monolingual settings.

ble 4 depicted the results in different low-resource settings. It can be seen from the results that our model performs generally better in cross-domain and cross-lingual settings concurrently than that only in cross-domain settings, which demonstrates the key insight to bridge the low-resource gap is to relieve the limitation imposed by the specific language resource dependency besides the specific domain. Our proposed adversarial contrastive learning framework could alleviate the low-resource issue of rumor detection as well as reduce the heavy reliance on datasets annotated with specific domain and language knowledge.

D Future Work

We will explore the following directions in the future:

1. We are going to explore the pre-training method with contrastive learning and then finetune the model with classification loss, which may further improve the performance and stability of the model.

2. Considering that our model has explicitly overcome the restriction of both domain and language usage in different datasets, we plan to evaluate our model on the datasets about more breaking events in low-resource domains and/or languages by leveraging existing datasets with rich annotation. We believe that our work could provide new guidance for future rumor detection about breaking events on social media.

DialoKG: Knowledge-Structure Aware Task-Oriented Dialogue Generation

Md Rashad Al Hasan Rony[1,3], **Ricardo Usbeck**[2], **Jens Lehmann**[1,3]

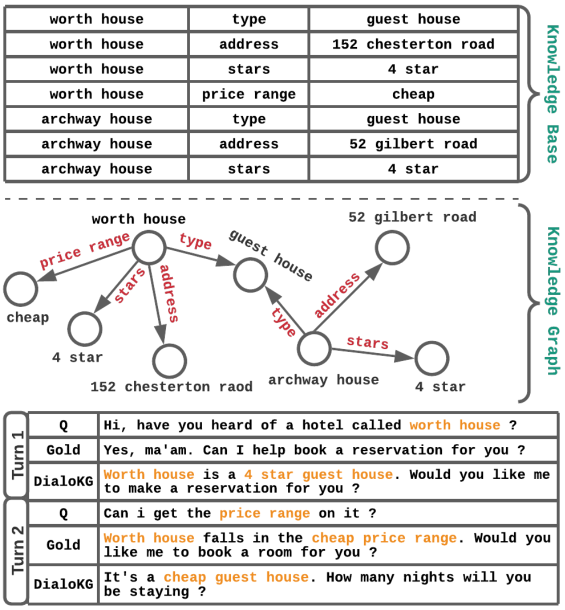
Abstract

Task-oriented dialogue generation is challenging since the underlying knowledge is often dynamic and effectively incorporating knowledge into the learning process is hard. It is particularly challenging to generate both human-like and informative responses in this setting. Recent research primarily focused on various knowledge distillation methods where the underlying relationship between the facts in a knowledge base is not effectively captured. In this paper, we go one step further and demonstrate how the structural information of a knowledge graph can improve the system's inference capabilities. Specifically, we propose DialoKG, a novel task-oriented dialogue system that effectively incorporates knowledge into a language model. Our proposed system views relational knowledge as a knowledge graph and introduces (1) a structure-aware knowledge embedding technique, and (2) a knowledge graph-weighted attention masking strategy to facilitate the system selecting relevant information during the dialogue generation. An empirical evaluation demonstrates the effectiveness of DialoKG over state-of-the-art methods on several standard benchmark datasets.

1 Introduction

Traditional task-oriented dialogue systems are designed to achieve specific goals such a restaurant reservation, hotel booking and car navigation. These systems are often empowered by external domain- or task-specific knowledge that enables them to generate informative dialogues (Eric et al., 2017; Wu et al., 2019; Qin et al., 2019; He et al., 2020b). The external knowledge in these systems is usually incorporated in the form of structured knowledge triples (Zhou et al., 2018; Liu et al., 2018a) or unstructured documents (Ye et al., 2020; Ghazvininejad et al., 2018). Figure 1 depicts a knowledge-grounded dialogue about reserving a hotel.



worth house	type	guest house
worth house	address	152 chesterton road
worth house	stars	4 star
worth house	price range	cheap
archway house	type	guest house
archway house	address	52 gilbert road
archway house	stars	4 star

Turn 1	Q	Hi, have you heard of a hotel called worth house ?
	Gold	Yes, ma'am. Can I help book a reservation for you ?
	DialoKG	Worth house is a 4 star guest house. Would you like me to make a reservation for you ?
Turn 2	Q	Can i get the price range on it ?
	Gold	Worth house falls in the cheap price range. Would you like me to book a room for you ?
	DialoKG	It's a cheap guest house. How many nights will you be staying ?

Figure 1: An illustration of knowledge-based multi-turn dialogue where DialoKG models the knowledge base as a Knowledge Graph. The user utterance is denoted by **Q**, the ground-truth response by **Gold**, and the words in orange are knowledge graph entries.

Recent research primarily concentrated on various knowledge filtering methods for selecting relevant knowledge (Wen et al., 2018; Kim et al., 2020; Wu et al., 2020b). These approaches treat the knowledge triples independently and leverage Pointer Networks and copy mechanisms to generate knowledge-grounded dialogues (Vinyals et al., 2015; Gu et al., 2016; Wu et al., 2019; Sukhbaatar et al., 2015; Raghu et al., 2021; Chaudhuri et al., 2021). Typically, these systems generate a template or sketch-response during training and learn to fill in the slots with knowledge graph entries. Such systems face two issues when they try to generate dialogues in a multi-domain setting. **Firstly**, they are unable to capture the underlying semantics of a knowledge graph, such as the relationship between entity and relation. This leads frequently to in-

(a) System architecture.

(b) Weighted-graph computation.

Figure 2: A high-level overview of DialoKG is shown in Figure (a). Figure (b) depicts the input and output of the *Graph Weight Computer* module of DialoKG.

correct and inappropriate dialogue generation (Lin et al., 2020). **Secondly**, they lack the ability to encode dynamic knowledge in a multi-domain setting, resulting in noisy dialogues (Madotto et al., 2020). Generally, integrating a knowledge base into the learning process and generating correct and coherent dialogues at the same time is a challenging task.

In this paper, we propose a novel task-oriented dialogue system, named DialoKG that employs structural information of the knowledge graph into a language model (LM) for generating informative dialogues (see Figure 2a). For this purpose, we exploit GPT-2 (Radford et al., 2019) - a language model developed based on a stack of Transformer decoders (Vaswani et al., 2017). Specifically, we introduce a novel structure-aware multiple embedding layer-based knowledge embedding technique that constructively embeds the underlying relationship between the knowledge triples . DialoKG interprets the knowledge as a knowledge graph; therefore, separate embedding layers for word token, entity, triple and token type enable the system to capture the graph features (e.g., subject, relation and object). This enables the system to generate correct and human-like dialogues and prevents generating erroneous responses such as "*4 miles is located at 792 Bedoin Street Starbucks away*". Furthermore, the ability to correctly capture the relationship in the knowledge graph eliminates the need for template-based or sketch-based response generation.

In order to guide the decoder on relevant parts of the knowledge graph, we propose a new knowledge attention masking method. For constructing the knowledge attention mask, in each dialogue turn, a weighted graph is computed in two steps: 1) Entity weights are computed using a pre-trained language model that estimates the importance of an entity for the given utterance, and 2) relation weights are computed based on the concept of graph convolution networks (GCN) (Kipf and Welling, 2017). Both steps take the user utterance into consideration, i.e., the obtained weighted graph is question specific. A set of triples is then selected based on the most relevant entities and relations of the weighted graph to construct a knowledge attention mask for the language model. This allows the masked language model to focus on relevant graph triples. We hypothesise that this leads to the generation of more accurate responses and enhance the model's capabilities of understanding the domain and task.

To assess the performance of DialoKG, we conduct experiments on three public benchmarks: SMD (Eric et al., 2017), CamRest (Wen et al., 2017) and Multi-WOZ 2.1 (Budzianowski et al., 2018). We evaluate the system generated responses using both human and automatic metrics. Furthermore, we analyse impact of the individual components on the overall performance to verify the effectiveness. Our experimental results show that DialoKG outperforms state-of-the-art models in knowledge-grounded dialogue generation and can generate human-like responses. We made our code publicly available [1].

---

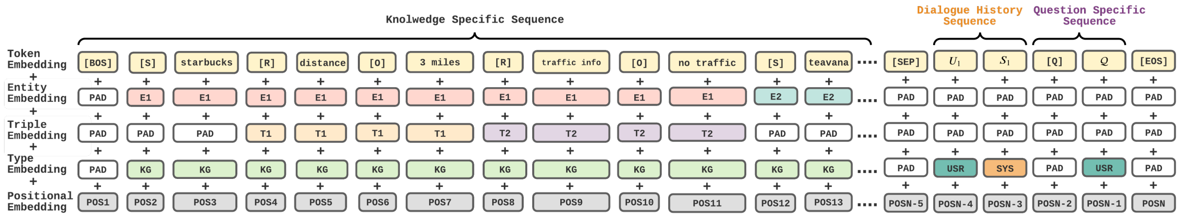

Figure 3: An illustration of knowledge and dialogue embedding techniques.

2 Approach

2.1 Problem Definition

DialoKG aims to generate informative responses given a dialogue history, a question and a knowledge base. We define the dialogue history $\mathcal{H}$ as a set of turns between two speakers, such that $\mathcal{H} = \{U_1, S_1, .., U_t, S_t\}$, where U_i and S_i are the sequences of words in turn i. We assume that the knowledge is stored in a multi-relational knowledge graph $\mathcal{G}$. Here, $\mathcal{G}$ is a set of triples $\mathcal{T}$ such that $\mathcal{T} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$, where $\mathcal{E}$ is the set of entities and $\mathcal{R}$ the set of relations. A triple $\mathcal{T} \in \mathcal{G}$ is denoted as (s, r, o) in which $s \in \mathcal{E}$ and $o \in \mathcal{E}$ denote the subject and object entities, respectively, and $r \in \mathcal{R}$ is the relation between them. We use the terms "Knowledge Graph" and "Graph" interchangeably throughout this paper. Furthermore, we denote the user utterance of the current dialogue turn as $\mathcal{Q}$. A GPT-2 (Radford et al., 2019) language model is used in this paper to generate responses. However, any Transformer decoder-based LM can be used. Formally, the probability distribution of generating a response by the language model is defined as:

$$p(S_t|\mathcal{H}, \mathcal{Q}, \mathcal{G}) = \prod_{i=1}^{n} p(s_i|s_1, ., s_{i-1}, \mathcal{H}, \mathcal{Q}, \mathcal{G}) \qquad (1)$$

Here, S_t is the generated response in turn t and n is the maximum length of the generated response.

2.2 Knowledge and Dialogue Embedding

DialoKG takes a knowledge graph $\mathcal{G}$, dialogue history $\mathcal{H}$, and the current user utterance $\mathcal{Q}$ together as input and constructs a single input sequence as depicted in Figure 3. The first part of the sequence contains graph related information (i.e., subject, relation, and object) and the latter part dialogue specific information such as dialogue history ($\mathcal{H}$) and the current user utterance ($\mathcal{Q}$). **Knowledge Specific Embedding.** To infuse structural information, DialoKG employs entity embedding, triple embedding and type embedding, besides the usual word token and positional embedding. Such an embedding technique allows the system to encode the knowledge graph structure. To do this, knowledge graph triples are linearized into a sequence as input, as depicted in Figure 3. To facilitate order invariance of the knowledge embedding, we shuffle the order of the graph triples in the input sequence during training. In the token embedding layer `[S]`, `[R]` and `[O]` are special tokens to separate subject, relation and object of a triple from each other in the sequence. Entity and triple embedding layers embed entity and triple-level information of the word token. For instance, `ENT1` in the entity embedding layer indicates that the corresponding words in the token embedding layer are related to the first subject, which is *starbucks* in this case. Likewise, `T1` and `T2` in the triple embedding layer indicate that the corresponding words in the token embedding layer are related to the first and second triple, respectively. Finally, the type embedding indicates that the corresponding tokens are from the knowledge graph as opposed to the dialogue history.

Dialogue Specific Embedding. The dialogue specific part of the input sequence is separated from the knowledge specific part by a `[SEP]` token in the token embedding layer. Furthermore, the user utterance/question ($\mathcal{Q}$) of the current turn is separated by a `[Q]` token from the dialogue history. The type embedding layer stores information about whether the corresponding utterance is from the user or system. This way, the decoder can use information about typical dialogue turn patterns.

The positional embedding in both knowledge and dialogue embeddings encodes the position of each word token in the sequence. Finally, embeddings from all five layers are summed up as depicted in Figure 3. *Layer Normalization* (Ba et al., 2016) is then applied to obtain the final embedding representation of the complete input sequence. It

(a) Graph transformation.

(b) Relation weight computation.

Figure 4: For the graph in Figure (a) and the question "*Find me the quickest route to the restaurant?*" the computation of the relation weight is shown in Figure (b), where $\hat{A} = A + I$.

normalizes the embedding representation of layers, which restricts the weights of the learning network from exploding.

We argue that the proposed design pattern of forming a single sequence and specifying each item in the input sequence further with additional embedding layers can improve the system's understanding of the task and domain.

2.3 Knowledge Attention Mask Construction

To notify the decoder about the relevant KG triples for answering the current user question, a knowledge graph weighted-attention mask is constructed. Prior to the construction of the knowledge attention mask, a weighted-knowledge graph, $\mathcal{G}_w$ is first computed by a *Graph Weight Computer* module, where the entity and relation weights are computed independently. We discuss the components of the *Graph Weight Computer* module below.

Entity Weight Estimator. A pre-trained language model RoBERTa (Liu et al., 2019), is used to compute the entity weights, similar to (Yasunaga et al., 2021). Each entity $E_i \in \mathcal{E}$ of graph $\mathcal{G}$ is concatenated with the user utterance $\mathcal{Q}$ to obtain the probability score from the language model.

$$E_{iw} = LM_{head}(LM_{enc}([\mathcal{Q}; E_i])) \tag{2}$$

In Equation 2, $LM_{head} \circ LM_{enc}$ represents the probability of the entity E_i computed by the language model. We consider E_{iw} as the weight of the entity E_i, which represents the relevance of the entity for the given user utterance $\mathcal{Q}$.

Relation Weight Estimator. We follow (Kipf and Welling, 2017; Vashishth et al., 2019) and leverage the concept of GCN to obtain the relation weight. In contrast to the previous works, our proposed relation weight estimator transforms the input graph into an undirected graph $\hat{\mathcal{G}}$, where the relations are considered as nodes of a graph. This transformation technique allows the relation estimator to obtain a score for each relation. The graph transformation is demonstrated in Figure 4a. The relation weight is computed as follows:

$$\begin{aligned} R_w &= \hat{H} M^r, \\ \hat{H} &= D^{-1}(A + I)X \end{aligned} \tag{3}$$

Here, $D^{-1}(A + I)$ computes the row-normalized adjacency matrix, where D and A are respectively the degree matrix and adjacency matrix of the graph $\hat{\mathcal{G}}$ as depicted in Figure 4b and I is the identity matrix. Let $d_g = |\mathcal{E}| + |\mathcal{R}|$ be the total number of entities and relations in the graph $\hat{\mathcal{G}}$, then $D, A, I \in \mathbb{R}^{d_g \times d_g}$. A feature vector $X \in \mathbb{R}^{d_g \times 1}$ is obtained by computing the cosine similarity between the embedding of knowledge graph entries (entities and relations) and the embedding of question. Furthermore, a relation mask $M^r \in \mathbb{R}^{d_g \times 1}$ is constructed by setting a value of 1 and 0 to the positions that correspond to relations and entities, respectively, to attend to the values that correspond to the relations only. The feature vector X eliminates the need for additional learnable parameters to capture the relationships, unlike GCN. Finally, values that correspond to the entities in $\hat{H}$ are masked out by multiplying with M^r to obtain final relation weights $R_w \in \mathbb{R}^{d_g \times d_g}$.

The computed weighted-graph assists the model to focus on the task by constructing a knowledge attention mask. We use the normalized score of R_w and E_w for constructing the knowledge attention mask. To filter-out irrelevant knowledge triples,

Dataset	#Dialogues	#Utterances	Avg. Length of Utt.	#Utt. with Entities	Avg. #Entities per Utt.
SMD (Eric et al., 2017)	3,031	15,928	9.22	4430	2.96
CamRest (Wen et al., 2017)	676	2,744	11.72	2366	2.43
MWOZ (Budzianowski et al., 2018)	2,877	19,870	16.68	6241	2.06

Table 1: Dataset statistics.

we obtain the top-k entities and relations from the weighted graph as denoted as $\hat{\mathcal{E}}$ and $\hat{\mathcal{R}}$ respectively. Here, k is a hyper-parameter which we chose from a range of [0, max(|$\mathcal{E}$|, |$\mathcal{R}$|)], based on the validation score. Finally, based on the selected $\hat{\mathcal{E}}$ and $\hat{\mathcal{R}}$, the knowledge attention mask is constructed as follows:

$$M_{i,j}^{kg} = \begin{cases} 0, & \text{if } ((s_i \vee o_i) \in \hat{\mathcal{E}}) \wedge (r_i \in \hat{\mathcal{R}}) \\ -\infty, & \text{otherwise} \end{cases}$$

Here r_i, s_i and o_i corresponds to the relation, subject and object entity of triple $\mathcal{T}_i$. Any position that corresponds to the value of $-\infty$ results in 0 after computing the *softmax* during the attention computation (discussed in the next sub-section). The final mask $M \in \mathbb{R}^{n \times n}$ is obtained by appending the mask for the dialogue related sequence with the knowledge attention mask where n is sequence length. Padding is added to adjust the dimension of the metrics.

2.4 Decoder

A Transformer (Vaswani et al., 2017) based GPT-2 (Radford et al., 2019) model is used for generating the response. The attention, computed in each of GPT-2's heads is formalized as follows:

$$\begin{aligned} Attn(Q,K,V) &= softmax(\frac{1}{\sqrt{d_k}}(QK^T) + M)V, \\ H_i &= Attn(QW_i^Q, KW_i^K, VW_i^V) \end{aligned} \quad (4)$$

where, $Attn(\cdot)$ computes the masked attention, H_i is the i-th head, d_k=d_m/h. Here, d_m is the dimension of the model where h the number of heads. Q, K and V are query, key and value where W_i^Q, W_i^K, W_i^V are trainable parameters. The objective of the model is to minimize the negative log-likelihood $\mathcal{L}$ for next-token prediction. For a dialogue dataset $D = \{D_1, D_2, ..., D_j\}$, we formally define $\mathcal{L}$ as follows:

$$\mathcal{L}(D) = -\sum_{j}^{|D|}\sum_{i}^{n} \log p(s_i^j|s_1^j, ., s_{i-1}^j, \mathcal{H}^j, \mathcal{Q}^j, \mathcal{G}^j), \quad (5)$$

where n is the maximum response length and $\mathcal{H}^j, \mathcal{Q}^j, \mathcal{G}^j \in D_j$. Top-k sampling (Fan et al., 2018) decoding is used to generate the next word token at each time step, during the inference.

3 Experimental Setup

3.1 Data

We evaluate DialoKG on three publicly available knowledge-grounded and task-oriented dialogue datasets: Stanford Multi-Domain dataset (SMD) (Eric et al., 2017), CamRest (Wen et al., 2017) and Multi-WOZ 2.1 (MWOZ) (Budzianowski et al., 2018). SMD consists of three domains: weather, navigation, and calendar. MWOZ contains five domains: train, hotel, restaurant, taxi and attraction. We use the splits provided with the datasets for train, validation, and test. Each dialogue is provided with a knowledge base. Table 1 shows the statistics of the benchmark datasets.

3.2 Hyper-parameter Settings

Throughout this paper, we use the GPT-2 (Radford et al., 2019) model with 117M parameters. AdamW (Loshchilov and Hutter, 2019) with ϵ = 1e-8 and learning rate of 6.25e-5 is employed as optimizer. GELU (Hendrycks and Gimpel, 2016) is used as activation function. The best hyper-parameters for each dataset were found using grid search and based on the results on the validation set. We run all experiments on a distributed training setting with 10 GPUs, each with 12 GB of memory. More implementation details can be found in Appendix A.

3.3 Evaluation Metrics

Automatic Metrics. Following the baseline models, we use BLEU (Papineni et al., 2002) and Entity F1 score (Eric et al., 2017) as automatic evaluation metrics. The Entity F1 score represents the model's capability of generating knowledge grounded responses. It computes the F1 score between the set of entities present in the ground truth and system-generated responses. Several studies (Novikova et al., 2017; Liu et al., 2016) on evaluation metrics suggest that word-overlap based metrics such as BLEU are insufficient for evaluating natural language generation (NLG) systems. Hence, we use MoverScore (Zhao et al., 2019) as

Model	SMD			CamRest			MWOZ		
	BLEU	MoverScore	Ent. F1	BLEU	MoverScore	Ent. F1	BLEU	MoverScore	Ent. F1
GLMP (Wu et al., 2019)	13.9	54.2	59.6	15.1	57.2	58.9	6.9	51.2	32.4
MLM (Gangi Reddy et al., 2019)	17.0	64.0	54.6	15.5	57.0	62.1	-	-	-
Ent. Const. (Qin et al., 2019)	13.9	53.8	53.7	18.5	65.9	58.6	-	-	-
GPT2+KE (Madotto et al., 2020)	17.4	66.4	59.8	18.0	65.8	54.9	**15.0**	60.9	39.6
TTOS (He et al., 2020a)	17.4	59.8	55.4	20.5	67.0	61.5	-	-	-
DF-Net (Qin et al., 2020)	14.4	56.3	62.7	-	-	-	9.4	54.2	35.1
EER (He et al., 2020c)	17.2	60.9	59.0	19.2	66.1	65.7	13.6	57.2	35.6
FG2Seq (He et al., 2020b)	16.8	60.2	61.1	20.2	66.6	66.4	14.6	58.4	36.5
CDNet (Raghu et al., 2021)	17.8	61.1	62.9	21.8	67.8	68.6	11.9	55.8	38.7
DialoKG	**20.0**	**70.6**	**65.9**	**23.4**	**70.4**	**75.6**	12.6	**62.6**	**43.5**

Table 2: Performance of DialoKG and baseline models on three benchmark datasets. Best scores in **bold** and second-best underlined.

addition metric to evaluate the semantic similarity between the system generated response and the ground truth. We compute both MoverScore and BLEU scores on the sentence level.

Human Evaluation. To assess the quality of the system-generated responses, we conduct a human evaluation based on the following criteria: 1) Naturalness: how human-like and fluent the generated responses are, and 2) Correctness: how correct the knowledge-grounded responses are. We asked three annotators (two from Computer Science (CS) and one from a non-CS background) who are not part of this research work to evaluate the quality of the system-generated responses. We randomly sampled 90 dialogues in total from the benchmark datasets and asked annotators to evaluate the system-generated responses given the ground truth response and the knowledge graph triples on a scale of [1,5] (higher is better). The inter-annotator agreement score (Cohen's kappa κ) of the annotated data is 0.82. The human evaluation process is explained in detail in Appendix D.

3.4 Baselines

We compare DialoKG with the following state-of-the-art methods: **GLMP** (Wu et al., 2019), **MLM** (Gangi Reddy et al., 2019), **Ent. Const.** (Qin et al., 2019), **DF-Net** (Qin et al., 2020), **CDNet** (Raghu et al., 2021), **GPT2+KE** (Madotto et al., 2020), **TTOS** (He et al., 2020a) and **EER** (He et al., 2020c). Most of these approaches adopt memory networks to generate knowledge grounded dialogues, whereas **GPT2+KE** (Madotto et al., 2020) directly embeds the knowledge base into the model's parameters and **TTOS** (He et al., 2020a) proposed a reinforcement learning-based framework.

4 Results and Analysis

4.1 Quantitative Results

We conduct both quantitative and qualitative analyses to assess system-generated responses. Table 2 summarizes the performance of DialoKG with respect to the baseline models. It is evident that DialoKG outperforms the baseline models significantly in Entity F1 score on CamRest, which contains mostly knowledge-grounded dialogues about restaurant reservations. A high Entity F1 score of 75.6 on CamRest shows DialoKG's ability to generate knowledge-grounded with high accuracy. Although DialoKG achieves an improved Entity F1 score on the MWOZ dataset, it has a lower BLEU score since MWOZ often contains lengthy responses. However, the high MoverScore across all datasets demonstrates that DialoKG can generate highly semantically similar responses. Domain-wise results are reported in Appendix B due to space limitation.

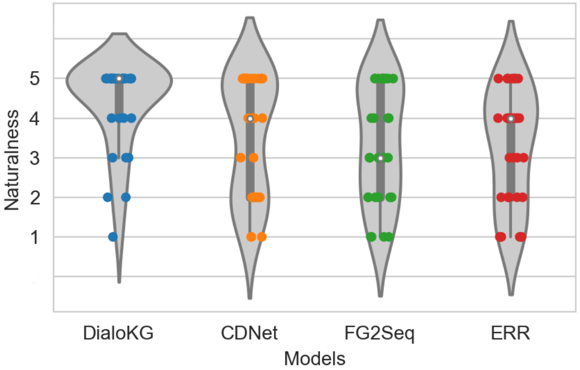

Figure 5: Distribution of human evaluation scores.

4.2 Qualitative Results

We obtain human evaluation scores (naturalness and correctness) for the closest three models. Re-

Model	**Naturalness**	**Correctness**
EER (He et al., 2020c)	3.27	3.61
FG2Seq (He et al., 2020b)	3.33	3.87
CDNet (Raghu et al., 2021)	3.53	3.94
DialoKG	**4.33**	**4.01**

Table 3: Human evaluation results.

Approach	**BLEU**	**Δ**	**Ent. F1**	**Δ**
DialoKG (seq2seq)	14.5	-	59.4	-
+ Entity embedding	17.7	3.2↑	63.0	3.6↑
+ Triple embedding	19.2	1.5↑	67.8	4.8↑
+ Type embedding	20.1	0.9↑	68.4	0.6↑
+ Knowledge attention mask	23.4	3.3↑	75.6	7.2↑

Table 4: Ablation study.

sults in Table 3 show that our proposed dialogue system can generate more human-like responses. An improved score is also achieved in terms of correctness, reflecting DialoKG's ability to generate highly accurate dialogues. Furthermore, Figure 5 shows the distribution of human evaluation scores. The figure allows a better direct comparison of the individual score levels. Details about the annotation process are reported in Appendix D.

4.3 Ablation Study

We conducted an ablation study to investigate the contribution of major components of DialoKG. The results on CamRest in Table 4 demonstrates that the *ses2seq* approach achieves the lowest scores, which represents the DialoKG model without the embedding layers: entity embedding, triple embedding, and type embedding. Inclusion of the entity and triple embedding layers significantly improved model's performance in both BLEU and Entity F1 scores. The type embedding further improved DialoKG's performance. The significant difference in results shows the effectiveness of the proposed embedding technique. Finally, we observed a remarkable improvement in DialoKG's overall performance after the inclusion of knowledge attention mask. Question-aware weighted-graph computation used to construct knowledge attention mask, helped the model focus on the task at the inference time.

4.4 Effectiveness of Knowledge Embedding

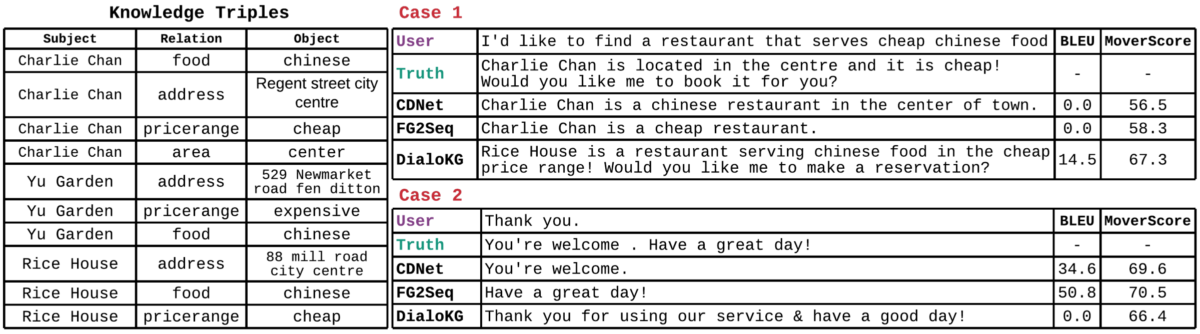
The proposed graph embedding technique works best in combination with the knowledge attention mask. The graph embedding design allows DialoKG to handle disconnected graphs and triples. This makes DialoKG suitable for large-scale graphs, where a cosine-similarity based triple selection may be used to fit the graph triples inside the model's input capacity. The entity and triple embedding layers allow the model to preserve the structural information of a particular triple even though triples from different parts of the input sequence are selected based on the top-k entities and relations to construct the knowledge attention mask. Overall, the graph embedding technique improves the Entity F1 score by 5.4, 9.0, and 3.7 points on SMD, CamRest, and MWOZ, respectively. This indicates the effectiveness of the proposed embedding techniques for capturing graph triples.

Top-k (entity)	**Top-k (relation)**	**BLEU**	**MoverScore**	**Entity F1**
3	5	10.8	65.3	48.2
3	7	11.0	65.4	48.9
5	5	16.9	68.0	62.1
5	7	17.4	68.1	62.5
7	5	19.3	70.4	64.4
7	7	**20.0**	**70.6**	**65.9**
All	All	15.9	67.2	59.0

Table 5: Effect of triple selection on the performance.

4.5 Impact of Knowledge Attention Mask

To understand the effect of the knowledge-graph weighted attention mask, we experiment with the triple selection process described in DialoKG's approach. Table 5 shows the performance of DialoKG with selected top-k entities and relations on the SMD dataset. We observe that DialoKG achieves the best performance on SMD when the top 7 entities and relations are chosen to construct the knowledge mask. Consider the question "*Do you have any local coffee shops?*" the ground truth is "*There is Coupa, it s just 6 miles away but there is heavy traffic on our way*". The ground truth contains traffic information in addition to the distance and name of the coffee shop. Selecting a high number of entities and relations increases the chance of generating such additional information related to the subject of the question. However, choosing too many entities harms the model since it is more likely to add irrelevant noise (see Table 5). Particularly, the entities that are irrelevant for answering the current user utterance act as a noise. For MWOZ, six entities and seven relations, and for CamRest, seven entities and five relations result in the best performance.



Knowledge Triples

Subject	Relation	Object
Charlie Chan	food	chinese
Charlie Chan	address	Regent street city centre

DialoKG	Thank you for using our service & have a good day!	0.0	66.4

Figure 6: Case study: comparison between ground truth and system-generated responses.

5 Case Study

Figure 6 shows two cases from the MWOZ dataset given a subset of the knowledge graph. In Case 1, we observe that in answering the user question, DialoKG correctly picked *Rice House* that serves *cheap* and *Chinese* food. However, in this case, multiple correct answers exist, e.g. *Charlie Chan* also falls into the same category of restaurant. Despite generating the correct answer based on the given knowledge and the user question, DialoKG receives a low Entity F1 score since the generated response entity does not match the ground truth. In Case 2, where the baseline systems focus on imitating the ground truth, DialoKG generates a fluent and engaging response. Despite generating a meaningful and semantically similar sentence, it obtained a BLEU score of 0.0 because of the low overlap with the ground truth response. However, a high MoverScore in both cases indicates DialoKG's ability to generate a semantically similar response. Overall, we observe that DialoKG can generate human-like, engaging, and informative responses in a multi-turn dialogue setting.

5.1 Influence of Dialogue History

Dialogue history is particularly crucial since it gives the model the context for generating the response. In some cases where the entity information is missing in the current user utterance, the dialogue context provides the model with enough information to perform the inference and generate the correct response. For instance, for the question, *What is the food type they serve?*, the name of the restaurant is not given in the question, but the system can infer it from the dialogue history. However, from the experiments, we found that too much dialogue context may inject noisy and irrelevant information to answer the current question, in particular for knowledge-grounded responses in MWOZ. To quantify this, we selected different numbers of dialogue turns as history for the model's input depending on the characteristics of the dataset and visualised the result in Figure 7.

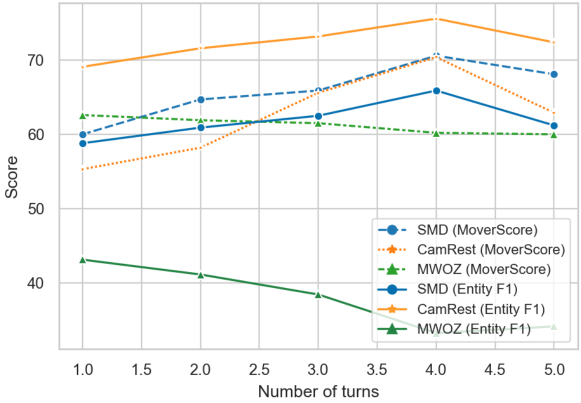

Figure 7: DialoKG's performance on benchmark datasets for different number of dialogue contexts.

6 Related Work

Task-Oriented Dialogue Systems. Recent dialogue systems mainly leverage Memory Pointer Networks (Sukhbaatar et al., 2015; Madotto et al., 2018; Wu et al., 2019), Copy mechanisms (Gu et al., 2016; Lin et al., 2020; Chaudhuri et al., 2019) and similarity-based knowledge distillation techniques (Wen et al., 2018; Raghu et al., 2021) for the knowledge selection and dialogue generation task. In this research direction, learning to generate template responses and fill in the slot is a common practice (Wu et al., 2019). Dialogue history and knowledge entities are stored in shared memory, facilitating these systems to apply copy mechanisms over the memory space. A multi-level memory architecture is proposed by (Gangi Reddy et al., 2019) that handles the dialogue history and knowledge entries separately.

Knowledge-Structure Aware Dialogue Generation. Recently, several knowledge-grounded dialogue systems have attempted to capture structural knowledge to improve the performance of dialogue generation. A sequence-to-sequence model is proposed by (Liu et al., 2018b) that employs global and local attention to understand structural information. Several studies found GCN to be effective for modeling graph-based data. Hence, they construct a graph from a document (Moghe et al., 2020) or the interaction between two speakers (Wu et al., 2021) for generating informative dialogues. In a different approach, an enhanced entity representation is proposed by (He et al., 2020c) by considering the entity information and the structural and relational information of the knowledge entries. In contrast to the previous works, our proposed approach represents the graph's structural information such as entities and triples through multiple embedding layers.

Language Model Based Dialogue Generation. Pre-training a language model with dialogue datasets (Zhang et al., 2020; Bao et al., 2020; Gu et al., 2021) and fine-tuning an already pre-trained model for various dialogue-related sub-tasks such as dialogue state tracking, action decision and response generation (Hosseini-Asl et al., 2020; Wu et al., 2020a; Galetzka et al., 2021) has received much attention in recent years. Recently, (Madotto et al., 2020) proposed a new method to embed the knowledge into the language model parameters. However, the authors noticed that the generated dialogues are sometimes noisy and requires high fine-tuning costs. Despite the success of language model-based approaches, integrating structured knowledge into the dialogue generation process remains a challenging task. Unlike the previous approaches, we designed a structure-aware embedding method and exploit GPT-2 to generate dialogues.

7 Conclusion

We have presented DialoKG, a novel knowledge-grounded task-oriented dialogue system improving the state-of-the-art across multiple benchmark datasets. DialoKG focuses on capturing the underlying semantics of the knowledge graph and pays attention to the relevant graph triples to understand the task and generate correct and human-like responses. The key contributions of DialoKG include 1) **Knowledge embedding technique**, that embeds the structural information of a knowledge graph effectively, and 2) **Knowledge graph-weighted attention masking**, which guides the masked language model to attend to the relevant knowledge entries for generating correct and informative responses. Finally, we showed DialoKG's ability to generate accurate, diverse, and human-like dialogues through quantitative and qualitative analysis. We performed an ablation study and studied the effect of dialogue history, knowledge embedding and knowledge attention masking.

A Hyper-parameter Settings

We report the hyper-parameters used to train DialoKG in Table 6 for SMD, CamRest, and MWOZ. GPT-2 specific hyper-parameters are also reported in Table 6. All the hyper-parameters are found after a grid search and evaluation on the validation set. We sample learning rate from {6.25e-01, 6.25e-04, 6.25e-05} and maximum history token and knowledge token from {128, 256, 384, 512}.

	SMD	**CamRest**	**MWOZ**
Learning rate	6.25e-05	6.25e-04	6.25e-05
Adam epsilon	1e-08	1e-08	1e-08
Batch size	4	4	4
Gradient accumulation steps	4	4	4
Max history turn	4	4	1
Maximum history token	128	256	128
Maximum knowledge token	384	256	384
Top relations	7	7	6
Top entities	7	5	7
Epochs	40	25	30

Table 6: Training parameters.

For both training and evaluation, we use a batch size of 4. Hyper-parameters used during the inference are reported in Table 7. We used 12 NVIDIA TitanX GPUs, each with 12GB of memory to train models. It took 30, 18 and 45 minutes to train on SMD, CamRest and MWOZ data.

	SMD	**CamRest**	**MWOZ**
Temperature	0.68	0.85	0.18
Top-k	6	8	10
Top-p	0.9	0.9	0.9
Maximum response length	100	80	120
Top entities	7	7	6
Top relations	7	5	7

Table 7: Decoding parameters.

B Results

We report the domain-wise results for SMD and MWOZ in Table 8 and Table 9 respectively. Baseline model's results are reported from (Raghu et al., 2021) and (Madotto et al., 2020). The MWOZ dialogue dataset contains conversations on the following domains as reported in the baseline works: attraction, restaurant, and hotel. The domain-wise results demonstrate that DialoKG achieves improved performance in almost all domains in a multi-domain setup. This demonstrates DialoKG's capacity to handle a dynamic knowledge base.

Models	BLEU	MoverScore	Entity F1	Schedule	Navigate	Weather
GLMP (Wu et al., 2019)	13.9	54.2	59.6	72.5	54.6	56.5

C Knowledge Triples to Sequence Transformation

Figure 8 depicts how we linearize a graph into a sequence. The sequence begins with a [BOS] token, followed by the token [S] and a subject (*worth house*). The token [S] indicates that the following word in the sequence is a subject (in this case *worth house*). Then we append all the triples that are connected to the subject *worth house* where the relation and object is separated by the token [R] and [O], respectively. Similarly, the second subject is appended to the sequence separated by a preceding [S] token.

D Human Evaluation

Figure 9 shows the interface of the annotation tool used to obtain human annotation scores. The interface displays a set of knowledge triples, a user utterance, the ground truth response, and a system-generated response for each point. Given the information displayed on the annotation tool, we asked the annotators to rate the system-generated responses against the ground-truth on a scale of [1,5] (higher is better). We explained the participants about the purpose of this research. The first two participants are male (over 30 years old), and the third participant is female (more than 35 years old), both with several years of experience in the domain.

E Example System Outputs

We show conversations performed by DialoKG on SMD and MWOZ 2.1 dataset in Figure 10 and Figure 11, respectively. The example conversations demonstrate that DialoKG can perform accurate and engaging conversations.

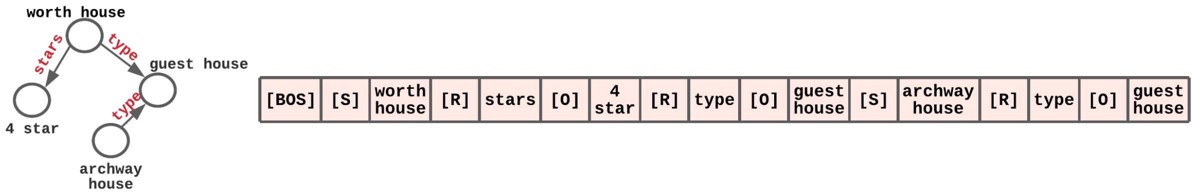

Figure 8: Illustration of graph to sequence transformation.

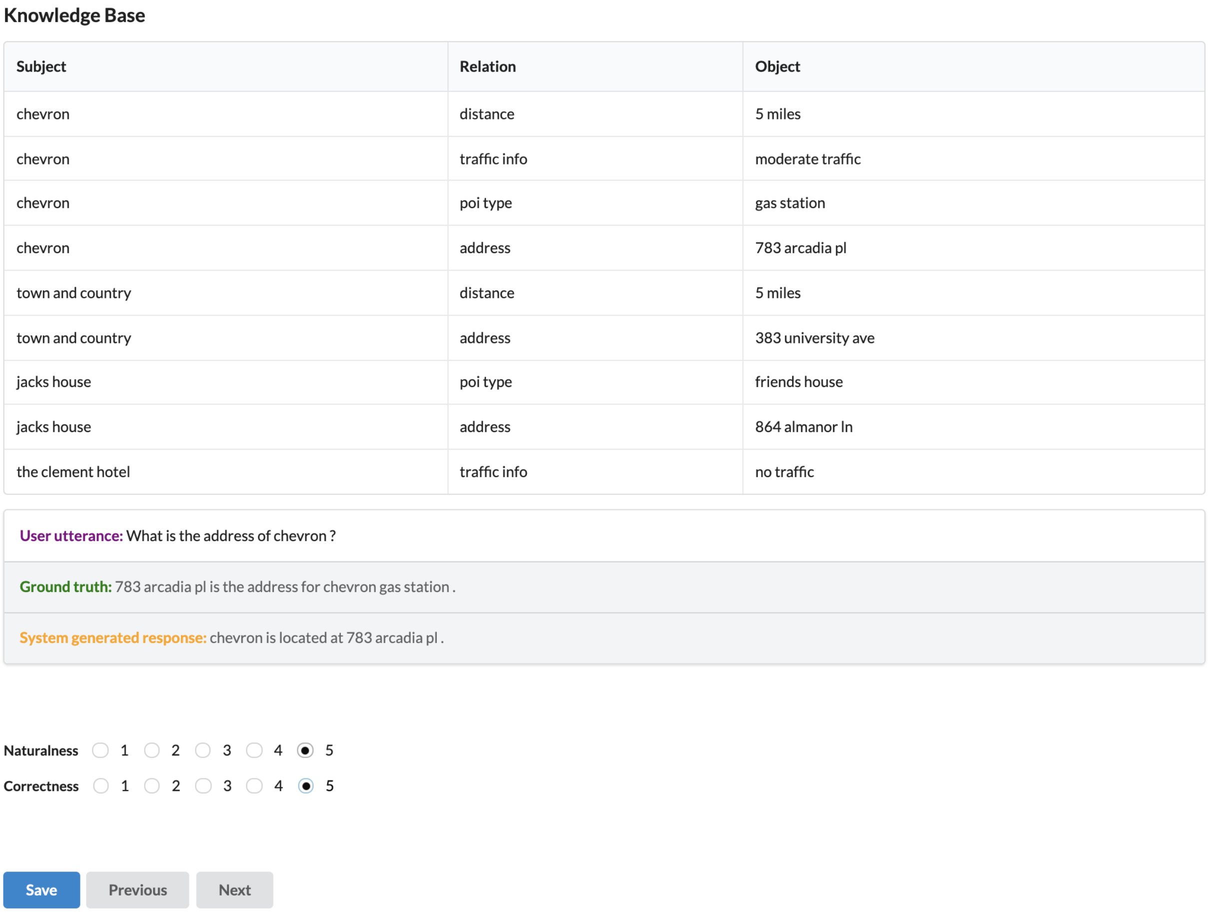

Knowledge Base

Subject	Relation	Object
chevron	distance	5 miles
chevron	traffic info	moderate traffic
chevron	poi type	gas station
chevron	address	783 arcadia pl
town and country	distance	5 miles
town and country	address	383 university ave
jacks house	poi type	friends house
jacks house	address	864 almanor ln
the clement hotel	traffic info	no traffic

User utterance: What is the address of chevron ?

Ground truth: 783 arcadia pl is the address for chevron gas station .

System generated response: chevron is located at 783 arcadia pl .

Naturalness ○ 1 ○ 2 ○ 3 ○ 4 ● 5

Correctness ○ 1 ○ 2 ○ 3 ○ 4 ● 5

Figure 9: The interface of the annotation tool to obtained the human annotation scores.

Abstract

Event detection is a classic natural language processing task. However, the constantly emerging new events make supervised methods not applicable to unseen types. Previous zero-shot event detection methods either require predefined event types as heuristic rules or resort to external semantic analyzing tools. To overcome this weakness, we propose an end-to-end framework named **Z**ero-Shot **E**vent Detection Based on **O**rdered Contrastive Learning and **P**rompt-Based Prediction (ZEOP). By creatively introducing multiple contrastive samples with ordered similarities, the encoder can learn event representations from both instance-level and class-level, which makes the distinctions between different unseen types more significant. Meanwhile, we utilize the prompt-based prediction to identify trigger words without relying on external resources. Experiments demonstrate that our model detects events more effectively and accurately than state-of-the-art methods.

1 Introduction

As a classic NLP task, event detection aims to identify events from natural language text. Most traditional supervised event detection methods (Nguyen and Grishman, 2018; Wadden et al., 2019; Lin et al., 2020) rely on a great number of event-specific annotated texts. However, in practice, obtaining large-scale and high-quality annotated data requires significant expertise and expensive resources. In the real-world scenarios shown in Figure 1, the constantly emerging of new events without annotated samples, making supervised event detection methods no longer applicable.

To solve this challenge, the zero-shot event detection task is proposed to automatically discover and classify new events from unstructured texts in the absence of manual annotation. Following previous works (Zhang et al., 2015; Huang et al., 2018; Huang and Ji, 2020; Wang et al., 2021), we denote the known types as *seen* types and the new types as *unseen* types. "Unseen" means that the event labels of samples are not visible to the model.

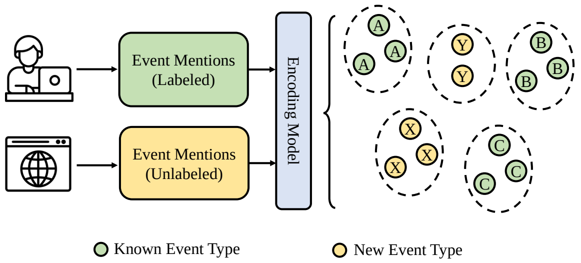

Figure 1: Zero-Shot Event Detection. A training dataset with a few known event types is already annotated manually. The Internet continually produce unlabeled text data every second, which contains a large number of new event types.

Recently, multiple zero-shot event detection methods have been proposed and show better performance than supervised methods on zero-shot tasks. However, they (Huang et al., 2018; Zhang et al., 2021b; Lyu et al., 2021; Huang and Ji, 2020) all require predefined event types as heuristic rules or external semantic analyzing tools. For example, event names are used to query trigger words by semantical similarity, or the part-of-speech tagging tools are used to find nouns and verbs in the text as candidate trigger words. In these ways, human effort and external resources are still necessary when detecting new event types. There is also a problem of error accumulation across the tools and models.

To overcome the above weakness, this paper proposes an end-to-end model named Zero-Shot Event Detection Based on Ordered Contrastive Learning and Prompt-Based Prediction. The main idea is introducing contrastive learning to move away from the dependence on heuristic rules for unseen event detection. As shown in Figure 2, traditional

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2572 - 2580
July 10-15, 2022

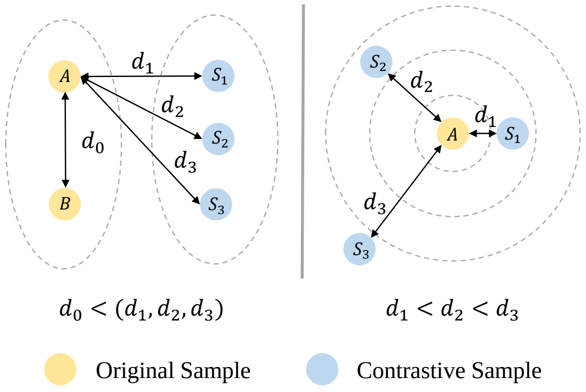

Figure 2: Traditional contrastive learning (left) only distinguish between positive and negative samples, while ordered contrastive learning (right) constructs an ordered sequence of contrastive samples by the similarity to the original sample.

contrastive learning simply divide samples into two opposite classes: positive or negative, while we construct four contrastive samples with different similarities to the original sample. Then, the ordered contrastive learning can draw a stronger distinction between different unseen type events by learning the partial order relationship of different contrastive samples. Meanwhile, in order to discover new event types without relying on heuristic rules, we utilize the prompt-based prediction (Brown et al., 2020; Schick and Schütze, 2021; Gao et al., 2021a) for trigger words identification, which has been proved to be an efficient few-shot learner.

The main work of this paper has the following three points:

- We proposed a zero-shot event detection model based on ordered contrastive learning. By constructing multiple contrastive samples with ordered similarities, the encoder could learn a better representation of unseen types.
- We creatively introduce the prompt-based prediction into the zero-shot event detection problem for trigger words identification, which removed the dependency on predefined event structures and heuristic rules.
- Experiments on two English datasets demonstrate that the both supervised and zero-shot event detection performance are improved via ordered contrastive learning and prompt-based prediction.

2 Related Work

2.1 Zero-shot event detection

The transfer learning-based zero-shot methods mainly rely on a predefined event structure as heuristic rules. In other words, models must know the unseen event name (e.g Attack) and the elements (e.g Attacker) consist of unseen events. Huang et al. (2018) and Zhang et al. (2021b) cluster unseen events by label semantic similarity with the help of semantic structures analyzing tools such as Abstract Meaning Representation (AMR) or Semantic Role Labeling (SRL). Additionally, Lyu et al. (2021) need to define QA queries for unseen event types manually. Although Huang and Ji (2020) proposed SS-VQ-VAE to discover new event types without human assistance, external part-of-speech tagging tool is needed to find candidate trigger words. Meanwhile, the semi-supervised loss function could only roughly separate all unseen event samples from seen events. And the variational autoencoder focuses on the feature learning of single instance. So it is still challenging to cluster unseen events into multiple new types.

2.2 Contrastive learning

Contrastive learning aims to learn high-quality feature representations through self-supervision. The core of contrastive learning is constructing positive and negative sample pairs. For labeled data, the construction is relatively simple, where random sampling by supervise label works in most cases. For unsupervised learning with unlabeled data, it needs more strategy to construct sample pairs. Wang et al. (2021); Logeswaran and Lee (2018) treat the target sentence's context as a positive sample. Wang et al. (2020) proposed various sample editing methods based on word masking and shuffle. Gao et al. (2021b) introduce a dropout mask for constructing contrastive samples, which doesn't need any textual edit. These approaches focus on instance-level feature contrastive and only divide samples into positive and negative. Zhang et al. (2021a) try to overcome this weakness by optimizing a top-down clustering loss. Considering that class-level features learning is as essential as instance-level features, it's necessary to improve the traditional contrastive learning framework for the zero-shot event detection task.

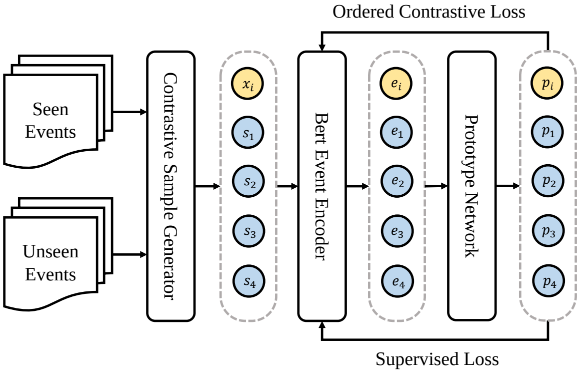

Figure 3: The architecture overview of ZEOP.

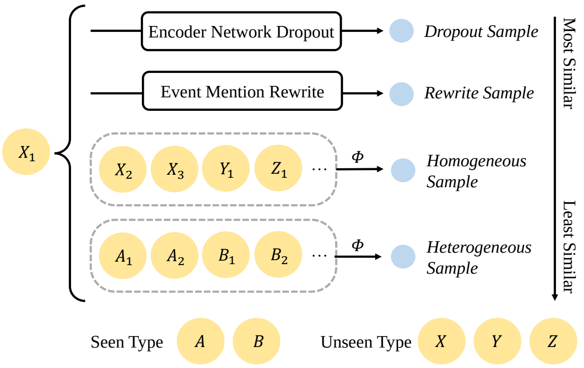

Figure 4: How contrastive samples are constructed for unseen types. The Φ denotes random sample operation.

2.3 Prompt-based prediction

Prompt-based prediction (Brown et al., 2020; Schick and Schütze, 2021; Gao et al., 2021a) treats the NLP downstream task as a masked language modeling problem. The language model first generates a label word to a given prompt defined by a task-specific template. Then the label word is mapped to downstream task output space. In this way, knowledge can be extracted from pretrained language models at low cost, which makes full use of pre-training corpus. This is an ideal approach for event trigger word identification in the zero-shot event detection task scenario, because it doesn't relay on any heuristic rules or external tools as multiple approaches mention in Section 2.1,

3 Methodology

The architecture overview of **Z**ero-Shot **E**vent Detection Based on **O**rdered Contrastive Learning and **P**rompt-Based Prediction (ZEOP) is shown in Figure 3. Given a set of seen events S and unseen events U, all samples are first input into the contrastive sample generator as the original sample x_i, where a list of multiple contrastive samples is constructed as $\{s_1, \ldots, s_4\}$. Subsequently, the event encoder encodes event mentions as embedding vector e_i, and the prototypical network predicts probability distribution over event types as p_i. Ordered contrastive loss is calculated for all samples, and supervised loss is calculated only for samples of seen events. Model parameters in the event encoder and prototypical network could be updated by gradient backward.

3.1 Contrastive sample generator

In this paper, we aim to resolve the zero-shot event detection task. On the one hand, seen events samples could offer supervised labels, which are ideal class-level contrastive samples. On the other hand, there are also some unseen events samples without supervised labels, which could only be used for instance-level contrastive samples. Therefore, we construct four constructive samples, including both class-level and instance-level, which are shown in Figure 4. The similarities between these contrastive and original samples differ from strong to weak.

3.1.1 Dropout sample

Dropout mask is proposed by (Gao et al., 2021b), which passes the same sentence to the pre-trained encoder twice. Because the network nodes of the encoder are randomly dropped when training, a different event embedding will be obtained for the second time. The dropout sample should be considered the most similar contrastive sample with the same input sentences.

3.1.2 Rewrite sample

The rewrite sample is textually edited from the original event mention. In order to ensure the consistency of semantics, we choose the back translation (Fadaee and Monz, 2018) for event mention rewriting. Rewrite samples should be considered the secondary similar contrastive sample because they keep the original event trigger and elements.

3.1.3 Homogeneous sample

Homogeneous samples are events with the homogeneous event type. For seen events, the homogeneous samples are random sampled from events with same label $\{s_i \in S | s_i.type = x_i.type\}$. For unseen types, the label of the original event is invisible for the model, so the homogeneous samples are randomly sampled from all unseen types U.

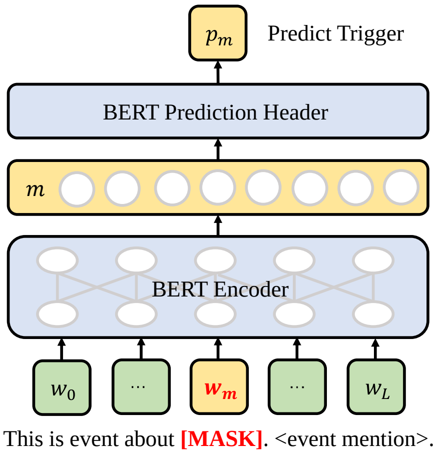

Figure 5: Prompt-based trigger word prediction. The prompt template is populated with the event mention and encoded by a pre-trained BERT. The contextual vector corresponding to the [MASK] tag is used for trigger prediction.

3.1.4 Heterogeneous sample

Heterogeneous samples are events with heterogeneous types. For seen events, heterogeneous types mean seen events with a different label $\{s_i \in S | s_i.type \neq x_i.type\}$. For unseen events, the heterogeneous type means all seen types S due to the label of the original event is invisible for the model.

It should be noted that a homogeneous sample may have a different label with the original sample. But it could be guaranteed that heterogeneous samples always have different label. Therefore the heterogeneous samples are regarded as the least similar contrastive samples.

3.2 Event encoder

Following existing zero-shot event detection approaches (Huang and Ji, 2020; Zhang et al., 2021b), the best embedding feature for an event should be the contextual vector of trigger words. The problem is how to identify the trigger words under the zero-shot setup. Inspired by (Brown et al., 2020; Schick and Schütze, 2021; Gao et al., 2021a), we utilize the prompt-based prediction for trigger word identification, which doesn't rely on any heuristic rules or external semantic analyzing tools.

3.2.1 Trigger word prediction

As shown in Figure 5, we use "This is event about [MASK]. <event mention>" as prompt template, where the [MASK] is the trigger word that pre-trained BERT (Devlin et al., 2019) language model should predict, and the <event mention> is the text describing an event. In specific, given a BERT input sequence $t = \{w_0, w_1, w_2, \ldots, w_L\}$, where w_i is the ith token of the template sentence, we obtain a word distribution $p_m(w_m = w_i|t)$ over all the words in the event mention.

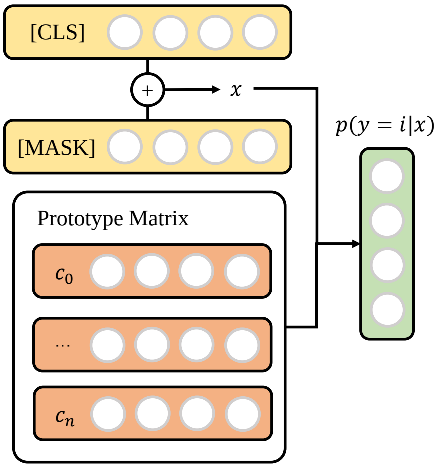

Figure 6: Event type prediction by prototype network. The query vector is the result of element-wise adding the contextual vector of [CLS] and [MASK] token.

3.2.2 Event type prediction

For event type prediction, we introduce prototype network (Snell et al., 2017). It defines a prototype matrix $C \in \mathbb{R}^{n\times h}$, where each row represents the prototype of one embedded event type c_i and h is the embedding dim of BERT. The number of embedding types is $n = k + l$, where k is the number of seen event types and l is the number of unseen event types. The value of the prototype matrix is randomly initialized and keeps updating while training the model. As shown in Figure 6, give a query vector x, the distribution over event types is calculated by the prototypical network as follow:

$$p(y = i \,|\, x) = \frac{\exp(-d(f(x), c_i))}{\sum_{i'} \exp(-d(f(x), c_{i'}))} \qquad (1)$$

where $d(x, c_i)$ is the Euclidean distance between embedding vector x and c_i.

One event type may correspond to multiple trigger words in the event detection task. If only the predicted trigger words were used as the query point, samples with the same event type would be mapped to hidden space with large distances. So we add the contextual vector of [CLS] and [MASK] token as query vector x to balance event type and trigger words features.

3.3 Ordered contrastive loss

The design goal of the contrastive loss function is to narrow the distance between similar samples and push away different samples. To better represent unseen events under the zero-shot setting, the proposed ordered contrastive learning constructs two represent contrastive samples (Dropout Sample and Rewrite Sample), an inner-cluster contrastive sample (Homogeneous Sample), and an inter-cluster contrastive sample (Heterogeneous Sample). Given four contrastive samples with different similarities to the original sample, we designed a novel ordered contrastive loss function by expanding the contrast loss function in (Hadsell et al., 2006). Our model could learn the partial order relationship in similarity: Dropout Sample > Rewrite Sample > Homogeneous Sample > Heterogeneous Sample. Thus model will distinguish between different unseen type events more significant.

Let p_0, p_1, p_2, p_3, and p_4 be the event type probability distribution of the original, dropout, rewrite, homogeneous, and heterogeneous samples, respectively. The distance between contrastive samples and the original sample are calculated as d_1, d_2, d_3, and d_4:

$$d_i = W_p(p_i, p_0), i \in \{1, 2, 3, 4\} \tag{2}$$

Considering the vectors to be compared are probability distribution, we utilize Wasserstein distance (Kolouri et al., 2019) as the distance function W_p. Compared to Euclidean distance and cosine distance commonly used in contrastive learning, Wasserstein distance could better measure the difference between probability distributions.

$$W_p(\mu, \nu) = \left(\inf_{\gamma \in \Gamma(\mu, \nu)} \int_{X \times Y} d^p(x, y) d\gamma(x, y) \right)^{\frac{1}{p}} \tag{3}$$

The similarities between contrastive samples and the original sample decrease. Four distances may form an increasing list. For seen events, this list is strictly increasing. For unseen events, this list is not strictly increasing because the homogeneous sample may carry a different label. Therefore, the ordered contrastive loss for sample x is calculated as:

$$\begin{aligned} L_c = d_1 + L_m(d_2, d_1) + L_m(d_3, d_2) \\ + \begin{cases} L_m(d_4, d_3) & x \in S \\ L_m(d_4, d_2) & x \in U \end{cases} \end{aligned} \tag{4}$$

Table 1: Statistics of datasets. The $|V|$ and $|D|$ are the number of samples and event types. The last two rows are the mean and standard deviation of samples by type.

Dataset	ACE-2005		FewShotED	
	$\|V\|$	$\|D\|$	$\|V\|$	$\|D\|$
Seen	2316	17	40893	50
Unseen	1489	16	33439	50
Total	3805	33	74332	100
Mean	115.30		743.32	
Stdev	206.32		2828.47	

where $L_m(d_x, d_y)$ is the margin loss:

$$L_m(d_x, d_y) = max(0, margin - (d_x - d_y)) \tag{5}$$

3.4 Supervised loss

Since the first k rows of the prototype matrix correspond to the seen event types, we could also apply supervised learning for seen events in addition to the contrastive learning. With the label and trigger word visible to the model, the negative log loss function is calculated as:

$$L_s = \begin{cases} -\hat{y}_x log(y_x) - \hat{z}_x log(z_x) & x \in S \\ 0 & x \in U \end{cases} \tag{6}$$

where $\hat{y}_x$ and $\hat{z}_x$ are the ground truth label of event type and trigger words, respectively.

The complete loss of ZEOP is the sum of ordered contrastive loss and supervised loss

$$Loss = L_c + L_s \tag{7}$$

4 Experiments

4.1 Implementation

We implement our model in PyTorch (Paszke et al., 2019) with Transformer Library (Wolf et al., 2020) and choose *bert-base-uncased* as the pre-trained language model. For back translation, we use Argos Translate[1] and set Chinese as the intermediate language. For model training, we use the AdamW(Loshchilov and Hutter, 2019) optimizer with batch size of 32, and the learning rate is grid searched in $[1e-7, 1e-4]$ for parameters of BERT, $[1e-4, 1e-2]$ for non-BERT parameters. The margin in contrastive loss is set to 1, and the unseen event types count l is set to the actual value of the dataset. With above settings, the total number of parameters in ZEOP is 109.53 million, of

which 109.51 million (99.98%) belong to the pre-trained BERT. All the experiments are performed on a Linux server with four RTX 3090 GPUs. The code of all experiments is available at GitHub[2].

4.2 Dataset

We evaluate the proposed model on two datasets in English. Ace-2005[3] is a widely used (Huang et al., 2018; Huang and Ji, 2020; Zhang et al., 2021b; Lyu et al., 2021) dataset for the event detection task. FewShotED (Deng et al., 2020) is a dataset proposed for the few-shot event detection task. To balance the sample count between seen and unseen types, we first sort the event types by the decreasing order of the sample count. Then take event types at the odd position as seen types and the even position as the unseen type. For example, given a list of event type list t_1, t_2, t_3, t_4 sorted by sample count, the t_1 and t_3 will be mark as seen event types, the t_2 and t_4 will be mark as unseen event types. The Statistics of the processed dataset are shown in table 1. We may assume that each sample only belong to one event type. In comparison, the number of samples and types in the ACE-2005 dataset is smaller than FewShotED. The problem of sampling bias is more evident on FewShotED. These datasets will be randomly divided into training set, validation set, and test set at a ratio of 8:1:1.

4.3 Evaluation

We set up two tasks for evaluation: supervised event detection for seen events and zero-shot event detection for unseen events. The f1 score will be used as the common metric for two tasks. For seen events, the predicted labels are directly output by the model. For unseen events, the predicted labels are mapped from model outputs by the Hungarian Algorithm. Additionally, following (Huang and Ji, 2020; Zhang et al., 2021a), Normalized Mutual Info (NMI) and Fowlkes Mallows (FM) will be used for unseen events detection to evaluate the clustering performance.

4.4 Baseline

Considering that the zero-shot event detection task focused in this study has no available pre-defined event types, many approaches mentioned in Section 2.1 are not applicable because they require event type names or QA queries as model input. So we use the following approaches as the experimental baselines.

- **SCCL** (Zhang et al., 2021a): A state-of-the-art model designed for unsupervised text clustering could detect new event types from unseen event mentions. We use the contextual vector of same candidate trigger words as SS-VQ-VAE instead of [CLS] token as event mention representation to fit event detection task.

- **SS-VQ-VAE** (Huang and Ji, 2020): A semi-supervised zero-shot event Detection model uses the variational autoencoder as regularizer. It considers all noun and verb concepts that can be mapped to OntoNotes senses as candidate trigger words.

- **BERT-OCL**: We fine-tune a BERT with the ordered contrastive framework proposed in this paper, where the distance between the contrastive sample and the original sample is calculated by Euclidean distance. Once event encoding is obtained, KNN algorithm is applied to seen events detection as the classifier and K-means algorithm is applied to unseen event detection as the cluster.

- **ZEO**: The version of ZEOP don't identify event trigger word by prompt-based prediction, and use the same heuristic rules as SS-VQ-VAE to identify candidate trigger words.

ZEOP-Kl	0.7910	0.3543	**0.3960**	0.2515	0.9245	0.3236	0.4465	0.3188
ZEOP	0.7771	**0.4591**	0.3797	**0.4913**	0.9306	**0.5814**	**0.4831**	**0.7139**

4.5 Overall performance

The overall performance of ZEOP and all baseline approaches are shown in Table 2. Our proposed model achieved the best overall performance on two datasets for both seen and unseen event detection tasks, except the BERT-OCL takes the lead on Normalized Mutual Info on ACE-2005, which may be due to the small number of samples in the dataset. The prototypical network used by ZEOP needs more samples to train its prototype matrix of classes, while Bert-OCL could directly use the embedding result of pre-trained bert. Besides, we could observe that: 1) Comparing the evaluation of ZEO and ZEOP, although ZEO shows a slight performance advantage on F1 score on FewShotED for seen event detection task, other metrics proved that prompt-based prediction gives model better performance than heuristic rules as trigger word identifier. 2) The SCCL and BERT-OCL show worse performance than SS-VQ-VAE on seen event detection task, which demonstrates that supervised learning is still necessary and could not be replaced by contrastive learning.

4.6 Ablation study

To explore the effect of four contrastive samples, we conduct an ablation experiment by introducing them one by one to the ZEOP-woCL model, which takes no contrastive samples. The comparison of their performance is shown in Table 3. As all contrastive samples are added to the model, the performance improves on the unseen event detection task, but there is a performance decrease on the seen event detection task. This demonstrates that contrastive learning does help the model to learn a better representation of unseen types, but its training objectives will conflict with the goal of supervised learning.

What's more, we also validate the effect of Wasserstein distance as the distance metric in the ordered contrastive loss. Table 4 indicates that the ZEOP model using Wasserstein distance performs better on unseen event detection task than ZEOP-Eu using Euclidean distance and ZEOP-Kl using Kullback-Leibler divergence. However, Euclidean distance shows better results on seen event detection task.

4.7 Qualitative analysis

For qualitative analysis, we visualize all unseen types samples in the dataset by t-SNE [4]. As Figure 7 and Figure 8 show, the model with ordered contrastive learning (ZEOP and BERT-OCL) could learn a better representation of unseen types than other baselines. The larger the number of samples a type contains, the better cluster will be achieved. Overall, the classification of unknown event types is significantly more complex than known types, and only a small number of types with large sample sizes are correctly classified. Many clusters could not be mapped one-to-one to the actual event type with the absence of supervision learning. The model may use event elements such as subject and location as clustering features rather than the event type itself.

4.8 Hyperparameter sensitivity analysis

The number of clusters is an essential hyperparameter in the clustering problem. In order to explore

---

[4] https://scikit-learn.org/stable/modules/generated/sklearn.manifold.TSNE.html

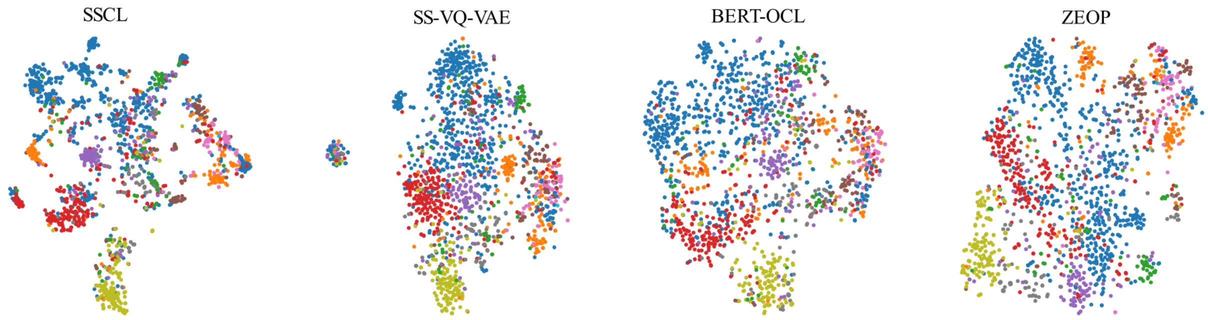

Figure 7: Visualization of unseen types on ACE-2005. Each color indicates a ground truth type.

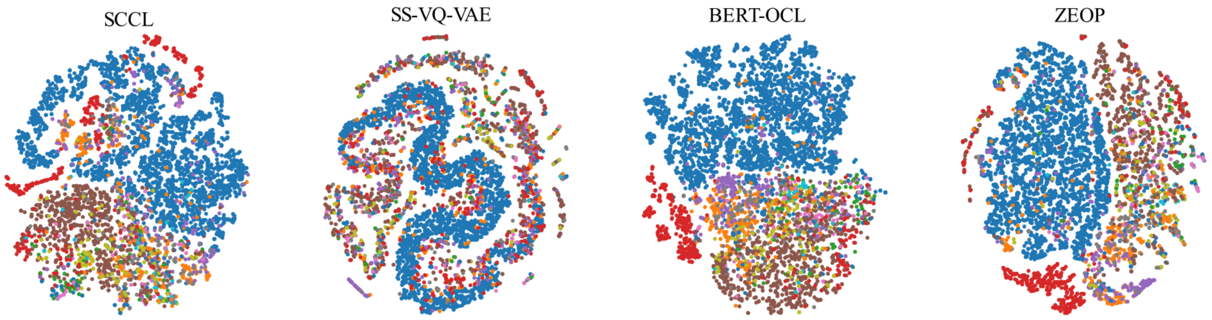

Figure 8: Visualization of unseen types on FewShorED. Each color indicates a ground truth type.

the impact of parameter unseen types l on the performance of ZEOP, we conduct a hyperparameter experiment by setting l to the 1, 2, 3, 4, and 5 times of the actual number of unseen types. As shown in Figure 9, ZEOP suffers a slight performance drop when unseen type numbers increase. The model is more likely to classify the same event type into different clusters. In practice, properly estimating the approximate number range of unknown event types will help the model to achieve a better performance.

5 Conclusion

In order to solve the problem of zero-shot event detection, this paper proposes an end-to-end model named Zero-Shot Event Detection Based on Ordered Contrastive Learning and Prompt-Based Prediction. By creatively introducing multiple contrastive samples with different similarities, the contrastive loss is extended from pairwise comparison to list-wise comparison. Therefore, the model could learn a better representation across instance-level and class-level. Meanwhile, the prompt-based prediction is utilized to identify event trigger words without relying on heuristic rules. Experiments demonstrate that our method can significantly improve the accuracy of identifying unseen event types while keeping the ability to classify seen event types. Future research should consider the po-

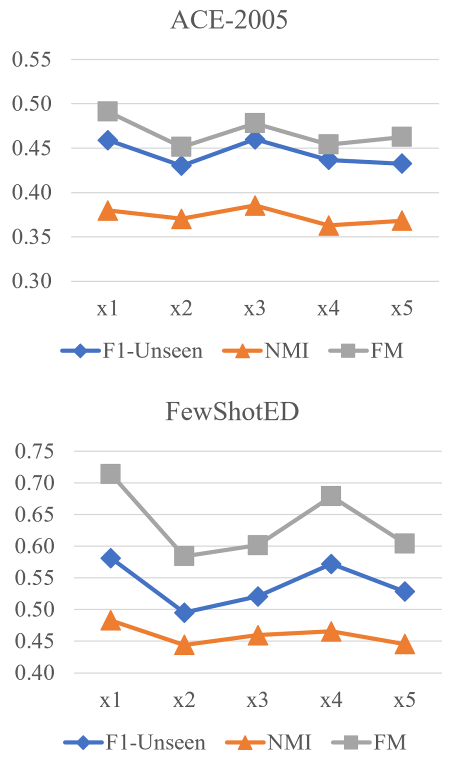

Figure 9: Effects of unseen types number.

tential effects of the initialization of the prototype matrix in the prototypical network more carefully. A better initial value may reduce the need for large training samples and speed up model training.

Abstract

Existing studies in dialogue system research mostly treat task-oriented dialogue and chit-chat as separate domains. Towards building a human-like assistant that can converse naturally and seamlessly with users, it is important to build a dialogue system that conducts both types of conversations effectively. In this work, we investigate how task-oriented dialogue and knowledge-grounded chit-chat can be effectively integrated into a single model. To this end, we create a new dataset, KETOD (Knowledge-Enriched Task-Oriented Dialogue), where we naturally enrich task-oriented dialogues with chit-chat based on relevant entity knowledge. We also propose two new models, SimpleToDPlus and Combiner, for the proposed task. Experimental results on both automatic and human evaluations show that the proposed methods can significantly improve the performance in knowledge-enriched response generation while maintaining a competitive task-oriented dialog performance. We believe our new dataset will be a valuable resource for future studies. Our dataset and code are publicly available[1].

1 Introduction

Dialogue systems have achieved substantial progress (Zhang et al., 2020; Hosseini-Asl et al., 2020a; Tao et al., 2021) due to recent success in language model pre-training (Radford et al., 2019; Raffel et al., 2020; Lewis et al., 2020). One major type of dialogue being studied is task-oriented dialogue (TOD) (Wen et al., 2017a; Budzianowski et al., 2018; Rastogi et al., 2020; Hosseini-Asl et al., 2020a), where the system aims to collect user intents/goals to complete certain tasks (e.g. restaurant-booking). In most of TOD systems, the system responses are concise and templated, as we only focus on the success of task completion but not providing a natural and engaging conversational experience. The latter is the target of another kind of popularly studied dialogue - knowledge-grounded chit-chat (Ghazvininejad et al., 2018; Zhang et al., 2018; Tuan et al., 2019; Dinan et al., 2019). Knowledge-grounded chit-chat enables dialog systems to access external knowledge so that they can provide more engaging and knowledgeable conversations and in the same time reduce hallucinations (Shuster et al., 2021).

What type of event do you prefer?

I would like to see a Musical show.

Alejandro Sanz is at Cal Coast Credit Union Amphitheater on March 7th at 7:30 pm. He is known for flamenco-influenced ballads, but experiments with other genres too, it's sure to be a good show!

Knowledge from Wikipedia
Alejandro Sánchez Pizarro, better known as Alejandro Sanz born December 18, 1968), is a Spanish musician, singer and composer. ... The singer is notable for his flamenco-influenced ballads, and has also experimented with several other genres including pop, rock, funk, R&B and jazz.

Figure 1: An example from the KETOD dataset: the green text is our enriched chit-chat based on the entity knowledge of *Alejandro Sanz* in the original TOD. Such knowledge-grounded chit-chat makes the dialogue more natural and engaging.

Existing studies mostly focus on one specific type of dialogue, either task-oriented dialogue or knowledge-grounded chit-chat. However, the ultimate goal of Conversational AI is a human-like, unified system capable of conversing with the users naturally and seamlessly among all kinds of dialogues. Current TOD systems can hardly make interesting and engaging conversations only with templated functional responses. Few previous works

like ACCENTOR (Sun et al., 2021) have studied the combination of TOD and chit-chat, but their chit-chat augmentation is largely limited to simple general responses like ‘you’re welcome’, ‘sounds good to me’. In this work, we propose to enrich TOD with knowledge-grounded chit-chat, as one step further towards the ultimate goal of building a human-like, unified system (See Figure 1 for an example). We believe that the proposed knowledge-enriched TOD system can conduct more social, natural, and engaging conversations.

To this end, we propose a new dataset, KETOD (Knowledge-Enriched Task-Oriented Dialogue). In order to obtain natural and high-quality knowledge-grounded chit-chat, we design the dataset construction framework by augmenting existing TODs and using the relevant entity knowledge to make the chit-chat enrichment. Specifically, for a given TOD, 1) extracting the entities from the dialogue states and actions; 2) retrieving the knowledge associated with the entities from external knowledge sources; 3) asking the human annotators to enrich the system responses with chit-chat using the retrieved knowledge. We demonstrate that the knowledge-enriched dialogues constructed with the proposed framework are consistently preferred by human judges across all axes of engagingness, interestingness, knowledge, and humanness.

We propose two models, and study the challenges and insights of our new dataset. The first model is an end-to-end language model that jointly learns and generates both the TOD results (dialogue states and actions) and the knowledge-enriched responses. The second model is a pipeline that first generates the TOD results, then uses another response generation model to generate the knowledge-enriched responses. We run comprehensive experiments to demonstrate the improvement over the baselines, and show that our models can generate better knowledge-enriched responses while maintaining competitive performance on the TOD tasks. To summarize, we make the following major contributions:

- We propose the task of combining TOD and knowledge-grounded chit-chat.
- We construct a new large-scale dataset, KETOD, with high-quality, manually annotated dialogue responses enriched with knowledge-grounded chit-chat. We will release the dataset upon acceptance of the paper.
- We propose two models for our dataset, and carry comprehensive experiments to study the challenges and insights. We believe our dataset should be a valuable resource for building a human-like conversational assistant.

2 Related Work

Task-oriented dialogue. Task-oriented dialogue (TOD) has been one of the most popular types of dialogue in the research community. There have been many works on building each component of the TOD system, such as dialogue state tracking, action prediction, and response generation (Wen et al., 2015, 2017b; Mrksic et al., 2017; Zhong et al., 2018; Eric et al., 2020; Liu et al., 2018; Peng et al., 2017; Zhou et al., 2017). Later works begin to investigate building end-to-end systems (Bordes et al., 2017; Liu et al., 2018, 2017; Xu et al., 2020). Most recent works on TOD also apply such language model pre-training style methods on building end-to-end systems (Hosseini-Asl et al., 2020a; Peng et al., 2020; Su et al., 2021), achieving top performances on various datasets. Popular datasets in TOD include the DSTC challenge series (Williams et al., 2016), MultiWOZ (Budzianowski et al., 2018), SGD (Rastogi et al., 2020), etc. As the primary goal of TOD is the successful completion of the functional tasks, the system responses are mostly concise and templated.

Chit-chat dialogue. Another type of popular studied dialogue is chit-chat, with the goal of making a natural and engaging conversation. Apart from the ‘pure’ simple chit-chat that mostly covers plain and general responses, more works focus on knowledge groundings to achieve better specificity and engagingness, such as using user profiles (Zhang et al., 2018), social media contexts (Sordoni et al., 2015), or knowledge graphs (Tuan et al., 2019; Moon et al., 2019), etc. In this work, our enriched chit-chat is grounded on open-domain knowledge, similar as the Topical-Chat (Gopalakrishnan et al., 2019) and the WOW dataset (Dinan et al., 2019), where the system converses with the users about certain topics involving entity knowledge in an open-ended setting. In contrast, their datasets specifically focus on knowledge-grounded chit-chat, while our dataset combines TOD and such chit-chat.

Combination of task-oriented dialogue and chit-chat. ACCENTOR (Sun et al., 2021) proposes to combine TOD with chit-chat by prepending or appending chit-chat to the TOD system re-

Figure 2: The pipeline of dataset construction: for each task-oriented dialogue, we first extract all the entities from the dialogue states and actions. Then we retrieve the knowledge associated with each entity from external knowledge sources (Wikipedia). At last, we ask human annotators to enrich the TOD system responses with chit-chat grounded on the retrieved knowledge.

sponses. But their chit-chat is mostly general responses like 'sounds good!', 'you're welcome'. FusedChat (Young et al., 2021) proposes to insert chit-chat turns into TOD as well as re-writing TOD turns, but their chit-chat is still mostly general responses or based on commonsense knowledge. Kim et al. (2020) propose to insert additional turns into TOD, where the system needs to respond based on the knowledge from domain FAQs. The DSTC10 task 2 (Kim et al., 2021) is based on the dataset from (Kim et al., 2020) with a similar focus. HyKnow (Gao et al., 2021) also proposes to insert turns into TOD grounded on knowledge from unstructured documents. These datasets focus on the challenge of detecting those turns requiring external knowledge and selecting the knowledge to generate the responses. In contrast, our dataset focuses on injecting knowledge-grounded chit-chats into the original TOD responses, to make the dialogue more natural and engaging. Our dataset poses more challenges in selecting knowledge based on the dialogue context and generating the responses with both the correct TOD information and the chit-chat seamlessly.

3 The KETOD Dataset

3.1 Dataset Construction

In this section, we describe our framework to construct the KETOD dataset. We start from existing TOD datasets and employ human annotators to augment the functional system responses with knowledge-grounded chit-chat. The proposed approach is demonstrated to give natural, contextual-relevant knowledge enrichment, and meanwhile easy to scale to different datasets. Figure 2 gives an overview of the dataset construction pipeline.

Data preparation. We build upon the SGD dataset (Rastogi et al., 2020), with TOD spanning 16 domains, such as `Restaurant, Wheather`, etc. Given each TOD, to obtain the knowledge relevant to the dialogue context, we first extract all the entities from the dialogue states and actions. We exclude the domains `Alarm`, `Banks`, and `Payment` as there are mostly no entities involved in these domains; Also, to simplify the human annotation process in the next step, we remove the dialogues with over 10 entities involved.

Knowledge retrieval. For each entity, we use the concatenation of the domain name and entity name as the query to retrieve Wikipedia articles. We use the DrQA retriever (Chen et al., 2017) to retrieve the top 2 Wikipedia articles and take the first 2 paragraphs of each article as the knowledge candidates associated with each entity. Then we break the retrieved articles into sentences, with each sentence as one knowledge snippet.

Response enrichment. In this step, we employ human annotators to enrich the system responses in the original TOD based on the dialogue context and the retrieved knowledge. For each TOD, we present to the annotators the full dialogue, as well as all the knowledge snippets associated with the entities in the dialogue. The annotators can click on each entity name to see the associated knowledge snippets in an expanded textbox. See Appendix A for our annotation interface.

The annotation process is as follows: 1) Read the full dialog first to have an overall story in mind, as well as the relevant knowledge snippets, then to decide how many turns to enrich with chit-chat and which turn(s) to enrich; If there is no way to make a natural chit-chat enrichment, skip the example. 2) After deciding the turn(s) to enrich with the chit-chat, select the knowledge snippets used to make the enrichment (at most 3 snippets for each turn); 3) Rewrite the system response to enrich with chit-chat grounded on the selected knowledge snippets; The functional information in the original response should be maintained, while may be rephrased to make the enriched response more natural.

To ensure the dataset quality, we first interview the annotators to select the appropriate hires through a few test examples. Then we launch a training session for all the annotators to learn the task and the annotation interface. We launch the official batches after the annotators can well-master the task. During annotation, we specifically emphasize the contextualization of the knowledge-grounded chit-chat - the enrichment should be contextualized closely on the dialogue context, but not a plain restatement of the knowledge snippets.

3.2 Dataset Statistics and Analysis

We end up with 5,324 dialogues with enriched system responses. We make the split of 4,247/545/532 as the train/dev/test set. Table 1 shows the statistics of the KETOD dataset. Around 12.1% of the turns (which indicates mostly 1 or 2 turns in one dialogue) are enriched with knowledge-grounded chit-chat. This intuitively complies with our goal of making the whole dialogue natural and engaging, since too frequent chit-chat may result in redundancy and unnaturalness.

Quality assessment of the annotation. During the annotation process, around 12% of the dialogues cannot be enriched with any turns and thus discarded. It takes around 100 seconds for the annotators to finish each dialogue. To assess the quality of the annotation, we sample 5% of the annotated dialogues and distribute them to linguistics to check: 1) If the chit-chat enrichment is relevant and natural; 2) If the knowledge snippets are accurately selected corresponding to the enrichment. We end up with a correct rate of 87.0%.

Justification of the chit-chat enrichment. To demonstrate that our proposed knowledge-enriched TOD can be more natural and engaging, we conduct human evaluations to compare KETOD dialogues and their corresponding original TOD dialogues without chit-chat enrichment (SGD). We follow (Li et al., 2019) to make pairwise comparisons of the full dialogues over the following four axes: engagingness, interestingness, knowledge, and humanness. The results in Figure 3 show the superiority of KETOD over all axes.

4 Approaches

In this section, we will describe the proposed two models for the KETOD dataset.

Dialogues	5,324
Vocabulary	27k
All turns	52,063
Turns enriched with chit-chat	6,302
All entities	4,639
All knowledge snippets	33,761
Avg. # turns per dialogue	9.78
Avg. # tokens in enriched responses	28.07
Avg. # entities per dialogue	4.98
Avg. # knowledge snippets per dialogue	70.50

Table 1: General statistics of KETOD.

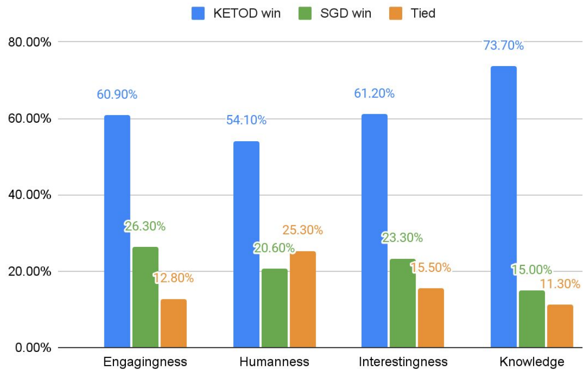

Figure 3: Results of pairwise comparison of KETOD vs SGD.

4.1 Overview and Formulations

For each dialogue turn, denote the dialogue context (history) as C, belief states as B, database search results as D, actions as A, the knowledge snippets used for chit-chat enrichment as K, the response as T. Then we formulate the problem as: given the dialogue context C and a knowledge source (Wikipedia in this dataset), the target is to generate the belief states B, actions A, and the response T, which may be enriched with chit-chat grounded on the knowledge based on the context. The goal of the optimization on KETOD is two-folded: 1) Optimizing the generation of knowledge-enriched responses; 2) Maintaining the task performances;

In this work, we propose the following modeling framework on KETOD: 1) given the dialogue context, generate the belief states and actions; 2) extract the entities in the belief states and actions, then use these entities to retrieve knowledge candidates (similar as in the dataset construction process); 3) conditioned on the dialogue context, use a knowledge selection model to select knowledge snippets from the knowledge candidates retrieved; 4) generate the knowledge-enriched response conditioned on both the dialogue context and the selected knowledge snippets.

Based on the above general framework, we pro-

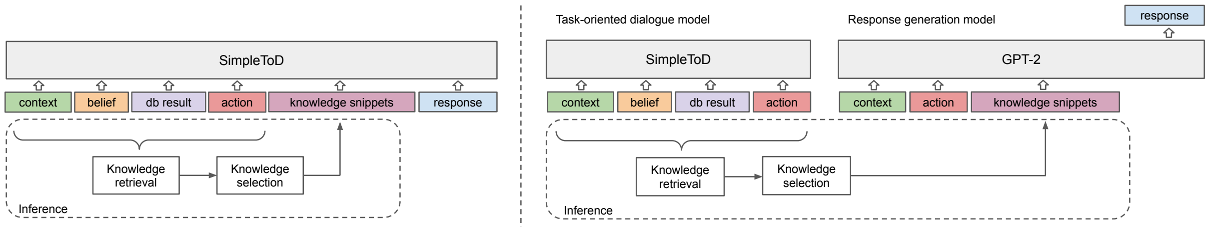

Figure 4: Illustration of the models. *Left*: the SimpleToDPlus model; *Right*: the Combiner model;

pose two architectural approaches, **SimpleToDPlus** and **Combiner**, respectively in §4.3 and §4.4.

4.2 Knowledge Selection

After the generation of belief states and actions, we retrieve the knowledge snippet candidates from Wikipedia using the entities in the belief states and actions. The average number of knowledge snippets candidates retrieved for each dialogue is around 70. It is impractical to input all of them into the models due to the large amount. As we have the annotation for the ground truth knowledge snippets used for each chit-chat enrichment, we train a knowledge selection model to select the top knowledge snippets most appropriate for chit-chat enrichment. Specifically, we concatenate the dialogue context with each knowledge snippet as the input. Then we use BERT (Devlin et al., 2019) to train a simple classifier to rank all the knowledge snippets candidates. We take the top 3 ones as the knowledge selection results. We use the same knowledge selection model for both architectures.

4.3 SimpleToDPlus

SimpleToD (Hosseini-Asl et al., 2020b) is a recent popular approach on TOD, which uses one single language model to sequentially generate the belief states, actions, and responses. It has achieved strong performances in all the above functional tasks. In this work, we propose its extension, **SimpleToDPlus**, to generate knowledge-enriched responses for TOD. The left part of Figure 4 shows the overview of SimpleToDPlus. We formulate the training sequence as:

$$[C, B, D, A, K, \text{<chitchat>}, T] \qquad (1)$$

Where <chitchat> is a tag to indicate the decision of whether to enrich the response with knowledge grounded chit-chat or not. If the response is not enriched, we insert the tag <nochitchat>. Since the number of the gold knowledge snippets varies from 1 to 3 (as in the dataset construction), to be compatible with inference time, here we first run the knowledge selection model on all training instances. Then we construct the knowledge snippets K as the merge of the gold knowledge snippets and the knowledge selection model results, truncated to 3 ones. If the response is not enriched with chit-chat, i.e., no gold knowledge snippets, we still put 3 snippets from the knowledge selection model ranking results here during training.

In the inference time, we first sequentially generate the belief states and actions. Then we extract the entities from the generated belief states and actions, and apply the same process of knowledge retrieval as in dataset construction. Next, we run the knowledge selection model on the retrieved knowledge candidates and take the top 3 knowledge snippets as the model input followed by the generated actions. At last, the model generates the decision to make chit-chat enrichment or not, followed by the final response.

Since the knowledge-enriched response is conditioned on the entity knowledge from the belief states and actions, we need to directly include the entities in the actions and responses during generation, instead of generating a delexicalized result first and then lexicalizing in the post-process as in the original SimpleToD. To simplify, we use the oracle database search results for all the experiments.

4.4 Combiner

SimpleToDPlus models all the generations in an end-to-end manner. In **Combiner**, we use a pipeline of a TOD model followed by a response generation model to separate the TOD part (belief states, actions) with the generation of knowledge-enriched responses. The goal is to study whether an independent model can better learn each task with less interference from the other. The overview of the architecture is shown on the right of Figure 4.

For the TOD model, we use SimpleToD to generate the belief states and actions, with the training

Models	**Joint GA**	**Avg GA**	**Act-Slot F1**	**BLEU-4$_{\text{aug}}$**	**BLEU-4$_{\text{orig}}$**	**BLEU-4$_{\text{all}}$**
SimpleToD-ref	27.6	54.2	67.6	-	-	-
SimpleToD	23.7	50.1	62.7	4.8	10.7	10.0
SimpleToDPlus	**28.6**	**52.2**	**66.9**	6.3	**11.7**	**11.0**
Combiner	24.5	51.5	64.5	**6.5**	9.9	9.5

Table 2: Main experiment results: Both SimpleToDPlus and Combiner outperform the baseline. Overall SimpleToDPlus obtains better response generation performance while maintaining competitive TOD performance.

sequence as:

$$[C, B, D, A] \tag{2}$$

We find that including the knowledge-enriched responses during training degrades the task performance, indicating the disturbance from the ungrounded knowledge in the responses.

For the response generation model, we use GPT-2 (Radford et al., 2019) with the concatenation of the dialogue context, actions, and the knowledge snippets as the prompt:

$$T = \text{GPT-2}(C, A, K) \tag{3}$$

We use the same way of constructing the merged knowledge snippets during training, and the same process of knowledge retrieval and selection during inference as in SimpleToDPlus.

5 Experimental Results

Baseline model. We use SimpleToD (Hosseini-Asl et al., 2020b) as our baseline model, i.e., with the training sequence as [C, B, D, A, T], without the injection of knowledge snippets. Therefore the knowledge-grounded chit-chat in the responses T do not have any knowledge groundings - we aim to show the necessity of knowledge grounding for our task, as well as the effectiveness of our proposed models to incorporate knowledge.

Experimental setups and evaluations. Check Appendix B for details of model training and parameter settings. For the TOD performances, we evaluate the belief states with joint goal accuracy (Joint GA) and average goal accuracy (Avg GA), and the actions with act-slot F1, same as (Sun et al., 2021). For the automatic evaluations of response generation, we use three BLEU-4 scores: BLEU-4$_{\text{aug}}$ for evaluating the responses enriched with knowledge; BLEU-4$_{\text{orig}}$ for evaluating the responses not enriched with knowledge; BLEU-4$_{\text{all}}$ for evaluating all responses;

5.1 Main Results

Performance on response generation. Table 2 shows our main experiment results. For the performances on response generation, we can see that both of our proposed models, SimpleToDPlus and Combiner, improve on the knowledge-enriched response generation (BLEU-4$_{\text{aug}}$) over the SimpleToD baseline. Since in the baseline, we do not include the knowledge snippets in the input, the generated responses are mostly enriched with random knowledge or frequent knowledge in the training data. The improvements demonstrate the necessity of knowledge grounding and the effectiveness of the proposed knowledge enrichment methods. Combiner performs slightly better on knowledge-enriched responses than SimpleToDPlus but falls short on the responses without knowledge-enrichment (i.e., original TOD responses). This is partially because of its pipeline nature - a separated response generation module can better learn the knowledge enrichment without the disturbance of other tasks, but the error cascading from the generated actions degrades the performance of the TOD responses part.

Performances on belief states and actions. To better study how the knowledge enrichment affects the TOD performances, we first train SimpleToD on our dataset without the knowledge enrichment, i.e., replace all the knowledge-enriched responses with the original responses in SGD. We name it as SimpleToD-ref in Table 2, serving as a reference of the original TOD performances. The SimpleToD baseline gives largely degraded performances due to the disturbance from the ungrounded knowledge in the responses during training. Therefore in Combiner, we do not include the responses in the training sequences of the TOD model (specified in section 4.4), and obtain better scores. SimpleToDPlus achieves the best TOD performances, which are nearly competitive with SimpleToD-ref. This is partially due to the enhancement of language modeling ability brought by the training on the

Metrics	SimpleToDPlus win (%)	Combiner win (%)	Tied (%)
Engagingness	47.8	24.5	27.8
Interestingness	34.5	19.0	46.5
Knowledge	29.5	26.3	44.3
Humanness	43.3	23.8	33.0

Table 3: Human evaluation of SimpleToDPlus vs. Combiner.

responses grounded on the input knowledge.

Human evaluations. In order to get the more comprehensive measure of the response generation performances, we conduct human evaluations for both dialogue-level pairwise comparison and turn-level factualness evaluation. For dialogue-level pairwise comparison, we randomly sample 200 dialogues from the test set and apply the same process as in dataset evaluation (3.2). For each model, we construct the full dialogue results by concatenating the generated response for each turn given the gold dialogue context. Table 3 shows the results of pairwise comparison between the SimpleToDPlus model and the Combiner model, demonstrating SimpleToDPlus is more performant. Table 4 shows the results of pairwise comparison between SimpleToDPlus and the gold reference, indicating there is still a large room for further improvements. See Appendix C for the human evaluation results of comparing both methods to the baseline. For turn-level factualness evaluation, we randomly sample one turn with chit-chat enrichment from each dialogue, and present both the generated response and the selected knowledge snippets to the annotators. The annotators are asked to check whether the chit-chat in the responses are factually correct based on the knowledge snippets. SimpleToDPlus and Combiner obtain the factualness correct rate of 64.2% and 66.1%, respectively. In summary, Combiner achieves better factualness of knowledge enrichment since its independent response generation model can better focus on the learning of knowledge groundings. But its error cascading due to the pipeline nature may degrade the overall consistency and human-likeness of the generated dialogue.

As we have two optimization goals on KETOD 1) Optimizing the generation of knowledge-enriched responses; 2) Maintaining the task performances, we consider SimpleToDPlus as a better model regarding the overall performances. We will use the results of SimpleToDPlus for the ablations and other analyses in the rest of the experiments.

Metrics	SimpleToDPlus win (%)	Gold win (%)	Tied (%)
Engagingness	16.8	60.5	22.8
Interestingness	12.0	51.0	37.0
Knowledge	14.5	44.8	40.8
Humanness	17.3	58.0	24.8

Table 4: Human evaluation of SimpleToDPlus vs. Gold.

	$\text{BLEU-4}_{\text{aug}}$	$\text{BLEU-4}_{\text{all}}$
Given gold TOD results, decision, and knowledge		
SimpleToD	6.5	13.1
SimpleToDPlus	9.7	14.6
Combiner	14.6	15.1
Given gold TOD results		
SimpleToD	6.3	12.8
SimpleToDPlus	7.4	14.0
Combiner	9.6	13.9

Table 5: Analysis of different inference stages: we provide the models with gold results up to certain stages, and investigate the performances for the inferences on following stages.

5.2 Ablations and Analysis

Analysis of different inference stages. There are several inference stages for this task - the TOD results (belief states and actions), the selection of knowledge snippets, and the final response generation, where each stage is conditioned on previous results. Therefore the errors accumulate through all the stages leading to the final performances. Here we run another two sets of experiments to study such error accumulations and compare the two models. Specifically, first, we feed the models with the gold TOD results, chit-chat decisions, and knowledge snippets, to solely test the abilities to generate the knowledge-enriched responses; Second, we feed the models with the gold TOD results to test the following stages of knowledge selection and the response generation. The results are shown in Table 5. Compared with the full inference results in Table 2, we can see that the Combiner model largely outperforms SimpleToDPlus if provided with more gold results for previous stages. However, it gradually falls behind SimpleToDPlus when moving to fully end-to-end inference due to the error cascading of its pipeline nature.

Importance of knowledge selection strategies. To demonstrate the importance of the knowledge selection strategies (and their subsequent recall performance), we run SimpleToDPlus with 1) gold knowledge snippets; 2) predicted knowledge snippets (with BERT); 3) knowledge snippets selected by heuristics (we use TF-IDF matching between the current dialogue turn and the knowledge snip-

	BLEU-4$_{aug}$	BLEU-4$_{all}$	Enrichment decision F1 (%)
Gold decision	9.7	14.6	100.0
Predicted decision	8.0	14.1	58.7

Table 7: SimpleToDPlus response generation performance using (1) the gold set of turns to enrich with chit-chat, and (2) the predicted set of turns.

	All	Hotels	Movies	Restaurant	Music
BLEU-4$_{aug}$	6.3	7.1	5.2	5.1	7.7
BLEU-4$_{all}$	11.0	10.3	12.2	14.0	12.3

Table 8: Domain breakdown of SimpleToDPlus response generation performances.

pets). To eliminate the influences brought by other inference stages, we feed the model with gold TOD results (dialogue states and actions). The results are shown in Table 6. There exists a certain level of variance for knowledge selection, e.g., when recommending a song for the user, you may talk about its genre, its singer, or the album.

Learning *when* to inject knowledge-enriched chit-chat. In all models, we use the special token '<chitchat>' and '<nochitchat>' to indicate the decision to inject knowledge enrichment for the responses. To study the effect of the chit-chat injection decision-making accuracy on the overall dialogue tasks, we run SimpleToDPlus (1) with the ground-truth information of turns to enrich with chit-chat, and (2) with the predicted decisions, using the gold TOD results. Table 7 shows the performance gap, which highlights the importance of knowing *when* to inject knowledge-enriched chit-chat. While such decisions are conditioned on the dialogue history, e.g., we may tend to not enrich a turn if many of the previous turns are enriched to avoid redundancy, there also exists some variance. In a real system, we may consider specifying the turns to make the chit-chat enrichment instead of letting the model make the decision.

Domain analysis. We investigate the model performance for each domain in Table 8. We observe that the performance differences may depend on the variance of the enriched knowledge. Domains with larger variance on selected knowledge tend to have lower automatic scores. For example, in `Hotels` domain, mostly the chit-chat is about the locations since there are mostly location entities involved in this domain. But for the `restaurants` domain, the enriched knowledge can be about the food, the restaurant, as well as the location. The selected knowledge shows more diversity and variance.

We provide case studies in Figure 5 to compare the predicted results with the gold references.

6 Conclusion

In this work, we propose to combine task-oriented dialogue with knowledge-grounded chit-chat, and construct a new dataset named KETOD, with manually composed knowledge-enriched system responses. We conduct comprehensive experiments on our new dataset to study the insights and challenges. We believe that our proposed task is an important step towards the ultimate goal to build a unified, human-like conversational AI. Our new dataset KETOD, annotated by experts, will greatly facilitate the research in this direction.

7 Ethical Considerations

Data Access and Licensing. We develop the KETOD dataset based on the publicly available SGD dataset[2] (Rastogi et al., 2020). The SGD dataset is publicly available under the CC-BY-SA-4.0 License.

Dataset Collection Process and Conditions. This project is approved by our Institutional Review Board (IRB). Our annotators are all U.S. based. For the annotation of our KETOD dataset, linguistics for assessing data quality, and all the human evaluations, our annotators were hired as full-time employees through a leading annotation services vendor, and were paid in accordance with a fair wage rate. During the data annotation, we instruct the annotators to skip any example that contains offensive or any unethical contents.

the textbox to see the knowledge snippets. We add index number to each knowledge snippet (shown in green brackets), and the annotators are asked to write down the indexes of the knowledge snippets they used for writing the knowledge grounded chit-chat. Figure 7 shows one example annotation turn using our interface.

Appendix B: Model and Training Details

All the implementations are based on the Huggingface Transformers library[3]. For all models, we use the Adam optimizer (Kingma and Ba, 2015). For the knowledge selection model, we use BERT-base with learning rate of 3e-5 and batch size of 16. For the baseline SimpleToD model, SimpleToDPlus model, and Combiner model, we all use learning rate of 1e-4 and batch size of 16. All the experiments are done using TESLA M40 GPU cards.

Appendix C: Evaluation Details

Table 9 and 10 show the human evaluation results of SimpleToDPlus vs. SimpleToD, and Combiner vs. SimpleToD, respectively.

History of Los Angeles
[1] The written history of Los Angeles city and county began with a small Mexican town that changed little in the three decades after 1848, when California became part of the United States.
[2] Much greater changes came from the completion of the Santa Fe railroad line from Chicago to Los Angeles in 1885.
[3] Immigrants flooded in, especially white Protestants from the Midwest.
[4] Los Angeles had a strong economic base in farming, oil, tourism, real estate and movies.
[5] It grew rapidly with many suburban areas inside and outside the city limits.
[6] Hollywood made the city world famous, and World War II brought new industry, especially high-tech aircraft construction.
[7] Politically the city was moderately conservative, with a weak labor union sector.
[8] Since the 1960s growth has slowed—and traffic delays have become famous.
[9] LA was a pioneer in freeway development as the public transit system deteriorated.
[10] New arrivals, especially from Mexico and Asia, have transformed the demographic base since the 1960s.
[11] Old industries have declined, including farming, oil, military and aircraft, but tourism, entertainment and high tech remain strong.

Los Angeles
[12] Los Angeles (, Spanish for "The Angels"), officially the City of Los Angeles and often known by its initials L.A., is the second-most populous city in the United States (after New York City), the most populous city in California and the county seat of Los Angeles County.
[13] Situated in Southern California, Los Angeles is known for its mediterranean climate, ethnic diversity, sprawling metropolis, and as a major center of the American entertainment industry.
[14] Los Angeles lies in a large coastal basin surrounded on three sides by mountains reaching up to and over .
[15] Historically home to the Chumash and Tongva, Los Angeles was claimed by Juan Rodríguez Cabrillo for Spain in 1542 along with the rest of what would become Alta California.
[16] The city was officially founded on September 4, 1781, by Spanish governor

TANET: Thread-Aware Pretraining for Abstractive Conversational Summarization

Ze Yang[1], **Liran Wang**[1], **Zhoujin Tian**[1], **Wei Wu**[2], **Zhoujun Li**[1*]

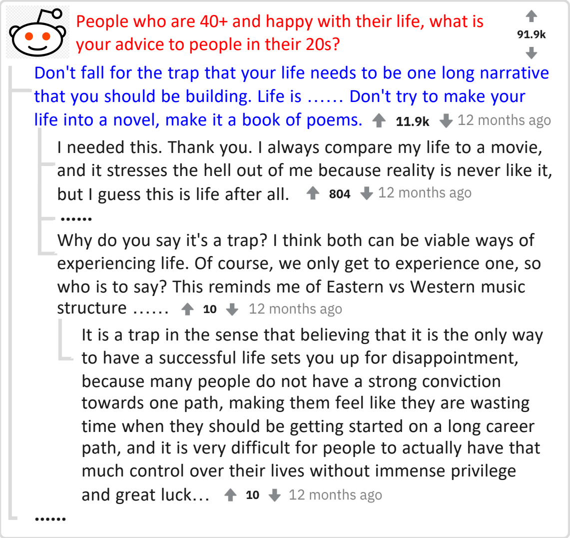
Abstract

Although pre-trained language models (PLMs) have achieved great success and become a milestone in NLP, abstractive conversational summarization remains a challenging but less studied task. The difficulty lies in two aspects. One is the lack of large-scale conversational summary data. Another is that applying the existing pre-trained models to this task is tricky because of the structural dependence within the conversation and its informal expression, etc. In this work, we first build a large-scale (11M) pretraining dataset called RCSUM, based on the multi-person discussions in the Reddit community. We then present TANET, a thread-aware Transformer-based network. Unlike the existing pre-trained models that treat a conversation as a sequence of sentences, we argue that the inherent contextual dependency among the utterances plays an essential role in understanding the entire conversation and thus propose two new techniques to incorporate the structural information into our model. The first is *thread-aware attention* which is computed by taking into account the contextual dependency within utterances. Second, we apply *thread prediction* loss to predict the relations between utterances. We evaluate our model on four datasets of real conversations, covering types of meeting transcripts, customer-service records, and forum threads. Experimental results demonstrate that TANET achieves a new state-of-the-art in terms of both automatic evaluation and human judgment.

1 Introduction

Text summarization is a long-standing challenging task in artificial intelligence, aiming to condense a piece of text to a shorter version, retaining the critical information. There are various promising applications of conversational summarization in the real world, emphasizing the need to build auto summarization systems. For example, online customer-service staff can improve work efficiency by recording the customer demands and current solutions after each communication. In the industry, meeting summaries are also generally required in order to track the progress of projects. The automatic doctor-patient interaction summary can save doctors much time from filling out medical records. Therefore, conversational summarization has been a potential field in summarization and has received increasing attention.



People who are 40+ and happy with their life, what is your advice to people in their 20s? ⬆ 91.9k ⬇

Don't fall for the trap that your life needs to be one long narrative that you should be building. Life is …… Don't try to make your life into a novel, make it a book of poems. ⬆ 11.9k ⬇ 12 months ago

I needed this. Thank you. I always compare my life to a movie, and it stresses the hell out of me because reality is never like it, but I guess this is life after all. ⬆ 804 ⬇ 12 months ago

……

Why do you say it's a trap? I think both can be viable ways of experiencing life. Of course, we only get to experience one, so who is to say? This reminds me of Eastern vs Western music structure …… ⬆ 10 ⬇ 12 months ago

It is a trap in the sense that believing that it is the only way to have a successful life sets you up for disappointment, because many people do not have a strong conviction towards one path, making them feel like they are wasting time when they should be getting started on a long career path, and it is very difficult for people to actually have that much control over their lives without immense privilege and great luck… ⬆ 10 ⬇ 12 months ago

……

Figure 1: An abbreviated example from RCSUM. It contains a total of 14k comments and more than 210k words in this post. The title and the lead comment are selected as the pseudo summary of this thread.

Benefiting from the availability of large-scale high-quality data, abstractive document summarization has been extensively explored in the past years (Rush et al., 2015; See et al., 2017; Chen and Bansal, 2018). Recently, the pretraining methods further extend the success (Lewis et al., 2020; Zhang et al., 2020). In contrast, abstractive conversational summarization is a more challenging but less studied task. The reason mainly lies in: (1) compared with news, there are no large-scale

---

July 10-15, 2022

publicly available labeled datasets for abstractive conversational summarization; (2) conversations are usually informal, verbose, and repetitive, sprinkled with false starts, backchanneling, reconfirmations, hesitations, and speaker interruptions (Sacks et al., 1978), which makes the whole session difficult to understand; (3) unlike the linear relationship in the one-speaker document, there are always multiple speakers in a conversation, and the inherent contextual relationships are structured; (4) conversations in some scenarios could be much longer than a document. For instance, in CNN/Daily Mail dataset (Hermann et al., 2015), the average number of words in a document is 781, while the average length of the transcripts in ICSI, a widely explored meeting corpus, is $10,189$. These challenges encourage us to explore conversation-oriented summarization methods.

To overcome the challenges, we study pretraining for abstractive conversational summarization in this work. To tackle the bottleneck of insufficient data, we first build a large-scale (11M) corpus for conversational summarization called RCSUM, based on the multi-person discussions crawled from the Reddit website. For the absence of the summary of discussions, we propose two heuristic strategies to select the title and the lead comment of a thread as its summary-like sentences. Figure 1 shows an abbreviated example in RCSUM. For the model architecture, we present TANET, a Thread-Aware NETwork for abstractive conversational summarization. As conversations are usually lengthy, we adopt the hierarchical encoders, which consist of a token encoder and an utterance encoder. Unlike the existing pre-trained models that treat a conversation as a sequence of sentences, we argue that the inherent contextual dependency among the utterances plays an essential role in understanding the entire conversation and thus propose two new techniques to incorporate the structural information into TANET. First, we replace the self-attention layers in the utterance encoder with the thread-aware relative attention. Second, we propose a new pretraining task, the thread prediction, to further enhance the representations by predicting the relations across a small set of utterances.

We evaluate TANET on four datasets of conversational summarization, covering domains of meeting transcripts (Carletta et al., 2005; Janin et al., 2003), customer-service records (Yuan and Yu, 2019), and forum threads (Tarnpradab et al., 2017). Experimental results indicate that TANET achieves new state-of-the-art on all datasets in terms of both automatic evaluation and human judgement.

In summary, our contributions in this work are three-fold: (1) We build a large-scale pretraining corpus based on real conversations for abstractive conversational summarization. (2) TANET is the first pre-trained abstractive conversational summarization model with inherent structure modeling. (3) The effectiveness of TANET is demonstrated on four downstream datasets of conversational summarization, covering types of meeting transcripts, customer-service records, and forum threads.

2 Problem Formalization

In general, the abstractive conversational summarization task could be formalized as follows. Denote the dataset as $\mathcal{D} = \{(C_i, S_i)\}_{i=1}^{N}$, where $\forall i$, (C_i, S_i) is a conversation-summary pair and N is the size of $\mathcal{D}$. The conversation $C_i = \{(u_{i,j}, a_{i,j})\}_{j=1}^{n_i}$ consists of n_i rounds of utterances $\{u_{i,j}\}_{j=1}^{n_i}$ and their associated attributes $\{a_{i,j}\}_{j=1}^{n_i}$. For example, each meeting transcript in the AMI dataset comprises multiple turns, where each turn is an utterance of a participant who has a specific role in the project, such as manager or designer. Our goal is to learn a generation probability $P(S|C)$, so that given a new conversation input C, we can generate a summary S .

Since there is always limited availability of $\mathcal{D}$ to support accurately learning for $P(S|C)$, we propose to build a large-scale summarization-like corpus $\mathcal{D}_p = \{(C_k, S_k)\}_{k=1}^{M} (M \gg N)$ by leveraging massive accessible conversation data. S_k represents the pseudo summary of the conversation C_k. In this way, we first pretrain our model on $\mathcal{D}_p$ and then finetune it on the respective dataset $\mathcal{D}$ of each downstream task.

3 Reddit for Conversational Summarization

Existing conversational summarization corpora (Carletta et al., 2005; Janin et al., 2003; Tarnpradab et al., 2017; Yuan and Yu, 2019; Gliwa et al., 2019) have a low number of conversations, which prevents research community from engaging into this problem. Different from (Zhu et al., 2020) that using news documents to simulate multi-person conversations for pretraining, it is reasonable to hypothesize that leveraging real conversation data could lead to better downstream performance. In this work, to benefit from the large-scale conversation corpus, we mined and processed a large-scale dataset from **R**eddit [1] for **C**onversational **Sum**marization called **RCSUM**. Figure 1 shows an example in the dataset. To our best knowledge, RCSUM is the first large-scale pretraining corpus with real conversations for abstractive conversational summarization.

We collected the posts on the Reddit site from 2019 to 2020. A post is composed of a title and its corresponding discussions which usually consist of multiple threads. The comments in a thread can naturally expand into a tree structure. Remarkably, each comment has rich attributes, including the user information, creation timestamp and the accumulated score[2], etc. With the large-scale real multi-person conversation data, the key is how to construct a summary-like instance for a thread. We consider two strategies to select sentences that appear to dominate the thread: (1) **Title**. The discussions of each post are all developed upon the topic of the title, so we select the title as a part of the pseudo summary; (2) **Lead Comment**. Despite the topic given by the title, the lead comment (i.e., the first comment of a thread) also well influences the future direction of what is discussed in this thread. We concatenate them as the pseudo summary of the discussions in a thread. Lead comment's original position is replaced by a special token `[MASK]`.

To clean up RCSUM, we adopted a series of heuristics including: (1) We removed any threads where the number of comments less than 10; (2) We discarded any not-safe-for-work posts, such as posts containing adult or violent content; (3) We replaced all URLs with a special token `[URL]`; (4) We removed all markup and any other non-text content such as "*, $\sim$, [,]"; (5) We removed any threads whose title or lead comment scored less than 0; (6) We removed any posts which contain quarantine, picture, or video, etc. After then, the dataset has $11,200,981$ instances.

4 Methodology

In this section, we present TANET, a thread-aware pretrained model which incorporates the inherent dependencies between utterances to enable improved conversation's representations for summary generation. Below, we first introduce the model architecture, thread-aware attention, and then introduce our pretraining objectives. Finally, we move on to the application of downstream tasks.

4.1 Model Architecture

Encoder. We employ hierarchical encoders, a *token encoder* and an *utterance encoder*, to represent the input conversation. This design mainly comes from two considerations: (1) The conversations in actual applications are lengthy (e.g., The Reddit post in Figure 1 has more than 210k words, and a meeting transcript usually consists of thousands of tokens.), thus it may not be feasible to simply apply the canonical transformer structure. (2) Hierarchical architecture is more suitable for the conversational tasks to carry out modeling of utterances and interactive structure of the conversation.

Let $C = (u_0, \cdots, u_{|C|})$ denote an conversation instance in the pretraining corpus $\mathcal{D}_p$. $u_i = (\langle \texttt{bos} \rangle, w_{i,1}, \cdots, w_{i,|u_i|})$ is the token sequence of $i\text{-}th$ utterance after tokenization, where $\langle \texttt{bos} \rangle$ is a special token in vocabulary $\mathcal{V}$ to represent the beginning of a turn. The token encoder takes each sequence u_i as the input and first converts it into input vectors $\mathbf{H}_i^{\mathcal{T},0} \in \mathbb{R}^{|u_i| \times d_h}$. For each token, its input vector is constructed by summing up the corresponding token embedding and the sine-cosine positional embedding (Vaswani et al., 2017). Then, N identical layers are nested over $\mathbf{H}_i^{\mathcal{T},0}$ to produce the contextual representations by:

$$\mathbf{H}_i^{\mathcal{T},N} = \text{Transformer}^{\mathcal{T}}(\mathbf{H}_i^{\mathcal{T},0}) \tag{1}$$

Each layer consists of two sub-layers, a self-attention sub-layer followed by a position-wise feed-forward sub-layer and uses residual connections around each of them. We adopt the pre-layer normalization following several recent works (Baevski and Auli, 2019; Child et al., 2019; Wang et al., 2019; Xiong et al., 2020), which place the layer normalization inside the residual connection. That is, given input x, the output of each sub-layer is $x + \text{Sublayer}(\text{LayerNorm}(x))$. The utterance encoder also has N identical transformer layers in structure, which processes the information at turn level. All utterances are arranged in the order of their timestamps, and we employ the sine-cosine positional embedding to model the chronological order. Let $\mathbf{H}^{\mathcal{U},0} = (h_{u_0}, \cdots, h_{u_{|C|}})$ denotes the sequence of representations of utterances. For the i-th turn u_i, the embedding of $\langle \texttt{bos} \rangle$ is chosen as its representation, i.e., $h_{u_i} = \mathbf{H}_{i,0}^{\mathcal{T},N}$. Different from

---

[1] https://www.reddit.com

[2] The score is the number of upvotes minus the number of downvotes.

the token encoder, we propose the Thread-Aware Attention sub-layer to replace the self-attention sub-layer to encode the tree-structure information into our model.

Thread-Aware Attention. Each sub-layer consists of h attention heads, and the results from each head are concatenated together and projected to form the output of the sub-layer. Formally, given the input $\mathbf{H}^{\mathcal{U},0}$, the k-th head computes a new sequence $z_k = (z_{k,0}, \cdots, z_{k,|C|})$ by:

$$\begin{aligned} z_{k,i} &= \sum_{j=1}^{|x|} \alpha_{ij}(h_{u_j} W_k^V), \\ \alpha_{ij} &= \frac{\exp e_{ij}}{\sum_{t=1}^{|x|} \exp e_{it}} \end{aligned} \tag{2}$$

where $z_{k,i} \in \mathbb{R}^{d_z}, d_z = d_h/h$. e_{ij} is the attention weight from h_{u_j} to h_{u_i}. Inspired by the relative position encoding (RPE) works (Shaw et al., 2018; Huang et al., 2020), we consider the interactions of queries, keys, and relative positions simultaneously to fully utilize the structural information of a conversation:

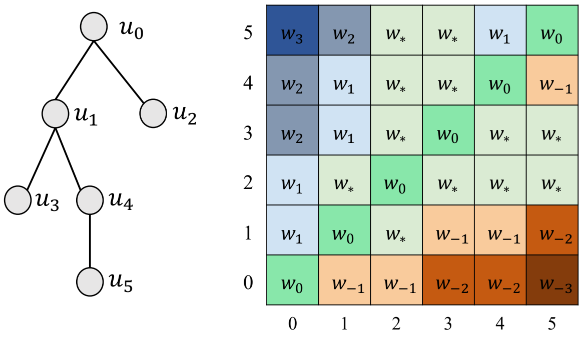
$$e_{ij} = \frac{(h_{u_i} W_k^Q + r_{ij})(h_{u_j} W_k^K + r_{ij})^\top - r_{ij} r_{ij}^\top}{\sqrt{d_z}} \tag{3}$$

where $W_k^Q, W_k^K, W_k^V \in \mathbb{R}^{d_h \times d_z}$ are parameter matrices. $\sqrt{d_z}$ is a scaling factor for stable training. The key to this mechanism is that $r_{i,j} \in \mathbb{R}^{d_z}$ encodes the relation from utterance u_j to u_i, which is defined as:

$$r_{i,j} = \begin{cases} w_{\text{clip}(\text{depth}(u_i) - \text{depth}(u_j), k)}, & 1) \\ w_*, & 2) \end{cases} \tag{4}$$

As illustrated in Figure 2, the relation between two utterances has two situations: 1) one is a parent or child utterance of the other, that is, they belong to the same path, e.g. u_1 and u_4; 2) otherwise, e.g. u_2 and u_3. We totally define $2k+2$ learnable thread-aware position embeddings $\{w_*, w_{-k}, \cdots, w_k\}$. where $\text{clip}(x, k) = \max(-k, \min(k, x))$, and the function $\text{depth}(u_i)$ returns the distance between utterance u_i and the first utterance u_0 in the thread, e.g. $\text{depth}(u_4) = 2$. The output of the utterance encoder is $\mathbf{H}^{\mathcal{U},N} \in \mathbb{R}^{|C| \times d_h}$.

Decoder. The decoder is a N-layer transformer to generate the summary S. At the training stage, the decoder takes the right-shifted token sequence of S as input. In each layer, the self-attention sub-layer leverages a lower triangular mask to prevent positions from attending to their future positions. Then, the cross-attention sub-layers attend with the outputs from the hierarchical encoder. In particular, we make an encoder-wise residual connection around the utterance encoder to propagate the token-level information directly to the decoder. We found that this can improve the model's capability to reproduce the words involved in the conversation. Denote the output of the decoder as $\mathbf{H}^{\mathcal{D},N} \in \mathbb{R}^{|S| \times d_h}$. When predicting the i-th token s_i, we reuse the embedding matrix of the vocabulary $\mathcal{E}_\mathcal{V} \in \mathbb{R}^{|\mathcal{V}| \times d_h}$ to project $\mathbf{H}_{i-1}^{\mathcal{D},N}$ into a probability distribution:



5	w_3	w_2	w_*	w_*	w_1	w_0
4	w_2	w_1	w_*	w_*	w_0	w_{-1}
3	w_2	w_1	w_*	w_0	w_*	w_*
2	w_1	w_*	w_0	w_*	w_*	w_*
1	w_1	w_0	w_*	w_{-1}	w_{-1}	w_{-2}
0	w_0	w_{-1}	w_{-1}	w_{-2}	w_{-2}	w_{-3}
	0	1	2	3	4	5

Figure 2: Illustration of Thread-Aware attention. The left is the tree structure of a conversation thread, and u_i represents the i-th utterance. The thread-aware attention weights across the utterances are on the right.

$$P(S_i | S_{<i}, C) = \text{Softmax}(\mathbf{H}_{i-1}^{\mathcal{D},N} \mathcal{E}_\mathcal{V}^\top) \tag{5}$$

4.2 Pretraining Objectives

In this section, we describe the pretraining objectives used for pretraining TANET. In addition to the causal language modeling, we newly introduce another thread-aware pretraining task to predict the contextual relation between utterances.

Causal Language Modeling. Following many previous works (Lewis et al., 2020; Zhang et al., 2020), we apply the causal language modeling objective, which seeks to minimize the cross-entropy loss:

$$\mathcal{L}_{CLM}(\theta) = -\frac{1}{|S|} \sum_{i=1}^{|S|} \log P(S_i | S_{<i}, C) \tag{6}$$

Thread Prediction. To enhance the representation of the thread structure in a conversation, we introduce a new pretraining task of thread prediction. The motivation is to encourage the model to learn thread-aware representations that encode the information of which comments this one was written based on, that is, its historical comments. Specifically, we randomly sample 20% utterances C_s from C and then let the model predict their historical comments. Formally, the pretraining objective is calculated as:

$$\mathcal{L}_{ThreadPred} = -\sum_{a_{ij}\in\mathcal{A}} \Big(\delta(a_{ij})\log p_{a_{ij}} + \big(1-\delta(a_{ij})\big)\log(1-p_{a_{ij}})\Big) \tag{7}$$

where $\mathcal{A} = C_s \times C \cup C \times C_s$ is the set of comment pair candidates for prediction. $\delta(a_{ij})$ returns 1 if u_j and u_i belong to one thread and u_j is history of u_i, otherwise 0. p_{ij} is the probability of u_j being the historical comment of u_i and is computed by:

$$p_{a_{ij}} = \text{Sigmoid}\big((\mathcal{H}^{\mathcal{T},N}_{i,0}W_a)(\mathcal{H}^{\mathcal{T},N}_{j,0}W_b)^\top\big) \tag{8}$$

$W_a, W_b \in \mathbb{R}^{d_h\times d_h}$ are two parameter matrices.

4.3 Application on Downstream Tasks

After pretraining on RCSum, we finetune our model on the downstream tasks. Different tasks will have some differences in data annotation that requires us to adapt it flexibly. For example, the interdependencies among the utterances in a meeting are not labeled in AMI and ICSI, so we treat them as a sequence arranged by time. Besides, some additional information is essential for the generation of summary, which can be prompted to the model by modifying the input utterances. For example, the name and role of each participant are useful for meeting summarization in AMI and ICSI. Without changing the model structure, we inform TANet of the information by replacing the original utterance with template "{*participant*} of role {*role*} said: {*utterance*}".

5 Experiments

5.1 Datasets

We evaluate TANet and all baseline models on four benchmark datasets of long and real-life conversations, covering domains of meeting transcripts, customer-service records, and threads in web forum. Table 1 summarizes the statistics of the four datasets.

Dataset	AMI	ICSI	MultiWOZ	FORUM
Domain	*Meeting*	*Meeting*	*Customer Service*	*Forum Thread*
# Speakers	4	6.2	2	6.8
# Conversations	137	59	10,438	689
# Conv. words	4,757	10,189	180.7	825.0
# Summ. words	322	534	91.9	190.6
# Turns	289	464	13.7	10.5

Table 1: Statistics of the converstional summarization datasets. The number of conversation words, summary words, turns and speakers are all averaged across all conversations in the dataset.

AMI (Carletta et al., 2005) is a multi-modal dataset consisting of 100 hours of meeting recordings with rich annotations. Following Shang et al. (2018); Zhu et al. (2020), we select 137 meetings of scenario where the participants play different roles in a design team. Each meeting is labeled with transcripts produced by automatic speech recognition (ASR) and an abstractive summary written by a human annotator. Furthermore, each dialogue is also associated with additional information, including its speaker id with role, dialogue act. We use the same data split of 100/17/20 as training/validation/test sets.

ICSI (Janin et al., 2003) is another widely-used meeting corpus consisting of about 70 hours of meeting audio recordings with orthographic transcription and other manual annotations. We follow the pre-processing pipeline from Zhu et al. (2020) and split the training/validation/test sets of size 43/10/6, respectively. Each meeting also contains a manually labeled abstractive summary and the associated role information for each participant.

MultiWOZ (Yuan and Yu, 2019) is an abstractive dialog summarization dataset based on the MultiWOZ corpus (Budzianowski et al., 2018; Ramadan et al., 2018; Eric et al., 2019; Zang et al., 2020), which is a fully-labeled collection of human-human written conversations spanning over multiple domains and topics. The dataset is built on various customer-service records in the corpus, such as booking restaurants, hotels, taxis. We use the summary annotation provided by Yuan and Yu (2019), and the same data split of 8438/1000/1000 as training/validation/test sets.

FORUM (Tarnpradab et al., 2017) contains 700 human-annotated forum threads. Each thread contains a human-annotated abstractive summary and multiple posts written by several different users. These threads are collected from tripadvisor.com and ubuntuforums.org. Bhatia et al. (2014) annotated 100 threads from TripAdvisor with human-writtern summaries, and Tarnpradab et al. (2017) further extend the summary annotation with 600 more threads. In our experiments, we divide the dataset into 500/100/89 examples for training/validation/test sets.

5.2 Metrics

ROUGE (Lin, 2004) is a standard metric for summarization task. Following Zhu et al. (2020), we use ROUGE-1, ROUGE-2, and ROUGE-SU4 to evaluate all meeting summarization models. The models on MultiWOZ and FORUM are evaluated by ROUGE-1, ROUGE-2 and ROUGE-L (Tarnpradab et al., 2017; Yuan and Yu, 2019). We obtain the scores by the rouge-metric package [3].

5.3 Evaluation Results and Discussions

5.3.1 Meeting Summarization

We compare TANET with a variety of models from previous literature: **Random** (Riedhammer et al., 2008), the template-based model **Template** (Oya et al., 2014), two ranking systems **TextRank** (Mihalcea and Tarau, 2004) and **ClusterRank** (Garg et al., 2009), the unsupervised method **UNS** (Shang et al., 2018), **Extractive Oracle**, which concatenates top sentences with the highest ROUGE-1 scores with the golden summary, the document summarization model **PGNet** (See et al., 2017), **Copy from Train**, which randomly copies a summary from the training set as the prediction, the multimodal model **MM** (Li et al., 2019), and the hierarchical Network **HMNet** (Zhu et al., 2020). Besides the baselines above, **BART** (Lewis et al., 2020) and **PEGASUS** (Zhang et al., 2020), two state-of-the-art pre-trained models on document summarization, and **Longformer-Encoder-Decoder** (**LED**) (an, 2020) are also included in comparison to have a thorough understanding towards our model. We concatenate all turns of a transcript into a sequence and then truncate it to meet the length constraints of the model input. LED$_{large}$ is initialized from BART$_{large}$ and able to process 16k tokens. Please refer to the Appendix for more implementation details .

Table 2: Automatic evaluation results on datasets AMI and ICSI. Numbers in bold indicate the best performing models on the corresponding metrics. Numbers marked with "*" mean that the improvement over the best baseline is statistically significant (t-test with p-value < 0.05). Models marked with "†" require additional human annotations of topic segmentation and visual signals from cameras.

Table 2 reports the automatic evaluation results on datasts AMI and ICSI. We can see that, except for ROUGE-1 on AMI, TANET outperforms all baseline models in all metrics. MM is a multi-modal model which requires additional annotation of topic segmentation (TopicSeg) and multi-modal features derived from the visual focus of attention (VFOA) collected by cameras. In practice, the visual information is rarely available, such as online chat, so the application scenarios of MM are very limited. In comparison, TANET is completely based on meeting transcripts from ASR systems, so it has better scalability. Comparable performance is achieved in ROUGE-1 on AMI, but it is significantly higher in ROUGE-2 by 7.2 points. In particular, TANET outperforms HMNet, indicating that pretraining on large-scale conversation data while incorporating the inherent structural information can lead to better performances on downstream tasks. Moreover, TANET significantly outperforms BART and PEGASUS on both AMI and ICSI. Although the two baselines own strong capabilities to summary a document, the tricky part is that a meeting transcript is very long and cannot be fully fed into the models. For example, the average number of words in ICSI is 10, 189, which far exceeds

---

the maximum input length 512 tokens of BART and PEGASUS. As a result, most of the content in a meeting transcript are discarded, which will inevitably limit the performances of the two models. LED can input all sentences, but it is still difficult to fully understand the conversation, which further demonstrate the effectiveness of the pretraining on the corpus RCSum.

5.3.2 Customer-service Records Summarization

To demonstrate the effectiveness of TANet on customer-service records summarization, following models are selected as baselines from previous literature: the pointer-generator network **PGNet** (See et al., 2017), **Transformer** (Vaswani et al., 2017) and **SPNet** which incorporates three types of semantic scaffolds - speaker role, semantic slot and dialogue domain for summarization (Yuan and Yu, 2019). Besides, we include **HMNet** (Zhu et al., 2020) as a baseline and implement it using the official code [4]. We also apply **Longformer-Encoder-Decoder** (**LED**) (an, 2020), **BART** (Lewis et al., 2020) and **PEGASUS** (Zhang et al., 2020) in this task by concatenating all utterances in a conversation as a document.

Table 3 reports the automatic evaluation results on MultiWOZ. We can observe that TANet achieves new state-of-the-art performance on ROUGE-2 and ROUGE-L, which demonstrate the effectiveness of pretraining on large-scale conversation data. Different from the results of the meeting summarization given in Table 2, PEGASUS$_{large}$ achieves close performance to TANet and even the best in ROUGE-1, showing its great generalization ability in this task. This is because: (1) the "documents" can be fully fed into the model without content loss. The average length of the dialogue in MultiWOZ is 180.7 words, which do not exceed the model's maximum input length 512. (2) each conversation takes place between two speakers (i.e. a customer and a staff), so the structure of a dialogue can be viewed as a sequence, which is similar to the sentences in a document. Compared with LED, HMNet and BART, the un-pretrained model SPNet obtains surprisingly better scores. This motivates us to combine richer conversation-related information, such as speaker role, dialogue act, semantic slot, and dialogue domain, to further improve model's summarization capabilities in the future.

5.3.3 Forum Threads Summarization

In this task, TANet is compared against a range of baselines, including following unsupervised methods: (1) **ILP** (Berg-Kirkpatrick et al., 2011), a baseline integer linear programming framework; (2) **Sum-Basic** (Vanderwende et al., 2007), a model that assumes words occurring frequently in a document cluster have a higher chance of being included in the summary; (3) **KL-Sum**, an approach that select the sentences decreasing the KL divergence as the summary; (4) **Lex-Rank** (Erkan and Radev, 2011), a graph-based model based on eigenvector centrality; (5) **MEAD** (Radev et al., 2004), a centroid-based approach which scores sentences based on length, centroid, and position; and supervised extractive systems, including (1) **SVM**

	Read.	Conc.	Kappa	Read.	Conc.	Kappa
HMNet	1.67	1.40	0.60	1.76	1.57	0.61
Bart$_{base}$	1.58	1.02	0.72	1.82	1.63	0.69
TANet	1.70	1.53	0.63	1.84	1.70	0.60

Table 6: Human evaluation results on AMI and FORUM. "Read.", "Conc." are abbreviations for readability and conciseness, respectively.

(Chang and Lin, 2011), the support vector machine; (2) **LogReg** (Fan et al., 2008), the logistic regression; (3) **HAN** (Tarnpradab et al., 2017), a hierarchical attention network with redundancy removal process; Besides, we also apply the cross-domain pre-trained model **HMNet** (Zhu et al., 2020) in this task and implement **Longformer-Encoder-Decoder** (**LED**) (an, 2020), **BART** (Lewis et al., 2020) and **PEGASUS** (Zhang et al., 2020) in a similar way to the adaptation in the above two tasks.

Table 4 reports the automatic evaluation results on the dataset FORUM. TANet outperforms all baseline models in terms of all metrics, and the improvements are statistically significant (t-test with p-value< 0.05), which further demonstrate the effectiveness of our method. In this task, the gains over the pre-trained baselines are relatively high , due to (1) the consistency of conversation domain between the pretraining stage and downstream fine-tuning. The conversation in FORUM and our pretraining corpus RCSum are both forum threads. Note that, although the data in FORUM is collected from TripAdvisor (tripadvisor.com) and UbuntuForums (ubuntuforums.org.), the subjects are also included in some specific sub-reddits on the Reddit website. In contrast, LED, HMNet, BART and PEGASUS are all pre-trained with document-like text, so there will be a domain gap in thread understanding; (2) structure modeling. The tree-like reply relationship in a thread plays a vital role in understanding the entire thread, but the baselines can only process it linearly, which poses challenges for the model to fully understand the context and generate accurate summaries.

5.3.4 Ablation Study

To understand the impact of our pretraining strategies on model performance, we compare the full TANet with the following variants: (1) -*Pretraining*: the pretraining stage is removed; (2) -*Thread-Aware Attention*: the Thread-Aware Attention sublayers in the utterance encoder degenerate into standard self-attention sublayers; (3) -*Thread Prediction*: $\mathcal{L}_{ThreadPred}$ is removed; and (4) -*Encoder-wise Residual*: the encoder-wise residual around the utterance encoder is removed. Table 5 reports the evaluation results on AMI and FORUM.[5] We can conclude that (1) the pretraining on RCSum helps to significantly improve the performance, as removing it results in dramatic performance drop on both AMI and FORUM; (2) both Thread-Aware attention and Thread Prediction objective are useful, indicating that the structure of thread is essential to facilitate the understanding of conversation, especially for the threads with tree structure; (3) the encoder-wise residual is meaningful, as removing it causes performance drop.

5.3.5 Human Evaluation

As the human annotation for this task is very time-consuming and labor-intensive, we also conduct human evaluation on the test sets of AMI and FORUM to verify whether the improvements on automatic evaluation is in line with the human perceived quality. We recruit 3 well-educated native speakers as annotators and compare TANet with BART$_{base}$ and HMNet on 2 aspects - *readability* and *conciseness*. The former measures how fluent a generated summary is, while the later measures how well the summary sums up the main ideas of a conversation. For each sample, we show its conversation, reference summary, as well as summaries generated by models (the order is shuffled to hide their sources) to the annotators and ask them to judge the quality and assign a score in {0,1,2} (indicating "bad", "fair", and "good") to each summary for each aspect. Table 6 reports the evaluation results. We can observe (1) the three models are comparable on readability on both datasets; (2) TANet outperforms the others on conciseness, which is consistent with the automatic evaluation results in Table 2 and Table 4; (3) Bart$_{base}$ does not perform well on conciseness on AMI, as most utterances of a conversation are discarded due to the input length

---

[5] Ablation results on AMI and FORUM could provide more insights, whereas ICSI is similar to AMI, and MultiWOZ is less challenging.

constraint 512. All kappa values are no less than 0.6, indicating substantial agreement among the annotators. For reference, we present case study in the Appendix.

6 Related Work

With the recent success of seq2seq models, the research focus of conversational summarization has been transferred from the extractive methods to abstractive models. Various semantic patterns have been applied to these abstractive approaches, such as dialogue acts (Goo and Chen, 2018), auxiliary key point sequences (Liu et al., 2019a), topic segments (Li et al., 2019; Liu et al., 2019b), conversational stages and dialogue overview (Chen and Yang, 2020), discourse relations (Murray et al., 2006; Bui et al., 2009; Qin et al., 2017). At the same time, some work is devoted to providing high-quality datasets to promote the development of this research direction (Carletta et al., 2005; Janin et al., 2003; Tarnpradab et al., 2017; Yuan and Yu, 2019; Gliwa et al., 2019). However, these corpora have a low number of conversations, which hinders the progress of abstractive summarization (an, 2021). Recently, large neural models pre-trained on huge corpora have led to strong improvements on numerous natural language understanding and generation tasks (Devlin et al., 2019; Radford et al., 2019; Lewis et al., 2020; Zhang et al., 2020). Encouraging by the promising progress of pretraining, Zhu et al. (2020) first introduce a hierarchical structure and propose pretraining on cross-domain data for meeting summarization. The pretraining data is collected from the news domain. Regarding one document as the utterances from one participant, multiple documents are combined and reshuffled to simulate a multi-person meeting. However, there are two disadvantages - the first is the style inconsistency between conversation and news, and the second is that there is no contextual relationship between the two documents, so the participants have no communication actually. In this work, we build a large-scale corpus based on real conversations. Besides, we further incorporate the structure information of thread in the model.

7 Conclusions

In this work, we introduce TANET, a thread-aware pre-trained model for abstractive conversational summarization. TANET employ the thread-aware attention and a new pretraining objective to fully leverage the structure information of conversation. Furthermore, we build a large-scale pretraining corpus based on the discussions on Reddit. Experiments on four downstream tasks demonstrate the effectiveness of TANET.

A Implementation Details

In TANET, the token encoder, utterance encoder, and decoder all have 6 layers, i.e., $N = 6$. Each multi-head attention sub-layer has 12 heads, i.e., $h = 12$. The size of feed-forward layer is 3072. The hidden size d_h is 768. We employ the same vocabulary as BART (Lewis et al., 2020), which has 50265 tokens. TANET has 180M parameters in total. We use a dropout probability of 0.1 for all layers. In the thread-aware attention layer, we define 20 learnable embeddings, i.e., $k = 9$. For optimization, both pretraining and downstream finetuning use AdamW optimizer (Loshchilov and Hutter, 2019) with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 1e-8$. We pre-train TANET with an accumulated batch size of 256. The initial learning rate is set as $5e-5$ and linearly decreased to 0 after 500k steps. We use beam search with the commonly used trigram blocking (Paulus et al., 2018; Lewis et al., 2020) to select the best candidate during inference for the downstream tasks. To improve the pretraining efficiency, we set the maximum number of utterances to 124, each utterance has a maximum of 200 tokens, and the pseudo-summary has a maximum of 256 tokens. BART$_{base}$ and PEGASUS$_{large}$ are implemented with the codes provided by HuggingFace at `https://github.com/huggingface/transformers/tree/v4.1.1/examples/seq2seq`. The initialized pre-trained models are available at `https://huggingface.co/facebook/bart-base` and `https://huggingface.co/google/pegasus-large`. We implement LED$_{large}$ by referring to the code at `https://colab.research.google.com/github/patrickvonplaten/notebooks/blob/master/Fine_tune_Longformer_Encoder_Decoder_(LED)_for_Summarization_on_pubmed.ipynb`. All experiments are conducted on a machine with 4 NVIDIA Tesla V100 GPUs.

B Case Study

Finally, we randomly sample two cases from the test sets of MultiWOZ and FORUM to conduct qualitative analysis. We show the conversation and the summaries generated by HMNet, LED$_{large}$, Bart$_{base}$, TANET, as well as the ground truth in Table 7 and Table 8. We can see that TANET can produce a more concise summary with less incorrect facts and has a higher level of abstraction ability about the conversations. In contrast, the summaries generated by HMNet and Bart$_{base}$ cannot cover all the important information and are prone to some mistakes. LED$_{large}$ tends to copy content from the original conversation, especially as in Table 8.

	Conversation
USER:	I'm looking for information on Cambridge University Botanic Gardens.
SYSTEM:	They are on bateman st, postal code cb21jf, they can be reach at 01223336265, the entrance fee is 4 pounds, can I help with anything else?
USER:	Yes can you help me find a restaurant?
SYSTEM:	The Botanic Gardens are in the centre. Would you like the restaurant to also be in the center? Do you have any type of cuisine in mind?
USER:	Never mind, I will worry about food later. I am actually looking for a hotel with a guesthouse and free parking would be great as well.
SYSTEM:	There are 21 guesthouses with free parking, do you have a price or area preference?
USER:	Cheap and in the south please.
SYSTEM:	I found a guest house listing for Rosa's Bed and Breakfast in the south. Would you like more information?
USER:	I really need a hotel in the west please.
SYSTEM:	i have 1 hotel in the west. the cambridge belfry is cheap with 4 stars. it offers free parking and wifi. do you need a room?
USER:	I'm sorry.I really was looking for a guesthouse.
SYSTEM:	Okay. And did you want it in the west or the south?
USER:	I would like the west please.
SYSTEM:	I found finches bed and breakfast matching your request. Would you like to book a room now?
USER:	Can you please book for Saturday, 2 people, 5 nights please?
SYSTEM:	Booking was successful. Reference number is : W1QIVTNY .
USER:	Thank you so much. I believe that is all I need today. Thanks again for all your help.
SYSTEM:	Have a nice day.

	Summaries
HMNet:	you are traveling to and excited about seeing local tourist attractions . you are looking for a place to stay . the hotel should be in the type of guest house and should include free parking . the restaurant should serve [att_name] food .make sure you get price range , area , and star of the hotel .
LED$_{large}$:	you are traveling to cambridge and looking forward to try local restaurants. you are looking for a particular attraction. its name is called [att_name]. make sure you get address. you you are also looking for information in cambridge. you're looking for places to go in town. the attraction should be in the type of museum. make sure to get postcode. you also are looking to book a hotel. the hotel should be a guest house.
Bart$_{base}$:	you are traveling to cambridge and excited about seeing local tourist attractions. you are looking for a particular attraction. its name is called [att_name] . make sure you get address. you are also looking for a place to stay. the hotel should include free parking and should be in the type of guest house. the hotel should be in the south and should be in the cheap price range. once you find the hotel you want to book it for [people_num] and [hotel_stay] starting from [week_day] . make sure you get the reference number.
TANET:	you are looking for information in cambridge. you are looking for a particular attraction. its name is called [att_name] . make sure you get area and phone number. you are also looking for a place to stay. the hotel should include free parking and should be in the type of guest house. the hotel should be in the cheap price range. if there is no such hotel, how about one that is in the west. once you find the hotel you want to book it for [people_num] and [hotel_stay] starting from [week_day] . make sure you get the reference number.
Ground Truth:	you are looking for information in cambridge. you are looking for a particular attraction . its name is called [att_name] . make sure you get phone number and entrance fee. you are also looking for a place to stay . the hotel should be in the type of guest house and should include free parking. the hotel should be in the west. once you find the hotel you want to book it for [people_num] and [hotel_stay] starting from [week_day] . if the booking fails how about [hotel_stay] . make sure you get the reference number.

Table 7: A case from MultiWOZ. We underline some vital facts in the conversation. Red denotes the incorrect content in the generated summaries. Blue indicates what appears in TANET's summary but is not covered by the ground truth.

	Conversation
N16E:	Hi, I'm hoping a local expert can help us out, we're traveling over to New York (on route to Florida) on Wednesday 28th March, flying out on Saturday 31st, this gives us around 2 and a half days to see the city, below is the list of places we are looking to visit/see. My only thoughts at the moment are to go to the ESB first thing around 8am and TOTR around dusk. I was hoping to use the subway to get around and our hotel is The Belvedere just off 8th Ave on 48th street, in which order should we visit these sights? is it possible? any info on which subway lines to take would be fantastic. We are two families of 4 - 4 adults 4 kids, aged 7 to 13. Maceys - browse for say 2 hours 5th Ave - stroll down and people watch Brooklyn Bridge - wander over, check out the skyline Central Park - relax Top of the Rock - watch the transition from day to night Ground Zero - must go and pay respect. Times Square - sense the hustle and bustle Staton Island Ferry - relax a little Statue of Liberty - view from the ferry? Empire State Building - must do! Grand Central Station - pass through and see the architecture Ellis Island - not sure about this? Carnegie Deli - take in a cheesecake. Have we missed anything? Given we are a party of 8 will we need to book restaurants? any suggestions nearby the hotel offering good steaks and pizza (sorry I know this is a very subjective question). Thanks very much in advance - counting down the days. N16E
SummerSh...:	Wow, that's a lot to try and squeeze into such a short visit! I'd eliminate Ellis Island and Macy's. Ellis Island just takes up too much time, and Macy's – even though it's the original and the world's largest store – is just a dept. store, you can find a branch in Florida too. You shouldn't have to make dinner reservations if you avoid the pre-theater crowd in the area. Just go at 8:00. The best pizza is at John's, on W. 44th (four blocks from your hotel). It's in a converted church, so very interesting. I will advise you to make reservations NOW for Carmine's. Even though the place is enormous, it's really tough to get a reservation. That's where I'd suggest you get your steak fix. Their Flintstone-sized Porterhouse is yummy! Everything in Carmine's is served family style, so you'll only need two steaks for your entire group. And one big bowl of pasta will feed everyone. If you go to the World Trade Center site, please also visit St. Paul's Chapel, it's just a block away: www.saintpaulschapel.org And don't go to the Carnegie JUST for the cheesecake (even though it's fantastic!). You've gotta try their pastrami!
N16E:	Thanks Bettina, What order do you think we should visit these places in? Took a look at Carmines - the pictures on the website make it look a little formal? Thanks again. N16E.
	Summaries
HMNet:	traveling over to new york on the route to florida on wednesday 28th march. he is hoping to use the subway to take the belvedere . they are two families of 4 -4 adults and they should visit around 8 am . is also looking for advice on what to do on which subway lines to take and their hotel is fantastic . mentions that they are a party of 8 in advance and they will need to book down ellis island . they also recommend going to carnegie deli and take pizza in carnegie deli . recommends to make reservations for 44th.
LED$_{large}$:	N16E is traveling to New York on Wednesday 28th March, flying out on Saturday 31st, gives them around 2 and a half days to see the city. They are two families of 4 - 4 adults 4 kids, aged 7 to 13. They have a list of places they are looking to visit/see. They would like to visit ESB first thing around 8am and TOTR around dusk. They were hoping to use the subway to get around and their hotel is The Belvedere just off 8th Ave on 48th street. They ask which order should they visit these sights? In which order? Any info on which subway lines to take would be fantastic. They also ask about steaks and pizza nearby the hotel offering good steaks. SummerShowers says to eliminate Ellis Island and Macy's. Ellis Island just takes up too much time, and Macy's – even though it's the original.
Bart$_{base}$:	N16E needed help to plan for a two day trip to New York. N16E was traveling with his family of four and had planned to visit the Empire State Building, Central Park, Top of the Rock, Times Square, Statue of Liberty, Grand Central Station, Ellis Island, Carnegie Deli, St. Paul's Chapel, Macy's, and John's all in the same short time frame. He/She also wanted to know the order of things to do in the city, and how to get around. Bettina said that they should make reservations NOW for Carmine's.
TANET:	N16E will be traveling to New York and needs help to plan for a two day stopover. They will be staying at the Belvedere Hotel, and would like to visit the Top of the Rock, and the Empire State Building. They are two families of four and will be going to Macy's. They plan on going to Ground Zero, Central Park, Times Square, Statue of Libery, and Grand Central Station. They also ask about dinner reservations, and suggestions on places that offer good steak and pizza. SummerShowers mentions that John's has a lot of steak and may be a little too formal. He/She suggests Ellis Island, and to avoid the pre-theater crowd. Paul's and Carmine's are two family of four. N16E asks about a cheesecake in the Carnegie Deli. Summershowers responds that Carmine's is a good option as well and recommended a place called Le Pain de St. Paul's. For steak Carmine, go to Paul's Chapel and get pastrami for cheesecake.
Ground Truth:	N16E needed help to plan for a two day stopover in NYC en route to Florida, and wanted opinion on his/her itinerary. N16E said that they were staying at the Belvedere, and wanted to start at the Empire State Building and end at the Top of the Rock. N16E said that they had a party of 8 and that the Empire State Building was a must stop. N16E planned to browse at Macy's, stroll down the Brooklyn Bridge, go to Central Park to relax, visit the Top of the Rock, and see Ground Zero on the first day. On the second day N16E said that they would go to Times Square, ride the Staten Island Ferry, and see the Statue of Libery. N16E wanted to know if they could fit in Ellis Island and a visit to Grand Central Station, and still get a cheesecake for Carnegie Deli. Summershowers responded saying that was a lot to do in two days, and recommended that they drop Macy's and Ellis Island. Summershowers said that John's had the best pizza and recommended that N16E get reservations for Carmine's immediately. Summershowers said that Carmine's was family style and recommended the Flintstone-sized Porterhouse steak. Summershowers said that if N16E goes to the World Trade Center, to stop by St. Paul's Chapel, and to get pastrami a Carnegie Deli as well as a cheesecake. N16E thanked Bettine, and asked for a recommended order in visiting places, and said the Carmine's might be a little too formal.

Table 8: A case from FORUM. The conversation's domain is trip. We underline some vital facts in the conversation. Red denotes incorrect content in the generated summaries. Blue indicates what appears in TANET's summary but is not covered by the ground truth.

AdapterBias: Parameter-efficient Token-dependent Representation Shift for Adapters in NLP Tasks

Abstract

Transformer-based pre-trained models with millions of parameters require large storage. Recent approaches tackle this shortcoming by training adapters, but these approaches still require a relatively large number of parameters. In this study, AdapterBias, a surprisingly simple yet effective adapter architecture, is proposed. AdapterBias adds a token-dependent shift to the hidden output of transformer layers to adapt to downstream tasks with only a vector and a linear layer. Extensive experiments are conducted to demonstrate the effectiveness of AdapterBias. The experiments show that our proposed method can dramatically reduce the trainable parameters compared to the previous works with a minimal decrease in task performances compared with fine-tuned pre-trained models. We further find that AdapterBias automatically learns to assign more significant representation shifts to the tokens related to the task in consideration.[1]

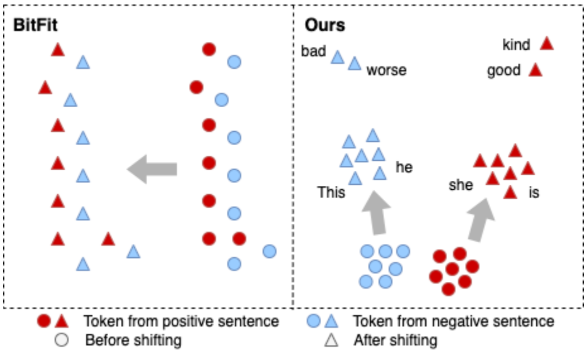

Figure 1: Overview of the main concept of our work compared to BitFit (Ben Zaken et al., 2021). Left: BitFit tends to add the same representation shift to different tokens. Right: Our work applies different representation shifts to tokens considering their importance to the downstream task and their characteristics. The shifts of the input words that are more task-related is more significant than that of other tokens. For example, in SST-2 (Socher et al., 2013), which is a semantic task, the representation shifts of the semantic words, such as "kind" and "worse", are larger than that of other words.

1 Introduction

While large pre-trained language models (PLMs) reached state-of-the-art results on natural language processing (NLP) tasks, PLMs require updating all parameters and storing the fully fine-tuned model for each downstream task. These requirements have led to difficulties in real-world applications. Moreover, fine-tuning PLMs on low-resource datasets is subject to instabilities.

To tackle these shortcomings, Adapters (Houlsby et al., 2019), a more parameter-efficient alternative training strategy for the transformer architecture (Vaswani et al., 2017) have been proposed. Instead of full fine-tuning the whole model, Adapters introduce extra tunable weights and freeze the original parameters of PLM. Adapters demonstrated comparable performance with fully fine-tuning the entire model. Although Adapters solve the problem of the PLM's massive parameters, researchers are curious about how many more parameters are required to reach state-of-the-art performance on standard NLP tasks. The results in Houlsby et al. (2019) have shown that the performance on GLUE benchmark (Wang et al., 2018) is almost the same when removing the Adapters in the lower layers, which indicates that not every adapter is useful. It raises the question of whether adapters can be even more parameter-efficient.

To develop practical and memory-efficient methods of utilizing PLMs, Diff pruning (Guo et al., 2020) enables parameter-efficient transfer learning that scales well with new tasks. The approach learns a task-specific "diff" vector that extends the original pre-trained parameters and encourages the sparsity of the vector through L_0-norm regularization. Another approach is BitFit (Ben Zaken et al.,

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2608 - 2621
July 10-15, 2022

2021), which shows that with small-to-medium training data, fine-tuning only a subset of the bias terms of pre-trained BERT models (Devlin et al., 2018) is competitive with fine-tuning the entire model. The central concept of these approaches is to add task-specific shifts to each output representation of the PLM layers so as to adapt to different tasks. In the previous works, Ben Zaken et al. (2021); Guo et al. (2020) both add the same shifts to the output representation regardless of which token is more relevant to the task. However, considering some specific tokens might be more critical to a particular task, the representation can better adapt to the downstream task under a limited amount of parameters if these shifts are based on the input tokens.

Based on this concept, in this study, we add token-dependent biases to the shifts by proposing AdapterBias, which consists of a vector and a linear layer (L_α). The vector represents the task-specific shift, and L_α produces the weights for input tokens. Thus, with the vector and the weights, AdapterBias can add a token-dependent shift to the transformer layer. Since the concept of BitFit (Ben Zaken et al., 2021) is similar to AdapterBias by adding a shift to the representation, we demonstrate the difference between BitFit and AdapterBias in Figure 1. BitFit assigns identical shifts to all the tokens, while AdapterBias adds more significant shifts to the representations that are related to the task.

With fewer trainable parameters required, AdapterBias achieves comparable performance on the GLUE benchmark with Houlsby et al. (2019); Pfeiffer et al. (2020a); Guo et al. (2020); Ben Zaken et al. (2021); Hu et al. (2021). We further decrease the parameters of AdapterBias in different ways, including partial weight-sharing in AdapterBias and adding L_0-norm regularization. Finally, AdapterBias has better interpretability due to its simplicity. We use different tools, including word cloud and PCA (Jolliffe, 2002), to visualize what AdapterBias has learned, and we found that the proposed approach automatically learns to assign larger representation shifts to the task-related tokens.

2 Related Work

For NLP tasks, adapters are introduced for the transformer architecture. A set of adapter parameters was added at each transformer layer, which is mostly bottleneck architectures Houlsby et al. (2019). By keeping the output dimension identical, they cause no change to the structure or parameters of the original model.

Adapters quickly gained popularity in NLP with various applications. For multi-task learning (Caruana, 1997; Zhang and Yang, 2017; Liu et al., 2019b), a projected self-attention layer is proposed by Stickland and Murray (2019), while Bapna et al. (2019) proposed an additional layer norm suitable for machine translation.

Besides the applications of adapters, researchers are also dedicated to improving their performance. Based on the architecture introduced by Houlsby et al. (2019), AdapterFusion (Pfeiffer et al., 2020a) leveraged knowledge from multiple tasks with a new two-stage learning algorithm. Despite the recent popularity of these methods, they still train a relatively large number of training parameters.

Recently, studies start to focus on improving the parameter-efficiency of adaptation to a new task. Diff-pruning (Guo et al., 2020) achieves parameter efficiency by adding a sparse, task-specific difference-vector to the fixed original parameters. The vector is adaptively pruned during training with a differentiable approximation to the L_0-norm penalty to encourage sparsity. Rücklé et al. (2020) introduced AdapterDrop, which has been recently integrated into AdapterHub (Pfeiffer et al., 2020b). It removes adapters from lower transformer layers during training and inference, which can dynamically reduce the computational cost. Mahabadi et al. (2021) proposed Compacter, which improved the trade-off between performance and trainable parameters per task with low-rank optimization.

On the other hand, without modifying the architecture of the PLM, BitFit (Ben Zaken et al., 2021) shows that fine-tuning only the bias terms of a large PLM is also competitive with fine-tuning the entire model. Fine-tuning only the bias terms can be considered as adding a task-specific shift to the token representation. BitFit is most similar to our work. While in BitFit, the shifts added to all the representations are exactly the same for all input tokens, in our work, the shifts are token-dependent.

3 Method

In this section, we present AdapterBias, an efficient way to adapt large-scale PLMs. In order to better adapt to different downstream tasks, the adapter module should be token-specific. AdapterBias produces a suitable weight for the bias based on the input token.

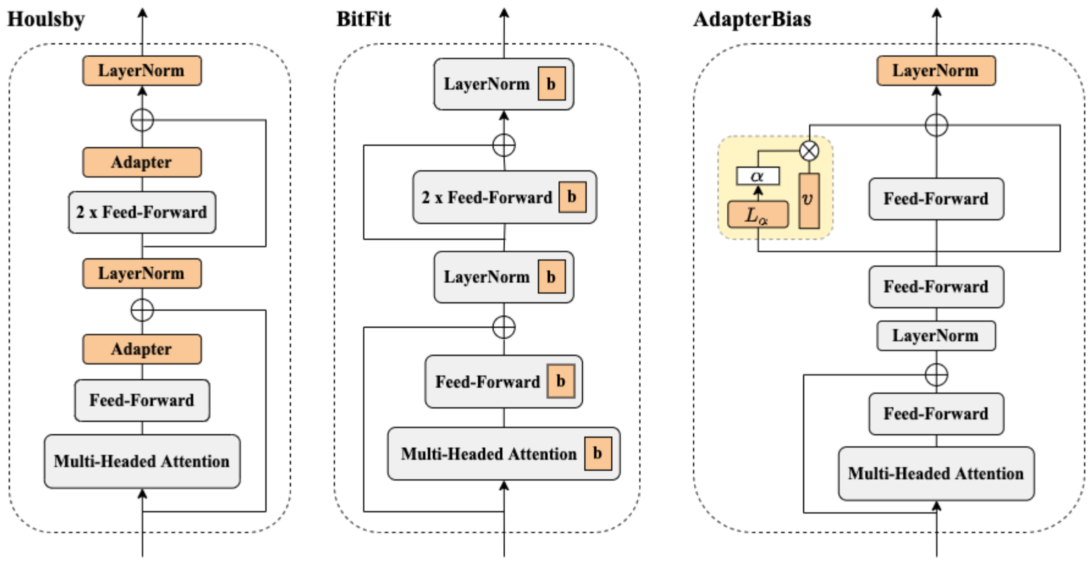

Figure 2: Model architectures comparison of Houlsby et al. (2019), BitFit (Ben Zaken et al., 2021), and the proposed method AdapterBias. The orange blocks indicate the trainable parts, while the gray blocks indicate the frozen parameters during the training stage. Left: Houlsby et al. (2019) add their Adapters after the feed-forward layers, and their Adapter consists of two linear layers and an active function. Middle: BitFit tunes all biases from the original transformer layers. Right: AdapterBias, consisting of a linear layer (L_α) and a vector (v), is added after the second feed-forward layer only in each transformer layer.

Problem Formulation We consider the general problem of fine-tuning PLMs, where the training data $D = (x_i, y_i)_{n=1}^{N}$ is given. Assume that given a PLM with parameters θ and AdapterBias with parameters θ'. During the training stage, we freeze θ and tune θ' only.

3.1 AdapterBias

The architecture of AdapterBias is shown in the right part of Figure 2. AdapterBias consists of two modules: a vector (v) and a linear layer (L_α). v is a task-specific shift added to the output of each transformer layer. The tokens which are more related to the task should be assigned larger representation shifts than other tokens. The linear layer (L_α) produces a token-dependent weight vector $\alpha = [\alpha_1, \alpha_2 \dots \alpha_m]^T$, where α_i is the weight of the i^{th} token's representation shift. By applying the token-specific weight to the task-specific representation shift (v), AdapterBias can focus on the tokens that are more important to the task and is able to adapt to different downstream tasks efficiently.

We define the output of AdapterBias as the bias (B), which is the outer product of v and the learned weights vector α. When the dimension of the token's representation is r with m input tokens, the function can be defined as follows:

$$B = v \otimes \alpha^T = \begin{pmatrix} \alpha_1 v & \alpha_2 v & \dots & \alpha_m v \end{pmatrix} \quad (1)$$

where $v \in \mathbb{R}^r$, $\alpha \in \mathbb{R}^m$, and $B \in \mathbb{R}^{r \times m}$.

To further elaborate on the details of AdapterBias, we give an example of how AdapterBias produces B and how B adds to the transformer layer. In Figure 3, we assume that there are three representation outputs (r_1, r_2, r_3) after the first layer normalization. The dimension of r_1, r_2 and r_3 is the dimension of the 2nd feedforward layer, while the input dimension of the linear layer (L_α) is the output dimension of the first feed-forward layer with the token representation (r_1, r_2, r_3) as its inputs. The linear layer (L_α) produces α, where $\alpha \in \mathbb{R}^3$. The blocks in different colors represent the difference of the weights ($\alpha_1, \alpha_2, \alpha_3$). Take BERT-base for example, after performing outer product with the weights vector α and the vector (v), the dimension of B becomes 768×3. For example, b_1, the first column of B, is the shift for the first token representation.

3.2 Further improvement on parameter-efficiency of AdapterBias

In this section, we experiment on two different methods to make AdapterBias more parameter efficient. One is partial weight-sharing of AdapterBias among transformer layers, another is enforcing the weights of the linear layer (L_α) to be sparse by utilizing L_0-norm penalty.

3.2.1 Cross-layer parameters sharing in AdapterBias

Redundancies have been observed in the information captured by adapters, with adapters in lower layers being less important (Houlsby et al., 2019). In addition, sharing parameters of the Adapter across layers leads to a comparatively small drop in performance in some tasks. In light of the above information, we further reduce the number of parameters required for each task by partially sharing the weights of the adapters across all transformer layers. The experimental results are discussed at Section 4.6.1.

3.2.2 L_0 regularization in AdapterBias

Sparsity has been utilized in various parameter-efficient methods. For applications in NLP tasks, Diff-pruning (Guo et al., 2020) learns a sparse vector added to the whole PLM with L_0-norm penalty. Inspired by their work, we further apply L_0-norm regularization to L_α in the AdapterBias module, aiming to encourage the sparsity of L_α. We choose to drop L_α because it contributes most of the parameters in AdapterBias. Encouraging its sparsity can further increase the parameter efficiency. Note that we specifically apply L_0 regularization in Section 4.6.2.

In AdapterBias, we add L_0-norm penalty to the linear layer (L_α). The optimization problem can be expressed as,

$$\min_{\theta'} L(D;\theta,\theta') + \lambda \|\theta'_{L_\alpha}\|_0, \tag{2}$$

where $L(D;\cdot)$ represents the original loss with training data D. λ is the hyperparameter for L_0-norm penalty. Note that θ' represents trainable parameters and θ'_{L_α} represents the parameters of L_α in AdapterBias. Following the work of Diff-pruning, we utilize a relaxed mask vector (Louizos et al., 2017) with a stretched Hard-Concrete distribution (Jang et al., 2016; Maddison et al., 2016) to encourage L_0 sparsity.

4 Experiments

In this section, we evaluate the effectiveness of our proposed adapter module in NLP training tasks, and provide the analysis of what AdapterBias has learned in different tasks.

4.1 Experimental settings

We base our experiments on HuggingFace PyTorch implementation (Wolf et al., 2019) of BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019c) models. The learning rate is set in the range [10^{-4}, 10^{-3}], with AdamW (Loshchilov and Hutter, 2017) as the optimizer. GLUE benchmark (Wang et al., 2018) and SQuAD v1.0 (Rajpurkar et al., 2016) are the training data in our settings.

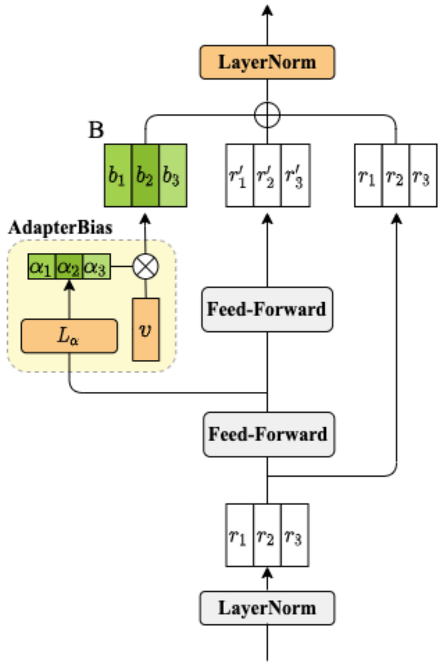

Figure 3: The detailed architecture of how AdapterBias produces the bias (B) and how B is added to the output of transformer layers.

The training details are shown in Appendix A.3. Note that the second layer normalization in each transformer layer is also tuned during the training stage, corresponding to the orange component in the right part of Figure 2. We experiment with 3 random seeds and choose the seed with the best performance on the validation set to evaluate on the GLUE server. We report the test metrics provided on the submission website[2].

4.2 Results on GLUE

In this section, we compare AdapterBias to other parameter-efficient methods, including Adapters (Houlsby et al., 2019), Diff-pruning (Guo et al., 2020), BitFit (Ben Zaken et al., 2021), and LoRA (Hu et al., 2021). In Table 1, we report the test scores on the GLUE benchmark and the required new parameters per task. Here we use BERT-large as the PLM. AdapterBias reaches 81.2 average score in GLUE benchmark, with the smallest amount of parameters (0.17M) added per task. AdapterBias shows competitive performance as its

RoL	AdapterBias	0.17M	63.9	96.4	90.4	94.7	83.6	91.3	89.8	89.4	72.3	85.8

Table 2: Performance of AdapterBias adding in different PLMs. Here we experiment with four models : BERT-base (BB), BERT-large (BL), RoBERTa-base (RoB), and RoBERTa-large (RoL). The settings are the same as in Table 1. The Full-FT corresponds to fine-tuning the whole PLM without adding adapters.

parameters are 40× less than the works of Houlsby et al. (2019). Although Diff-pruning (Guo et al., 2020) achieves the best average score among all parameter-efficient methods, their work trains an additional vector whose parameter count is equivalent to the parameters of the whole PLM. Thus, Diff-pruning requires 340M trainable parameters of BERT-large during the training stage, while AdapterBias only trains 0.17M parameters. Furthermore, AdapterBias achieves comparable performance with BitFit and LoRA with fewer parameters needed per task. This shows that AdapterBias is a worthwhile targeted fine-tuning method.

4.3 Different base models

To analyze the generalization ability of this approach to different PLMs on different models of AdapterBias, as shown in Table 2, we apply AdapterBias in different transformer-based PLMs, including BERT-base (BB), BERT-large (BL), RoBERTa-base (RoB), and RoBERTa-large (RoL), on the GLUE benchmark. All results are scored by the GLUE evaluation server. Compared with BitFit, In Table 2, not only can AdapterBias perform well on BERT but also achieve competitive performance on larger PLMs such as RoBERTa.

4.4 Size of training data

In the previous experimental results, we observe that AdapterBias tends to have higher performance on tasks with a smaller amount of data (i.e. CoLA, SST-2, and RTE). To further validate this observation, we follow the work of BitFit (Ben Zaken et al., 2021) by training AdapterBias on subsets of SQuAD v1.0 (Rajpurkar et al., 2016) of increasing size. The experiments are conducted with BERT-base. The results on the validation set of the SQuAD dataset are listed in Figure 4, which shows the tendency of AdapterBias outperforming full fine-tuning when the size of the training dataset is smaller. However, with more training data available, the trend is reversed. The results

Method	**Params**	**CoLA**	**SST-2**	**MRPC**	**QNLI**	**RTE**	**STS-B**	**MNLI-m**	**MNLI-mm**	**QQP**	**Avg**
w/o L_α	27.6K	45.6	91.5	87.4	88.3	65.6	81.0	77.9	78.4	65.7	75.7
AdapterBias	64.5K	**51.6**	**93.1**	**87.5**	**89.4**	**66.1**	**84.6**	**80.9**	**80.5**	**67.9**	**78.0**

Table 3: Evaluating the importance of the linear layer (L_α) in AdapterBias. The settings are the same as in Table 1. The backbone model is BERT-base. w/o L_α means that there is only a vector (v) in AdapterBias.

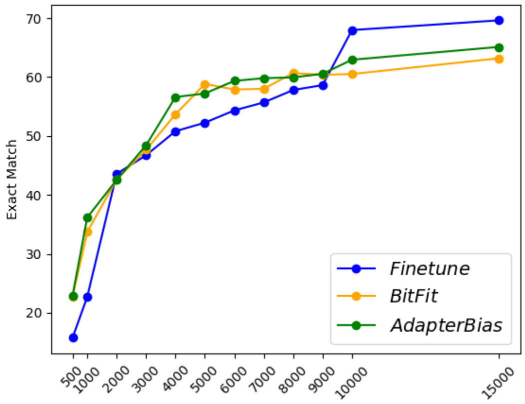

Figure 4: Comparison of Finetune, BitFit (Ben Zaken et al., 2021), and AdapterBias with BERT-base on SQuAD validation set. The x-axis represents the total number of training examples while the y-axis represents the exact match score.

show that AdapterBias has the ability to outperform fine-tuning the whole PLM with small-to-medium data size, similarly to BitFit.

4.5 Investigation on the effectiveness of token dependent representation shift

Different from BitFit (Ben Zaken et al., 2021), where the bias terms in all transformer layers are tuned, we claim that the bias added to the representation should be token-dependent, and proposed AdapterBias based on this concept. We conduct ablation studies to verify this claim. In this experiment, the linear layer (L_α) in AdapterBias that produces the token-dependent weights vector (α) is removed; that is, only the v is trained. All shifts added to the representation outputs are identical within the same transformer layer. The experiments are conducted with BERT-base model. We report the test scores on the GLUE benchmark in Table 3. The performance of AdapterBias without the linear layer (L_α) dramatically decreases. Without L_α, it is hard for the vector (v) to adapt to different downstream tasks. This result demonstrates the importance of L_α. In other words, assigning different shifts to different token representations improves the performance of the method.

4.6 Improving the parameter efficiency of AdapterBias

We further apply two additional methods to AdapterBias to enhance its parameter efficiency. Experiments are conducted to examine whether AdapterBias can be more parameter-efficient by sharing its components across all layers. Moreover, we experiment on adding L_0-norm regularization during the training stage to encourage the sparsity of AdapterBias.

4.6.1 Sharing components in AdapterBias

In this experiment, we conduct an ablation study of partial weight-sharing in the AdapterBias module. In Table 4, we share components of AdapterBias among different transformer layers. *Share v* represents sharing v across all transformer layers, while *Share* L_α means sharing the linear layer (L_α). *Share* v+L_α denotes sharing one AdapterBias across all transformer layers. As can be seen in Table 4, the performance of *Share* L_α stands out among other partial weight-sharing methods, while *Share v* leads to a poor performance.

From the experiments above, we conclude that the linear layer (L_α) captures general task information by learning the weights of the bias for different tokens. Thus, sharing L_α across all layers results in better performance compared to other components. The vector module (v) in AdapterBias aims to learn local information in each transformer layer. If v among different transformer layers are shared, the performance drops dramatically. This might be due to a failure of v to learn general information which can be adapted to each individual transformer layer.

4.6.2 L_0-norm regularization in AdapterBias

We observed that many of the trained parameters in L_α have values that are extremely close to zero after tuning on downstream tasks, which might cause redundancy of the parameters. To further encourage the sparsity of AdapterBias, we add L_0-norm regularization to L_α during the training stage.

Method	Params	CoLA	SST-2	MRPC	QNLI	RTE	STS-B	MNLI-m	MNLI-mm	QQP	Avg
Share v	56.1K	50.1	90.8	87.1	87.6	65.0	84.9	77.5	77.9	65.1	76.2
Share L_α	30.7K	50.4	91.9	**88.1**	89.1	65.4	85.2	79.8	79.9	66.6	77.4
Share v+L_α	22.3K	46.8	90.9	87.3	87.8	64.8	**85.7**	77.7	78.0	64.9	76.0
AdapterBias	64.5K	51.6	**93.1**	87.5	89.4	66.1	84.6	80.9	80.5	67.9	78.0

Table 4: Analysis of more parameter-efficiency methods in AdapterBias. The settings are the same as in Table 1. The backbone model is BERT-base. Share v, Share L_α, and Share v+L_α means that we share vector, linear layer, and both of them, respectively.

	Method	CoLA	SST-2	MRPC	QNLI	RTE	STS-B	MNLI-m	MNLI-mm	QQP	Avg
BB	Full-FT	52.1	93.5	88.9	90.5	66.4	85.8	84.6	83.4	71.2	79.6
BB	AdapterBias	51.6	93.1	87.5	89.4	66.1	84.6	80.9	80.5	67.9	78.0
BB	AdapterBias (L_0)	53.7	92.5	87.5	90.3	68.3	85.7	81.7	81.5	69.8	79.0
BL	Full-FT	60.5	94.9	89.3	92.7	70.1	87.6	86.7	85.9	72.1	82.2
BL	AdapterBias	60.0	94.4	88.2	91.2	70.5	87.5	84.3	83.9	70.5	81.2
BL	AdapterBias (L_0)	58.0	93.7	88.2	91.5	69.2	87.2	84.2	84.1	71.2	80.8

Table 5: Performance of our AdapterBias with L_0-norm regularization. Here we experiment with two models: BERT-base (BB), and BERT-large (BL). The settings are the same as in Table 1. The Full-FT represents fine-tuning the whole PLM without adding adapters.

In Table 5, we use BERT-base (BB) and BERT-large (BL) as the PLMs. We compare the performance of fine-tuning, the original AdapterBias, and the one trained with L_0-norm regularization. The experiment shows that adding L_0-norm regularization during the training step improves the performance on 7 out of 9 tasks in BERT-base models. However, the performance did not improve when applied to BERT-large models. As for the parameter efficiency of applying L_0-norm penalty, the linear layer (L_α) with L_0-norm penalty saves about 17% parameter on average compared to the original AdapterBias. The details of the reduced parameters of each task are shown in Appendix A.3.

4.7 What AdapterBias learns

AdapterBias has good interpretability due to its simplicity. Compared to the similar work BitFit (Ben Zaken et al., 2021), where the shifts are identical for all tokens, AdapterBias adds token-dependent shifts to the output representation. By observing these token-dependent shifts, we analyze what AdapterBias learns when adapting to downstream tasks.

4.7.1 Average representation shifting in transformer layers

In light of the works of Liu et al. (2019a); Tenney et al. (2019); Kovaleva et al. (2019), which show that different information is being encoded by different transformer layers of PLMs. We assume that AdapterBias provides different repre-

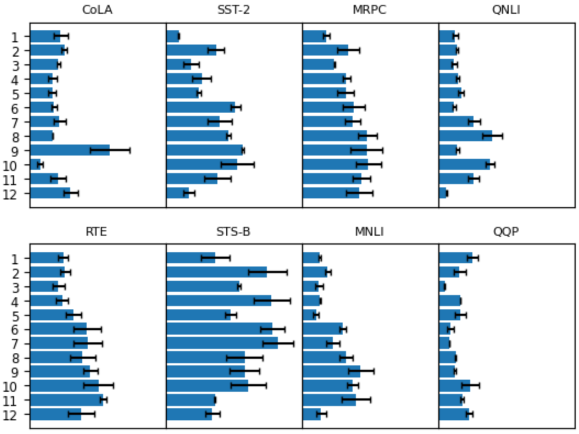

Figure 5: We analyze the average absolute value of weights vector α, the output of the linear layer (L_α), in each layer for different tasks. The y-axis represents the index of transformer layers, ordered from earlier to later (i.e. the embedding layer is shown at the top). The x-axis represents the average absolute value of α.

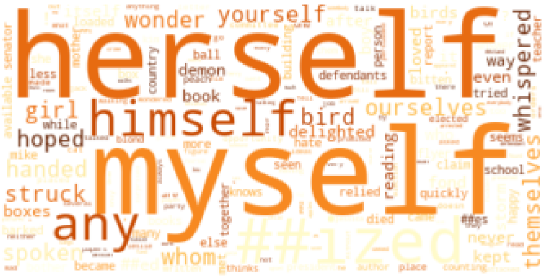

Figure 6: Word cloud of CoLA, a corpus of linguistic acceptability. We utilize BERT-base model as the PLM and words come from validation data. The weights of the words are the summation of their weights produced by the linear layer (L_α) in twelve transformer layers.

sentation shifts to the transformer layers through task-specific fine-tuning.

In AdapterBias, the linear layer (L_α) produces a weights vector α for representation shifts, therefore, the average absolute value of vector α can give us a look at the shifting amount in the transformer layers when adapting to downstream tasks. In Figure 5, the layers are ordered from lower to upper. From the experimental result, we find that the weight in each layer is considerably different in different tasks in general.

CoLA (Warstadt et al., 2019) is a syntactic task that consists of English acceptability judgments in the GLUE benchmark. As shown in Figure 5, its average shift at the ninth layer is the highest among all layers, which is quite different from the others. We speculate that the ninth layer has the ability to extract the syntactic information, leading AdapterBias to add the largest shift in this layer. Our experiment has a similar observation with the work of Jawahar et al. (2019). They observe on a syntactic task with BShift (Conneau et al., 2018) that the ninth layer of BERT embeds a rich hierarchy of syntactic information. (Jawahar et al., 2019)

Moreover, we observe similar distributions between specific tasks. For instance, RTE (Giampiccolo et al., 2007; Bentivogli et al., 2009) and MNLI (Williams et al., 2017), where both recognize textual entailment, have higher values in the upper layers than the lower ones.

Based on these findings, we find that AdapterBias assigns suitable representation shifts in different tasks. For tasks with similar objectives, AdapterBias tends to add similar representation shifts.

4.7.2 Which kind of word does L_α focus on

Since α_i represents the weight of the representation shift for i^{th} token in a transformer layer, we can observe the significance of i^{th} token from the summation of α_i in all the transformer layers. Special tokens, including [CLS], [SEP], and [PAD], are not included for analysis. We use the validation sets of CoLA and SST-2, and word cloud is used for visualizations.

In Figure 6, we visualize all words in the validation data of CoLA. The result shows that AdapterBias focuses more on reflexive pronouns, such as yourself, himself, and myself. This is because there are many incorrect sentences with misused reflexive pronouns, such as "He washed yourself."

In Figure 7, we visualize all words in the validation data of SST-2. The result shows that AdapterBias focuses more on adjectives, such as "bad", "awful", and "worst". SST-2 is a binary sentiment analysis dataset, which classifies movie reviews into positive and negative classes. AdapterBias learns that adjectives often constitute a crucial factor in sentiment analysis during tuning, and adds larger shifts to these adjective tokens.

Figure 7: Word cloud of SST-2, a corpus of movie reviews categorized in two sentimental classes (i.e. positive, negative). The visualization approach is the same as in Figure 6.

5 Conclusion

In this study, we present AdapterBias. By adding token-dependent representation shifts to the PLM, AdapterBias shows competitive results even though it uses far fewer parameters than the existing methods. Through extensive experiments, not only does AdapterBias reach competitive results on the GLUE benchmark, but also obtain good performance on small-to-medium datasets. In addition, we demonstrate the robustness of AdapterBias to different PLMs. Finally, we provide analysis on what AdapterBias learns by comparing α, the weights of representation shift for different tokens, finding AdapterBias has the ability to identify task-specific information. Our study is different from the previous architectures of adapters by proposing a simple adapter that can produce suitable representation shifts for different tokens.

A Appendix

A.1 Training Details

We train our model on Pytorch. The training details are shown in Table A. In addition, the bottleneck of Adapters (Houlsby et al., 2019) and is 32.

A.2 L_0-norm regularization in AdapterBias

In Table B, we report the remaining parameters of utilizing L_0-norm regularization compared with the original AdapterBias. BERT-base (BB) and BERT-large (BL) are used as PLMs.

A.3 The direction of representation shifts in different tasks

Different from BitFit (Ben Zaken et al., 2021), where all the representation shifts are identical within one task, AdapterBias produces different weights for the shift based on each token. In this section, we compare the transformed tokens in AdapterBias and BitFit. We utilize PCA (Jolliffe, 2002) to reduce the dimension of the vectors. In Figure A, we input five sentences from the evaluation set of SST-2. We experiment on the last transformer layer since it has the most obvious shifts compared to the previous layers. '0' with lighter color indicates the representation before shifting, which is the output of the first layer normalization. '1' with darker color is the shifted representation, which is the output of the second layer normalization. The color red represents positive sentences, and blue are the negative ones.

The result shows that BitFit shifts all tokens towards the same direction regardless of the ground-truth label. On the other hand, AdapterBias discerns the label of the sentences and thus shifts the tokens of different sentences toward different directions.

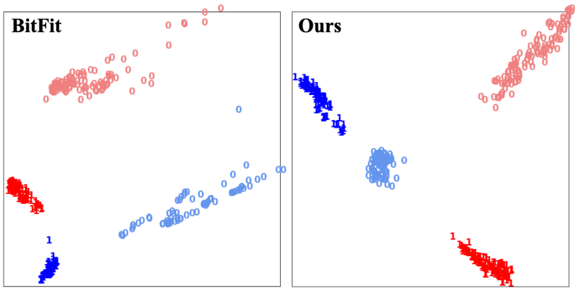

Figure A: We utilize PCA (Jolliffe, 2002) to visualize the shifting difference between Bitfit (Ben Zaken et al., 2021) and AdapterBias on SST-2 validation set. '0' with light color means the embedding before shifting. '1' with dark color means the embedding after shifting. The color red represents positive sentences, and blue represents negative sentences.

Abstract

Diverse NMT aims at generating multiple diverse yet faithful translations given a source sentence. In this paper, we investigate a common shortcoming in existing diverse NMT studies: the model is usually trained with single reference, while expected to generate multiple candidate translations in inference. The discrepancy between training and inference enlarges the confidence variance and quality gap among candidate translations and thus hinders model performance. To deal with this defect, we propose a multi-candidate optimization framework for diverse NMT. Specifically, we define assessments to score the diversity and the quality of candidate translations during training, and optimize the diverse NMT model with two strategies based on reinforcement learning, namely hard constrained training and soft constrained training. We conduct experiments on NIST Chinese-English and WMT14 English-German translation tasks. The results illustrate that our framework is transparent to basic diverse NMT models, and universally makes better trade-off between diversity and quality. Our source code is available at `https://github.com/DeepLearnXMU/MultiCanOptim`.

1 Introduction

Recently, neural machine translation (NMT) has achieved impressive progress in improving translation quality (Sutskever et al., 2014; Luong et al., 2015; Vaswani et al., 2017). Despite the remarkable success, NMT models still suffer from lacking translation diversity, which is essential due to the following reasons. First, similar to natural language, variability and expressiveness are the core features of translations. Second, only focusing on increasing translation accuracy during training will bias the NMT model to common phrases, exacerbating data sparsity (Khayrallah et al., 2020). In conclusion, improving translation diversity is a promising direction in NMT community.

To achieve diverse NMT, several studies have explored various training or decoding strategies, including: 1) constraining decoding with diversity regularization (Li et al., 2016; Vijayakumar et al., 2018), 2) sampling from the mixture of models (Shen et al., 2019; Wu et al., 2020), and 3) conditioning decoding with diverse signals (Shu et al., 2019; Sun et al., 2020). However, all these approaches train models on single-reference corpus, while expecting them to generate multiple candidate translations during inference. We argue that such discrepancy between training and inference prevents the models from learning one-to-many relations efficiently. Firstly, since the predictions of NMT models are encouraged to fit the one-hot distribution of single-reference corpus, the model confidence of generating Top1 candidate translations will be much larger than that of the rest candidates, limiting translation diversity. Secondly, only one reference is used to get optimization signal at the training time, resulting in significant quality drops of Top2-Top$K$ translations. One direct way addressing these issues is to train the models using multi-reference training data. Nevertheless, its construction is quite expensive and thus impractical.

To overcome the above issues, in this paper, we propose a novel multi-candidate optimization framework for diverse NMT. The basic idea is to guide an NMT model to learn diverse translation from its candidate translations based on reinforcement learning (RL). During training, the model generates multiple candidate translations, of which rewards are quantified according to their diversity and quality. Since directly optimizing model parameters with the above two rewards involves backpropagating through discrete decoding decision, we explore two specific methods to train the diverse NMT model: 1) *Hard constrained training*. We transform the rewards to discrete scalars, prevent-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2622 - 2632
July 10-15, 2022

ing the model from learning those candidate translations with low rewards. 2) *Soft constrained training*. We introduce minimum risk training (MRT) to minimize the risks of obtaining diversity and quality rewards. Compared with previous works, our proposed framework reduces the confidence variance among candidate translations and improves the quality of Top2-Top$K$ translations during inference, achieving better performance in terms of both diversity and quality. Overall, the major contributions of our work are three-fold:

- We point out and empirically verify that the discrepancy between training and inference in diverse NMT negatively impacts the translation diversity and quality.
- We propose a novel multi-candidate optimization framework based on RL, enabling an NMT model to learn one-to-many relations from its candidate translations. Our framework is transparent to model architecture, thereby can be employed individually or complemented to existing diverse NMT models.
- Extensive experimental results on NIST Chinese-English and WMT14 English-German datasets show that our framework can efficiently smooth the confidence distribution and raise the quality of Top2-Top$K$ candidate translations, surpassing several commonly-used diverse NMT models.

2 Related Work

Diverse NMT. Improving translation diversity has been a hot topic in NMT community in recent years, such as lattice-based NMT (Su et al., 2017; Tan et al., 2018) and personalized NMT (Michel and Neubig, 2018; Lin et al., 2021). Existing works for diverse NMT can be categorized into three major categories. The first category produces diverse translations by applying diversity regularization to decoding algorithm (Li et al., 2016; Vijayakumar et al., 2018). The second category improves translation diversity by sampling from a mixture of models. In this aspect, Shen et al. (2019) adopt conditional mixture models to control the generation of translations. Wu et al. (2020) derive a large number of models with Bayesian modeling, which are sampled to generate diverse translations. Unlike the former two categories, the third one attempts to condition the decoding procedure with diverse signals. Typically, Shu et al. (2019) use syntactic codes to condition translation process. Further, Lachaux et al. (2020) replace the syntactic codes with latent domain variables derived from target sentences, which is more computationally efficient. Sun et al. (2020) sample the encoder-decoder attention heads of Transformer to affect source word selection. Despite their successes, an obstacle of these approaches lies in the discrepancy between training and inference, that is, learning diverse translations from a single-reference corpus. This enlarges the confidence and quality gaps among candidate translations, limiting the potential of diverse NMT models.

Multi-Candidate Optimization in Natural Language Generation. Since single-reference corpus is insufficient to model one-to-many relations in natural language generation (NLG), researchers have introduced multi-candidate optimization to NLG tasks such as image captioning and paraphrasing. Most of representative works among them generate pseudo training references and focus on improving diversity (Zheng et al., 2018; Hou et al., 2018; Gao et al., 2020). Conversely, in NMT community, previous studies on multi-candidate optimization mainly aim at improving low-resource translation quality rather than diversity, which is similar to other data augmentation methods in NMT, such as back-translation and forward-translation (Sennrich et al., 2016; Edunov et al., 2018a; Cheng et al., 2020; Wan et al., 2020). For example, Khayrallah et al. (2020) improve the translation quality of low-resource language pairs by sampling paraphrases of the reference sentence. Different from these tasks, diverse NMT is more challenging since it requires the generation results to be accurate as well as diverse. For better balancing quality and diversity, we propose a novel multi-candidate optimization framework with RL.

Reinforcement Learning in NMT. Reinforcement learning (RL) has become an appealing path for advancement in NMT, as it firstly allows to optimize non-differentiable objectives, and secondly reduces exposure bias in auto-regressive sequence generators. To this end, various methods have been proposed. In Ranzato et al. (2016), Wu et al. (2017) and Edunov et al. (2018b), the authors employ the REINFORCE algorithm to optimize models with metric-based reward (i.e. senetnce-level BLEU). Different from them, He et al. (2016) propose to train two reverse NMT models through a dual-learning mechanism. And Bahdanau et al. (2017)

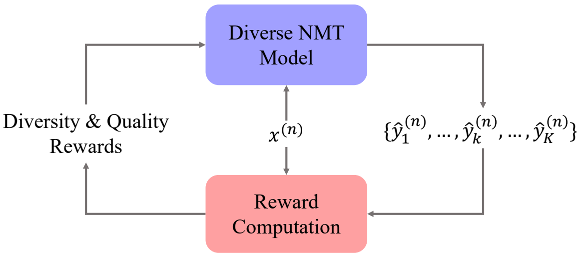

Figure 1: Our multi-candidate optimization framework: the diverse NMT model generates K candidate translations to receive individual diversity and quality rewards, which are then used for model optimization.

use actor-critic method that predicts the reward by a critic network. In this work, we follow Shen et al. (2016), Wieting et al. (2019) and Wang and Sennrich (2020) that adopt minimum risk training (MRT) to minimize the reward during training. To the best of our knowledge, our work is the first attempt employing RL to model one-to-many relations for diverse NMT.

3 Multi-Candidate Optimization Framework

As a significant extension of conventional NMT, given a source sentence, a diverse NMT model aims at producing a set of different candidate translations. Similar to conventional NMT, the most commonly-used training strategy of diverse NMT is to minimize the training objective based on maximum likelihood estimation (MLE):

$$\mathcal{L}_{mle}(\theta) = -\sum_{n=1}^{N} \log P_\theta(y^{(n)}|x^{(n)}), \qquad (1)$$

where $(x^{(n)}, y^{(n)})$ is the n-th instance in the training corpus of size N, and $P_\theta(y^{(n)}|x^{(n)})$ denotes the translation model with parameters θ. It can be said that the one-to-many relations are the basis of diverse NMT. However, as mentioned above, the model is unable to effectively learn such relations from a single-reference training corpus. Accordingly, the discrepancy between training and inference has become a bottleneck limiting the performance of diverse NMT models.

To deal with the above issue, we propose a multi-candidate optimization framework based on reinforcement learning (RL). As shown in Figure 1, a diverse NMT model generates K candidate translations using its original method as additional references during training. Particularly, given a source sentence $x^{(n)}$, the model picks an action each time it generates a candidate translation $y_k^{(n)}$. Diversity and quality rewards of $y_k^{(n)}$ are observed once it is completed, which are then used to optimize model parameters. Please note that our framework is model-irrelevant and thus can be compatible with any diverse NMT model. Next, we will introduce the reward computation and training procedure in following subsections.

3.1 Reward Computation

Conventional RL in NMT usually takes sentence-level BLEU (Papineni et al., 2002) as reward. However, in diverse NMT, ideal translations should be semantically equal to their source sentences, as well as diverse from each other. To this end, we exploit two highly generic evaluation metrics to encourage the diversity and quality of candidate translations:

Diversity Reward. This reward measures the difference between each candidate translation $\hat{y}_k^{(n)}$ and other translations, including the original reference $y^{(n)}$ and the rest candidate translations $\{\hat{y}_{k'}^{(n)}\}_{k'=1,k'\neq k}^{K}$. We can model the difference with arbitrary method such as Jaccard distance (Jaccard, 1901), edit distance (Levenshtein et al., 1966) or BLEU (Papineni et al., 2002). Here, we serve BLEU as the similarity assessment since it is less sensitive to sentence length. Formally, the diversity reward of $\hat{y}_k^{(n)}$ is defined as follows:

$$\mathrm{DR}(\hat{y}_k^{(n)}) = 1 - \mathrm{BLEU}_{\mathrm{s}}\left(\hat{y}_k^{(n)}, \{y^{(n)}\} \cup \{\hat{y}_{k'}^{(n)}\}_{k'=1,k'\neq k}^{K}\right), \qquad (2)$$

where $\mathrm{BLEU}_{\mathrm{s}}(*)$ indicates sentence-level BLEU[1].

Quality Reward. One common approach to evaluate the quality of each candidate translation is to compare it with the corresponding reference. However, such a method biases the model to candidate translations syntactically similar to original references, therefore harms translation diversity. In order to tackle this problem, it is better to use semantic evaluation metrics such as reconstruction-BLEU (He et al., 2016), COMET (Rei et al., 2020), BLEURT (Sellam et al., 2020), UniTE (Wan et al., 2022) and so on. Here, we choose reconstruction-BLEU, which uses a reverse NMT model trained on initial single-reference corpus to translate each candidate $\hat{y}_k^{(n)}$ back to a source sentence $\hat{x}_k^{(n)}$, and

---

[1] We calculate sentence-level BLEU with SacreBLEU in `https://github.com/mjpost/sacrebleu`

then evaluates the BLEU score between $\hat{x}_k^{(n)}$ and $x^{(n)}$:

$$\mathrm{QR}(\hat{y}_k^{(n)}) = \mathrm{BLEU_s}\left(\hat{x}_k^{(n)}, x^{(n)}\right). \tag{3}$$

Compared with COMET and BLEURT that pretrained using out-of-domain data, the reconstruction model in our metric is trained on the same corpus as NMT model, thereby reducing the impact of domain inconsistency on evaluation accuracy.

3.2 Model Training

The calculations of diversity and quality rewards involve undifferentiated discrete operations, leading to a challenge in the back-propagation at training time. To address this issue, we explore two approaches, separately termed as *hard constrained training* and *soft constrained training*.

Hard Constrained Training (HCT). An intuitive idea is utilizing translations only with high diversity and quality rewards. Along with this strategy, we pair $x^{(n)}$ with its candidate translations $\{\hat{y}_k\}_{k=1}^K$ and original reference $y^{(n)}$ to form a new multi-reference training instance, then optimize the model with MLE objective:

$$\begin{aligned}\mathcal{L}_{hct}(\theta) = & \sum_{n=1}^{N} \log P_\theta(y^{(n)}|x^{(n)}) \\ & + \sum_{n=1}^{N}\sum_{k=1}^{K} \alpha_k \cdot \log P_\theta(\hat{y}_k^{(n)}|x^{(n)}),\end{aligned} \tag{4}$$

where

$$\alpha_k = \begin{cases} 0 & \mathrm{DR}(\hat{y}_k^{(n)}) < \delta_d \text{ or } \mathrm{QR}(\hat{y}_k^{(n)}) < \delta_q \\ 1 & \text{else.} \end{cases}$$

Here, α_k is used to re-weight the training objective of candidate translations. δ_d and δ_q indicate corpus-level diversity and quality rewards of the initial model (i.e. a pre-trained diverse NMT model) on development set, respectively. Hard constrained training is easy to implement. However, the candidate translations are still far from utilization. First, all candidate translations are treated equally although they possess different diversity and quality. Second, some candidate translations are totally discarded although they may provide guidance for the model training.

Soft Constrained Training (SCT). To fully utilize all candidate translations, we employ MRT to directly optimize diversity and quality rewards. We choose MRT since it does not require extra parameters compared with other RL techniques (He et al., 2016; Bahdanau et al., 2017). Similar to hard constrained training, a multi-reference training instance consists of each original source sentence and all its candidate translations. Specifically, we define the losses of diversity and quality rewards as $1 - \mathrm{DR}(\hat{y}_k^{(n)})$ and $1 - \mathrm{QR}(\hat{y}_k^{(n)})$, respectively. Please refer to Equations 2 and 3 for definitions of $\mathrm{DR}(*)$ and $\mathrm{QR}(*)$. We then apply these two losses to softly weight the posterior distribution $P_\theta(\hat{y}_k^{(n)}|x^{(n)})$. The goal is to minimize two risks:

$$\mathcal{R}_d(\theta) = \sum_{n=1}^{N}\sum_{k=1}^{K} P_\theta(\hat{y}_k^{(n)}|x^{(n)}) \cdot (1 - \mathrm{DR}(\hat{y}_k^{(n)})), \tag{5}$$

$$\mathcal{R}_q(\theta) = \sum_{n=1}^{N}\sum_{k=1}^{K} P_\theta(\hat{y}_k^{(n)}|x^{(n)}) \cdot (1 - \mathrm{QR}(\hat{y}_k^{(n)})). \tag{6}$$

Completely different to MLE (Equation 1) that aims at reducing the discrepancy between a candidate translation and its single reference, MRT encourages the model to maximize rewards via generating more diverse and accurate translations. Following Wieting et al. (2019), we first pre-train the diverse NMT model with $\mathcal{L}_{mle}(\theta)$, and then fine-tune it with the combination of $\mathcal{L}_{mle}(\theta)$, $\mathcal{R}_d(\theta)$ and $\mathcal{R}_q(\theta)$:[2]

$$\mathcal{L}_{sct}(\theta) = \mathcal{L}_{mle}(\theta) + \mathcal{R}_d(\theta) + \mathcal{R}_q(\theta). \tag{7}$$

Consequently, soft constrained training possesses two advantages comparing with its hard counterpart: 1) It provides more guidance for model training by exploiting all candidate translations; 2) It directly incorporates the diversity and quality rewards into training objective, thereby distinguishing different effects of candidate translations.

4 Experiments

In this section, we carry out several groups of experiments to investigate the effectiveness of our proposed framework on Chinese-English and English-German translation tasks.

---

[2] We have also tried weighted sum of three terms. Results shows no significant difference with the non-weighted version.

4.1 Setup

In order to make comparison with existing diverse NMT models (Li et al., 2016; Vijayakumar et al., 2018; Shen et al., 2019; Sun et al., 2020), we build multi-reference corpus and examine our framework on translation tasks commonly used in previous diverse NMT studies:

- **NIST Chinese-to-English.** This training set contains about 1.34M news sentence pairs.[3] We use MT03 as development set and MT04, MT05, MT06 as test sets, and report the average scores on test sets as final results.
- **WMT14 English-German.** This training data consists of 4.5M sentence pairs[4]. We use the newstest 2013 as the development set, and the newstest 2014 as the test set.

For the above two datasets, We adopt Moses tokenizer (Koehn et al., 2007) to deal with English and German sentences, and segment the Chinese sentences with the Stanford Segmentor[5]. Following common practices, we employ byte pair encoding (Sennrich et al., 2015) with 32K merge operations to segment words into subword units. We use a joint dictionary for English-German translation task while assigning individual vocabularies for Chinese-English translation task. In addition, we remove the examples in datasets where the length of source or target sentence exceeds 100 words.

We develop all diverse NMT models on Transformer-base (Vaswani et al., 2017)[6]. At the pre-training stage, we set the batch size as 32,768 tokens for NIST and 12,500 tokens for WMT14. Other configurations are identical to common settings in previous studies (Vaswani et al., 2017; Shu et al., 2019; Sun et al., 2020). During fine-tuning, we keep other settings consistent with the pre-training stage, but reduce the learning rate by a factor of 10. Using early-stopping strategy, we evaluate the model every 500 steps and stop training if the translation diversity or quality on development set does not raise for 10 consecutive evaluations. Considering computational efficiency, we set K as 3 in all our experiments as default.

4.2 Evaluation

We use the following three metrics to assess the quality and diversity of candidate translation sets.

- **BLEU.** Following previous studies (Shen et al., 2019; Wu et al., 2020; Sun et al., 2020), we use average BLEU of K candidate translation sets to evaluate translation quality.
- **COMET.** It is based on pre-trained language model and has shown higher correlations with human judgements in a variety of metrics tasks (Mathur et al., 2020b). We adopt it since n-gram-based metrics may fail to robustly match paraphrases and capture distant dependencies, resulting in a diverse translation with high faithfulness and fluency but a low BLEU score (Smith et al., 2016; Mathur et al., 2020a). Similar to BLEU, we report the average COMET score of K candidate translation sets as default. Particularly, we normalize the results of COMET with sigmoid function.
- **divBLEU.** We define divBLEU to measure the differences among K candidate translations on a test set of size S:

$$1-\mathrm{BLEU_c}(\{\hat{y}_k^{(s)}\}_{s=1}^{S},\{\hat{y}_{k'}^{(s)}\}),$$

where $1 \leq k \leq K, 1 \leq k' \leq K, k \neq k'$. The second term denotes pairwise-BLEU (Shen et al., 2019; Wu et al., 2020; Sun et al., 2020) that compares each candidate translation set with each other.

All BLEU metrics used in this paper are case-sensitive. Concretely, corpus-level BLEU is calculated with Moses script[7]. To raise the reliability, we run all models three times with different random seeds and report the average results.

4.3 Baselines

We apply our framework to the following models:

- **Transformer** (Vaswani et al., 2017) refers to the baseline. We pick its Top$K$ hypotheses in beam search as the diverse translations.
- **Tree2Code** (Shu et al., 2019) generates diverse candidates with various syntactic codes.
- **Head Sampling** (Sun et al., 2020) generates different words by sampling attention heads.

We also display the reported results of several dominant diverse NMT models on the same datasets: **Diverse Decoding** (Li et al., 2016) employing diversity regularization terms to encourage translation

Table 1: Main results on NIST Chinese-English (average scores of MT04, MT05 and MT06) and WMT14 English-German tasks. "HCT" and "SCT" individually indicate hard constrained training and soft constrained training. "BLEU" and "COMET" denote translation quality assessed by the n-gram-based and the model-based metrics, respectively. "divBLEU" indicates the diversity among candidates. We also calculate p-value with bootstrap sampling (Koehn, 2004) to estimate statistical significance. ‡/†: significantly better than corresponding basic models ($p < 0.01/0.05$). All results are derived from 3 independent runs.

diversity during beam search; **Diverse Beam** (Vijayakumar et al., 2018) that improves the method of Li et al. (2016) by grouping the outputs; **Hard-MOE** (Shen et al., 2019) utilizing a mixture model, where different translations are obtained by controlling hidden states; **Multinominal Sampling** (Sun et al., 2020) that randomly selects words at each timestep to form diverse translations.

4.4 Main Results

Table 1 shows the main results. Obviously, all basic models equipped with multi-candidate optimization achieve higher diversity while preserving semantic quality of translations, including conventional NMT model (Transformer) and diverse NMT models (Head Sampling and Tree2Code), showing universal effectiveness of the proposed framework. We further draw several conclusions:

1) The higher diversity among translations, the lower BLEU score they obtain, which is consistent with prior findings (Shen et al., 2019; Wu et al., 2020; Sun et al., 2020). The main reason is that the n-gram-based metric (BLEU) fails to accurately evaluate the quality of translations that syntactically differ from their references. The model-based metric (COMET) shows that our framework yields comparable translation quality compared with corresponding basic models. More discussions about the correlation between these two automatic metrics and human evaluation are given in Section 4.6.

2) Soft constrained training exhibits better performance than hard constrained training on three basic models. The underlying reason is that soft constrained training can fully utilize candidate translations to optimize models.

3) The improvement of Transformer is smaller than that of Head Sampling and Tree2Code. We attribute this to the relatively less diversity of references generated by conventional NMT model, which limits the effects of our framework.

4.5 Ablation Study

To investigate the effectiveness of different components in our framework, we further compare hard constrained training and soft constrained training with their several variants upon our best basic model Tree2Code on Chinese-English translation task, as concluded in Table 2:

1) Directly fine-tuning models on the whole multi-reference training set (Tree2Code+HCT without DR and QR) benefits translation quality while significantly harms its diversity, suggesting the importance of two rewards.

2) Using only the diversity reward (HCT_d and

Model	DR	QR	BLEU (Top1)	BLEU	COMET	div-BLEU
Tree2Code	✗	✗	44.97	42.99	56.79	35.09
+HCT	✗	✗	45.14	43.10	57.05	33.80
	✓	✗	44.50	42.16	56.40	37.23
	✗	✓	44.72	43.38	56.98	34.88
	✓	✓	44.31	42.52	56.88	37.72
+SCT	✓	✗	44.57	41.87	56.63	38.95

	✓	CM	43.98	41.67	56.16	38.64
	✓	✓	44.17	42.22	56.76	38.93

Table 2: Ablation study examined on the Chinese-English translation task. "HCT" and "SCT" individually represent hard constrained training and soft constrained training. "DR" and "QR" denote diversity and quality rewards, respectively. "ED": using edit distance as diversity reward; "CM": using COMET as quality reward.

SCT$_d$) significantly increases divBLEU while decreases BLEU and COMET. We speculate that candidate translations with high diversity but low quality lead to this phenomenon.

3) On the contrary, when we only consider the quality reward (HCT$_q$ and SCT$_q$), the results show high COMET but limited improvements on divBLEU. This is because candidate translations are semantically closer to references under current setting, which may harm the diversity of multi-reference pseudo corpus.

4) Jointly considering both diversity and quality (HCT and SCT) makes a better trade-off between translation diversity and quality, suggesting that both rewards are essential for diverse NMT.

5) When replacing BLEU with edit distance to define diversity reward, we observe the diversity drop of translations (SCT (ED) v.s. SCT). Meanwhile, changing reconstruction-BLEU to COMET also harms the translation quality (SCT (CM) v.s. SCT). All these confirm the advantages of our proposed two rewards.

6) We additionally report the BLEU score of Top1 candidate translation set (BLEU (Top1)). Interestingly, BLEU fluctuates more than BLEU (Top1) among different variants, which gives us a hint that the superiority of our frameworks lies in the translation on Top2-Top$K$ variants. We will further explore this problem in Section 4.6.

4.6 Analyses

Furthermore, we propose several hypotheses and experimental analyses for deeper insights to diverse NMT task, therefore explain why and how our framework benefits the model performance. Specifically, we choose to analyze Transformer, Tree2Code and Tree2Code+SCT on Chinese-English translation task.

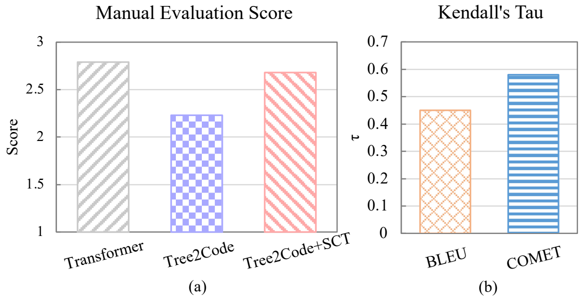

Figure 2: Manual Evaluation Results. (a) Basic model equipped with our framework (Tree2Code+SCT) achieves comparable manual evaluation score with conventional NMT model (Transformer). (b) COMET has higher correlation with manual evaluation considering Kendall's Tau coefficient (Kendall, 1938).

Hypothesis 1 *Model-based metric COMET is more suitable for quality evaluation of diverse translations than n-gram-based metric BLEU.*

Analysis Intuitively, the improvement of translation diversity may cause more mismatched n-grams between hypotheses and references, leading to a drop in n-gram-based metrics, i.e. BLEU. In order to make the evaluation more convincing, we conduct human evaluation on the translation results. Specifically, we randomly sample 300 source sentences from MT04-06 sets, and then use three models to generate diverse translations as human-evaluated cases. Next, three linguistic experts are asked to score (0-5) these translations according to the fluency and the accuracy. Each sentence is evaluated by two experts independently, and will be further reviewed by another expert if the disagreement of the former two experts exceeds 3. From Figure 2 (a), we can observe that Tree2Code+SCT gets higher manual evaluation scores than its basic model (Tree2Code), and yields comparable translation quality to the Transformer baseline.[8]

Furthermore, we employ the Kendall's Tau coefficient τ (Kendall, 1938) to quantify the correlation between automatic evaluation and manual evaluation, which is calculated over all the human-evaluated cases and defined as

$$\tau = \frac{2}{m(m-1)}(|C| - |D|). \qquad (8)$$

---

[8] More details of manual evaluations are in Appendix A.

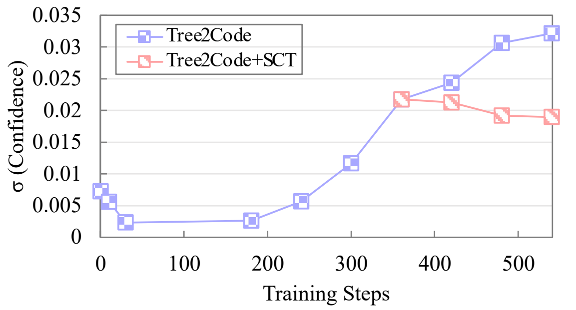

Figure 3: The confidence variances among Top$K$ hypothesis translations at different training steps.

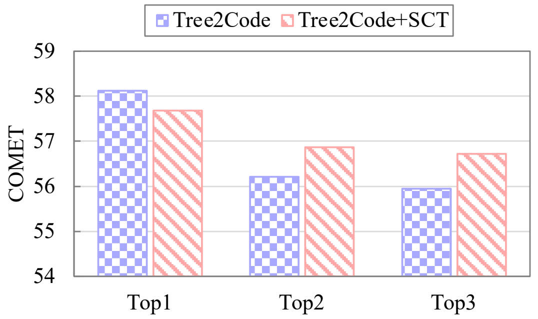

Figure 4: The COMET scores of Top$K$ hypothesis generated by Tree2Code and Tree2Code+SCT.

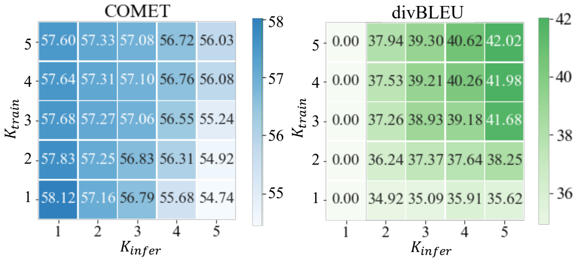

Figure 5: The COMET and divBLEU scores under different settings of K_{train}/K_{infer}. K_{train} represents the reference number during training, while K_{infer} indicates the candidate translation number during inference.

Here, m is the number of human-evaluated cases, $|C|$ is the number of times a metric assigns a higher score to the "better" hypothesis and $|D|$ is the number of times a metric assigns a higher score to the "worse" hypothesis. As illustrated in Figure 2 (b), we find that the τ is 0.45 for BLEU and 0.58 for COMET, indicating the latter one is more suitable for evaluating translation quality of diverse NMT models than the former one.

Hypothesis 2 *Multi-candidate optimization improve translation diversity by reducing the confidence variance among candidate translations.*

Analysis We serve the predicted translation probability as the confidence of each candidate translation (Nguyen and O'Connor, 2015; Wang et al., 2019), and draw the confidence variance of Top$K$ translations during training in Figure 3. When training on a single-reference corpus (Tree2Code), the confidence variance of Top$K$ translations shows an upward trend as the pre-training step grows. Then, it will keep growing if we fine-tune the diverse NMT model with original training strategy, while starting to decline if using our training strategy. This proves that single-reference training encourages the model to fit the one-hot translation. On the contrary, multi-candidate optimization can reduce the confidence variance, and thus offer NMT model more opportunities to generate diverse translations.

Hypothesis 3 *Multi-candidate optimization improves the quality of Top2-Top$K$ translations.*

Analysis We measure the quality of Top$K$ candidate translations using COMET and manual evaluation, respectively. As shown in Figure 4, there exist large quality gaps between Top1 and the rest translations. However, after introducing our framework, the COMET and manual evaluation scores of Top2-Top$K$ translations are improved. This shows that multi-candidate optimization can provide effective guidance for Top2-Top$K$ candidate translations, thus improving overall quality. [9]

Hypothesis 4 *More references during training leads to better overall performance.*

Analysis We explore different combinations of reference number for training and candidates translation number for inference on Tree2Code+SCT. as illustrated in Figure 5, each row (K_{train}) and column (K_{infer}) represents the number of generated references for training and the candidate translation number during inference, respectively. We have several interesting observations:

As for the quality, the COMET scores in upper left triangle ($K_{train} \geq K_{infer}$) are higher than those in lower right triangle ($K_{train} \leq K_{infer}$). This suggests that references for training should be more than candidates generated during inference for sufficient guidance. As for the diversity, it is obvious that the divBLEU scores in the upper right triangle are also higher than those in the lower left triangle. That is, divBLEU raises as K_{infer}

---

[9] From another point of view, the existing optimization on mini-batch is a local fit to single-reference training data, while multi-candidate optimization narrows such quality gap by affecting the distribution of training data.

and K_{train} grow. However, the improvements of diversity gradually become marginal.

5 Case Study

From Figure 6, we can see that there are only some simple substitutions (highlighted in blue) in Transformer's results. Tree2Code generates more diverse translations, while containing more mis-translation and under-translation problems (highlighted in red). After applying our framework, Tree2Code+SCT generates better translations in terms of both diversity and quality.

6 Conclusion

In this paper, we first point out that the widely used single-reference training is not the preferred solution for diverse NMT. It causes discrepancy between training and inference, and prevents the model from learning one-to-many mapping relationships. Consequently, we propose a novel multi-candidate optimization framework which is model-irrelevant and can be compatible with any diverse NMT model. Empirical results suggest that: 1) Multi-candidate optimization is an universally effective manner on boosting the performance of diverse NMT; 2) Model-based metrics can better reflect the translation quality than its n-gram-based counterpart under diverse NMT context; 3) Multi-candidate optimization offers NMT abilities to reduce the confidence variance and improve the translation quality of candidate translations.

A Manual Evaluation Details

A.1 Score Definition

We define the quality in manual evaluation as follows: **1 - Totally incomprehensible.** The content is confused and most of the target is left untranslated or unintelligible. **2 - Bad.** Only a small part of target sentence can be understood, specific details are unintelligible, target is very poor in terms of readability or fluency. **3 - Neither good nor bad.** Translation has notable fluency and readability issues, but it is understandable overall. **4 - Good.** It is grammatically correct, but could be better in terms of style and readability. **5 - Very good.** It equals quality of human translation. Only a few minor issues (like capitalization), that don't affect the readability of the target, are allowed.

A.2 Results of Top$K$ Hypotheses

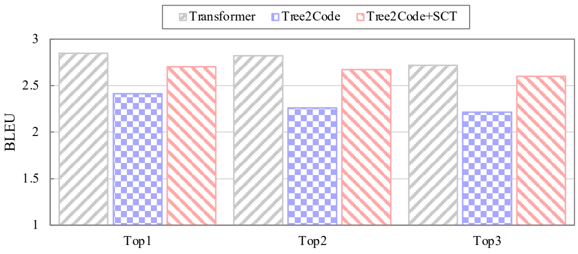

Figure 7: Manual scores of Top$K$ hypotheses.

As illustrated in Figure 7, our framework (Tree2Code+SCT) leads to higher manual scores than basic model (Tree2Code) in terms of Top1-Top$K$ hypotheses, which is consistent with the overall results in Figure 2 (a).

Learning from Bootstrapping and Stepwise Reinforcement Reward: A Semi-Supervised Framework for Text Style Transfer

Zhengyuan Liu, Nancy F. Chen
Institute for Infocomm Research, A*STAR, Singapore
`{liu_zhengyuan,nfychen}@i2r.a-star.edu.sg`

Abstract

Text style transfer is an important task in controllable language generation. Supervised approaches have pushed performance improvement on style-oriented rewriting such as formality conversion. However, challenges remain due to the scarcity of large-scale parallel data in many domains. While unsupervised approaches do not rely on annotated sentence pairs for each style, they are often plagued with instability issues such as mode collapse or quality degradation. To take advantage of both supervised and unsupervised paradigms and tackle the challenges, in this work, we propose a semi-supervised framework for text style transfer. First, the learning process is bootstrapped with supervision guided by automatically constructed pseudo-parallel pairs using lexical and semantic-based methods. Then the model learns from unlabeled data via reinforcement rewards. Specifically, we propose to improve the sequence-to-sequence policy gradient via stepwise reward optimization, providing fine-grained learning signals and stabilizing the reinforced learning process. Experimental results show that the proposed approach achieves state-of-the-art performance on multiple datasets, and produces effective generation with as minimal as 10% of training data.

1 Introduction

Text style transfer is a task in natural language generation, which aims to automatically control certain attributes during sentence paraphrasing, such as formality, sentiment, and humor (Rao and Tetreault, 2018; Li et al., 2018). Style transfer has many practical applications, such as altering emotions of spoken utterances, removing biases in transcripts, and conveying politeness in messages (Hovy, 1987). The key for a successful rewrite is to preserve the semantic content of the source sentence, while transforming it to a particular target style without sacrificing fluency and grammatical accuracy. Therefore, the performance of style transfer models is commonly assessed on both style accuracy and content preservation. When large-scale annotated sentence pairs are available, training neural sequence-to-sequence models via supervised learning shows impressive generation quality (Rao and Tetreault, 2018; Lai et al., 2021). However, in many use cases, it is unfeasible to adopt supervised approaches because parallel samples are unavailable. To address data insufficiency bottlenecks, various unsupervised approaches have been proposed for text style transfer, including learning disentangled representations of style and content (Shen et al., 2017) and adopting pairwise back-translation (Prabhumoye et al., 2018). Recently, reinforcement learning (RL) is introduced to develop unsupervised models such that rewards of content preservation and style conversion are used to optimize sequence generation (Luo et al., 2019; Gong et al., 2019). However, RL-based methods are often challenging to train in practice. For instance, the rewards have high variance during early stages when learning from scratch, which affects the training stability; and they cannot provide fine-grained learning signals as traditional token-level maximum likelihood estimation, since they are often calculated on the entire generated sequence (de Masson d'Autume et al., 2019). As a result, models are prone to mode collapse and often fail to produce acceptable generations in reality.

Herein, we propose a semi-supervised framework for text style transfer, and optimize it on training stability and signal fineness. Our semi-supervised model uses a small amount of parallel data for supervised learning, and gets further improvement by learning from a large amount of unlabeled data. In contrast to prior work that often relies on human-annotated parallel pairs like (Chawla and Yang, 2020), the approach we propose bootstraps the training process with automatically constructed pseudo parallel data. Two pseudo pair

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2633 - 2648
July 10-15, 2022

matching methods are investigated: a lexical-based strategy, which is straightforward by calculating the token-level overlap; and a semantic-based strategy, which uses semantic similarity as criteria and would have better general potential.

Furthermore, to obtain fine-grained signals for the RL-based sequence-to-sequence training process, we propose a stepwise reward re-weighting strategy. This is inspired by the observation that the style transfer weights are not uniform across tokens/spans in the source sentence: some tokens weigh more during attribute-guided text style transfer (Li et al., 2018). Therefore, instead of using the reward (e.g., style strength scores) calculated from the entire generated sentence (Luo et al., 2019; Lai et al., 2021), we use the token-level reward. Specifically, we extract attribute-related attentive scores from a pre-trained style discriminator, obtain a stepwise reward by re-weighting the sequence-level score, and utilize it as a fine-grained signal for policy gradient back-propagation.

We evaluate the proposed framework that incorporates both supervision and reward-based learning on three style transfer corpora (Section 4). Experiments show that our model achieves state-of-the-art performance. Particularly, the proposed model can produce reasonable generations with only 10% training data on the Yelp and Amazon corpora, and it also outperforms the supervised baselines when applying on the well-annotated GYAFC dataset.

2 Related Work

Neural Text Style Transfer The aim of text style transfer is to automatically convert text to a certain style while preserving the content (McDonald and Pustejovsky, 1985; Hovy, 1987). It has many applications, like persona-based dialogue generation (Niu and Bansal, 2018). Recently, neural sequence-to-sequence architectures becomes popular for this task. When parallel data are available, supervised training with cross-entropy loss is typically applied (Rao and Tetreault, 2018). However, annotated data are hard to obtain in many use cases, thus learning from non-parallel corpora has become an active research area. There are two approaches: (1) Disentangling style and content by learning a distinct representation for each element. For example, variational autoencoders are first used to transform a sentence into a low-dimension hidden state. Then the attribute-related latent representation is extracted to guide the decoder for target style generation (Shen et al., 2017; Fu et al., 2018; John et al., 2019); (2) Back translation, which uses cyclic reconstruction to improve content preservation (Zhang et al., 2018; Prabhumoye et al., 2018; Lample et al., 2019; Luo et al., 2019). For model optimization, some studies focus on applying reinforcement learning (RL), which defines a reward from a style classifier or a reward from back-translation to enhance style strength and content preservation (Gong et al., 2019; Luo et al., 2019; Wu et al., 2019; Sancheti et al., 2020). Recently, large-scale pre-trained language models are introduced to improve generation quality (Radford et al., 2019), and have been incorporated in both semi-supervised (Chawla and Yang, 2020) and supervised approaches (Lai et al., 2021). In this work, we use the BART (Lewis et al., 2020) as our language model backbone.

Pseudo Data Augmentation To tackle the data scarcity challenge in text style transfer, one solution is to build pseudo pairs from massive non-parallel data. Zhang et al. (2020b) proposed several augmentation methods for pre-training a Transformer-based model and fine-tuning on human annotations. Wang et al. (2019) proposed using harness-rule-based pre-processing, and joint training of bi-directional transfer and auto-encoder with two auxiliary losses (Wang et al., 2020). Jin et al. (2019) and Nikolov and Hahnloser (2019) constructed the pseudo corpora by iteratively matching via cosine similarity of sentence embeddings and hierarchical alignment. In this work, we use pseudo data as weak-supervision to bootstrap the training process, and further combine it with RL-based learning.

Attribute Salience Assessment In template-based and prototype editing methods for text style transfer, attribute marker detection is used to label the salient words and spans (Li et al., 2018). Aside from n-gram statistical features, neural attention-based methods train attribute-related classifiers, and consider words with attention weights higher than average as markers (Bahdanau et al., 2015; Xu et al., 2018; Sudhakar et al., 2019). Zhou et al. (2020) use the attribute salient scores as one of the model prediction output. To the best of our knowledge, we are the first to employ token-level attribute salience scores for reward re-weighting on policy gradient for sequence generation, and prior work only focuses on using attribute markers for text manipulation such as token replacement and template construction (Niu and Bansal, 2018).

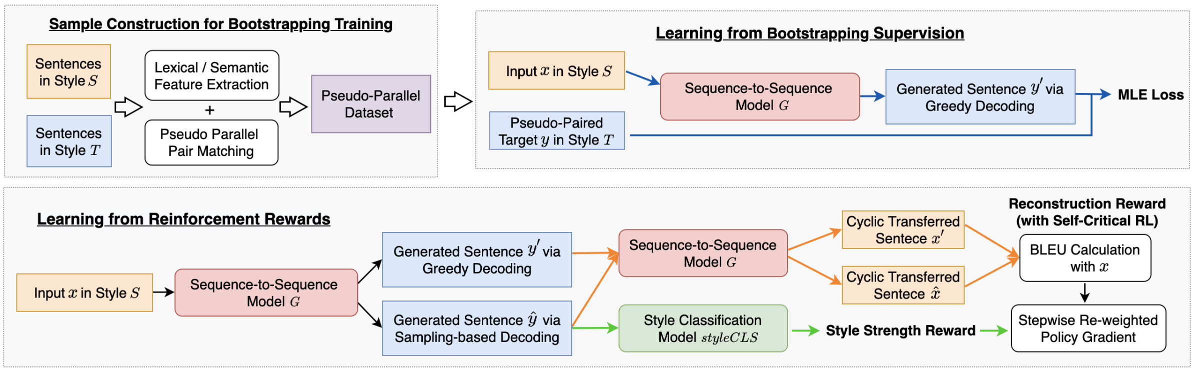

Figure 1: Overview of the proposed framework. Text samples in two different styles are in yellow and in blue. The sequence-to-sequence model is shared by style transfer and cyclic generation. The MLE loss, reconstruction reward, and style reward flows are in blue, yellow, and green arrow lines, respectively. See Algorithm 1 for training process.

3 Methodology

Define S as the source style and T as the target style (e.g., $S = negative$, $T = positive$). Let $\mathcal{D}_S$ and $\mathcal{D}_T$ be the two datasets which are comprised of sentences in each style respectively. The style transfer system, denoted as a text encoding-decoding model G, is to generate sentences in the target style. The goal is formulated to maximize $P(\boldsymbol{y}|\boldsymbol{x};\theta_G)$, where θ_G are the model parameters. In our setting, we make the rewriting bidirectional, i.e. it can be used to transfer source style to target style and verse versa. In this case, an additional input $\boldsymbol{c} \in \{S, T\}$ is fed to G specifying the style to which the sentence is to be converted. Hence, the objective is to maximize $P(\boldsymbol{y}|\boldsymbol{x},\boldsymbol{c};\theta_G)$.

3.1 Framework Overview

The overview of our proposed semi-supervised framework is shown in Figure 1. Given the non-parallel datasets $\mathcal{D}_S$ and $\mathcal{D}_T$, we use lexical or semantic features for pseudo parallel pair matching. The training process consists of two stages: (1) the generator model G is trained on the pseudo parallel samples, where cross-entropy loss over the target sentence tokens is used to optimize generated output probabilities, i.e. the **bootstrapping** step; (2) we incorporate reconstruction and style rewards to enhance attribute rewriting and content preservation, where reinforcement learning is used to optimize the generation, i.e. the **reward-based learning**. Moreover, the second stage can use pseudo parallel pairs as well as the non-parallel samples.

3.2 Pseudo Parallel Data Construction

To build the pseudo parallel data for bootstrapping, we investigate lexical similarity and semantic similarity for sentence matching.

Lexical Similarity In text style transfer, rewriting is often accomplished by changing a few words or phrases that are indicative of a particular attribute in the source sentence, namely attribute markers, while leaving the rest largely unaltered (Li et al., 2018). For example, *"Moving past the shape, they were dry and truly tasteless."*, a sentence with a negative sentiment style, can be transferred to a positive style by changing or replacing sentiment-specific words *"dry"* and *"tasteless"*, while keeping other words intact. This intuition has inspired the template-based and editing-based rewriting approaches (Li et al., 2018). Here we employ it for the lexical feature extraction. First, from unaligned corpora of two styled subsets (e.g., positive, negative), we identify attribute markers by sorting phrases that occur with far higher frequency within one attribute than the other (e.g., *"worst"* and *"very disappointed"* are negative markers). Second, for each sentence in the two subsets, we remove those markers, and regard the remaining words as its content-preserved spans. Then we match the content-preserved spans of style S to those of style T with the smallest Levenshtein editing distance (see examples shown in Table 1).

Semantic Similarity While the lexical features are straightforward and computationally-efficient, it may not generalize well in some tasks like formality conversion due to the ubiquitous span paraphrasing. Therefore, in this paper, we introduce semantic features for the pseudo data construction. While samples in different styles stand in different polarities, they are expected to be similar in the content-level semantic space. More specifically, for a sample i in style S, we match it to the closest sentence in style T in a semantic space. We use an unsupervised sentence representation

Source Sentence: if there were a way to put no stars, i would!
Lexical Match: i'd give it more stars if i could.
Semantic Match: love love love, if i could give you _num_ stars i would.

Source Sentence: the manager sat us at our table, and she seemed very angry.
Lexical Match: the manager and employees are very nice.
Semantic Match: the manager alice herself came by our table and greeted us as well.

Source Sentence: furthermore, i would rather drive _num_ minutes more to concord to race there.
Lexical Match: furthermore, they have a nice bar that goes both indoor and outdoor.
Semantic Match: i drive _num_ minutes to get here and it is definitely worth it!

Table 1: Pseudo parallel sentence pairs extracted from Yelp sentiment transfer dataset. Source sentences are from the negative polarity set, and are matched to sentences from the positive set.

model with contrastive learning (Gao et al., 2021), which achieves comparable performance to the supervised sentence embedding models, and calculate cosine similarity to measure the distance.[1] As shown in Table 1, the pseudo parallel data are similar at the semantic level, and they can be used as weak-supervision samples.

3.3 Learning with Supervision

With the pseudo parallel data, we can conduct supervised learning with token-level maximum likelihood estimation (MLE). In our framework, we use a sequence-to-sequence neural network. Since the large-scale pre-trained language models boost the performance of various downstream tasks, we use BART (Lewis et al., 2020) as the language backbone, which is a denoising autoencoder with strong language generation capability. Given a source sentence $\boldsymbol{x}$ and a reference sentence $\boldsymbol{y}$, the cross-entropy loss is calculated between the decoder's output and the reference sentence:

$$L_{\text{MLE}} = -\Sigma_i \log(p(\boldsymbol{y}_i|\boldsymbol{y}_{1:i-1}, \boldsymbol{x}, \boldsymbol{c}; \theta_G)) \quad (1)$$

Moreover, to avoid the generation becoming overfitting to the pseudo parallel data, we add the label smoothing on the cross-entropy loss (Müller et al., 2019), with the smoothing weight $\lambda = 0.15$.

3.4 Learning with Rewards

Upon the supervised learning from the pseudo parallel data, the model can be further improved by unsupervised learning from the massive unlabeled data. For the unsupervised stage, we adopt reinforcement learning, and use two rewards to enhance style rewriting and content preservation.

Reconstruction Reward Back translation has proved effective to improve content preservation, we feed the transferred sentence to model G for the backward rewriting, and calculate reconstruction reward on the cyclic generation. Here we measure the reward based on BLEU (Papineni et al., 2002) score as in (Sancheti et al., 2020) to foster content preservation, and adopt policy gradient (Sutton et al., 1999) with Self-Critical Sequence Training to reduce the variance (Rennie et al., 2017):

$$R_{cyclic} = \text{score}(G(\boldsymbol{y}'), \boldsymbol{x}) - \text{score}(G(\hat{\boldsymbol{y}}), \boldsymbol{x}) \quad (2)$$

where $\boldsymbol{x}$ is the backward target, $G(\hat{\boldsymbol{y}})$ is the back-translated output from greedy decoding generation $\hat{\boldsymbol{y}}$, and $G(\boldsymbol{y}')$ is the back-translated from sampling-based generation $\boldsymbol{y}'$ over a multi-nominal distribution. Noted that the score function can also be ROUGE and language model perplexity. The former is more suitable for summarization tasks; the latter needs additional computation.

Style Classification Reward Aside from content preservation, we use a style strength reward to optimize the model. We train a Transformer model for the binary style classification, and use it to evaluate how well the transferred sentence $\boldsymbol{y}'$ matches the target style. The style reward is R_{style} defined as the classification score:

$$p(s_{style}|\boldsymbol{y}') = \text{softmax}(\text{styleCLS}(\boldsymbol{y}', \phi)) \quad (3)$$

where styleCLS denotes the style classifier, ϕ are the parameters of the classifier, which are fixed during the training of the generation framework. $\boldsymbol{y}'$ is the generated sentence by sampling from the multi-nominal distribution at each step. Then, the reward-based learning is conducted via Policy Gradient (Sutton et al., 1999) back-propagation:

$$R = \lambda_{cyclic} R_{cyclic} + \lambda_{style}(R_{style} - \gamma) \quad (4)$$

$$\nabla_{\theta_G} J = E[R \cdot \nabla_{\theta_G} log(P(\boldsymbol{y}'|\boldsymbol{x}, \boldsymbol{c}; \theta_G))] \quad (5)$$

where R is the sum of cyclic and style reward, $\boldsymbol{y}'$ is the generated sentence by sampling from the multinominal distribution at each step, θ_G are trainable parameters of the generator, the weight ratio λ are added on cyclic and style reward separately, and γ is a style reward penalty (see Table 9). The overall objectives for θ_G are the loss of the base model (Eq. 1) and the policy gradient of RL rewards (Eq. 5).

---

[1] Additionally, we observed that in some corpora like Amazon (Li et al., 2018), there are a number of samples labeled with incorrect style due to data noise, and the semantic approach is sensitive on this issue. Therefore, we use a style classifier to filter out the incorrectly clustered samples.

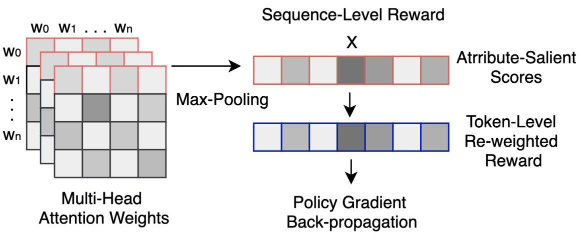

Figure 2: Our proposed stepwise reward re-weighting.

Corpus	Train	Valid	Test
Yelp (Sentiment-Positive)	270K	2,000	500
Yelp (Sentiment-Negative)	180K	2,000	500
Amazon (Sentiment-Positive)	277K	985	500
Amazon (Sentiment-Negative)	278K	1,015	500
GYAFC E&M (Formality-Paired)	52.6K	2,877	1,416
GYAFC F&R (Formality-Paired)	51.9K	2,788	1,432

Table 2: Statistics of the style transfer datasets. The GYAFC Entertainment&Music (E&M) and Family&Relationships (F&R) are comprised of paired samples. For Yelp and Amazon, only their test sets include human-written parallel references.

Stepwise Reward Re-weighting When applying reinforcement learning algorithms on sequence-to-sequence training, it is difficult for models to conduct end-to-end back-propagation due to the discrete nature of text. One of the common solutions is adopting policy gradient optimization (Sutton et al., 1999), where the rewards are generally calculated on the whole output sequence. Since all generated tokens obtain the same reward value, this coarse-grained signal is suboptimal for learning performance and stability (de Masson d'Autume et al., 2019). For instance, when positive sentiment is targeted, the output sentence *"I dislike this movie!"* will obtain a negative reward of style strength if its gold reference is *"I love this movie!"*. In this context, the word *"dislike"* should be punished more than the others in the sentence, but with sequence-level reward all words receive the same penalty. To address this drawback, we propose a solution by granulating the sequence-level reward with token-level salience scores, namely, stepwise re-weighting.

To re-weight the coarse-grained reward, we use the normalized attentive scores from the style classification model as the token-level attribute-salient scores. For the Transformer architecture, it is shown that heavily attended tokens correlate strongly with tokens that are indicative of the target style (Hewitt and Manning, 2019; Vig and Belinkov, 2019). Since the softmax linear layer is used over the attention stack of the first token ⟨s⟩ in a *'RoBERTa-base'* model, the attention weights of other input tokens that correspond to ⟨s⟩ are of special interest in identifying significant sentence tokens. We inspect the attentions computed by the Transformer with 12 multi-head layers, and empirically observed that the attention weights of top layers correlate strongly with salient tokens (see the visualization in Appendix Figure 4). Given the attention matrix A_i in the i-th multi-head layer, a_i^j represents the attention vector of the first token (e.g., ⟨s⟩ , *"[CLS]"*) from the j-th attention head, which is normalized across all tokens. We max-pool A_i over all attention heads to form a_i, which represents the maximum extent to which each token was attended to by any head, and further max-pool the weights across the top-2 layers as the final stepwise attribute-salient scores (see layer selection in Section 5.2), which are in the range of (0, 1). Then sequence-level rewards are expanded to the token length n, and re-weighted by the stepwise scores (see Figure 2 and Algorithm 1), and the policy gradient is formulated as following:

$$\nabla_{\theta_G} J = E[\frac{1}{n}\sum_{t=1}^{n} R'_t \cdot \nabla_{\theta_G} log(P(\boldsymbol{y}'_t|\boldsymbol{y}'_{1:t-1}, \boldsymbol{x}, \boldsymbol{c}; \theta_G))] \tag{6}$$

4 Experiments

4.1 Experimental Datasets

For extensive experiments, in this paper, we select three representative text style transfer corpora: Yelp (business reviews), Amazon (product reviews), and Grammarly's Yahoo Answers Formality Corpus (GYAFC) (Li et al., 2018; Rao and Tetreault, 2018). The training, validation, and test split are the same as previous work (Luo et al., 2019; Chawla and Yang, 2020), and their task types and statistics are shown in Table 2. In the non-annotated corpora Yelp and Amazon, human-written references are only available for the test set. Therefore, to build the pseudo parallel data described in the previous section, we filter out the sentence pairs with lexical or semantic similarity lower than a threshold, and remove sentences that are shorter than 5 words. The pseudo parallel set is used for the bootstrapping training (Section 3.3), and the rest samples are used for the unsupervised stage (Section 3.4).

4.2 Experiment Setup

The framework is implemented with Pytorch and Hugging Face Transformers[2]. The *'BART-base'*

Semantic Pseudo + Reward-Learning (100K)	86.5	59.8	**71.9**	**70.7**	**87.1**

Table 3: Automatic evaluation scores on the Yelp sentiment style transfer task. Baseline results are reported with the model generations provided in published studies. Text examples are shown in Appendix Table 11.

model is selected as the generator G. For style classification, *'RoBERTa-base'* is used. We fine-tune models with AdamW (Kingma and Ba, 2015) with batch size 32; initial learning rates are all set at $2e^{-5}$. Style reward penalty γ is 0.2. Values for λ are set to 1.0 for style reward and 0.8 for cyclic reward. Beam search size is set at 6. Test results are reported with best validation scores (see Appendix Table 9 for environment and hyper-parameter setting details, and Algorithm 1 for the training process).

As previous work (Luo et al., 2019; He et al., 2020; Sancheti et al., 2020), we adopt the following evaluation metrics: (1) **Style Accuracy** is calculated via binary classification to measure the style strength of re-writing. While the *TextCNN* (Kim, 2014) is used in previous studies, we also adopt a Transformer *'RoBERTa-base'* classifier, where the reported scores are similar in our settings; (2) **BLEU** score is calculated on the prediction and human references to measure the content preservation; (3) We also compute the geometric mean (**G2**) and harmonic mean (**H2**) of style accuracy and BLEU score; (4) Since recent metrics with semantic similarity show better correlation with human judgments than traditional lexical measures. We also calculate **BertScore** between generation and references (Zhang et al., 2020a).

4.3 Results on Yelp Corpus

A number of representative unsupervised baseline models are selected for extensive comparison on the Yelp corpus: (1) models that adopt content-style disentanglement such as Cross Aligned (Shen et al., 2017) and Style Embedding (Fu et al., 2018); (2) models that adopt back-translation such as Unsupervised MT (Zhang et al., 2018), and Dual RL (Luo et al., 2019), and recent state-of-the-art models Deep Latent (He et al., 2019) and Direct Rewards w/ GPT-2 (Liu et al., 2021). For our semi-supervised framework, we first (1) apply vanilla supervised learning to assess the effectiveness of the pseudo parallel data construction; (2) bootstrap the model with 30K pseudo parallel pairs, then further train it via reward-based learning; (3) apply semi-supervised learning by bootstrapping the model with 30K pseudo parallel pairs, and using 70K non-parallel samples for the reward-based training. As shown in Table 3, vanilla supervised training on the 30K pseudo parallel data lead to favorable scores of style accuracy, though they do not perform well in terms of BLEU scores, as the pseudo pairs emphasize style converting rather than content preservation. Further training with rewards improves both the style accuracy and BLEU score, and models with both lexical and semantic pseudo data produce comparable results with only 30k samples. Performance is further improved by using additional non-parallel data (70k samples), where our models outperform state-of-the-art baselines significantly.

4.4 Results on Amazon Corpus

For the Amazon sentiment transfer corpus, we adopt the same training strategies described in Section 4.3. Aside from unsupervised models, we also select the semi-supervised model Semi-LM-MMI

Model	Accuracy	BLEU	G2	H2	BertScore
Cross Aligned (Shen et al., 2017)	74.1	0.4	5.4	0.8	55.3
Style Embedding (Fu et al., 2018)	43.3	10.0	20.8	16.2	68.1

Table 5: Automatic evaluation scores on the GYAFC formality transfer task of baselines and our framework. Baseline results are reported with the generations provided as in (Chawla and Yang, 2020). *The style accuracy is calculated with a fine-tuned *'RoBERTa-base'* model (see Appendix for the result with *TextCNN* classifier).

w/ BART (Chawla and Yang, 2020), which adopted a language model-based discriminator for maximizing token-level conditional probabilities for training. Due to label noise in online-crawled data, the style accuracy for all models becomes lower than those trained on Yelp, and the classifier precision is only 86% (see Table 4). We also observed that the lexical similarity of pseudo parallel pairs is smaller than Yelp samples, and results in lower BLEU scores, especially when we apply supervised training on the 30K pseudo parallel data. On the other hand, content preservation largely benefits from the reward-based learning. Unsurprisingly, after bootstrapping, training with rewards significantly improves the generation quality, and our framework achieves state-of-the-art performance. Moreover, bootstrapping with lexical-based and semantic-based pseudo data resulted in a similar final performance with reward learning.

4.5 Results on GYAFC Corpus

In recent work, it is shown that style transfer models trained on parallel data can benefit from additional reward-based learning (Lai et al., 2021). Here we conduct additional experiments to assess our semi-supervised framework on the GYAFC formality transfer corpus with well-annotated data. We evaluate the proposed model on the *informal*-to-*formal* task as previous work (Chawla and Yang, 2020), and compare them with strong baselines. As shown in Table 5, while the baselines show impressive BLEU scores on the formality transfer task, our framework outperforms them significantly in terms of style accuracy, approaching upper-bound human performance. Moreover, compared with the contemporary supervised work (Lai et al., 2021), which also introduced additional RL-based optimization, our model still achieves higher G2 and H2 scores. The examples shown in Appendix Table 13 demonstrate that our approach generates sentences with accurate formality paraphrasing.

4.6 Human Assessment

Additionally, we conducted a human evaluation on Yelp, Amazon and GYAFC datasets. Following previous work (Chawla and Yang, 2020; Liu et al., 2021), we evaluated the generated sentences from three aspects: style transfer strength (*Style*), text flu-

	Yelp Data				Amazon Data			
Model	Accuracy	BLEU	G2	H2	Accuracy	BLEU	G2	H2
Sequence-Level Reward (30K Data)	85.1	26.5	47.5	40.4	78.4	19.0	38.5	30.5
Stepwise Reward (30K Data)	81.1	50.4	**63.9**	**62.1**	71.2	36.1	**50.6**	**47.9**
Sequence-Level Reward (100K Data)	84.8	35.3	54.7	49.8	81.4	21.9	42.2	34.5
Stepwise Reward (100K Data)	86.2	59.4	**71.5**	**70.3**	73.1	46.3	**58.1**	**56.6**

Table 6: Ablation study on the proposed stepwise reward on the Yelp and Amazon dataset. *Sequence-level* denotes the reward is calculated on the whole sequence, without the stepwise re-weighting.

Layer No.	Accuracy	BLEU	G2	H2
Layer-12	78.5	46.2	60.2	58.1
Layer-11	81.1	45.5	**60.7**	**58.2**
Layer-10	84.2	38.7	57.0	53.0
Layer-9	72.3	43.8	56.2	54.5
Layer-8	76.1	44.5	58.1	56.1
Layer-7	70.3	41.6	54.0	52.2

Table 7: Layer selection for the proposed stepwise reward re-weighting. The Yelp sentiment transfer dataset and the semantic-based matching are used. We conduct experiments on the last 6 Transformer layers of the style classifier.

Train Size	Accuracy	BLEU	G2	H2
1,000	62.9	31.6	44.5	42.0
5,000	68.2	36.8	50.0	47.8
10,000	73.3	43.6	56.5	54.6
15,000	76.1	45.5	58.8	56.9
30,000	83.5	49.6	64.3	62.2

Table 8: Results from different pseudo sample sizes using the proposed framework. The Yelp sentiment transfer dataset and semantic-based matching are used.

ency (*Fluency*), and content preservation (*Content*), separately. The three aspects are rated with range [1, 5], then their average value is calculated and reported as *Mean* (see Table 14 in Appendix). For each corpus, we randomly selected 80 test samples and compared the outputs of representative and previous state-of-the-art models. Each candidate was rated by three linguistic experts, and we report the average scores. Our model achieves better overall performance when considering all three evaluation metrics on each dataset. Moreover, we observe that leveraging the pre-trained language models such as BART and GPT-2 is beneficial for the text fluency.

5 Analysis

To extensively assess the effectiveness of the proposed methods, we conduct the following in-depth analyses.

5.1 Ablation Study on Stepwise Re-weighting

We conduct an ablation experiment to assess the effectiveness of stepwise reward re-weighting. As shown in Table 6, the performance degrades significantly without the stepwise reward re-weighting, especially the BLEU score. In particular, we observed that when removing stepwise optimization, the generator was prone to mode collapse. In one manifestation of mode collapse, the model appended a limited set of phrases to the source sentences, resulting in generation with disfluency and low diversity. It demonstrates that token-level reward optimization provides finer-granularity for policy gradient of sequence-to-sequence training. This approach can also be potentially extended to other text generation tasks.

5.2 Attention Layer Selection for Stepwise Reward Re-weighting

We utilize attentive scores from the top-2 multi-head layers for stepwise reward re-weighting. To study the effect of layer selection, we compared the results using attention scores extracted from different Transformer layers in the style classifier described in Section 3.4. As shown in Table 7, the performance shows an overall increasing trend from the 7-th to the 12-th layer, and we obtained better results with the top layers. In scores of lower layers, we found that the model tended to assure content preservation rather than style accuracy. This is consistent with the observations from recent linguistic probing and model interpretation studies (Hewitt and Manning, 2019; Xu et al., 2020): the information modeled in the Transformer-based networks, especially the pre-trained language backbones, is represented in a hierarchical manner, and the higher layers provide more effective information on scoring the span importance for text classification (see visualization in Appendix Figure 4).

5.3 Bootstrapping Sample Size

We investigate the effect of different pseudo parallel sample sizes. As shown in Table 8, the result shows that the evaluation result by automatic metrics becomes acceptable when training reaches 10K samples. Results comparable to state-of-the-art are achieved with merely 30K data (10% of the Yelp training set). We speculate that the relatively weak performance with 10K samples is because the BART model uses a denoising autoencoding paradigm (Lewis et al., 2020), which is trained to reconstruct the input sentence, and style strength of sentence rewriting is strongly affected in this low resource scenario.

Additionally, we conduct an ablation study on the bootstrapping step, and the result shows that with the same training sample size, the generation performance (considering both style accuracy and content preservation) obtained significant improvement by adding the bootstrapping learning stage (see Appendix Table 15).

6 Conclusions

In this paper, we proposed a framework for text style transfer taking advantage of both supervised and unsupervised paradigms. The training process is bootstrapped with supervision guided by automatically constructed pseudo parallel data. Both lexical-based and semantic-based sentence matching proved effective. Moreover, the stepwise reward re-weighting significantly improved the generation performance, and is a generic design that can be easily extended. Experimental results showed that the proposed approach achieved state-of-the-art performance in multiple datasets, while producing reasonable generation even with minimal training data (10% of original size).

Acknowledgments

This research was supported by funding from the Institute for Infocomm Research (I2R) under A*STAR ARES, Singapore. We thank Ai Ti Aw for the insightful discussions. We also thank the anonymous reviewers for their precious feedback to help improve and extend this piece of work.

A Appendix

Algorithm 1 Training process of the proposed semi-supervised text style transfer framework.

```
Given non-labeled datasets $\mathcal{D}_S$ and $\mathcal{D}_T$ in two different styles $S$ and $T$, construct pseudo parallel dataset $\mathcal{D}_{pseudo}$ with sentence pairs matched with lexical-based or semantic-based similarity
Pre-train a binary style classifier $\mathbf{styleCLS}$ on the two datasets $\mathcal{D}_S$ and $\mathcal{D}_T$
Pre-train the text style transfer model $\boldsymbol{G_\theta}$ using pseudo-parallel sentence pairs in dataset $\mathcal{D}_{pseudo}$, with MLE loss (Eq. 1).
for each iter $i = 1, 2, ..., M$ do
    Sample sentence $\boldsymbol{x}$ of source style $S$ from $\mathcal{D}_S$
    Generate sentence $\boldsymbol{y}'$ of target style $T$ via model $\boldsymbol{G_\theta}$ by greedy decoding
    Generate sentence $\hat{\boldsymbol{y}}$ of target style $T$ via model $\boldsymbol{G_\theta}$ by sampling-based decoding
                                        ▷ Reconstruction Reward Calculation (Content Preservation)
    Given $\boldsymbol{y}'$, generate back-translated sentence $\boldsymbol{x}'$ of source style $S$ via model $\boldsymbol{G_\theta}$ by greedy decoding
    Given $\hat{\boldsymbol{y}}$, generate back-translated sentence $\hat{\boldsymbol{x}}$ of source style $S$ via model $\boldsymbol{G_\theta}$ by greedy decoding
    Compute reconstruction reward $R_{cyclic}$ based on BLEU scores of the pair [$\boldsymbol{x}$, $\boldsymbol{x}'$] and the pair [$\boldsymbol{x}$, $\hat{\boldsymbol{x}}$], following Self-Critical Sequence Training (Eq. 2)
                                        ▷ Style Reward Calculation (Style Strength)
    Compute style reward $R_{style}$ of generated sentence $\hat{\boldsymbol{y}}$ using the style classifier $\mathbf{styleCLS}$
                                        ▷ Stepwise Reward Re-weighting
    Compute the stepwise re-weighting values by max-pooling attentive scores from style classifier $\mathbf{styleCLS}$ on the generated sentence $\hat{\boldsymbol{y}}$
    Expand $R_{style}$ and $R_{cyclic}$ from 1-D (sequence level) to 2-D (token level), and re-weight $R_{style}$ with stepwise values
    Compute the total stepwise reward $R'$ by adding $R_{style}$ and $R_{cyclic}$, based on Eq. 4
    Update $\boldsymbol{\theta}$ using reward $R'$ based on Eq. 6

Environment Details	
Sequence Generator	BART-Base (12-layer, 768-hidden, 16-heads, 139M parameters).
Style Classifier	RoBERTa-base (12-layer, 768-hidden, 12-heads, 125M parameters).
GPU Model	Single Tesla A100 with 40 GB memory; CUDA version 11.0.
Library Version	Pytorch==1.8.1; Transformers==4.8.2.
Computational Cost	Average 5 hours training time for one round. Average 3 rounds for each reported result (calculating mean of the result scores).
Hyper-parameter	**Setting Detail**
Learning Rate and Batch Size	We set the learning rate and batch size according to regular language model fine-tuning strategy (Lewis et al., 2020).
Beam Search Size	We evaluated models on beam search sizes from 3 to 10, and 6 provided the best balance of performance and inference speed.
Style Reward Penalty γ (Eq. 4)	(1) In our experiment, we observed that the style reward R_{style} values given by the style classifier were up to 0.9 (indicating a high level of style transfer strength), while the cyclic reconstruction reward R_{cyclic} values were at a lower level (average was 0.5). Therefore, we added the γ to adjust the R_{style} to the same level of R_{cyclic}. (2) We evaluated values from 0.1 to 0.4 (0.1 as step), and empirically set the γ at 0.2. Training without the penalty γ did not produce significantly degraded results.
λ_{cyclic} and λ_{style} (Eq. 4)	We evaluated both values with 1.0 +/- 0.2, and empirically set λ_{cyclic} at 1.0, λ_{style} at 0.8. Setting at 1.0 by default did not produce degraded results.
Sequence-Level & Stepwise Reward	For the comparison of using sequence level and stepwise rewards, we run experiments with the aforementioned parameter setting.
Combination of lexical and semantic pseudo-parallel data	In our pilot experiment, we tried to combine both lexical and semantic pseudo-parallel data, but this did not bring any improvement on the Yelp and Amazon. Presumably this is because the semi-supervised model only requires weak supervision from the pseudo-parallel data, and either the lexical and semantic data can provide sufficient information at the bootstrapping training stage.

Table 9: The detailed environment settings and search strategy of training parameters in our experiment. It is worth mentioned that our proposed semi-supervised approach with bootstrapping strategy and stepwise reward re-weighting is targeted to tackle the unstable learning issue of RL-based models.

Model	E&M Domain Accuracy*	BLEU	G2	H2	F&R Domain Accuracy*	BLEU	G2	H2
Human Reference (Rao and Tetreault, 2018)	58.7	100.0	76.6	73.9	51.4	100.0	71.6	67.8

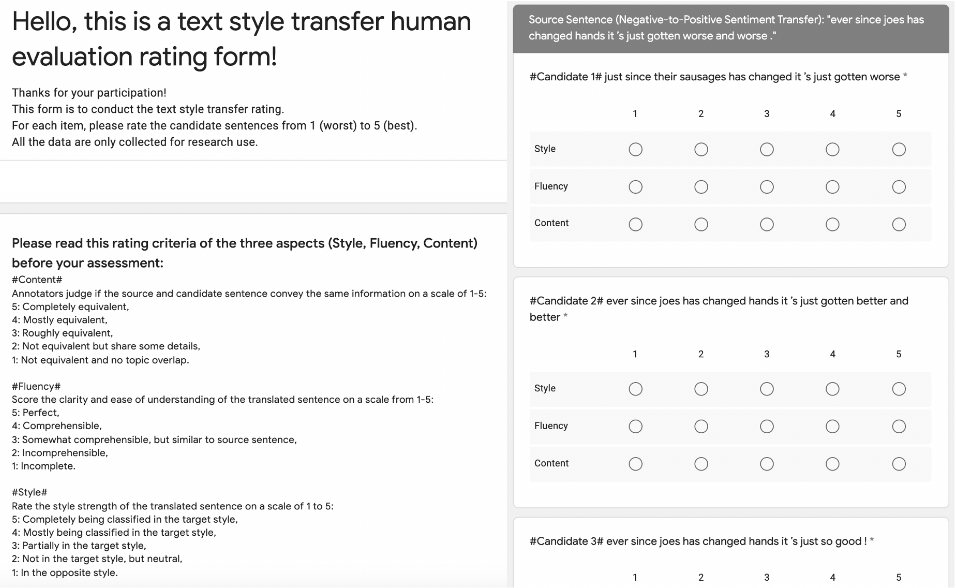
Table 14: Human evaluation are conducted on the Yelp, Amazon, and GYAFC style transfer datasets. Following previous work (Chawla and Yang, 2020; Liu et al., 2021), we evaluated the generated sentences from three aspects: style transfer strength (**Style**), text fluency (**Fluency**), and content preservation (**Content**), separately. The three aspects are rated with range [1, 5], then their average value is calculated and reported as **Mean**. For each corpus, we randomly selected 80 test samples and compared the outputs of representative and previous state-of-the-art models. Each candidate was rated by three linguistic experts, and we report the average scores. Our model achieves better overall performance when considering all three evaluation metrics on each dataset. Moreover, we observe that leveraging the pre-trained language models such as BART and GPT-2 is beneficial for the text fluency.



Hello, this is a text style transfer human evaluation rating form!

Thanks for your participation!
This form is to conduct the text style transfer rating.
For each item, please rate the candidate sentences from 1 (worst) to 5 (best).
All the data are only collected for research use.

Please read this rating criteria of the three aspects (Style, Fluency, Content) before your assessment:

#Content#
Annotators judge if the source and candidate sentence convey the same information on a scale of 1-5:
5: Completely equivalent,
4: Mostly equivalent,
3: Roughly equivalent,
2: Not equivalent but share some details,
1: Not equivalent and no topic overlap.

#Fluency#
Score the clarity and ease of understanding of the translated sentence on a scale from 1-5:
5: Perfect,
4: Comprehensible,
3: Somewhat comprehensible, but similar to source sentence,
2: Incomprehensible,
1: Incomplete.

#Style#
Rate the style strength of the translated sentence on a scale of 1 to 5:
5: Completely being classified in the target style,
4: Mostly being classified in the target style,
3: Partially in the target style,
2: Not in the target style, but neutral,
1: In the opposite style.

Source Sentence (Negative-to-Positive Sentiment Transfer): "ever since joes has changed hands it 's just gotten worse and worse ."

#Candidate 1# just since their sausages has changed it 's just gotten worse *

	1	2	3	4	5
Style	○	○	○	○	○
Fluency	○	○	○	○	○
Content	○	○	○	○	○

#Candidate 2# ever since joes has changed hands it 's just gotten better and better *

	1	2	3	4	5
Style	○	○	○	○	○
Fluency	○	○	○	○	○
Content	○	○	○	○	○

#Candidate 3# ever since joes has changed hands it 's just so good ! *

1	2	3	4	5

Figure 3: Rating interface for the human evaluation. Text candidates are shuffled for each sample.

Model	Yelp Data Accuracy	BLEU	G2	H2	Amazon Data Accuracy	BLEU	G2	H2
Lexical Pseudo + Reward-Learning (30K)	81.1	50.4	63.9	62.1	71.2	36.1	50.6	47.9
Pure Reward Learning (30K)	70.8	41.3	54.0	52.1	61.2	26.1	39.9	36.5
Lexical Pseudo + Reward-Learning (100K)	86.2	59.4	71.5	70.2	73.1	46.3	58.1	56.6
Pure Reward Learning (100K)	75.5	46.1	58.9	57.2	65.6	26.5	41.6	37.7

Table 15: Ablation study of the proposed bootstrapping on the Yelp and Amazon datasets. Models are running in a RL-based unsupervised manner, and we used the same data sizes as the experiments in Table 3 and Table 4.

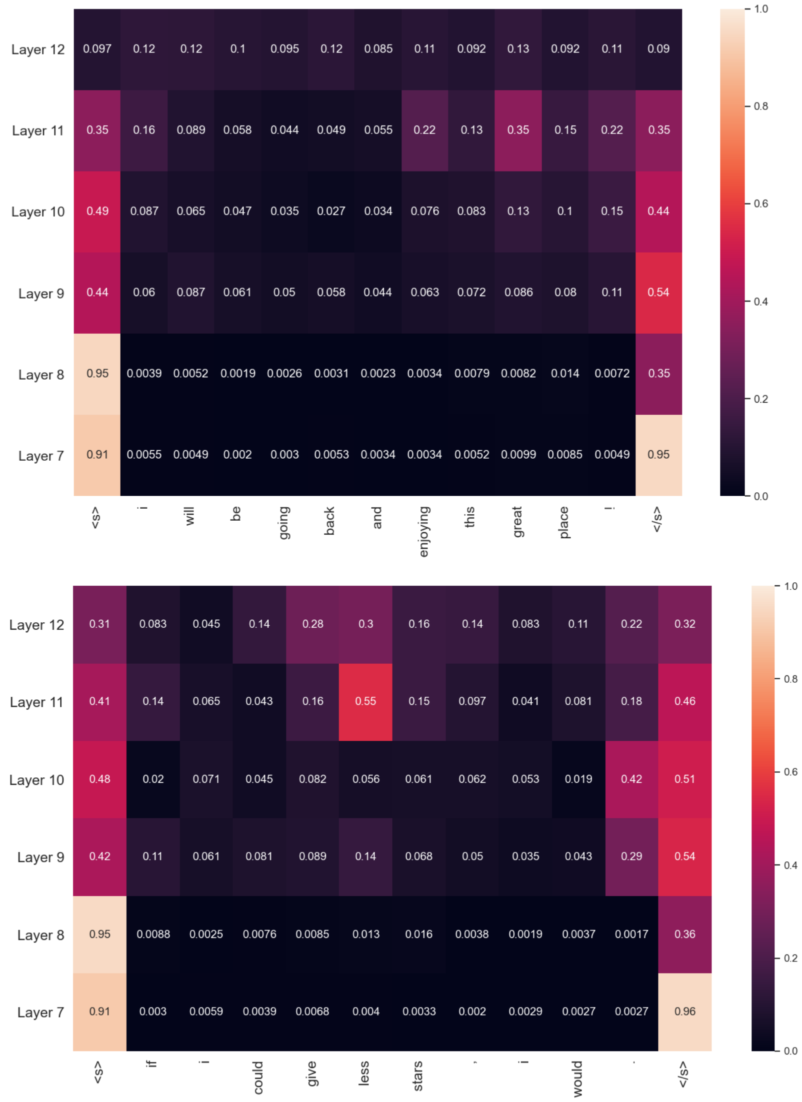


Figure 4: Attention heatmap examples of the attention scores with layer-level max-pooling. The *'RoBERTa-base'* model is fine-tuned on the Yelp data for style classification. The higher scores denotes higher attention weights on the tokens, and the top layers (especially the 11-th layer) shows better attribute-specified correlation. At the token level, the attention values and the max-pooled step-wise values described in Section 3.4 are all in the range of (0, 1).

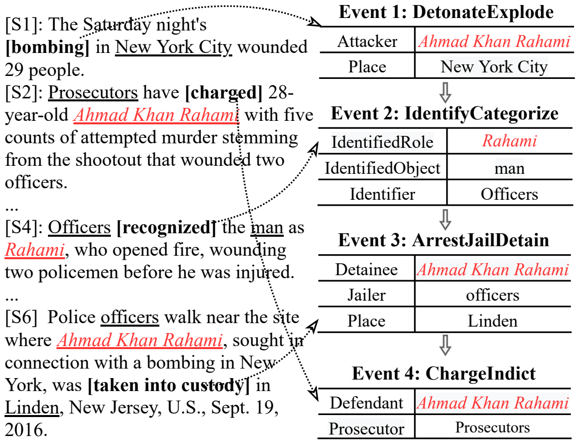
EA^{2}E: Improving Consistency with Event Awareness for Document-Level Argument Extraction

Qi Zeng[*], **Qiusi Zhan**[*], **Heng Ji**
University of Illinois Urbana-Champaign
`{qizeng2, qiusiz2,hengji}@illinois.edu`

Abstract

Events are inter-related in documents. Motivated by the one-sense-per-discourse theory, we hypothesize that a participant tends to play consistent roles across multiple events in the same document. However recent work on document-level event argument extraction models each individual event in isolation and therefore causes inconsistency among extracted arguments across events, which will further cause discrepancy for downstream applications such as event knowledge base population, question answering, and hypothesis generation. In this work, we formulate event argument consistency as the constraints from event-event relations under the document-level setting. To improve consistency we introduce the Event-Aware Argument Extraction (EA^{2}E) model with augmented context for training and inference. Experiment results on WIKIEVENTS and ACE2005 datasets demonstrate the effectiveness of EA^{2}E compared to baseline methods[1].



[S1]: The Saturday night's **[bombing]** in New York City wounded 29 people.
[S2]: Prosecutors have **[charged]** 28-year-old *Ahmad Khan Rahami* with five counts of attempted murder stemming from the shootout that wounded two officers.
...
[S4]: Officers **[recognized]** the man as *Rahami*, who opened fire, wounding two policemen before he was injured.
...
[S6] Police officers walk near the site where *Ahmad Khan Rahami*, sought in connection with a bombing in New York, was **[taken into custody]** in Linden, New Jersey, U.S., Sept. 19, 2016.

Event 1: DetonateExplode

Attacker	*Ahmad Khan Rahami*
Place	New York City

⇩

Event 2: IdentifyCategorize

IdentifiedRole	*Rahami*
IdentifiedObject	man
Identifier	Officers

⇩

Event 3: ArrestJailDetain

Detainee	*Ahmad Khan Rahami*
Jailer	officers
Place	Linden

⇩

Event 4: ChargeIndict

Defendant	*Ahmad Khan Rahami*
Prosecutor	Prosecutors

Figure 1: Examples of extracting arguments for multiple events in one document. The casual relation between the *Arrest* event and the *Detonate* event puts their arguments under consistency constraints: *Ahmad Khan Rahami*, the detainee in Event 3, is very likely to be the attacker in Event 1. Sentence-level models tend to miss the cross-sentence attacker argument in Event 1.

1 Introduction

Document-level Event Argument Extraction aims at identifying arguments and their roles for multiple events in a document. It is a practically more useful but more challenging task than sentence-level Argument Extraction (Nguyen et al., 2016; Wadden et al., 2019; Lin et al., 2020) because in a typical long input document events usually scatter across multiple sentences and are inherently connected.

Multiple events in one document are usually interconnected, and thus the arguments are under certain consistency constraints. In Figure 1, the roles of the shared argument *Ahmad Khan Rahami* in multiple events are constrained because the *Attacker* in the *DetonateExplode* event is likely to be the *IdentifiedRole* in *IdentifyCategorize* event, the *Detainee* in the *ArrestJailDetain* event, as well as the *Defendant* in *ChargeIndict* event. Motivated by the one-sense-per-discourse theory (Gale et al., 1992) that mentions of an ambiguous word usually tend to share the same sense in a given discourse, we hypothesize that **a participant tends to play consistent roles across multiple events in the same document**. However, previous work such as (Li et al., 2021; Du et al., 2021; Yang et al., 2021) on document-level event argument extraction focuses on modeling each event independently and ignores the relation between events, and thus the extracted arguments of multiple events may violate the constraints from event-event relations. We call this inconsistency phenomenon.

Though received much attention in various areas like Abstractive Summarization (Nan et al., 2021; Zhu et al., 2021; Kryscinski et al., 2020) and Question Answering (Honovich et al., 2021; Ribeiro

---

[*] Equal contribution.

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2649 - 2655

et al., 2019), the inconsistency phenomenon addressed in previous research focuses on factual consistency instead of self-contained consistency as in document-level argument extraction. We approach this problem with inspiration from human behavior: while reading, humans subconsciously infer the event-event relations and correctly identify the event arguments under the perceived constraints. Therefore, we refer consistent argument extraction to applying the underlying Event-Event Relations as constraints in multi-event argument extraction.

An intuitive solution to improve consistency is to incorporate explicit Event-Event Relations into the extraction process as additional input. However, the underlying event-event relations are hard to identify and classify due to the lack of reliable resources as supervision signals, especially when the arguments are unknown. In addition, precise event-event relations may not be necessary for argument extraction when the implicit connections can already well support argument extraction.

To avoid explicit modeling of event-event relations, we label the arguments of other events in the context as an implication of event-event relations. We propose an **Event-Aware Argument Extraction (EA^{2}E)** model, which incorporates alignment-enhanced training and iterative inference. When extracting arguments, the context can be self-augmented by tagging the argument labels of other events. Alignment-enhanced training implicitly introduces event awareness by pulling close the argument representation distributions under regular context and augmented context, where ground-truth argument labels of neighboring events are labeled. Iterative inference explicitly encourages event awareness by augmenting the context with the extracted arguments from the last inference iteration. The advantage of this method is that no predefined Event-Event Relation is required, nor event schema. Our experiments on WIKIEVENTS and ACE2005 datasets show that our EA^{2}E model brings improvement against previous methods.

2 Event-Aware Argument Extraction

Motivated by the observation that introducing event-event relations benefits the consistency of event argument extraction, we propose to incorporate implicit event-event relations with an Event-Aware Argument Extraction (EA^{2}E) model. As shown in Figure 2, EA^{2}E contains alignment-enhanced training and iterative inference with self-augmented context. When extracting the arguments for a target event, the context is augmented by labeling the arguments from neighboring events. During training, an auxiliary training loss pulls close the event argument representations under the regular context and self-augmented context. During inference, iterative inference encourages event awareness by using the extraction arguments from the last inference iteration as inputs.

2.1 Base Encoder-Decoder Model

Following (Li et al., 2021), we formulate event argument extraction as a conditional generation task under the assumption that there exists a pre-defined event ontology describing each event type with an unfilled template with argument placeholders. For example, the template for *Attack* events is *<arg> detonated or exploded <arg> explosive device using <arg> to attack <arg> target at <arg> place*. Formally, given a document context c and an event trigger x with template t, the task is to extract a set of arguments $y = \{a_1, a_2, ...a_n\}$, where each a_i corresponds to a role predefined in the ontology.

We base our model on BART (Lewis et al., 2020), an encoder-decoder pretrained model. The input sequence is the concatenation of the document context and an event template, constructed as *<s> template </s> </s> context </s>*. The output is a filled-in template, where the tokens are all selected from the input context or template.

The model parameter θ is trained by minimizing the argument extraction loss, the conditional probability over all instances:

$$\mathcal{L}_E = -\sum logp_\theta(y|x, t, c) \tag{1}$$

2.2 Self-augmented Context

We refer event awareness as the implication of event-event relations and reach this goal by labeling the arguments of other neighboring events in the context. Given the arguments of the neighboring events $\{j \in \mathcal{N}_i\}$, which have small token-wise distances to the target event i, we augment the regular context c by labeling them with <*tag*>:

$$c_i' = \mu(c_i, \{y_j\}), \tag{2}$$

where μ is the tagging operation, and y_j is the arguments of event j.

For example in Figure 1, when extracting arguments for the target event *bombing* (Event 1), the augmented context is “The Saturday night's <trg>

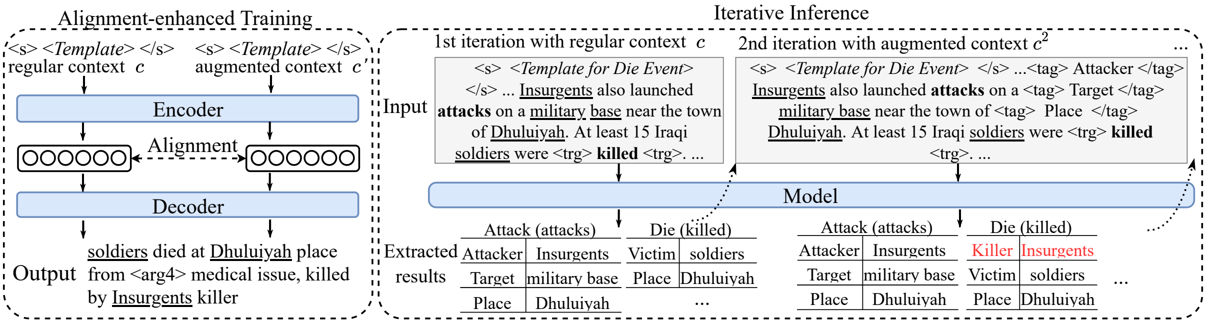

Figure 2: Our proposed Event-aware Argument Extraction model with alignment-enhanced training and iterative inference. During training, an auxiliary training loss aligns the event argument representations under regular context and augmented context. During inference, the context is augmented with results from the last iteration.

bombing <trg> in New York City, wounded 29 people. <*tag*> *Prosecutor* <*tag*> Prosecutors have charged 28-year-old <*tag*> *Defendant* <*tag*> Ahmad Khan Rahami...", where the two tags highlight the arguments of Event 4.

2.3 Alignment-enhanced Training

An encoder is considered consistent when it is able to understand and encode the underlying relation between events into the text representations. Therefore, we propose to enhance the encoder with an auxiliary training loss $\mathcal{L}_T$ that pulls close the argument representation distributions under regular context c and under augmented context c'. During training, c' is constructed by tagging the ground-truth arguments of neighboring events.

$$\mathcal{L}_T = \sum \|p(a|c), p(a|c')\|_2 \tag{3}$$

The final training loss is a weighted sum of argument extraction losses ($\mathcal{L}_E$ for regular context c and $\mathcal{L}_{E'}$ for augmented context c') and alignment-enhanced loss ($\mathcal{L}_T$) with weights α and β :

$$\mathcal{L} = \mathcal{L}_E + \alpha\mathcal{L}_{E'} + \beta\mathcal{L}_T \tag{4}$$

2.4 Iterative Inference

Iterative inference explicitly introduces event awareness by utilizing extracted results in multiple inference iterations. In the first iteration, for each target event trigger i, the model obtains the predicted results y_i^1 given the regular context c_i^1. For the k-th iteration of inference, for each event trigger i the context c_i^k is augmented by labeling the extracted arguments $\{y_j^{k-1}\}$ of neighboring events $\{j \in \mathcal{N}_i\}$ from the $(k-1)$-th iteration.

$$c_i^k = \mu(c, \{y_j^{k-1}\}) \tag{5}$$

3 Experiments

3.1 Datasets and Baselines

We evaluate our proposed method on WIKIEVENTS (Li et al., 2021) dataset and ACE 2005 dataset[2]. Following previous work (Li et al., 2013), we consider an argument span to be correctly identified when its offsets match any of the reference arguments of the current event (i.e., **Argument Identification**), and to be correctly classified when its role matches (i.e., **Argument Classification**). We report the argument extraction performance in terms of Head Word F1 and Coreferential Mention F1. For the latter, full credit will be given when the extracted argument is coreferential with the gold-standard argument.

We compare EA^{2}E with document-level BART-Gen (Li et al., 2021), sentence-level ONEIE (Lin et al., 2020) and BERT-CRF (Shi and Lin, 2019).

3.2 Implementation Details

We implement our models with Huggingface (Wolf et al., 2019). We train each model for 4 epochs with a batch size of 4 for baselines and 2 for EA^{2}E. The model is optimized with the Adam optimizer with a learning rate of 3e-5, α = 1 and β=0.5. We define event neighborhood as trigger distance less than 40 tokens. For inference, the maximum number of iterations is 3. For numerical consistency, all experiment results are averaged across three random runs. The hyper-parameters are selected by grid search based on model performance on development set. [3] On average it takes approximately

3.3 Results and Analysis

Table 1 and Table 2 show that our proposed EA^{2}E consistently performs better than strong baseline methods across datasets and evaluation metrics. In general document-level methods have better performance, especially in terms of recall, because sentence-level methods are more likely to miss cross-sentence arguments.

Alignment-enhanced training brings a significant improvement over BART-Gen but comes with higher training costs since the inputs are doubled.

Iterative inference brings unstable improvement. Figure 3 shows that more iterations brings higher performance only to a certain range. Since the only differences among iterations are their inputs, we conclude that labeling the arguments of other events helps the model extract the arguments of the current event. The upper bound of this improvement is limited by the error propagation in the augmented context.

Qualitative Analysis Table 3 presents some representative examples. BART-Gen incorrectly assigns *Tsarnaev* to the Target role, and *police* to the attacker role in the first example. It also misses the killer *brothers* in the second example and the attacker *Laden* in the third example. The second example shows the advantage of the Alignment-enhanced Training component in EA^{2}E, which helps extract the killer argument. The third example shows how Iterative Inference works with the augmented input: The tagged attacker in the neighboring *bombing* event is also the attacker in the target *attack* event.

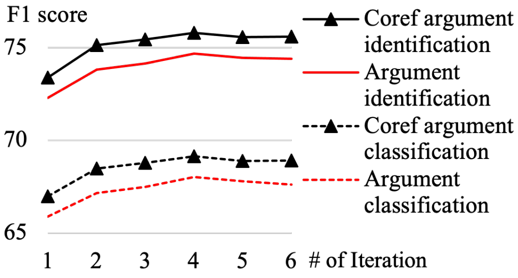

Figure 3: F1 score (%) of EA^{2}E for different iterations in a single run on WIKIEVENTS.

Remaining Challenges Though effective, iterative inference may propagate errors among iterations. In addition, the success of event awareness relies on the assumption that events in a neighborhood defined by trigger distance are inter-related to the target event. However, this assumption is not always held true in the case that distant events bring redundant information. It is not necessarily hurting the information but it brings noise by incorrectly implying the relations between the distant events and the target event.

Table 3: Examples of extracted arguments from BART-Gen, EA^{2}E w/o II, and EA^{2}E. We label **target event mention** with bold, gold arguments with underlines, correct but not annotated arguments with waves, and incorrect arguments with red. In the third example we also present the augmented input for Iterative Inference, in which the arguments of the bombing event are tagged.

4 Related Work

Sentence-level argument extraction approaches, where the event trigger and its arguments are usually located within a single sentence, cannot handle the cross-sentence trigger-argument distribution and the existence of multiple events within one document. Though recent attempts on document-level argument extraction have gone beyond sentence boundaries, they either focus on one-event-per-document setting, or model each event independently. The most related work to ours is (Li et al., 2021), which formulates the task as conditional generation following event templates and extracts arguments for each event independently, while our work focuses on the consistency among arguments for different events. The methods in (Du et al., 2021) and (Du and Cardie, 2020) are designed for Role-filler Entity Extraction (REE) task under the assumption that one generic template is produced for each document, while our work focuses on extracting arguments for multiple events for each document. (Yang et al., 2021) introduces Parallel Prediction Network that generates all possible events in parallel based on the document-aware representations, while we adopt a generative framework. (Xu et al., 2021) model the whole document as graphs and capture the interdependency among events by tracking the extracted events with a global memory, while we introduce event awareness for interdependency without external memory modules.

5 Conclusion

We introduce Event-Aware Argument Extraction (EA^{2}E) model to improve self-contained consistency in document-level event argument extraction. We conclude that in iterative inference brings higher performance only to a certain range of iterations and alignment-enhanced training brings significant improvement with costs.

Abstract

Distantly-supervised named entity recognition (NER) locates and classifies entities using only knowledge bases and unlabeled corpus to mitigate the reliance on human-annotated labels. The distantly annotated data suffer from the noise in labels, and previous works on DSNER have proved the importance of pre-refining distant labels with hand-crafted rules and extra existing semantic information. In this work, we explore the way to directly learn the distant label refinement knowledge by imitating annotations of different qualities and comparing these annotations in contrastive learning frameworks. the proposed distant label refinement model can give modified suggestions on distant data without additional supervised labels, and thus reduces the requirement on the quality of the knowledge bases. We perform extensive experiments and observe that recent and state-of-the-art DSNER methods gain evident benefits with our method.

1 Introduction

Named entity recognition (NER) refers to the sequence tagging task of detecting the interested entities in unstructured texts and classifying them into predefined categories. NER serves as a foundation part of information extraction in natural language processing (NLP) with applications in many downstream tasks such as question answering (Khalid et al., 2008; Jin et al., 2021), knowledge graph construction (Jia et al., 2018; Zhao et al., 2018), and dialog systems (Bowden et al., 2018). Supervised NER models have been developing rapidly in recent years and have achieved enormous success (Huang et al., 2015; Wang et al., 2020). However, acquiring abundant high-quality human annotations where every word within a sentence should be labeled can be very expensive and limits the application of NER models in many domains.

To alleviate the reliance on human annotations, a practical approach is to introduce distant supervision (Mintz et al., 2009) to automatically generate labeled data by matching entities in easily-obtained knowledge bases. Meanwhile, after years of development, there are many open access knowledge bases or dictionaries such as WikiData[1] and YAGO[2] in the general domain and UMLS (Lindberg et al., 1993) and MeSH[3] in the biomedical domain, which makes it possible to annotate large scale training data for NER models automatically. However, distant annotation suffers from two issues: **incomplete annotation** and **noisy annotation**. The knowledge bases with limited coverage of entities usually label only part of the entities in text, and the remaining entities are incorrectly labeled as background, denoted as incomplete annotations. The noisy annotation occurs when an entity with more than one word and the knowledge bases only contain a sub-sequence of the entity, resulting in partial annotation and sometimes wrong labeling of the entity type.

The neural network-based NER model has a strong ability in fitting the noise in training data, resulting in poor performance with distant labels. Some previous works focusing on distantly-supervised named entity recognition (DSNER) attempt to mitigate the two issues by applying techniques including: (1) entity selection (Yang et al., 2018; Zhang et al., 2021) or noisy entity removal (Onoe and Durrett, 2019); (2) label smoothing (Yang et al., 2018; Shang et al., 2018), (3) iteration and early stopping Liang et al. (2020); (4) PU-learning (Meng et al., 2021).

In addition, many works have found that pre-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2656 - 2666
July 10-15, 2022

refining the distant labels by artificial rules (Shang et al., 2018; Zhang et al., 2021; Liang et al., 2020; Meng et al., 2021) and extra semantic information (Zhang et al., 2021; Liang et al., 2020) effectively improves the performance of DSNER models. Inspired by this, we propose a framework to train an automatic distant label refinement model. Specifically, we generate annotations of different qualities by adding noises to weaken the annotations or enhancing the annotations with semantic parsing (Chen and Manning, 2014). Then we apply contrastive learning to guide a sequence scoring model to learn which annotations are better based on the sentence given two different annotations. Finally, the sequence scoring model can make a refinement suggestion on each token in arbitrary sentences and corresponding annotations. Therefore, it is model-agnostic, which can be stably and effectively used in data preprocessing for all DSNER models and consequently improves the performance of the DSNER models.

Due to the complex nomenclature (Névéol et al., 2018) and massive amounts of terminology in the biomedical domain, incomplete and noisy annotations are more evident in the distantly annotated corpus. Therefore, we focus on distant data refinement for DSNER in this work. Experiments show that the framework is good at amending the noisy or incomplete entities in distant data and significantly increases recall and F1 scores for DSNER models. The proposed method is named **CReDEL**, for **C**ontrastive **Re**finement of **D**istant **E**ntity **L**abels. The source code of our model is publicly available at `https://github.com/yinghy18/CReDEL`.

We summarize our contributions as follows:

- We propose an automatic label refinement method to mitigate the issues in distant NER data. The CReDEL is model-agnostic and consequently improves the performance of all DSNER models.
- We introduce a contrastive learning technique combined with a novel contrastive sample generation module. Trained on automatically annotated enormous corpus with knowledge bases, it empowers the proposed scoring model to evaluate annotation qualities.
- We conducted experiments on BC5CDR and NCBI-Disease to verify the effectiveness of CReDEL with classical NER and state-of-the-art DSNER methods. We show that our model brings consistent improvement for these methods.

2 Related Work

Distantly-Supervised Named Entity Recognition

Compared to fully supervised NER, DSNER gets rid of human annotations and uses knowledge bases or dictionaries to annotate the corpus automatically. Some DSNER works adopt entity selection (Yang et al., 2018; Zhang et al., 2021) or noisy entity removal (Onoe and Durrett, 2019) strategies, while some works design new components to handle multiple possible labels (Yang et al., 2018; Shang et al., 2018). Besides, Liang et al. (2020) applies early stopping to prevent fitting the noise and iteratively self-trains the model to recognize more entities. Peng et al. (2019) formulates DSNER as a positive-unlabeled learning problem. Meng et al. (2021) uses a noise-robust loss and a noisy label removal module and uses a self-training method to improve the generalization ability.

The works mentioned above (Shang et al., 2018; Zhang et al., 2021; Liang et al., 2020; Meng et al., 2021) also demonstrate that the pre-refinement of distant labels significantly improves the performance of DSNER methods. Before applying the DSNER models, these works refine the distant labels by tailoring corpus-aware dictionary (Shang et al., 2018), extending entity boundary by a distant phrase mining model (Shang et al., 2018; Zhang et al., 2021), annotating potential entities via POS tagging, and hand-crafted annotation rules (Liang et al., 2020; Meng et al., 2021). In this work, we propose a model to learn the refinement knowledge of distant NER annotations, which consequently has a lower requirement of the dictionary, corrects labels automatically, and facilitates DSNER models.

Contrastive learning

Intuitively, the contrastive model is trained via comparing between input data (Le-Khac et al., 2020), in which way the embeddings learn to put together similar samples and push away different ones. The core of contrastive learning is thus generating positive and negative sample pairs (Kalantidis et al., 2020). Previous works in NLP fields provide various ways of designing positive-negative sample pairs. Yuan et al. (2020) uses CODER to learn term representations by maximizing similarities between positive term-term pairs, where the word "positive" indicates that the terms are synonyms in the UMLS. Gao et al. (2021) constructs positive sentence embedding pairs using the embeddings of the same sentence passed through different dropouts in BERT in their unsupervised version. Contrastive learning has also been applied to the NER task. Lin et al. (2020) figures out the triggers for entity recognition by generating negative samples after randomly mixing triggers and sentences. Das et al. (2021) also utilizes contrastive learning to optimize distributional divergence and improve few-shot NER performance.

The design of contrastive loss always attempts teaching the model to minimize the distance within clusters despite the difference in forms, such as triplet margin loss (Balntas et al., 2016), contrastive loss (Chopra et al., 2005) and probabilistic NCE-based loss (Ma and Collins, 2018). We also mix hard negative samples in this work and transform the typical margin loss for CReDEL.

3 Methods

In this section, we detailedly describe the whole pipeline of CReDEL (Figure 1). Firstly, a knowledge base is used to obtain the distantly labeled tagging sequence. Then we construct sample pairs on a large corpus and train a scoring model via contrastive learning. We also introduce a module to generate high-quality positive samples by modifying the entity boundary. For the purpose of improving the quality of distant labeled training data, we apply the scoring model to modify datasets used by existing DSNER models, leading to their better performances.

3.1 Distant Labels Generation

For a given knowledge base and corpus, the distantly labeled data always refer to the corpus tagged by matching all entities in the knowledge base following the previous works (Peng et al., 2019; Zhang et al., 2021). The matching algorithm is maximum matching which greedily searches the longest string in the knowledge base. We adopt the "BIO" tagging scheme in this work to represent if a token is at the beginning (B) or inside (I) of a matched entity or does not belong (O) to any entity.

3.2 Contrastive Model Training

Given a sentence consisting of m words $\boldsymbol{X} = (x_1, \cdots, x_m)$ and two "BIO" tag sequences $\boldsymbol{Y_P}, \boldsymbol{Y_N}$ of $\boldsymbol{X}$, the scoring model takes the triple $(\boldsymbol{X}, \boldsymbol{Y_P}, \boldsymbol{Y_N})$ as input and learns to assign a better score to the tag sequence of higher quality, $\boldsymbol{Y_P}$, and a worse score for the other one $\boldsymbol{Y_N}$. This naturally comes down to contrastive learning, and the tag pair $(\boldsymbol{Y_P}, \boldsymbol{Y_N})$ are sampled as follows:

Negative samples generation For one sentence $\boldsymbol{X}$, we imitate the distant annotations to generate two pairs of positive-negative tag sequences: (1) Positive sample $\boldsymbol{Y_{1,P}}$ is the original distant tag sequence described in Section 3.1, while negative sample $\boldsymbol{Y_{1,N}}$ is obtained by randomly subtracting one entity from $\boldsymbol{Y_{1,P}}$. This is the negative tags created by imitating **incomplete** annotations. (2) Positive sample $\boldsymbol{Y_{2,P}}$ is the previous negative one, $\boldsymbol{Y_{1,N}}$. The negative sample $\boldsymbol{Y_{2,N}}$ is produced by changing $\boldsymbol{Y_{2,P}}$ to a different tag sequence within "BIO" tagging scheme with probability p in each position. This pair contains the incomplete annotation and its inferior version by imitating **noisy** annotations. To avoid the model from remembering our dictionary tagging, the pair $(\boldsymbol{Y_{1,P}}, \boldsymbol{Y_{1,N}})$ is only used in development set.

As the scoring model trained through contrastive learning can be insensitive to entity boundary with the aforementioned triples, we also generate another training tag pair using Parser[4]. In this triple, the negative sample $\boldsymbol{Y_{3,N}}$ is the distant tag sequence $\boldsymbol{Y_{1,P}}$ and the positive sample $\boldsymbol{Y_{3,P}}$ is the **parse-enhanced** version of $\boldsymbol{Y_{3,N}}$, which can be obtained from the rules in appendix A.2.

These three cases are hard negative samples and are shown in 1. However, the model requires more easy samples to learn some basic rules of the scoring task, so three other kinds of easy samples are mixed with existing hard samples. Specifically, a certain percentage of existing negative samples will be changed into (1) a random permutation of the distant tag sequence $\boldsymbol{Y_{1,P}}$, (2) a sequence of the same length containing only tag "B", (3) a **shift** of the $\boldsymbol{Y_{1,P}}$ by two tokens, For example, the first tag of $\boldsymbol{Y_{1,P}}$ will be the third in the negative tag sequence, and the second tag will become the fourth in the negative one.

Training Procedure For one triple $(\boldsymbol{X}, \boldsymbol{Y_P}, \boldsymbol{Y_N})$,

---

[4] In this paper, we use the Stanford Parser(?).

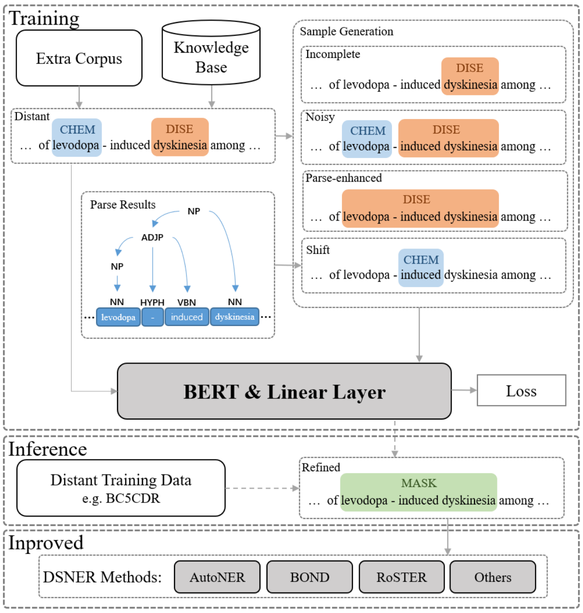

Figure 1: The framework of CReDEL. In training, CReDEL takes a sentence and a generated sample tag pair of distant labels as input, and uses contrastive loss to update model parameters. In inference, CReDEL masks tokens according to the distance between the probability score of the input sentence and distant labels. We use the same sentence as an example in both training and inference for brevity. The refined distant data is then used to train the DSNER models. “CHEM” and “DISE” refer to chemical and disease.

the architecture of the scoring model is as follows:

$$\begin{aligned} \boldsymbol{h} &= BERT(\boldsymbol{X}), \\ \boldsymbol{a} &= [\boldsymbol{s}_O, \boldsymbol{s}_I, \boldsymbol{s}_B] = softmax(\boldsymbol{hW}). \end{aligned} \tag{1}$$

The sentence $\boldsymbol{X}$ is passed through the BERT language model and turned into the hidden representation $\boldsymbol{h}$. Then a linear layer with output dimension three acts on $\boldsymbol{h}$ to get the probability score for “B”, “I” and “O” in each position respectively, denoted by $\boldsymbol{a}$, which is a matrix of m rows and 3 columns.

Bounded Cross-Entropy Distance We expect the output score sequence $\boldsymbol{a}$ close to the one-hot encoded positive tag sequence $\boldsymbol{p}$ and away from the encoded negative tag sequence $\boldsymbol{n}$. This is where contrastive learning applies. The "close" and "away" are defined through a distance. We first utilize cross-entropy (CE) loss function value to describe this distance, but the model collapses after enlarging the numerical gap through multiplying this distance by a constant only. To avoid this, a parameter ε is introduced and gives an upper bound to the distance. Finally, our loss function is the margin loss with distance, written as:

$$\mathcal{L} = \max(d(\boldsymbol{a}, \boldsymbol{p}) - d(\boldsymbol{a}, \boldsymbol{n}) + margin, 0), \tag{2}$$

where d is the introduced distance with upper bound:

$$d(x, y) = -\log \frac{\exp(-\text{CE}(x, y)) + \varepsilon}{1 + \varepsilon}. \varepsilon > 0. \tag{3}$$

3.3 Distantly Label Improving

CReDEL will not directly predict a tag sequence, as we find the scoring model cannot effectively discriminate “B” from “I” and a single “I” may appear in the tags without a leading “B”. Alternatively, we use the output score defined below to refine distantly labeled data.

During inference, CReDEL takes a sentence and distant tag sequence as input and outputs the token-level distance $d(\boldsymbol{a}, \boldsymbol{Y})$ of classification probability score matrix $\boldsymbol{a}$ and the one-hot encoded distant tag sequence as in 3.2. Then, it evaluates each tag by setting a threshold and masking all positions where the distance is larger than this threshold. Finally the masked sequence $\boldsymbol{Y_{mask}}$ obtained from the original distant tag sequence $\boldsymbol{Y}$ is fed to NER or DSNER models. Here mask means that this tag in this position will not contribute to the calculating of loss in DSNER models.

Since specific NER datasets usually contain several types of entities while the proposed model considers all entities, we add an entity typing module to classify the types of entities extracted from the contrastive scoring model. Then we only mask the tokens predicted to be the desired type in datasets. The entity typing module consists of a classical BERT-based classification model which takes an entity and its surrounding words as input to predict the entity type. The architecture of the entity typing module is described in Appendix A.3.

4 Experiments

4.1 Datasets

Our knowledge base for distant annotation is selected from UMLS by retaining the entities from specific high-quality sources and applying basic cleaning procedures (see Appendix A.1). For simplicity, the knowledge base is still denoted as UMLS in the follow-up sections.

We select 1 million sentences extracted from PubMed abstracts and distantly label them with

UMLS for the training of CReDEL. The size of this distant data is much larger than biomedical NER datasets and provides more semantic knowledge for the contrastive scoring model.

The public datasets we used to test the improvements are listed below:

BC5CDR (Li et al., 2015) is a biomedical Chemical Disease Relation dataset, which is also widely used in biomedical Named Entity Recognition. It consists of 1,500 PubMed articles with 4,409 annotated chemicals, 5,818 diseases entities. The training, development, and test set has 500 articles respectively. Since the types of entities in BC5CDR are "Disease" or "Chemical", We only use the terms of these two types in knowledge bases to label the training set.

NCBI-Disease (Doğan et al., 2014) is a dataset focusing on disease entities. The corpus texts are made of 793 abstracts and 6,881 annotated entities. We use the raw texts of the training set, consisting of 593 abstracts, and test on its test set consisting of 100 human-annotated abstracts. We only regard the "Disease" entity type in this corpus.

For both BC5CDR and NCBI-Disease, we adopt two sources of knowledge bases, the UMLS in Section 3.1 and the core dictionaries containing domain-specific terms from AutoNER (Shang et al., 2018), to annotate the two datasets. The four distantly annotated datasets are denoted as BC5CDR-UMLS, NCBI-UMLS, BC5CDR-AutoNER, and NCBI-AutoNER, respectively.

4.2 Settings

The proposed method pre-refines the training data for DSNER models. Therefore, we select three recent DSNER models to train on the distant data or the refined distant data and compare their performance. Besides, we select classical fully-supervised methods for better illustration and dictionary match as a baseline:

Dictionary Match is the distant annotation method in Section 3.1. For better adaptation to specific datasets, we only keep the entities of corresponding types. **Fully-supervised Methods**. We select two fully-supervised NER models for comparison: (1) **BiLSTM-CRF** (Huang et al., 2015) is the classical RNN-based NER model. It is trained with the distant annotated data or the data refined by CReDEL without language model pre-training. (2) **RoBERTa** (Liu et al., 2019) is a pre-trained language model, and we fine-tune the RoBERTa on the same data as we use in BiLSTM-CRF. **Distantly-supervised Methods**. Three recent or the state-or-art DSNER methods are applied to the distant annotated data or the data refined by CReDEL, including: (1) **AutoNER** (Shang et al., 2018) is a DSNER model with a "Tie or Break" tagging scheme containing entity span detection module and type classification module. (2) **BOND** (Liang et al., 2020) fine-tunes a RoBERTa on distant data with early stopping, then it iteratively expands the dictionary and self-trains the model. (3) **RoSTER** (Meng et al., 2021) uses the noise-tolerant mean absolute error loss with the self-training method and augmented sequences generated by the pre-trained language model without fine-tuning.

4.3 Implementation Details

The contrastive scoring model uses the BERT pre-trained model with dimension 768 followed by a three-class classification layer. In the loss function, The hyperparameter ε is set to 0.2 and the margin equals 0.3. The training adopts a warming up procedure with the learning rate initialized as 8×10^{-6} and reaching its peak 3×10^{-5} at warming step 1000. We use a batch size of 16 sentence with a max length of 256. The training will take about one day on RTX 2080 Ti.

For the compared methods, we preserve their default or recommended parameters unchanged most of the time. The ensemble model number is set to 1 in RoSTER as our computation resources are limited. And the full dictionary of AutoNER containing high-quality phrases without type information is abandoned because our dictionary does not have a counterpart to compare with.

5 Results

5.1 NER Performance Comparison

The datasets improved by the CReDEL with Parser tend to produce more complete term phrases after training, which can be seen in the case study in Section 5.2. However, the case study also shows that the complete term may be away from the test annotations which are part of a long entity. The completeness cannot be captured with traditional exact match F1-score, where predicted entities contribute to the true positive only if the left and right boundary and the entity type all match the test annotations. Motivated by the Boundary IoU (intersection over union) metric (Cheng et al., 2021), we promote another precision, recall, and F1 com-

Table 1: The Boundary Intersection metric and correspoding precision, recall and F1 score of the distantly supervised methods on datasets BC5CDR and NCBI-Disease annotated by our UMLS dictionary and AutoNER dictionary. Boldface numbers indicate that this experiment with the left-side model achieves the best performance on one specific dataset among the three data conditions.

puting method, called **BI** (Boundary Intersection) score , by considering intersection as follows:

$$\begin{aligned} \text{Prec.} &= \frac{|P_e \cap G_e|}{|P_e|}, \\ \text{Rec.} &= \frac{|P_e \cap G_e|}{|G_e|}, \\ \text{F1} &= \frac{2 \times \text{Prec.} \times \text{Rec.}}{\text{Prec.} + \text{Rec.}}. \end{aligned} \tag{4}$$

Here P_e and G_e are the set of predicted label positions and true label positions within some entity. Intuitively speaking, the new F1 is token-level F1 after excluding the condition that both prediction and ground truth are 'O'. This metric can describe the actual performance of the methods on data improved by CReDEL with parser in the aspect of improving term completeness. Moreover, it is suitable for real-world settings like extracting terms. The new F1-score, precision, and recall on all datasets and methods are demonstrated in Table 1. The "Original Distant", "Refined w/o Parser" and "Refined" refer to the distant data, the data refined by CReDEL trained without parse-enhanced samples, and the data refined by CReDEL, respectively.

We should compare the scores on the same dataset by the same DSNER model trained with original distant data and the refined data. Under the BI score metric, Table 1 tells us that the data modified by the CReDEL with Parser achieves an almost universal improvement in F1-score compared to original data. In BC5CDR-UMLS, BC5CDR-AutoNER, and NCBI-AutoNER it also beats the CReDEL without Parser. The promotion of F1 is mainly obtained through relatively more considerable progress in recall score and a slight change in precision score. This can prove the superiority of our method.

We also produce the exact match F1-scores in Table 2 denoted as the precision*, recall*, and F1-score* on the same datasets. In general, both data modified by CReDEL with and without Parser achieve higher recall scores on all the datasets and all the methods, and the one modified by CReDEL with Parser further increases the recall on much more than half the experiments. Meanwhile, the precision scores are boosted on about half of the experiments, especially on the two datasets tagged by the UMLS subset. Consequently, over $\frac{3}{4}$ of the data reach a higher F1-score among the experiments in Table 2 and not in a trade-off manner.

It is worth noticing that the gain in F1-score differs in range, and we claim that for a dictionary not dataset-specific, such as our dictionary, which can be generally applied, the improvement will be rather noticeable. On the other hand, the construction of AutoNER dictionaries includes more handcrafted cleaning rules which reduce the noise in annotations. They only consist of about 1k terms rather different from general domain dictionaries

and thus have a higher precision score.

5.2 Efficacy of Distant Label Refinement

This section conducts experiments to explain what CReDEL does when noisy annotations exist in distant labels. Specifically, we define the tokens whose labels are different in distant data and golden test data as noisy tokens. The tokens of “O” labels in test data refer to the negative tokens while the remaining tokens refer to the positive tokens. Then we count the positive tokens, noisy tokens, masked, and noise tokens masked by CReDEL. Besides, we also count the false-positive (FP) tokens and false-negative (FN) tokens as well as the masked FP and FN tokens.

For NCBI-Disease, there are 124,250 tokens in all sentences in the test set, while 18,380 tokens are positive, 10,199 are noisy. CReDEL masks 24,652 tokens, and 5,345 of them are noisy. The accuracy of correct masks is much higher than random masking, indicating that CReDEL is conducive to reducing noise. The results in BC5CDR are similar. In addition, CReDEL is better at handling the FN tokens than FP tokens since CReDEL masks 77.6% of FN tokens in NCBI-Disease, and only 22.1% FN tokens are masked. The above observations also explain the increase in recall for the DSNER model trained with the refined data.

For better understanding, the case study is shown in Table 4. In the first example, the phrase “ectopic intracranial retinoblastoma” appears in the golden annotation as a disease entity, while the distant annotation makes an incomplete annotation. CReDEL disagrees with the distant annotation and suggests masking this phrase correctly and masking "child with" redundantly. Correspondingly, the BOND trained with the refined data correctly predicts "ectopic intracranial retinoblastoma" and the BOND trained by original data makes mistakes. In the second example, the golden and distant annotation both label "levodopa" as a chemical entity and "dyskinesia" as a disease entity, while CReDEL masks all tokens in "levodopa-induced dyskinesia". The BOND trained with the refined data predicts the disease entity "levodopa-induced dyskinesia", which is better than the prediction of BOND trained with distant data. This case fits our parse-enhanced entity boundary modifying strategy, and both CRe-

Table 5: Here * represents model collapsing with strange predictions or not converging after ablation. The exact match F1-score of the CReDEL, the CReDEL w/o the entity typing module ,the CReDEL trained using negative sample case $(\boldsymbol{Y}_{1,\boldsymbol{P}}, \boldsymbol{Y}_{1,\boldsymbol{N}})$ and easy samples, the CReDEL trained using easy samples/hard samples only, and the DSNER method with parse improvement after it. The results are computed on the dataset BC5-UMLS by methods BOND and RoSTER.

DEL and the DSNER model trained with refined data prefer to predict complete entities.

6 Ablation Study

To verify the effectiveness of each design of CReDEL, we conduct the ablation studies. We mainly discuss three parts, the first of which is the effectiveness of parse and it has been fully exploited in the results part. The second ablation is CReDEL **w/o typing**, that is, without the final entity typing module. The other part of ablation considers the selection of training sample cases. We train CReDEL (1) **w.** $(\boldsymbol{Y}_{1,\boldsymbol{P}}, \boldsymbol{Y}_{1,\boldsymbol{N}})$, using only sample pair $(\boldsymbol{Y}_{1,\boldsymbol{P}}, \boldsymbol{Y}_{1,\boldsymbol{N}})$ in Section 3.2 and easy samples; (2) **w. easy only**, as no hard samples are included; and (3) **w. hard only**, where only easy samples are used. The results are shown in Table 5. The model trained without easy samples simply cannot converge. Its predicted phrases are meaningless and in chaos. The data modified by CReDEL with only easy samples lead the RoSTER method to collapse with zeros or NaN in output probabilities and achieve low scores with BOND method. Other ablations also result in a drop in the F1 score, revealing the contributions of their corresponding part in the model design.

Finally we discuss the condition where the parser does not act on the training set of CReDEL but on the output of DSNER models without CReDEL, denoted as Method **w. parse after**. As an automatic refinement model, we should outperform the baseline refinement with Parser. We apply the same parse-enhancing rule and find the F1-score is far behind CReDEL as demonstrated in Table 5. Even adopting the new BI metric, this model also performs badly with 0.538 and 0.489 BI F1-score on method BOND and RoSTER respectively.

These drops can be explained. Without entity type classification, the model will mask much more phrases that are valid but beyond the dataset annotation types. The BOND or RoSTER models potentially learn to pay attention to these phrases, resulting in a decline in precision. The model trained with $(\boldsymbol{Y}_{1,\boldsymbol{P}}, \boldsymbol{Y}_{1,\boldsymbol{N}})$, on the other hand, tends to fit the positive samples $\boldsymbol{Y}_{1,\boldsymbol{P}}$ which are fixed by dictionary annotations. The BERT model may recognize these words in some batches, and the trained CReDEL can lose generalization abilities. If using

Parser after DSNER methods, it is only a rigid tool rather than a model exploiting semantic information. The CReDEL with Parser takes effect because it is combined with our other designs.

7 Conclusion

This paper proposes a novel approach to automatically learn the refinement knowledge of distantly annotated NER labels and modify the distant labels to enhance DSNER models. The proposed method consists of a contrastive samples generation module, a contrastive training procedure, and a distantly label improving strategy. Experiments demonstrate that our method consistently and significantly improves DSNER and NER models on distantly annotated NER data, and it can be stably applied to all the datasets and methods.

Acknowledgements

Upon the completion of this paper, we would like to thank Zheng Yuan and Hongyi Yuan for their helpful comments and suggestions. We also gratefully acknowledge the support of Jun Xia and his providing of raw data.

A Appendix

A.1 Processing of UMLS

The Unified Medical Language System (UMLS) (Lindberg et al., 1993) is a large-scale resource containing over 4 million unique medical concepts. The restricted set of source ontologies in UMLS include "CPT", "MEDLINEPLUS", "RXNORM", "SNOMED-CT" and so on (Table 6). After that, we apply necessary cleanings such as removing ambiguous or illegal words and abbreviations that are prone to mismatch.

Source	Name or Explanation
CPT	Current Procedural Terminology
HPO	Human Phenotype Ontology
MEDLINEPLUS	Certified patient-oriented web-content
MSH	Medical Subject Headings
MTH	UMLS Metathesaurus Names
NCI	National Cancer Institute Thesaurus
RXNORM	NLM's Nomenclature for Clinical Drugs for Humans
SNOMEDCT	US edn. of the Systematized Nomenclature of Medicine-Clinical Terms

Table 6: The restricted set of source ontologies.

A.2 Parse-based Entity Boundary Modifying

The parser will give a syntax tree of a sentence, with the tokens in the sentence as leaves and syntax labels as other nodes. We set four rules for the parse modifying: (1) If one token is within an entity, we find its parent in the syntax tree generated by the Stanford parser and tag the whole new noun phrase as an entity in the "BIO" tagging scheme if the parent label is "Noun Phrase". (2) If the new entity in (1) starts with a comparative form of an adjective, cardinal number, conjunction, or pronoun, then we repeatedly delete the first token until it does not belong to one of those labels. (3) If the extension of the original entity encounters conjunction or some specific punctuation, then we reserve the original entity. (4) If none of the tokens in an original entity is a noun word and none of the parent labels is “Noun Phrase”, then we delete the entity from the original tag sequence.

A.3 Entity Typing Module

In the entity typing module, we train a BERT-base classifier with the distant data labeled by the same knowledge base. The classifier takes an entity and its surrounding words as input. Then it predicts the entity type of the input entity. In training, the entity type is from the knowledge base, and the model updates with cross-entropy loss.

Negative Sample is Negative in Its Own Way: Tailoring Negative Sentences for Image-Text Retrieval

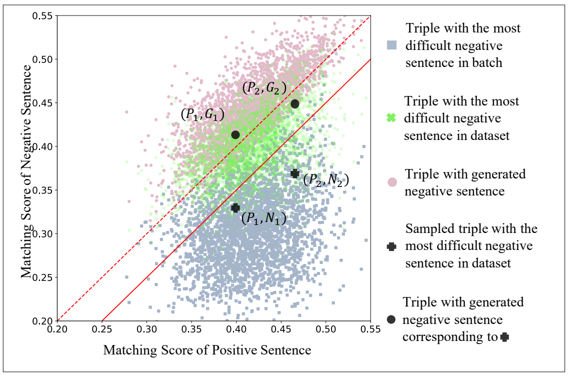
Abstract

Matching model is essential for Image-Text Retrieval framework. Existing research usually train the model with a triplet loss and explore various strategy to retrieve hard negative sentences in the dataset. We argue that current retrieval-based negative sample construction approach is limited in the scale of the dataset thus fail to identify negative sample of high difficulty for every image. We propose our TAiloring neGative Sentences with Discrimination and Correction (TAGS-DC) to generate synthetic sentences automatically as negative samples. TAGS-DC is composed of masking and refilling to generate synthetic negative sentences with higher difficulty. To keep the difficulty during training, we mutually improve the retrieval and generation through parameter sharing. To further utilize fine-grained semantic of mismatch in the negative sentence, we propose two auxiliary tasks, namely word discrimination and word correction to improve the training. In experiments, we verify the effectiveness of our model on MS-COCO and Flickr30K compared with current state-of-the-art models and demonstrates its robustness and faithfulness in the further analysis.



(a) The diagram plots a triplet (image, positive sentence, negative sentence) as a dot is defined by matching score of the positive pair on the X-axis and that of the negative pair on the Y-axis. The matching scores are also computed by CLIP(ViT-B/32) (Radford et al., 2021).

Image	Sentence	Score
	P_1: A man with a gray beard rides his bike on the beach of the ocean. N_1: Man on bike, with bike clothing and helmet on, having trouble maneuvering through sand from beach. G_1: A woman with a gray beard rides his bike on the beach of the ocean.	0.40 0.34 0.41
	P_2: A little girl is posing on some pumpkins within an area surrounded by flowers. N_2: A girl wearing a red and black striped shirt is sitting on a brick wall near a flower garden . G_2: A little girl is posing on some pumpkins within a beach surrounded by flowers.	0.47 0.36 0.45

(b) Two images with the positive sentence (P), the most difficult negative one (N) retrieved from dataset by CLIP and the generated negative one (G). The score is the cosine similarity computed by CLIP and larger is better. The underlined red words are non-correspondence ones to the image.

Figure 1: Diagram of matching scores (a) and two examples (b) in Flickr30K (Plummer et al., 2015).

1 Introduction

The task of image-text retrieval takes a query image (sentence) as input and finds out matched sentences (images) from a candidate pool. The key component of the retrieval framework is the similarity computation of an image-sentence pair and it aims to assign higher scores to positive pairs than negative ones. Triplet loss is widely applied for training. Take image-to-text as example[1], it constructs two image-sentence pairs using an image and two sentences (one is relevant and the other is not), and the optimization process increases the similarity of the positive pair while decreasing that of the negative one. Previous research (Xuan et al., 2020) reveals that models trained with harder negative samples, i.e., sentences that are more difficult to be distinguished, can generally achieve better performance. In this line of work, researchers explore various strategies to search mismatched sentences for a query image, from randomly choosing mismatched sentences to using the most similar one. The search

---

[1] To keep the presentation simple and clear, we use image-to-text as example to represent tasks in both ways throughout the paper.

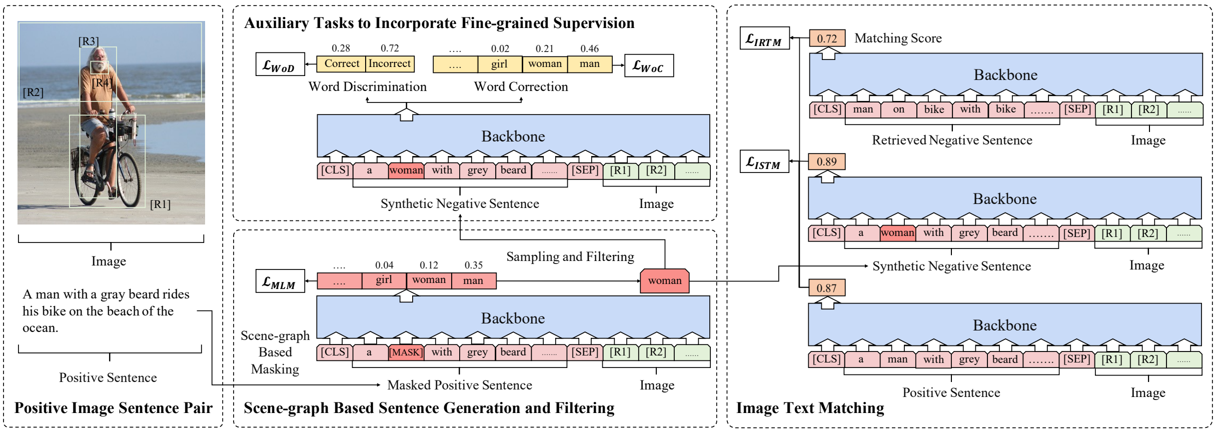

Figure 2: Framework of TAiloring neGative Sentences with word Discrimination and Correction (TAGS-DC).

scope moves from a single training batch (Karpathy and Fei-Fei, 2015; Faghri et al., 2018; Kiros et al., 2014; Socher et al., 2014; Lee et al., 2018; Li et al., 2019) to the whole dataset (Chen et al., 2020a; Zhang et al., 2020). Although promising results have been reported by searching for harder negative samples in a larger scope, the effectiveness is limited by the scale of the dataset.

To compare the effectiveness of these strategies, we randomly sample $3,000$ images in Flickr30K (Plummer et al., 2015) and plot training triples constructed in Figure 1. Each dot stands for a triple (image, positive sentence, negative sentence), and X-axis is the matching score of the positive image-sentence pair while Y-axis is that of the negative one. In general, triples located on the left of the dotted line are more difficult to be distinguished because matching score of the negative pair is higher than the positive one or comparable. As we can see, triples obtained by searching the most difficult mismatched sample in the batch are largely located on the right of the dotted line, and the matching scores of negative pairs are much smaller with a gap larger than 0.05 on average (in the right of the solid line). When enlarging the searching scope to the whole dataset, triples move up in positions, and around 40% of negative pairs obtain higher matching scores than positive ones. However, there are still 18% of images that can only recruit negative samples with a matching score 0.05 lower than its positive counterpart. This confirms the limitation of retrieve-based negative sample construction strategy.

To have a better understanding, we present two triples in Figure 1 i.e., (P_1, N_1) and (P_2, N_2) (denoted as black cross). It shows that negative sentences N_1 and N_2 describe scenes with significant differences compared with the query images, therefore, they are easy to be distinguished. Given that a high percentage of images obtain these low-quality negative sentences in the dataset, we believe it is necessary to collect negative samples beyond retrieval. Instead of searching for original sentences in the dataset, we explore constructing artificial negative samples by editing positive sentences. We demonstrate two generated sentences in Figure 1, G_1 replaces "man" with "woman" on P_1 and G_2 replaces "area" with "beach" on P_2. The generated sentences obtain comparable or even higher matching scores than positive ones. We further generate artificial sentences for all images to form a new set of triples. These triples are plotted in Figure 1 as pink dots. We can see all of them located on the left side of the dotted line, which means they are more difficult to be distinguished.

In this paper, we propose TAiloring neGative Sentences (TAGS) by rewriting keywords in positive sentences of a query image to construct negative samples automatically. In specific, we employ the strategy of *masking* and *refilling*. In masking, we construct scene graph for the positive sentence and mask elements in the graph (objects, attributes, and relations). Refilling replaces the masked original words with mismatched ones to construct the negative sample. In the training process, we further propose two word-level tasks, *word discrimination* and *word correction*, to incorporate fine-grained supervision into consideration. Word discrimination requires the model to distinguish which words lead to the mismatch, and word correction demands the regeneration of the original words. Both tasks evaluate the capability of the model to identify minor differences between synthetic sentences and positive ones. During inference, the output of two tasks can provide fine-grained information through highlighting and revising mismatched words, and these can be regarded as the explanation for the decision made by the model to improve the interpretability. We evaluate our model on MS-COCO (Lin et al., 2014) and Flickr30K (Plummer et al., 2015). Experiment results show the effectiveness of our model.

Our contributions are three-fold: (1) We propose a generation-based method to construct negative samples to improve the training efficiency of image-text retrieval model. (2) To fully exploit the synthetic negative sentences, we propose two training tasks, word discrimination and word correction, to incorporate the fine-grained supervision to enhance the multi-modal local correspondence modeling. (3) Our model generates state-of-the-art performance on two public datasets MS-COCO and Flickr30K.

2 Framework

The overall framework of TAiloring neGative Sentences with word Discrimination and Correction (TAGS-DC) is shown in Figure 2. For each positive image-text pair (I_i, T_i), we first generate negative sentences $\mathbb{T}_i^-$ through scene-graph based masking and refilling T_i on the basis of masked language model (MLM) in §2.1. Second, we utilizes both retrieved and synthetic negative sentences for the training of image-text matching (IRTM and ISTM) in §2.2, where synthetic negative sentences are exploited in sentence-level. Third, we propose to train the synthetic sentence generator in a dynamic way to keep pace with the upgrading of matching model. Fourth, in §2.4, we apply word-level tasks of word discrimination (WoD) and word correction (WoC) on $\mathbb{T}_i^-$ to discover their differences with T_i for further training. MLM, IRTM, ISTM, WoC and WoD share the same backbone M_θ and have their own heads, namely, H_{MLM}, H_{ITM}, H_{WoC} and H_{WoD}. The detailed training step is illustrated in Algorithm 1 in appendix.

2.1 Scene-graph based Sentence Generation and Filtering

In general, negative sentences with more overlapped words with positive sentences tend to obtain higher matching scores with the query image, thus are more difficult to be distinguished. Therefore, we propose to edit relevant sentences to construct negative samples for a query image. After the sentence generation, we control the quality by filtering the false negative sentences. To ensure the editing operates on key semantic units of the sentence, we use a strategy based on scene-graph.

2.1.1 Scene-graph based Sentence Editing

The module of sentence editing takes a relevant sentence of the query image as input and outputs a synthetic sentence. It first identifies some key semantic units in the sentence and replaces them with other words. We employ a masked language model for this process following two steps namely, masking and refilling.

To identify the key semantic of a sentence, we construct the scene graph for a relevant sentence through scene graph parser of SPICE (Anderson et al., 2016) following SGAE[2] (Yang et al., 2019). We then collect objects, relations, and attributes as candidates for masking. To control the semantic offset of the synthetic sentence $T_i^{(k)}$, we randomly mask 15% tokens of sentence.

In the step of refilling, we use the output head H_{MLM}, which is a two-layer feed-forward network (FFN), on top of the backbone M_θ for masked language modeling. Thus, image I_i also gets involved in MLM to guide the refilling later. The detailed computation of $\mathcal{L}_{MLM}$ is shown in Eq. (1), where $\circ$ is the function composition and *NLL* is the loss of negative log-likelihood.

$$\begin{aligned} &MLM : H_{MLM} \circ M_\theta\big(I_i,\ T_i^{(k)}\big) \rightarrow T_i/T_i^{(k)} \\ &\mathcal{L}_{MLM} = NLL\big(MLM\big(I_i, T_i^{(k)}\big), T_i/T_i^{(k)}\big) \end{aligned} \tag{1}$$

Then during refilling process, we put $T_i^{(k)}$ into MLM to produce the logit scores, then sample the synthetic sentence $T_i^{(k,l)}$ following the distribution which originates from the logit with temperature τ as Eq. (2).

$$T_i^{(k,l)} \sim Softmax\left(MLM\big(I_i, T_i^{(k)}\big)/\tau\right) \tag{2}$$

We conduct the masking and refilling steps for K and L times to generate candidate synthetic sentences.

2.1.2 False Negative Sample Filtering

It hurts the training of using sentences that are relevant to the query image as negative samples (Chuang et al., 2020; Huynh et al., 2020). Therefore we propose a filtering process to remove

---

[2] `https://github.com/yangxuntu/SGAE`

false negative ones of synthetic sentences. In vision and language datasets, each image is annotated with multiple descriptive sentences. For example, there are five in MSCOCO and Flickr30K. For a synthetic sentence, if its replaced tokens are completely included in these annotated sentences, we will treat it as relevant. Based on this, we filter synthetic sentences which are relevant.

2.2 Image Text Matching

Given an image I_i and a sentence T_j, the retrieval model assigns a matching score $s \in [0, 1]$ of (I_i, T_j) with an output head H_{ITM}, which is a one-layer FFN, as Eq. (3).

$$\mathit{ITM} : H_{\mathit{ITM}} \circ M_\theta(I_i, T_j) \rightarrow s \tag{3}$$

Triplet loss (TripL) is widely applied in image text matching. With a hyper-parameter α, it takes a query image (text) U as an anchor for the matched (positive) image-text pair (U, V) against the mismatched (negative) pair (U, W) as the following equation.

$$\begin{aligned} &\mathit{TripL}_\alpha(U, V, W) \\ &= \mathit{max}\left(\alpha - \mathit{ITM}(U, V) + \mathit{ITM}(U, W),\ 0\right) \end{aligned} \tag{4}$$

Matching on Retrieved Cases During training, for each positive image-text pair (I_i, T_i), we retrieve a negative image I_i^- and a sentence T_i^-, then employ the loss of ITM in Eq. (5) for training,

$$\mathcal{L}_{\mathit{IRTM}} = \mathit{TripL}_\alpha\big(I_i, T_i, T_i^-\big) + \mathit{TripL}_\alpha\big(T_i, I_i, I_i^-\big) \tag{5}$$

Matching on Synthetic Sentences First, we pick up these relatively better generated negative sentences. In practice, we compute the matching score between each synthetic negative sentence and I_i as Eq. (6), and keep a synthetic negative sentence pool $\mathbb{T}_i^-$ to make each of them as difficult as possible.

$$\mathbb{T}_i^- = \underset{T_t^- \in \{T_i^{(k,l)} | T_i^{(k,l)} \neq T_i\}}{\mathit{argmax\text{-}m}} \mathit{ITM}(I_i, T_t^-) \tag{6}$$

where *argmax-m* is to pick out m sentences that earn the top-m matching scores.

Second, with synthetic sentences $\mathbb{T}_i^-$ in Eq. (6), we utilize them and the positive one T_i to compute the triplet loss, and get $\mathcal{L}_{\mathit{ISTM}}$ in Eq. (7).

$$\mathcal{L}_{\mathit{ISTM}} = \frac{1}{|\mathbb{T}_i^-|} \sum_{T_t^- \in \mathbb{T}_i^-} \mathit{TripL}_\alpha\big(I_i, T_i, T_t^-\big) \tag{7}$$

2.3 Dynamic Training Strategy of Negative Sample Generation for Image-Text Matching

The naive choice of MLM is to keep a pre-trained static one: pre-training a MLM in advance and fixing its parameters during the training of ITM. Recall that $\mathcal{L}_{\mathit{ISTM}}$ encourages the ITM model to learn the pattern of synthetic sentences and keep them away from the image, we consider that negative sentences generated by the static MLM would be no longer difficult for the ITM model as the training goes on. We propose to use the dynamic MLM that shares the M_θ with ITM for mutual improvement. Through the sharing, MLM continuously learns what is more relevant to the positive sentences and produces challenging negative ones for the improvement of ITM. The stronger ITM helps MLM to better identify the semantic alignment of image and keywords. MLM achieves the improvement synchronously with ITM through interaction.

2.4 Auxiliary Tasks to Incorporate Fine-grained Supervision

$\mathcal{L}_{\mathit{ISTM}}$ only provides sentence-level supervision and we argue it does not fully exploit the synthetic negative sentence. We introduce two auxiliary tasks to utilize the word-level difference and further enhance the model capability in multi-modal local correspondence modeling.

Word Discrimination The task is to determine whether each word of the synthetic sentence $T_t^- \in \mathbb{T}_i^-$ is matched with I_i, and we regard the replaced words of T_t^- as mismatched ones and others as matched ones. The target label G_t of $T_t^- \in \mathbb{T}_i^-$ is determined following $G_{t,j} = 1$ if $s_{i,j} = s_{t,j}$ else 0, where $s_{i,j}$ and $s_{t,j}$ are the j-th token of T_i and T_t^-. We set up a new output head H_{WoD}, and the objective of word discrimination is in Eq. (8).

$$\begin{aligned} &\mathit{WoD} : H_{\mathit{WoD}} \circ M_\theta\big(I_i, T_t^-\big) \rightarrow G_t \\ &\mathcal{L}_{\mathit{WoD}} = \mathit{NLL}\big(\mathit{WoD}\big(I_i, T_t^-\big), G_t\big) \end{aligned} \tag{8}$$

Word Correction This task is to correct these mismatched words in T_t^- as Eq. (9). The task not only requires the model to comprehensively understand the gap between the synthetic negative sentences and the original positive ones, but also word-dependency knowledge and local cross-modal alignment to fill the gap. H_{WoC} is the output head for word correction, and the objective is

Table 2: Effectiveness of Different Modules. *TAGS w/ WM* means replace the scene-graph based masking with word masking in TAGS. *TAGS w/ SG* means replace dynamic generator with static generator in TAGS.

shown in Eq. (9).

$$\begin{aligned} WoC &: H_{WoC} \circ M_\theta(I_i, T_t^-) \rightarrow T_i \\ \mathcal{L}_{WoC} &= NLL(WoC(I_i, T_t^-), T_i) \end{aligned} \tag{9}$$

2.5 Overall Training

Details of our training step are shown in Algorithm 1 in appendix. The overall training loss of our model has five components as Eq. (10) with hyperparameters λ_{IRTM}, λ_{MLM}, λ_{ISTM}, λ_{WoD} and λ_{WoC}.

$$\begin{aligned} \mathcal{L} = \lambda_{IRTM}\mathcal{L}_{IRTM} + \lambda_{MLM}\mathcal{L}_{MLM} \\ + \lambda_{ISTM}\mathcal{L}_{ISTM} + \lambda_{WoD}\mathcal{L}_{WoD} + \lambda_{WoC}\mathcal{L}_{WoC} \end{aligned} \tag{10}$$

During inference, we employ the ITM to determine the matching score of the query image (text) and the candidate text (image) as Eq. (3).

3 Experiment

Dataset We evaluate our model on MS-COCO (Lin et al., 2014) and Flickr30K (Plummer et al., 2015). In MS-COCO, each image is accompanied with 5 human annotated captions. We split the dataset following (Karpathy and Fei-Fei, 2015) with 113,287 images in the training set and 5,000 images in the validation and test sets, respectively. Flickr30K (Plummer et al., 2015) consists of 31000 images collected from the Flickr website, and every image contains 5 text descriptions. We take the same splits as in (Karpathy and Fei-Fei, 2015), with 1000 images for validation and 1000 images for testing, and the rest for training. 500

Models for Comparison We compare our model with some competitive approaches, including MMCA (Wei et al., 2020), and AOQ (Chen et al., 2020a). We also compare with methods based on vision language pre-trained models: UNITER+DG (Zhang et al., 2020), Unicoder-VL (Li et al., 2020), LightningDOT (Sun et al., 2021), UNITER (Chen et al., 2020b), CLIP (Radford et al., 2021) and ERNIE-ViL (Yu et al., 2020).

Implementation We employ the pre-trained UNITER (Chen et al., 2020b) with base (B) and large (L) settings as our backbone.

Evaluation Metrics We report recall at K (R@K) and Rsum. R@K is the fraction of queries for which the correct item is retrieved among the closest K points to the query. RSum is the sum of R@1+R@5+R@10 in both image-to-text and text-to-image.

3.1 Overall Performance

The overall result is shown in Table 1. TAGS is the model trained with generated negative samples, using the dynamic training strategy. TAGS-DC is our model built on top of TAGS, further trained using two auxiliary tasks. In the base setting, our model achieves the best performance in terms of all metrics except R@1 and R@5 of in text-to-image on Flickr30K. In the large setting, our model also outperforms other models across all metrics except R@5 MS-COCO text-to-image and Flickr30K image-to-image R@10. Compared with UNITER(L), our model achieves an improvement of 4.0 and 6.4 RSum points in MS-COCO and Flickr30K.

3.2 Ablation Study

We further demonstrate the effectiveness of different modules, namely, scene-graph based masking (denoted as PM), dynamic sentence generation (denoted as DG), and fine-grained training tasks (denoted as WoD and WoC) in Flickr30K. Original TAGS is trained with PM and DG. TAGS-DC is further trained with WoD and WoC.

Scene-graph VS Word based Masking We replace the scene-graph based masking with word-based masking (denoted as WM) to form TAGS w/ WM. Detailed results are shown in Table 2. WM follows the original sampling method of UNITER (Chen et al., 2020b) that randomly sample 15% tokens to mask, and PM is introduced in §2.1. TAGS outperforms TAGS w/ WM in terms of all metrics, and this verifies the effectiveness of PM.

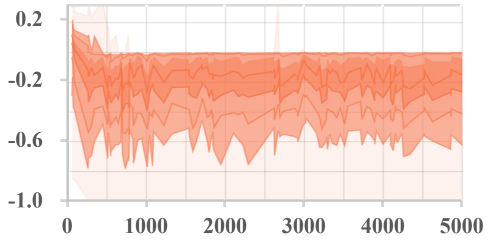
Dynamic VS Static Generator We replace DG with a static sentence generator (denoted as SG) to form TAGS w/ SG. The difference between TAGS and TAGS w/ SG lies in that the former shares the parameters of ITM and MLM while the latter does not. Both of them are initialized with the pre-trained UNITER-base and share the same hyperparameters. In detail, we set $\lambda_{MLM} = 0.1$ and $\lambda_{ISTM} = 0.001$. The static generator is fixed as a fine-tuned UNITER+MLM model. The performance of TAGS w/ SG is not so good as TAGS. This demonstrates the effectiveness of DG.

WoD and WoC In Table 2, TAGS-DC outperforms TAGS in both MS-COCO and Flickr30K. This reveals that word discrimination and correction contribute to the performance of ITM.

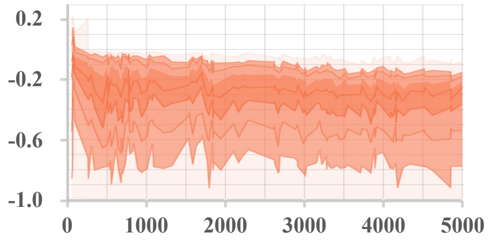
4 Further Analysis

4.1 Difficulty Distribution of Samples from Dynamic and Static Generator

To see the difficulty of negative samples constructed by various generation strategies, we plot the value distribution of samples. To evaluate the difficulty, we compute the similarity gap between the positive pair $\text{ITM}(I_i, T_i)$ and the negative one $\text{ITM}(I_i, T_t^-)$. We plot the value of negative pair minus positive one with respect to training steps (X-axis). In general, higher value means higher difficulty. The result is shown in Figure 3 where the darker color means more samples. The overall values of TAGS w/ SG (Figure 3 (a)) are higher than TAGS w/ DG (Figure 3 (b)). This implies that the static generator fails to provide negative sentences close to the image for ITM during training while our generator with dynamic generating strategy is effective.



(a) Dynamic



(b) Static

Figure 3: Value $\{\text{ITM}(I_i, T_t^-) - \text{ITM}(I_i, T_i)\}$ distribution of triples generated by dynamic and static generators respectively during the training. X-axis is training steps.

4.2 Quality Evaluation of Synthetic Sentences

We evaluate the quality of generated synthetic sentences in terms of automatic metrics and human evaluation.

Fluency We utilize the pre-trained language model GPT-2 (Radford et al., 2019) to compute the perplexity of synthetic negative sentences for the measurement of their fluency. We use positive sentences in the test set of Flickr30K as original ones and generate negative samples by TAGS and VSE-C. Furthermore, we look into sentences after correction. The overall results are shown in Table 3. Compared with sentences produced by VSE-C, our synthetic sentences have much smaller perplexity. After correction, the fluency of synthetic sentences can be improved.

Human Evaluation We perform a human evaluation to see whether all negative sentences generated are true negative. We randomly sample 200 sentences generated by TAGS and ask two annotators to determine whether the synthetic sentences are mismatched to the corresponding images. The result shows that 96.5% of synthetic sentences generated are true negative.

	Positive	Synthetic	Corrected	VSE-C
Perplexity	51.13	87.63	70.87	292.76

Table 3: Perplexity of synthetic negative sentences.

4.3 Negative Sentences Discrimination

In this section, we explore to see if the generator can discriminate positive sentences from synthetic ones. We compare UNITER and TAGS. For a pair of sentences (one is positive and the other is a synthetic negative one), the generator should assign a higher score to the positive one. We report the accuracy of discrimination. We utilize two negative sentence generators TAGS and VSE-C (Shi et al., 2018). Two versions of TAGS with different seeds are used for cross-validation. Results are shown in Table 4. We have several findings as follows. (1) TAGS2 is trained with a different seed with TAGS1, but the performance of TAGS1 almost makes no difference in discriminating their generated sentences. (2) Although the synthetic sentences of VSE-C are constructed with human efforts, TAGS also outperforms UNITER by about 9%. (3) Three generators produce negative sentences with different distributions, but TAGS performs better than UNITER consistently. These facts validate the robustness of TAGS.

Generator	Discriminator	Accuracy
TAGS1	*TAGS1*	98.7%
	UNITER	2.3%
TAGS2	*TAGS1*	99.7%
	UNITER	2.8%
VSE-C	*TAGS1*	96.3%
	UNITER	87.5%

Table 4: Accuracy of TAGS1 and UNITER in discriminating the negative sentences constructed by TAGS1, TAGS2 and VSE-C (Shi et al., 2018).

4.4 Effectiveness of Two Auxiliary Tasks

Image	Type	Sentence	U	T
	Positive	A man wearing a helmet, floating in the water	92.35	99.90
	Synthetic	**A man carrying white helmet , swimming in the water**	93.17	98.92
	Corrected	A man wearing a helmet, swimming in the water	-	-
	Positive	A young man about to throw a football	89.54	99.90
	Synthetic	**A man playing playing to catch a ball**	90.61	75.39
	Corrected	A man player about to throw a ball	-	-

Figure 4: Examples of TAGS-DC. The second column is the sentence type including positive one, synthetic one and corrected one. The third column is the corresponding sentence of the second column. The fourth and fifth columns are the UNITER(U) and TAGS-DC(T) scores for the sentence in the third column, respectively. The word color in synthetic sentences from green to yellow means the increase of the word mismatching scores. Words with underline mean the regenerated words are different from the original ones.

We show the performance of our model in two auxiliary tasks, namely, word discrimination and correction in the testing set of Flickr30K. In word discrimination, we use a threshold of 0.5 to split the positive and negative ones in terms of probability. The accuracy of word discrimination is 66.5%. In word correction, the accuracy is 87.3%. With the probability, we can provide additional support information accompanied to the final decision of our model.

Two examples are presented in Figure 4. (1) TAGS-DC assigns lower scores for synthetic negative sentences than positive ones, but UNITER fails. (2) Color of "carrying" and "playing playing" are yellow which means that our word discrimination successfully detects these mismatched words. Our model finds the local alignment in word-level and grammatical errors, then generates "wearing" and "man player" for correction. In the examples, word discrimination marks the mismatched components and word correction provides reasons for mismatching. (3) Our model fails to identify two mismatched words, "swimming", and "ball". Considering they are partially related to the image, our model is less effective in determining the relevance of these fuzzy words.

5 Related Work

Image-Text Retrieval Most works in image-text retrieval focus on better feature extraction and cross-modal interaction. Nam et al. (2017) and Ji et al. (2019) represent the image by semantics gathered from block-based attention. A line of research (Lee et al., 2018; Li et al., 2019; Wang et al., 2020; Wei et al., 2020; Li et al., 2021; Chen et al., 2022; Zheng et al., 2021; Fan et al., 2019, 2021b) detects features by pre-trained Faster R-CNN (Ren et al., 2015). Some other methods also focus on enhancing cross-modality relationship modeling, such as the dual attention network (Nam et al., 2017), the stacked cross attention (Lee et al., 2018; Liu et al., 2019; Hu et al., 2019), the graph structure attention (Liu et al., 2020), and the multi-modal transformer modeling (Wei et al., 2020; Fan et al., 2021a). UNITER (Chen et al., 2020b), Unicoder (Li et al., 2020) and ERNIE-ViL (Yu et al., 2020) follow BERT (Devlin et al., 2019) to pre-train the vision-language transformer model on the large-scale image-text datasets, and finetune in image-text retrieval.

Negative Samples in Contrastive Learning Selection strategies for negative samples have been widely studied in metric learning (Schroff et al., 2015; Oh Song et al., 2016; Harwood et al., 2017; Suh et al., 2019; Zhang et al., 2020; Chen et al., 2020a). Wu et al. (2017) employ distance weighted sampling to select more informative and stable examples. Ge (2018) present a novel hierarchical triplet loss capable of automatically collecting informative training samples. In image-text retrieval, early works (Kiros et al., 2014; Karpathy and Fei-Fei, 2015; Socher et al., 2014) utilize random negative samples for training. VSE++ (Faghri et al., 2018) incorporates difficult negative ones in the multi-modal embedding learning. The method is widely applied in the following works (Lee et al., 2018; Wei et al., 2020), and achieves significant performance improvement. UNITER (Chen et al., 2020b) randomly samples a portion of texts (∼512) from the dataset and picks up the hardest ones. AOQ (Chen et al., 2020a) selects these hard-to-distinguish cases from the whole dataset through a pre-trained ITM model and assigns hierarchical and adaptive penalties for samples with different difficulties. UNITER+DG (Zhang et al., 2020) samples hard negative sentences according to the structure relevance based on denotation graph (Plummer et al., 2015). These methods are retrieval-based and inspire us to find more difficult negative sentences through generation. Chuang et al. (2020) propose a method for debiasing, i.e., correcting for the fact that some negative pairs may be false negatives. In our work, we mask keywords (objects, attributes, and relationships) in the positive sentence then refilling, and exclude these sentences of which each token is included in image annotated sentences. This method introduces new keywords and alleviates the generation of false negative samples. Kalantidis et al. (2020) consider applying mixup to produce hard negatives in latent space. In our work, we directly rewrite the positive sentences that is missing in the latent space based method, and this improves the robustness and faithfulness. The most similar work is VSE-C (Shi et al., 2018) that attacks the VSE++ (Faghri et al., 2018) through replacing the nouns, numerals, and relations according to language priors of human and the WordNet knowledge base. Compare with VSE-C (Shi et al., 2018), our method has three advantages. (1) Our model does not depend on rules. (2) Our model is more flexible and can generate negative sentences with any number, but this is intractable for VSE-C. (3) The generated sentences of our model are more fluent than these of VSE-C as the results in Table 4.

6 Conclusion

In this paper, we focus on the image-text retrieval task and find that retrieve-based negative sentence construction methods are limited by the dataset scale. To further improve the performance, we propose TAiloring neGative Sentences (TAGS). It utilizes masking and refilling to produce synthetic negative sentences as negative samples. We also set up the word discrimination and word correction to introduce word-level supervision to better exploit the synthetic negative sentences. Our model shows competitive performance in MS-COCO and Flickr30k compared with current state-of-the-art models. We also demonstrate the behavior of our model is robust and faithful.

A Appendix

A.1 Implementation Details

We have two settings, base and large. The base setting of model has 12-layers, 768 hidden size and 12 attention heads and the large one has 24-layers, 1024 hidden size and 16 attention heads.

We utilize grid search to determine the hyperparameters. In retrieval-based matching, we randomly samples 399 negative sentence (image) from the whole dataset for the query image (sentence), and pick out the top 31 ones from them according to the matching scores. In the masked language modeling, we utilize the scene graph parser in SPICE to extract the phrases of objects, relationships and attributes from the positive sentence, and take these phrases as a whole to sample and mask. The mask probability is 0.15. In the generation enhanced matching, the temperature $\tau \in \{1.0, 1.5\}$, and we set $K = L = 20$ and $|\mathbb{T}_i^-| = 31/23$ for the base and large settings. λ_{ITM}, λ_{MLM}, λ_{ISTM}, λ_{WoD} and λ_{WoC} is sampled from $\{1.0\}$, $\{$5e-2, 1e-1$\}$, $\{$1e-4, 5e-4, 1e-3$\}$, $\{$5e-4, 1e-3$\}$ and $\{$5e-4, 1e-3$\}$, where we set $\lambda_{WoD} = \lambda_{WoC}$.

Our training is composed of two steps, (1) we train with *ITM*, *MLM* and *ISTM* with 5,000 steps as *NSG*; (2) we further train the model with the whole loss function as *NSGDC* with 1,500 steps. The learning rate lr is sampled from $\{$5e-5, 4e-5, 1e-5$\}$. We use a linear learning rate scheduler with 10% warmup proportion. The Adam with $\beta_1 = 0.9$ and $\beta_2 = 0.98$ is taken as the optimizer. The dropout is 0.1.

Our code is implemented with pytorch. For base setting in Flickr30K, we utilize 8 V100 for training and the computation time is about 8 hours.

A.2 Algorithm of TAGS-DC

Algorithm 1 Training step of TAGS-DC

Input: A positive image-text pair (I_i, T_i).
Parameter: Backbone M_θ, the head of masked language model H_{MLM}, image-text matching H_{ITM}, word discrimination H_{WoD} and word correction H_{WoC}.

```
# negative sentence generation.
Initializing $\widehat{\mathbb{T}}_i^- := \{\}$.

Abstract

Sign language recognition and translation first uses a recognition module to generate glosses from sign language videos and then employs a translation module to translate glosses into spoken sentences. Most existing works focus on the recognition step, while paying less attention to sign language translation. In this work, we propose a task-aware instruction network, namely TIN-SLT, for sign language translation, by introducing the isntruction module and the learning-based feature fuse strategy into a Transformer network. In this way, the pre-trained model's language ability can be well explored and utilized to further boost the translation performance. Moreover, by exploring the representation space of sign language glosses and target spoken language, we propose a multi-level data augmentation scheme to adjust the data distribution of the training set. We conduct extensive experiments on two challenging benchmark datasets, PHOENIX-2014-T and ASLG-PC12, on which our method outperforms former best solutions by 1.65 and 1.42 in terms of BLEU-4. Our code is published at `https://github.com/yongcaoplus/TIN-SLT`.

1 Introduction

Sign language recognition and translation aims to transform sign language videos into spoken languages, which builds a bridge for communication between deaf and normal people. Considering the unique grammar of sign languages, current effective recognition and translation systems involve two steps: a tokenization module to generate glosses from sign language videos, and a translation module to translate the recognized glosses into spoken natural languages. Previous works (Li et al., 2020; Sincan and Keles, 2020; Sharma and Kumar, 2021; Kumar et al., 2020; Camgoz et al., 2020) have proposed various solutions to address the first step, but paid less attention to the translation system. Hence, this paper aims to solve the problem of sign language translation (SLT) with the goal of translating multiple recognized independent glosses into a complete sentence.

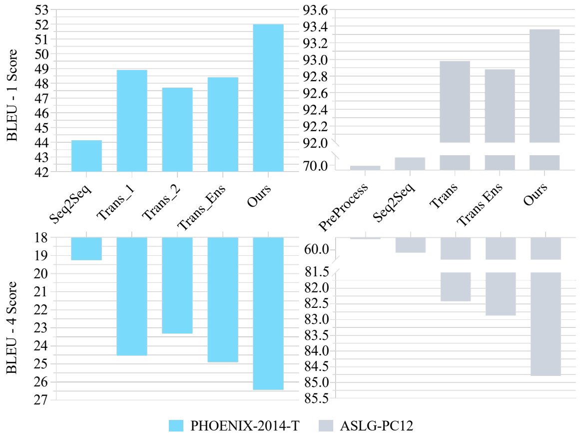

Figure 1: Comparing the sign language translation performance on two challenging datasets, i.e., PHOENIX-2014-T (blue) and ASLG-PC12 (gray), in terms of BLEU-1 and BLEU-4 metrics. Clearly, our approach achieves the highest scores on both datasets compared with others. The experiments section contains more results and analysis.

To do so, most existing works (Ko et al., 2019; Stoll et al., 2018) directly apply advanced techniques, e.g., Seq2Seq model (Sutskever et al., 2014) or Transformer (Vaswani et al., 2017), from neural machine translation to SLT. However, different from the lingual translation task in neural machine translation, SLT poses several unique challenges. First, it is hard to collect and annotate a large amount of sign language corpus. It is still an open question that how to explore more guidance and external information for SLT task by incorporating the pre-trained language models based on masses of unlabeled corpus. Second, since sign languages are developed independently from spoken languages with quite different linguistic features, the discrep-

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2679 - 2690
July 10-15, 2022

ancy of representation space between glosses and spoken sentences is significant, thus increasing the translation difficulty.

To address the above issues, we propose a novel task-aware instruction network, called TIN-SLT for sign language translation, further enhanced with a multi-level data augmentation scheme. Our TIN-SLT is capable of encoding pre-trained language model's ability into the translation model and also decreasing the discrepancy between the representation space of glosses and texts.

To begin with, we leverage the extracted hidden features from the pre-trained model as extra information to guide the sign language translation. Besides, we apply an instruction module to transform general token features into task-aware features. In this way, we can fully utilize the language skills originating from the external world, thus reducing the demand for sign language training data.

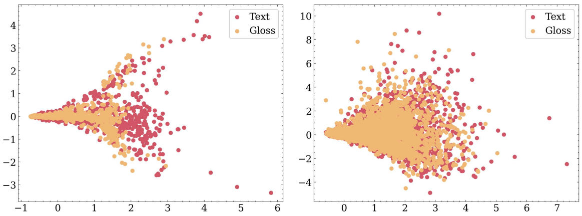
Next, to better inject the information from pre-trained model into the SLT model, we design a learning-based feature fusion strategy, which has been analyzed and validated to be effective compared with existing commonly-used fusion ways.

Finally, considering the large difference between the sign language glosses and texts in terms of the representation space, we propose a multi-level data augmentation scheme to enrich the coverage and variety of existing datasets.

In summary, our contributions are threefold: (i) a novel TIN-SLT network to explore more guidance of pre-trained models, (ii) a learning-based feature fusion strategy, and (iii) a multi-level data augmentation scheme. Extensive experiments on challenging benchmark datasets validate the superiority of our TIN-SLT over state-of-the-art approaches; see Figure 1 for example results.

2 Related Works

Methods for sign language recognition. SLR task mainly focuses on the extraction of extended spatial and temporal multi-cue features (Zhou et al., 2020; Koller et al., 2017). Most existing works (Yin et al., 2016; Qiu et al., 2017; Wei et al., 2019; Cui et al., 2019) study the strong representation of sign language videos such as multi-semantic (Cui et al., 2019) and multi-modality (Koller et al., 2019) analysis. Although extracting representative features from sign language videos is fully explored, how to effectively conduct the subsequent translation by considering the unique linguistic features of sign language is often ignored in these SLR works.



(a) Vocab distribution on PH14 dataset

(b) Vocab distribution on ASLG dataset

Figure 2: Comparing the sample distribution between the input sign glosses (yellow dots) and the output translated texts (red dots) on two datasets.

Methods for sign language translation. Early approaches for SLT rely on seq2seq model and attention mechanism (Arvanitis et al., 2019), while facing the limitation of long-term dependencies. Later, motivated by the ability of the Transformer (Vaswani et al., 2017), many researchers utilize it to effectively improve SLT performance. For example, the work in Camgoz et al. (2020) tried to use Transformer for both recognition and translation, and promote the joint optimization of sign language recognition and translation. The subsequent work (Yin and Read, 2020) proposed the STMC-Transformer network which first uses STMC networks (Zhou et al., 2020) to achieve better results for SLR, and then exploits Transformer for translation to obtain better SLT performance.

General neural machine translation. Broadly speaking, sign language translation belongs to the field of neural machine translation, with the goal of carrying out automated text translation. Earlier approaches deployed recurrent network (Bahdanau et al., 2014), convolutional network (Gehring et al., 2017), or Transformer (Vaswani et al., 2017) as encoder-decoder module. Among them, Transformer has achieved state-of-the-art results, but the translation performance still needs to be improved due to the limited training corpus. In addition, there are some explorations in bringing the pre-trained models into neural machine translation (Imamura and Sumita, 2019; Shavarani and Sarkar, 2021; Zhu et al., 2020).

3 Challenges

The goal of this work is to translate the recognized multiple independent glosses (network input) into a complete spoken sentence (expected output). Compared with general neural machine translation tasks, SLT faces two main challenges:

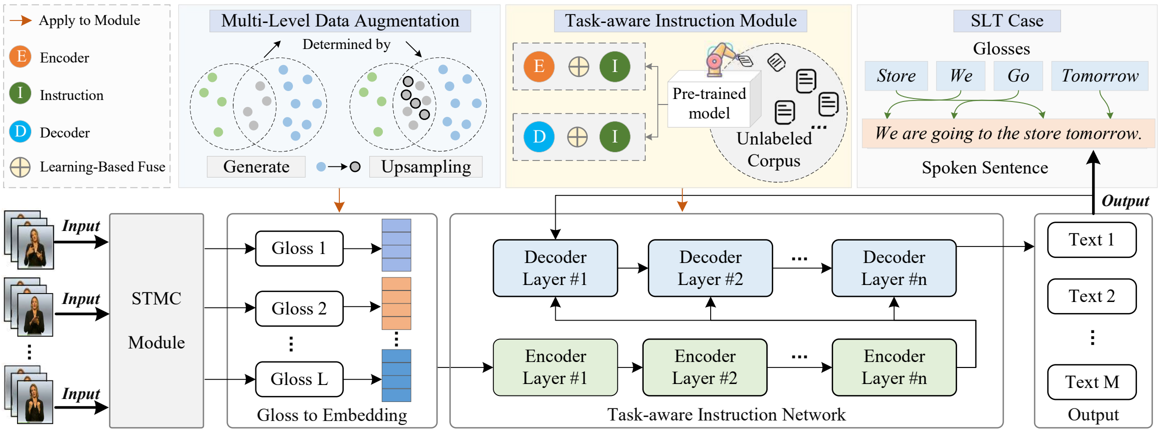


Figure 3: Network architecture of TIN-SLT. As shown in the bottom row, we first employ STMC model (Zhou et al., 2020) to recognize sign language videos to independent glosses. Next, we design a multi-level data augmentation scheme to enrich existing data pool for better feature embedding from glosses. Then, we design a task-aware instruction network with a novel instruction module to translate glosses into a complete spoken sentence.

Limited annotated corpus: Compared with natural languages, the data resources of sign languages are scarce (Bragg et al., 2019). As a result, the SLT models trained on limited data often suffer from the overfitting problem with poor generalization (Moryossef et al., 2021; Yin et al., 2021).

Discrepancy between glosses (input) and texts (output): Figure 2 shows the representation space of sign glosses (yellow dots) and translated texts (red dots) using Word2Vec (Mikolov et al., 2013) on two different datasets. We can observe that the representation space of sign glosses is clearly smaller than that of the target spoken language, thus increasing the difficulty of network learning.

4 Our Approach

To address the above challenges, we propose TIN-SLT by effectively introducing the pre-trained model into SLT task and further designing a multi-level data augmentation scheme. Figure 3 depicts the detailed network architecture. In the following subsections, we will firstly introduce the network architecture of TIN-SLT, followed by our solutions to address the above two challenges.

4.1 Network Architecture of TIN-SLT

Given a sign language video $\mathcal{V} = \{V_1, \ldots, V_T\}$ with T frames, like existing approaches, we also adopt a two-step pipeline by first (i) recognizing $\mathcal{V}$ into a sequence $\mathcal{G} = \{g_1, \ldots, g_L\}$ with L independent glosses and then (ii) translating $\mathcal{G}$ into a complete spoken sentence $\mathcal{S} = \{w_1, \ldots, w_M\}$ with M words, but we pay more attention to solve step (ii). Hence, for step (i), as shown in the bottom-left part of Figure 3, we empirically use the spatial-temporal multi-cue (STMC) network (Zhou et al., 2020), which consists of a spatial multi-cue module and a temporal multi-cue module. For more technical details of STMC, please refer to (Zhou et al., 2020). Below, we shall mainly elaborate on the details of addressing step (ii).

After obtaining the sequence $\mathcal{G}$ of sign glosses, considering that the representation space of glosses is much smaller than that of texts (see Figure 2), we thus design a multi-level data augmentation scheme to expand the gloss representation space; see the top-left part of Figure 3 as an illustration and we shall present its details in Section 4.3.

Next, as shown in the bottom-middle part of Figure 3, the key of our design is a task-aware instruction network, where we adopt Transformer as the network backbone consisting of several encoder and decoder layers, whose objective is to learn the conditional probabilities $p(\mathcal{S}|\mathcal{G})$. Since SLT is an extremely low-data-resource task as we have discussed in Section 3, we thus focus on exploring more task-aware guidance by learning external world knowledge, which is dynamically incorporated into the Transformer backbone via our designed task-aware instruction module. We shall present its details in Section 4.2.

Lastly, the outputs of last decoder are passed through a non-linear point-wise feed forward layer and we can obtain the predicted sentence $\mathcal{S}$ by a linear transform and softmax layer.

4.2 Task-aware Instruction Module

As is shown in Figure 3, our task-aware instruction network is composed of a series of encoder and decoder layers. To handle the limited training data, we propose to leverage the learned external knowledge from natural language datasets to guide the learning of sign languages. More specifically, we design a task-aware instruction module to dynamically inject external knowledge from pre-trained models into our encoder and decoder. Below, we shall present the details.

Encoder. Given the recognized glosses,let H_I denotes the instruction features encoded by the pre-trained model (PTM), H_E and H'_E denotes the input and output of encoder which is randomly initialized. As shown in Figure 4, H_I and H_E are fed into the task-aware instruction module for feature fusing. Then, the output of the instruction module is fed into residual connection (Add&Norm) and feed forward network (FFN).

The light yellow box of Figure 4 shows the detailed design of task-aware instruction module. Specifically, we feed H_E into a self-attention module to learn the contextual relationship between the features of glosses, while H_I is fed into a PTM-attention, which is the same architecture as self-attention. Different from existing work which employ PTM in general neural network (Zhu et al., 2020), we insert an adaptive layer to fine-tune PTM-attention output for SLT task, to transform general gloss features into task-aware features.

$$h_i = \sigma(Attn_I(h_t, H_I, H_I)) \tag{1}$$

where $\sigma()$ denotes the adaptive layer (we set it as fully connection layers here), and h_t denotes the gloss features at time step t. Then, the output of two modules are combined via α strategy. The whole process is formulated as follows:

$$\hat{h}_t = (1-\alpha)Attn_E(h_t, H_E, H_E) + \alpha h_i \tag{2}$$

where $Attn_E$ and $Attn_I$ are two attention layers with different parameters, which follow (Vaswani et al., 2017). The way of setting an optimal α will be introduced later.

Decoder. Let S_D and S'_D denotes the input and output of decoder, s_t denote the hidden state at time step t, and s_0 denotes the beginning token of a sentence, i.e., $< bos >$. The hidden states are passed to a masked self-attention ensuring that each token may only use its predecessors as follows:

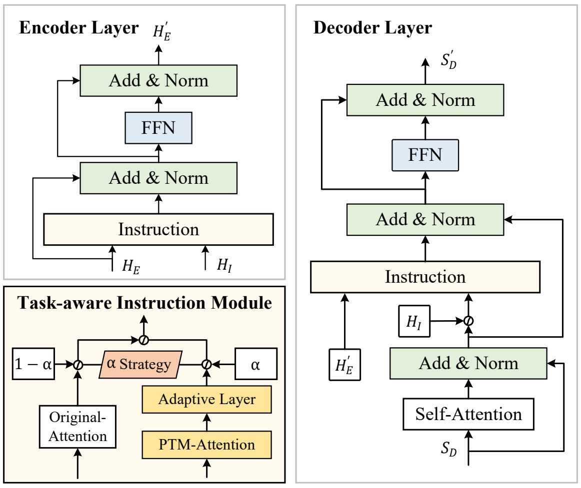

Figure 4: Details of Encoder layer, Decoder layer, and and Instruction Module.

$$\tilde{s}_t = Attn_D(s_t, s_{1:t}, s_{1:t}) \tag{3}$$

Representations H'_E and H_I extracted from encoder and PTM are fed into the decoder-attention and PTM-attention module, respectively, as shown in the right part of Figure 4. Similar to Encoder, we formulate this decoding output as:

$$\hat{s}_t = (1-\alpha)Attn_D(\tilde{s}_t, H'_E, H'_E) + \alpha h_i \tag{4}$$

where $Attn_D$ represent decoder-attention, and $\hat{s}_t$ is the output of decoder instruction module.

Learning-based feature fusion. As shown in Eq. (2), representations extracted from both PTM- and self- attention are fused via a parameter α. How to set a reasonable and optimal α will directly affects the learning performance, which is a problem worthy of exploration. Instead of manually setting a constant α, we propose a learning-based strategy to encourage the network to learn the optimal α by itself for better feature fusion.

Specifically, learning-based strategy means that we adopt the back-propagation learning algorithm to update α during the network training process:

$$\alpha_{t+1} = \Gamma(\alpha_t, g_t) \tag{5}$$

where g_t indicates the gradient and $\Gamma(\cdot)$ represents the optimization algorithm. Though the idea of self-learning is straightforward, we shall show in the experiment section that it is quite effective compared with many other strategies.

4.3 Multi-level Data Augmentation

To decrease the discrepancy between glosses (input) and texts (output), we propose a multi-level data augmentation scheme. Our key idea is that, besides existing gloss-text pairs, we use upsampling as our data augmentation algorithm and generate text-text pairs as extended samples to introduce texts information into glosses, thus enlarging the feature distribution space of glosses.

Actually, there is a trade-off between augmentation and overfitting, which means the upsampling ratio Φ_{upsamp} should be determined by the degree of gloss-text difference. We here propose four factors $\phi = [\phi_v, \phi_r, \phi_s, \phi_d]$ to calculate the difference in terms of token, sentence and dataset level, and set weighted ϕ as Φ_{upsamp}.

Token level. Vocabulary Different Ratio (VDR, ϕ_v) is used to measure the difference of gloss vocabulary space and text's, as calculated by Eq. (6).

$$\phi_v = 1 - \frac{|W_{\mathcal{G}}|}{|W_{\mathcal{G}} \cup W_{\mathcal{S}}|} \tag{6}$$

where $W_{\mathcal{G}}$ and $W_{\mathcal{S}}$ represent gloss and text vocabularies, and $|\cdot|$ denotes the size of set.

We present Rare Vocabulary Ratio (RVR, ϕ_r) to calculate the ratio of the rare words:

$$\phi_r = 1 - \frac{\sum_{\mathcal{G} \in W_{\mathcal{G}}} \#(Counter(\mathcal{G}) < \tau_r)}{|W_{\mathcal{G}} \cup W_{\mathcal{S}}|} \tag{7}$$

where $\#(\cdot)$ is 1 if the value is true, else 0, $Counter(\mathcal{G})$ is to calculate the gloss vocabulary frequency, and τ_r means the empirical thresh frequency determined by the vocabulary frequency, which is empirically set to be 2.

Sentence level. We propose Sentence Cover Ratio (SCR, ϕ_s) to compute the gloss-text pair similarity and covered ratio, calculated as:

$$r_i = \frac{|\mathcal{G}_i \cap \mathcal{S}_i|}{|\mathcal{S}_i|}, \quad \phi_s = 1 - \frac{1}{N} \sum_{i, r_i > \tau_c} r_i \tag{8}$$

where r_i denotes the covered ratio of gloss-text pair $\mathcal{G}_i$ and $\mathcal{S}_i$, while τ_c means the empirical thresh (set $\tau_c = 0.5$). We labeled gloss-text pairs which satisfy $r_i > \tau_c$ as candidates $\mathcal{C}$.

Dataset level. We use Dataset Length-difference Ratio (DLR, ϕ_d) to calculate the length of sentence distance, calculated as:

$$\phi_d = 1 - \frac{\sum_i |\mathcal{G}_i|}{\sum_i |\mathcal{S}_i|} \tag{9}$$

Then we can get the upsampling ratio by:

$$\Phi_{upsamp} = \theta * \phi \tag{10}$$

where the weight matrix θ is empirically set as $[0.1, 0.1, 0.6, 0.2]$, corresponding to the weight of $[\phi_v, \phi_r, \phi_s, \phi_d]$, as we suppose the sentence level matters the most and the weight of token level is the same as dataset level. Lastly, we obtain the upsampling ratio and use upsampling strategy among all candidates $\mathcal{C}$ to enrich the dataset.

5 Experiments

5.1 Implementation Details

Datasets. We conduct our experiments on two popular benchmark datasets of different languages and scales, including PHOENIX-2014-T (Camgoz et al., 2018) dataset and ASLG-PC12 (Othman and Jemni, 2012) dataset.

Specifically, PHOENIX-2014-T, i.e., PH14, is an open-source German sign language dataset, recorded from broadcast news about the weather. This dataset contains parallel sign language videos from 9 different signers, gloss annotations with a vocabulary of 1066 different signs, and their translations with a vocabulary of 2887 different words.

ASLG-PC12, i.e., ASLG, is a parallel corpus of English written texts and American Sign Language (ASL) glosses, which is constructed based on rule-based approach. It contains more than one hundred million pairs of sentences between English sentences and ASL glosses.

Evaluation metrics. To fairly evaluate the effectiveness of our TIN-SLT, we follow (Yin and Read, 2020) to use the commonly-used BLEU-N (N-grams ranges from 1 to 4) (Papineni et al., 2002), ROUGE-L (Lin, 2004) and METEOR (Banerjee and Lavie, 2005) as the evaluation metrics.

Experimental setup. The experiments are conducted on Ubuntu 18.04 system with two NVIDIA V100 GPUs. Our Transformers are built using 2048 hidden units and 8 heads in each layer. Besides, we adopt Adam (Kingma and Ba, 2014) as optimization algorithm with $\beta_1 = 0.9$, $\beta_2 = 0.998$ and use inverse sqrt learning rate scheduler with a weight decay of 10^{-3}. Please refer to Appendix for more hyper-parameter settings.

Table 1: Comparing the translation performance of TIN-SLT against state-of-the-art techniques on PHOENIX-2014-T and ASLG-PC12 datasets. Clearly, our TIN-SLT achieves the best performance on most metrics.

5.2 Comparison with Others

To compare our TIN-SLT against state-of-the-art approaches on sign language translation task, we conducted two groups of experiments, Gloss2Text (G2T) and Sign2Gloss2Text (S2G2T).

Evaluation on G2T. G2T is a text-to-text translation task, whose objective is to translate ground-truth sign glosses to spoken language sentences. In specific, for PH14 dataset, we should output German spoken language sentences; while for ASLG dataset, we should output English sentences. Table 1 summarizes the comparison results. Clearly, our TIN-SLT achieves the highest values on most evaluation metrics with a significant margin. Particularly, the superiority of our method on PH14 dataset is more obvious, where almost all the evaluation values are the highest. Thanks to our multi-level data augmentation scheme, the integrity of translated sentences has been improved, which is reflected in the significant improvement of BLEU-N metric. In addition, the strong guidance from external knowledge also encourages our network to generate translated sentences in correct grammar, consistent tense and appropriate word order. For the lower ROUGE-L metric, we think that although the instruction module obviously help improve the accuracy and fluency of translation results, it leads to a slight decrease of continuous texts' recall rate in this task.

Model	Test Set					
	BLEU-1	BLEU-2	BLEU-3	BLEU-4	ROUGL-L	METEOR
G2T	44.13	31.47	23.89	19.26	45.45	-
S2G-G2T	41.54	29.52	22.24	17.79	43.45	-
S2G2T	43.29	30.39	22.82	18.13	43.80	-
Sign2	46.61	33.73	26.19	21.32	-	-

Luong	47.08	33.93	26.31	21.75	45.66	44.84
Transformer Ens.	50.63	38.36	30.58	25.40	**48.78**	47.60
TIN-SLT (Ours)	**51.06**	**38.85**	**31.23**	**26.13**	48.56	**47.83**

Table 2: Comparing the S2G2T performance by using our TIN-SLT and state-of-the-art techniques on PHOENIX-2014-T dataset. The results of G2T, S2G-G2T and S2G2T are from (Camgoz et al., 2018). The results of Sign2 are from (Camgoz et al., 2020). The results of Bahdanau, Luong, and Transformer Ens. are from (Yin and Read, 2020). Clearly, our TIN-SLT achieves the highest values on most metrics.

Evaluation on S2G2T. S2G2T is an extended task beyond G2T, which aims to recognize sign language videos to sign glosses, and then translate the recognized glosses to spoken sentences. Hence, unlike the task of G2T, in this comparison, we focus on the evaluation of the whole two-step pipeline, that is, obtaining spoken language sentences from sign language videos. Considering that only PH14 contains sign language videos, we thus conduct experiments on this dataset for S2G2T task, and the results are reported in Table 2. Note that, for the recognition step, we employ STMC model to realize vision-based sequence learning (Zhou et al., 2020). From the comparison we can see that, our TIN-SLT still outperforms existing approaches on most evaluation metrics.

5.3 Analysis and Discussions

Here, we conducted a series of detailed experiments to analyze our method and give some insights behind our network design.

Figure 5: Various analysis results. (a) & (b) present the results by using different feature fusion strategies on two datasets, respectively. (c) & (d) show our learned value of α during the training process on the two datasets, respectively. (e)-(h) explore how beam size, layer number, learning rate, and dropout rate affect the model performance.

Effect of learning-based feature fusion. In this work, we propose a learning-based strategy to set α dynamically. Here, we conducted experiments by comparing this strategy with other four different strategies, including (1) cosine annealing (Loshchilov and Hutter, 2016), (2) cosine increment, (3) cosine decrement, and (4) constant value. The update of α by the three cosine strategies are calculated as Eq. (11) with different settings of the epoch cycle coefficient T_c:

$$\alpha_{t+1} = \alpha_{min}+\frac{1}{2}(\alpha_{max}-\alpha_{min})(1-cos(\frac{T_t}{T_c}\pi+\gamma)) \tag{11}$$

where α is the fusion ratio, T_t is current epoch step, and γ is the time-shift constant. We set T_c as (25, 100, 100) and γ as (0, 0, π) for cosine annealing, cosine decrement, and cosine increment, respectively. The minimum value α_{min} and maximum value α_{max} of α are set to be 0 and 1.

Figures 5(a)-5(b) are the experimental results on the two datasets. We can observe that the learning-based strategy (red line) gets the best result on ASLG and comparable result with the constant setting (α=0.8) on PH14, but still better than other three cosine strategies. Moreover, we also visualize the learned value of α during the training process as shown in Figures 5(c)-5(d) to find out the contribution ratio of the BERT model to the final performance. We can see that, the value of α is gradually decreasing on PH14, meaning that the model depends more on the BERT pre-trained knowledge at the beginning of the training process and gradually inclines to our employed training corpus. The observation is just opposite on ASLG, since it is a much larger dataset than PH14 and our model relies more on BERT to further boost the performance near the end of training.

Table 3: Ablation analysis of our major network components on the G2T task.

Analysis on major network components. In our TIN-SLT, there are two major components: the multi-level data augmentation scheme and the instruction module. To validate the effectiveness of each component, we conduct an ablation analysis on the G2T task with the following cases.

- Baseline: We use two layers Transformer (Yin and Read, 2020) without data augmentation and instruction module as baseline.

Model[1]	Size(MB)	Dataset	Gloss(%)	Text(%)	BLEU4
	PHOENIX-2014-T Dataset Evaluation				
Multilingual	641.10	PH14	59.96	74.62	25.48
Distilbert	257.30	PH14	44.50	71.15	24.73
Gbert	421.80	PH14	44.50	71.15	25.13
Dbmdz	421.80	PH14	73.72	88.13	**26.55**
	ASLG-PC12 Dataset Evaluation				
Base-Tiny	16.90	ASLG	76.77	96.35	82.44
Electra	51.70	ASLG	76.77	96.35	82.60
Distilbert	255.60	ASLG	76.77	96.35	83.06
Base-uncased	420.10	ASLG	76.77	96.35	**84.29**

Table 4: Comparing different pre-trained models in terms of BLEU-4.

- w/ DataAug: Based on the baseline, we add our data augmentation scheme back.
- w/ Encoder: Based on w/ DataAug, we fuse instruction module only into the encoder.
- w/ Decoder: Based on w/ DataAug, we fuse instruction module only into the decoder.

As a contrast, in our full pipeline, the instruction module is inserted into both encoder and decoder. Table 3 shows the evaluation results on both PH14 and ASLG. By comparing the results from Baseline and w/ DataAug, we can see that our data augmentation improves the translation performance, especially for the PH14 dataset. A reasonable interpretation is that the translation task on PH14 dataset is more difficult than on ASLG, thus our data augmentation contributes more. On the other hand, w/ Encoder, w/ Decoder and Full pipeline explore the best location to introduce PTM information into the model. Results in Table 3 show that our full model achieves the best performance. Particularly, by comparing the results from w/ Encoder and w/ Decoder against the results from SOTA methods (Tables 1 & 3), we can observe that as long as we employ the pre-trained model, no matter where it is inserted into the network, the performance is always better than existing methods.

Effect of different pre-trained models. We here explored the translation performance by using different pre-trained models; see Table 4. We analyzed the model size and vocabulary coverage of the pre-trained model with gloss and text of our dataset. We can see that introducing a pre-trained model with larger vocabulary coverage of the target dataset will gain better performance, since a pre-trained model with larger vocabulary coverage can inject more knowledge learned from another unlabeled corpus into the translation task. For ASLG, although the vocabulary coverage is the same, we can see that the bigger model has better performance since it can learn contextual representation better.

Table 5: Qualitative evaluation of translation performance in different BLEU-4 scores on ASLG dataset.

Analysis on hyper-parameters. To search the best settings of our hyper-parameters, we employed Neural Network Intelligence (NNI) (Microsoft, 2018), a lightweight but powerful toolkit. As shown in Figures 5(e)-5(h), we explored how beam size, layer number, learning rate and dropout rate affect the model performance on PH14 dataset. First, beam search enables to explore more possible candidates, but large beam widths do not always result in better performance as shown in Figure 5(e). We obtain optimal beam size as 10 on PH14. Second, the layer number decides the model size and capacity, where the larger model would overfit on a small dataset. In Figure 5(f), we find the optimal layer number to be 3 on PH14. Lastly, as shown in Figures 5(g) & 5(h), we adopt an early-stopping strategy to avoid overfitting and find the best learning rate and dropout rate are 0.0003 and 0.45, respectively.

Case study. Table 5 presents some intuitive translation results on ASLG by reporting the translated spoken sentences. Overall, the translation quality is good, even the translated sentences with low BLEU-4 still convey the same information. Also, we can observe that our translated sentences are basically the same with ground truth, although using different expressions, i.e., “decision making” vs. “decision made”. The translation results on PH14 are reported in Appendix.

---

[1] The pre-trained models links are listed in Appendix.

6 Conclusion

In this paper, we proposed a task-aware instruction network for sign language translation. To address the problem of limited data for SLT, we introduced a pre-trained model into Transformer and designed an instruction module to adapt SLT task. Besides, due to the discrepancy between the representation space of sign glosses and spoken sentences, we proposed a multi-level data augmentation scheme. Extensive experiments validate our superior performance compared with state-of-the-art approaches. While there is obvious improvement among most evaluation metrics, the complexity of our models is also increased, causing a longer training period. In the future, we would like to explore the possibility of designing a lightweight model to achieve real-time efficiency.

A Appendix

A.1 Dataset Description

In this section, we will introduce two public benchmark datasets used in sign language translation tasks, namely PHOENIX-2014-T and ASLG-PC12. We conducted statistical analysis on the datasets and the results are shown in Table 6. It is obvious that PHOENIX-2014-T is a small-scale dataset, while ASLG-PC12 is a large-scale dataset.

Dataset		Gloss			Translation		
		Train	Dev	Test	Train	Dev	Test
PH14	Samples	7096	519	642	7096	519	642
	Vocabs	1066	393	411	2887	951	1001
	Words	67781	3745	4257	99081	6820	7816
ASLG	Samples	82709	4000	1000	82709	4000	1000
	Vocabs	15782	4323	2150	21600	5634	2609
	Words	862046	41030	10503	975942	46637	11953

Table 6: The descriptive statistics of PHOENIX-2014-T and ASLG-PC12 datasets. Samples row means the sample size of the dataset, Vocabs row represents the total vocabularies contained in the dataset, and Words row means the total words of the dataset.

A.2 PHOENIX-2014-T Qulitative Result

BE-SLT performance of G2T task on PHOENIX-2014-T is shown in Table 7, from which we can observe that sign language translation results are of good quality with different BLEU-4 scores and the predicted sentences can convey effective information even for low BLEU-4 scores.

A.3 Experiment Parameter

In order to help reproduce BE-SLT and its translation performance, as shown in Table 8 and 9, we list the hyper-parameters of the best results on two benchmark datasets. For G2T task on PHOENIX-2014-T, we list the best hyper-parameter settings for the experiments which apply data augmentation scheme, or fuse BERT-attention module into encoder, decoder, and both respectively (namely,w/DataAug, w/Encoder, w/Decoder, w/All). W/All obtains the highest BLEU-4 using the initial learning rate of 0.00025, dropout rate of 0.45, beam search with width 5, and the max epoch size of 120. For G2T task on ASLG-PC12, we also list the hyper-parameter settings for the four experiments that achieve significant results, listed in Table 9. For more experiment details, please refer to our code which will be published upon the publication of this work.

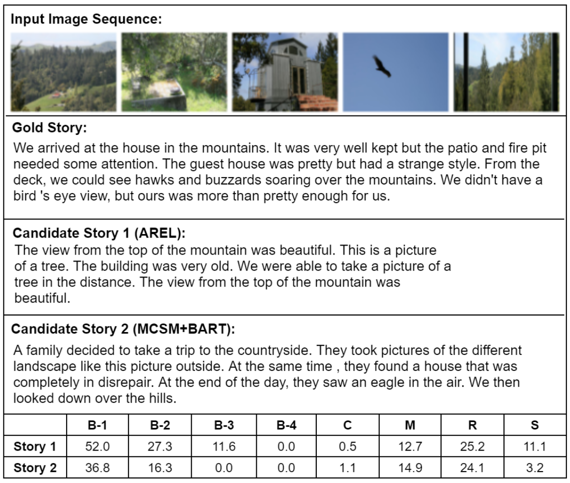
RoViST: Learning Robust Metrics for Visual Storytelling

Eileen Wang **Soyeon Caren Han**[*] **Josiah Poon**
School of Computer Science, The University of Sydney, NSW, Australia
{Eileen.Wang, Caren.Han, Josiah.Poon}@sydney.edu.au

Abstract

Visual storytelling (VST) is the task of generating a story paragraph that describes a given image sequence. Most existing storytelling approaches have evaluated their models using traditional natural language generation metrics like BLEU or CIDEr. However, such metrics based on n-gram matching tend to have poor correlation with human evaluation scores and do not explicitly consider other criteria necessary for storytelling such as sentence structure or topic coherence. Moreover, a single score is not enough to assess a story as it does not inform us about what specific errors were made by the model. In this paper, we propose 3 evaluation metrics sets that analyses which aspects we would look for in a good story: 1) visual grounding, 2) coherence, and 3) non-redundancy. We measure the reliability of our metric sets by analysing its correlation with human judgement scores on a sample of machine stories obtained from 4 state-of-the-arts models trained on the Visual Storytelling Dataset (VIST). Our metric sets outperforms other metrics on human correlation, and could be served as a learning based evaluation metric set that is complementary to existing rule-based metrics.[1]



Input Image Sequence:

Gold Story:
We arrived at the house in the mountains. It was very well kept but the patio and fire pit needed some attention. The guest house was pretty but had a strange style. From the deck, we could see hawks and buzzards soaring over the mountains. We didn't have a bird 's eye view, but ours was more than pretty enough for us.

Candidate Story 1 (AREL):
The view from the top of the mountain was beautiful. This is a picture of a tree. The building was very old. We were able to take a picture of a tree in the distance. The view from the top of the mountain was beautiful.

Candidate Story 2 (MCSM+BART):
A family decided to take a trip to the countryside. They took pictures of the different landscape like this picture outside. At the same time , they found a house that was completely in disrepair. At the end of the day, they saw an eagle in the air. We then looked down over the hills.

	B-1	B-2	B-3	B-4	C	M	R	S
Story 1	52.0	27.3	11.6	0.0	0.5	12.7	25.2	11.1
Story 2	36.8	16.3	0.0	0.0	1.1	14.9	24.1	3.2

Figure 1: Example gold story found in the VIST dataset versus machine output from 2 VST models and their n-gram based metrics.

1 Introduction

Visual storytelling (VST) is a natural language generation (NLG) task that aims to automatically generate a cohesive story given a sequence of images (Huang et al., 2016). The task is fundamental to the development of intelligent agents capable of understanding complex visual scenarios, and can be further applied to assist the visually impaired in understanding images on the web. Recently, progress has been made on designing network architectures to accomplish the VST task but little work has been done to explore new metrics that automatically evaluate and quantify the errors produced by these systems. As to date, a majority of the past works on VST have used existing popular n-gram based metrics such as BLEU, METEOR, ROUGE, CIDEr, and SPICE to evaluate their models (Wang et al., 2018; Kim et al., 2018; Hsu et al., 2019; Chen et al., 2021). However, it is known that such metrics are unreliable for VST. Figure 1 shows two machine generated stories for a photo sequence and their corresponding n-gram matching based metrics (BLEU, CIDEr, METEOR, ROUGE-L and SPICE). Evidently, the first candidate story is more repetitive and lacks a narrative style but achieves higher scores across a majority of the n-gram based metrics in Figure 1. The second story however, has greater word diversity and is more expressive through its use of phrases like '*completely in disrepair*'. Relevant words like '*trip*', '*countryside*' and '*hills*' are also used but are not rewarded since they are not mentioned in the gold story.

The low level of agreement between human judgement and current automatic metrics may be because such metrics were originally developed to assess machine translation, summarization and image captioning tasks (Sharif et al., 2018), which

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2691 - 2702

are significantly different problems to VST. Specifically, VST is a multimodal task that firstly requires: 1) generating text relevant to the image content but unlike image captioning, there is less emphasis on describing relationships between objects and may contain concepts that are inferred from the image. It additionally needs to ensure that: 2) the story must be topically coherent, similar to how a human would tell a story in a social setting. Sentences should not sound disjointed e.g. '*We went to the park. I grew up in Sydney*'. And finally 3) avoids repetition which appears to be a common issue in current VST models. For instance, Candidate Story 1 in Figure 1 exhibits inter-sentence repetition between the first sentence and last sentence. We also find that some output stories may contain repetition *within* sentences (i.e. intra-sentence repetition) e.g. '*we had a good time and had a great time!*'.

Moreover, it is noted that open-ended text generation tasks usually suffer from the one-to-many issue, whereby there are multiple plausible outputs for the same input which are not fully reflected in the reference sentences (Guan and Huang, 2020). This issue is even more prominent in the VST task as different individuals may tell significantly different stories and have diverse interpretations given the same image sequence. All these issues suggest that we require evaluation metrics that do not simply rely on comparison with reference sentences. In addition, given that the VST task requires several aspects, one single metric is not sufficient to evaluate a story and there is a need to design multiple interpretable metrics that each target a specific VST criteria. Hence, in this paper, we propose several unreferenced metrics for the VST task based on the three aforementioned criteria: 1) visual grounding, 2) coherence, and 3) non-redundancy.

To address criteria 1), we propose a learned metric to calculate relevance scores between nouns in the VST sentences with the bounding box regions in the images. We decide to focus on nouns as they provide the most visual information. Other words like adjectives and adverbs are difficult to ground and such words may differ significantly depending on the person writing the story. The second criteria which is story coherence requires that consecutive sentences flow and that each sentence is not just an isolated description of the image. Existing methods for measuring coherence have used next sentence prediction (NSP) to find the probability that a sentence comes after a preceding sentence (Hu et al., 2020). Inspired by this method, we fine-tune the ALBERT (Lan et al., 2019) model on story sentences and build a sentence-order prediction (SOP) model. Finally, to address criteria 3), we propose an additional metric to explicitly measure inter-sentence and intra-sentence repetition.

The contributions are summarized as follows: 1) We propose an interpretable and reference-free metric that addresses 3 criteria required for VST - visual grounding, coherence and non-redundancy. 2) We conduct human evaluation studies to assess a sample of machine generated stories obtained from 4 state-of-the arts VST models. 3) We test the effectiveness of our proposed metrics by analyzing its correlation with human scores and show that our metrics outperform other existing metrics that are commonly used for VST and NLG tasks.

2 Related Works

Natural Language Generation Metrics The most popular NLG evaluation metrics are BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016). All these metrics are widely used in evaluating image captioning tasks (Anderson et al., 2018; Zhou et al., 2020) and have also been predominantly used in VST tasks (Wang et al., 2018; Hsu et al., 2019; Chen et al., 2021) due to the lack of metrics designed for VST. While these metrics are computationally efficient, they have limited ability in accounting for synonym matches or phrase reordering. This poses a problem for many open-ended text generation tasks like VST where different annotators may have slightly different (but still plausible) ways of describing the same image. To address this, some metrics focus on comparing distance and similarity between word embeddings such as Word Mover's Distance (Kusner et al., 2015), MoverScore (Zhao et al., 2019) and BERTScore (Zhang et al., 2019). However, these metrics mentioned so far still heavily rely on similarity with references, potentially leading to bias for VST tasks as the references may not fully cover the possible ways to write a story for an image sequence.

Visual Grounding Metrics Past studies have proposed examining the images in addition to human written references. Cui et al. (2018) trained a binary classifier to discriminate between human and machine captions using image and text representations obtained from a CNN and RNN. TIGEr

(Jiang et al., 2019) employs the pretrained SCAN model (Lee et al., 2018) to calculate the text-to-image grounding scores and compares the relevance ranking and grounding weights distribution among image regions between the references and the candidate. Lee et al. (2020) later introduced ViLBERTScore which uses the same approach as BERTScore but utilizes the ViLBERT model (Lu et al., 2019) to retrieve image-conditioned token embeddings. However, we note that these methods are initially designed for evaluating image captioning systems. Hence, while they do consider the text-to-image similarity aspect, they do not explicitly address the extra criteria required for VST such as story coherence. Moreover, such metrics still rely on reference sentences to some extent.

Story Generation Metrics Language models like BERT (Devlin et al., 2018) trained with NSP and masked language modelling tasks can identify appropriate use of words and sentences and hence, may show promising results when applied to evaluating open-ended text generation. Guan and Huang (2020) proposed UNION, an unreferenced metric for scoring machine generated stories. They leverage a BERT model trained with negative samples created by perturbing ground truth stories and predicts a score representing how human-like a story is. They showed the effectiveness of BERT in identifying stories with conflicting logic, repeated plots and incoherence. However, UNION purely evaluates the output text and cannot be applied to analyse the text-to-image relatedness required for the VST multimodal task. Additionally, a single score is outputted which is not informative enough to gauge what specific errors were made by the model. Moving to VST, Hu et al. (2020) designed reward functions to capture story quality for VST models that use a reinforcement learning framework based on 3 criteria: image relevance, coherence and expressiveness. Image relevance is measured by n-gram precision of entities between candidate and reference sentences, coherence through BERT's NSP task, and word diversity by computing BLEU scores between generated sentences.

Inspired by this, we also analyze story quality from 3 similar perspectives 1) visual grounding, 2) coherence, and 3) non-redundancy. We attempt to extend the methods of Hsu et al. (2019), provide a reference-free approach and conduct a comprehensive analysis with human evaluation.

3 Method

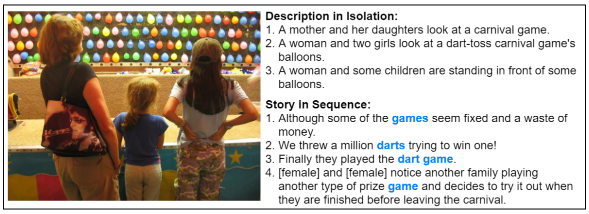
We describe our proposed metric in detail. Given a machine story, we aim to output 3 scores that explicitly evaluates the story based on 1) visual grounding, 2) coherence, and 3) non-redundancy.

3.1 RoViST-VG: Visual Grounding Scorer

To detect the visual relationship between image and text, we build a model that computes the similarity between the nouns in the story sentences with the bounding box regions in the images. We focus specifically on nouns because despite the diverse range of words one can use when storytelling, we notice that the main commonality among the ground truth sentences is the noun mention. This is most likely because nouns (in particular, tangible nouns) tend to offer the most visual information and is the common element that people would recognize when observing an image. An example of this case is in Figure 2 where we can see that the nouns '*dart*' and '*game*' tends to appear in multiple gold sentences, even though each sentence is quite different in structure.

Our visual grounding scorer is inspired by the phrase localization task (Plummer et al., 2015) which involves learning to align sentence entities with image regions. We note that we could have just employed typical image-text matching models like SCAN (Lee et al., 2018) to calculate a similarity score between image and text. However, such models are trained on image captioning sentences and do not explicitly focus on the more fine-grained task of word-region alignment. Moreover, retraining these models with VIST images and whole sentence pairs would be challenging as previously mentioned, story sentences tend to differ significantly in semantics and structure due to human imagination. This is in contrast to image captions where ground truth sentences typically tend to be similar to each other even across different human annotators (e.g. see description in isolation sentences in Figure 2).

Inspired by CLIP (Radford et al., 2021), we create a model that learns the image region and text embeddings such that the noun mention corresponding to an image region will have similar vector representations in geometric space. Let I_i be an image of a bounding box region and T_i be the matching noun. For the image encoder, we follow Radford et al. (2021) and leverage the Vision Transformer (ViT) (Dosovitskiy et al., 2020) to first



Description in Isolation:
1. A mother and her daughters look at a carnival game.
2. A woman and two girls look at a dart-toss carnival game's balloons.
3. A woman and some children are standing in front of some balloons.

Story in Sequence:
1. Although some of the **games** seem fixed and a waste of money.
2. We threw a million **darts** trying to win one!
3. Finally they played the **dart game**.
4. [female] and [female] notice another family playing another type of prize **game** and decides to try it out when they are finished before leaving the carnival.

Figure 2: Example ground truth description in isolation (dii) and story in sequence sentences (sis) sentences corresponding to an image from the VIST dataset.

Algorithm 1 RoViST-VG

Input: **1)**A mini-batch of image regions I_n with shape $(m \times 3 \times 224 \times 224)$ where m is the batch size, and the last 3 dimensions correspond to the image channels, height and width respectively. **2)**A mini-batch of matching noun pairs T_n with shape $(m \times 300)$ where 300 represents the dimensions of the GLoVe vectors. **Output:** Symmetric loss for the mini-batch.

Initialization: Pretrained ViT Model with linear head for the image encoder, and a single linear layer for the text encoder.

```
$h_n = \text{VisionTransformer}(I_n)$
$I_e = \tanh(\mathbf{W}_i \mathbf{h}_n + \mathbf{b}_i)$   ▷ image embeddings; shape = [m,1024]
$T_e = \tanh(\mathbf{W}_t T_n + \mathbf{b}_t)$   ▷ text embeddings; shape = [m,1024]
$\text{logits} = T_e \times I_e^T$   ▷ shape = [m, m]
$I_{sim} = I_e \times I_e^T$   ▷ shape = [m, m]
$T_{sim} = T_e \times T_e^T$   ▷ shape = [m, m]
$\text{labels} = (I_{sim} + T_{sim})/2$   ▷ shape = [m, m]
$\mathcal{L}_{image} = \text{cross\_entropy\_loss}(\text{labels}^T, \text{logits}^T)$
$\mathcal{L}_{text} = \text{cross\_entropy\_loss}(\text{labels}, \text{logits})$
$\mathcal{L}_{symmetric} = (\mathcal{L}_{image} + \mathcal{L}_{text})/2$
```

extract the image features from I_i. An additional linear head is further added to project the features to a vector embedding of dimension 1024. For the text encoder, T_i is first converted to 300 dimensional GLoVe vectors (Pennington et al., 2014). If T_i is composed of more than one word, the GLoVe vectors of each token are simply averaged. These vector representations are then passed through a single linear layer to project the text features into the 1024-dimensional joint embedding space. We train the model in a contrastive manner to minimize the symmetric loss. The psuedocode for each batch iteration is provided in Algorithm 1.

To compute the visual grounding score, we extract all nouns from the output story sentences and the top 10 bounding box regions for each image in the story based on the confidence scores generated from Faster R-CNN (Ren et al., 2015). This results in 50 regions for a 5-image story. Each extracted noun and image region is fed through our trained text and image encoder respectively to obtain the image and text embeddings which we denote by I_e and T_e. For each noun, the cosine similarity (cos) is calculated between its text embedding with all other region image embeddings. It is noted that a noun mention from a sentence can match with a region from other images and not necessarily just with regions from its corresponding image as we find that words in story sentences may refer to concepts in other images of the sequence. We then use a greedy matching approach to obtain the maximum similarity score for each noun. Following Zhang et al. (2019), we further experiment by multiplying the similarity score by the inverse document frequency (idf) of the noun calculated from the corpus. This is to put less emphasis on abstract nouns that are not visually grounding but frequently occur in stories (such as '*time*' and '*today*'). Given N stories, the idf score of a token T_i is:

$$idf(T_i) = log(\frac{N}{1 + df(T_i)}) \tag{1}$$

where $df(T_i)$ is the number of stories containing token T_i. Finally, inspired by Lee et al. (2018), a recall score is computed by using LogSumExp (LSE) pooling:

$$S_{VG} = \log \sum_{i=1}^{|T_e|} \exp(idf(T_i) \max_{I_{e,j} \in I_e} (cos(T_{e,i}, I_{e,j}))) \tag{2}$$

For interpretability, one can optionally scale the score between 0 and 1 using a shifted and scaled version of the sigmoid function:

$$S_{VG(scaled)} = \frac{1}{1 + \exp\left(-0.5 \times S_{VG}\right)} \times 2 - 1 \tag{3}$$

3.2 RoViST-C: Coherence Scorer

To measure the story's inter-sentence coherence, we leverage the ALBERT model to perform sentence order prediction (SOP) (Lan et al., 2019). The SOP task is a binary classification task, whereby positive samples are consecutive sentences while negative samples are simply constructed by swapping the two sentences around. This forces the model to primarily focus on learning coherence properties rather than topic prediction. We fine-tune the ALBERT model with adjacent story sentences extracted from the VIST and ROCStories dataset. In total, 822,920 training samples were created where 15% was used in the validation split.

Let $\{s_{i-1}, s_i\}_{i=1}^{N}$ denote the training data where s_{i-1} and s_i are adjacent segments. The input sequence fed into ALBERT is in the format $\mathbf{s}_n =$ '[CLS], s_{i-1}, [SEP], s_i, [SEP]', where [CLS] and [SEP] are special tokens. Then, the pooled 1024-dimensional vector representation $\mathbf{h}_n$ of the input sequence is obtained by the output of ALBERT:

$$\mathbf{h}_n = \text{ALBERT}(\mathbf{s}_n) \tag{4}$$

To perform SOP, we add a task-specific linear layer on top of ALBERT to predict the probability that s_i follows s_{i-1}:

$$\hat{p}_n = \text{softmax}(\mathbf{W}_c\mathbf{h}_n + \mathbf{b}_c) \tag{5}$$

where $\mathbf{W}_c$ and $\mathbf{b}_c$ are the trainable weights and bias. For the loss function, we optimize the binary cross-entopy loss as follows:

$$\mathcal{L} = -p_n \text{log}(\hat{p}_n) - (1 - p_n)\text{log}(1 - \hat{p}_n) \tag{6}$$

To obtain the final coherence score for each story, we compute $\hat{p}_n$ for each adjacent sentence pair in the story and average the probabilities across all sentence pairs.

3.3 RoViST-NR: Non-redundancy Scorer

A common problem faced by system output stories is redundancy of words in the form of whole sentences or phrases. While existing methods (Hu et al., 2020) for assessing word diversity and repetition do consider inter-sentence repetition, they do not address repetition *within* sentences. Therefore, to calculate the inter- and intra-sentence non-redundancy score, we propose calculating the Jaccard Similarity (JS) between and within sentences. The JS is defined as the intersection size divided by the union size of two sets (Singh and Singh, 2021). That is, in our problem, the intersection would be the number of co-occurring words between two texts, while the union is the total number of words in both texts. In particular, we compute the Jaccard Similarity with sentence $\hat{y}_i$ and all its preceding sentences $\{\hat{y}_1, ..., \hat{y}_{i-1}\}$ as in Eq. 7. Here, $C(\hat{y}_i)$ and $C(\hat{y}_j)$ are the count of unique words in sentence $\hat{y}_i$ and $\hat{y}_j$ respectively. The inter-sentence repetition score is then just simply the average JS scores across the $\binom{n}{2}$ sentence pairs where n is the number of sentences in the story.

$$JS(\hat{y}_i, \hat{y}_j) = \frac{C(\hat{y}_i) \cap C(\hat{y}_j)}{C(\hat{y}_i) \cup C(\hat{y}_j)} \tag{7}$$

We also measure the intra-sentence redundancy by first splitting each sentence into non-overlapping n-grams and then calculating the JS score between consecutive n-grams within sentences. The intra-sentence repetition score for a story is then the average JS scores across all consecutive n-gram computations. Lastly, we take the mean of the final inter- and intra-sentence score to obtain the final repetition score for the story and subtract from 1. The result is a score between 0 and 1 where a value closer to 1 means that the story tends to contain less redundancy.

4 Data

4.1 Supporting Datasets

VIST The Visual Storytelling Dataset (VIST) dataset (Huang et al., 2016) consists of 10,117 Flickr albums and 210,819 unique images. Each sample is one sequence of 5 photos selected from the same album paired with a single human constructed story, where each story is comprised of mostly one sentence per image.

ROCStories Corpora (Mostafazadeh et al., 2016) is used as additional data along with VIST to train the ALBERT model. It contains 98,161 stories where each story consists of 5 sentences written by humans after being given a prompt.

Flickr30K Entities (Plummer et al., 2015) is derived from the Flickr30K dataset (Young et al., 2014), consisting of 31,783 images each matched with 5 captions. The dataset links distinct sentence entities (i.e. a noun/noun phrase) to image bounding boxes, resulting in 70K unique entities and 276K unique bounding boxes. We use the Flickr30K Entities data to train our visual grounding scorer. After filtering out stopwords from the entity mention, we obtained 566K unique entity-region pairs.

4.2 VST Models

We evaluate our proposed metric on the output stories produced by 4 state-of-the art VST models: 1) **AREL (Wang et al., 2018)**: adopts an inverse reinforcement learning approach trained adversarially. The policy model is a CNN+GRU that generates sub-stories for each image, while the reward model is a CNN-based model designed to output the story reward. 2) **GLACNet** (**Kim et al., 2018**): combines both local and global attention. Image features are fed sequentially to a bi-LSTM where the output is a global representation of the entire story. This is concatenated with local image-specific features to create *glocal* vectors which are passed to a decoder for story generation. 3) **KG-Story** (**Hsu et al., 2020**): For each image, a word-form conceptual representation is created by predicting a set of terms which are then used to query Visual Genome (Krishna et al., 2017) and OpenIE (Pal et al., 2016) to identify links between sets of terms across images. Finally, a Transformer (Vaswani et al., 2017) takes in the term paths to decode the story. 4) **MCSM+BART** (**Chen et al., 2021**): image concepts and related concepts extracted from ConceptNet (Liu and Singh, 2004) are used as input for generating richer stories with BART (Lewis et al., 2020). To incorporate the most appropriate concepts, their Maximal Clique Selection Module model learns a correlation map, reflecting co-occurrence probabilities of all candidate concepts.

5 Evaluation Setup[2]

Evaluation Metrics To assess the performance for RoViST, we analyze its correlation with reliable human judgements by recruiting many responders (26) whereas related works (Guan and Huang, 2020; Hu et al., 2020) have used 3-7 annotators. In total, the 26 responders analysed 400 machine generated sentences across 80 stories and 4 models, including AREL, GLACNet, KG-Story and MCSM+BART. A Likert scale was used to score 3 different criteria for each story based on what we believe defines a good story - 1) the story is visually grounded, 2) sentences are natural sounding and topically coherent, and 3) there is no repeating plots within the story. Annotators were additionally asked to vote for which of the 4 models produced the best story relating to the visual prompt based on no particular criteria. We follow existing literature and report the Spearman's correlation ρ, Pearson's correlation r and Kendall's correlation τ.

Baseline We select 11 baseline metrics to compare with our metric: BLEU-1,2,3,4 (Papineni et al., 2002), ROUGE-L (Lin, 2004), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015), SPICE (Anderson et al., 2016), WMD (Kusner et al., 2015), F_{BERT} (F1-measure version of BERTScore) (Zhang et al., 2019) and TIGEr (Jiang et al., 2019).

AREL: I went on a boat trip to the lake . This is a picture of a lake. This is a picture of a field . The water was clear and the water was calm. The boats were docked in the water .	**Grounding Score:** 3.4 / 5 **Coherence Score:** 2.7 / 5 **Non-redun. Score:** 2.7 / 5 **Proportion of votes:** 4%
GLACNet: The cruise ship was getting ready to go. They were off to a great spot. The beach was beautiful. There was a lot of boats. It was a very nice day.	**Grounding:** 2.5 / 5 **Coherence Score:** 3.3 / 5 **Non-redun. Score:** 4.6 / 5 **Proportion of votes:** 12%
KG-Story: We had a great time at the lake. There were so many boats. It was very beautiful. I spent all day out on this field. And even saw one boat.	**Grounding:** 2.8 / 5 **Coherence Score:** 3.3 / 5 **Non-redun. Score:** 3.9 / 5 **Proportion of votes:** 24%
MCSM+BART: We had a nice summer in [location]. The fields were absolutely gorgeous. We also had a farm that looked like a real farm all around. There were even boat campsites. Some of the boats were out at night to camp.	**Grounding:** 3.7 / 5 **Coherence Score:** 3.6 / 5 **Non-redun. Score:** 4.1 / 5 **Proportion of votes:** 60%

Figure 3: Average human scores for an example story across 3 criteria for 4 different VST models. 'Proportion of votes' refers to the percentage of voters who voted that model's story as the best out of the 4. Blue highlighted words visually relate to the image.

6 Results

6.1 Human Scores versus Story Ranking

We first investigate whether there is any correlation between the human scores for each 3 criteria and the model that was voted as the best for each photo sequence. For each photo sequence, we rank each of the 4 models' stories based on the proportion of votes that it received. The correlations were then calculated between the mean human scores for each criteria and the model rankings, and the average correlation coefficients were finally taken across the unique stories to obtain the values in Table 2. We also sum up the human scores across the 3 criteria and measure its correlation with the rankings to further analyze at an *Overall* level.

Interestingly, we find that sentence coherence plays the most significant role when ranking stories whereas non-redundancy and visual grounding are less important. Figure 3 provides an example of this case where our human annotators preferred KG-Story and GLACNet over AREL which was more visually grounding but less coherent-sounding. We observe even stronger correlation when we sum the 3 criteria scores, suggesting that all 3 aspects combined can give better guidance when judging a story as can be seen in Figure 3 where most of the votes went to MCSM+BART which scored relatively well in all 3 areas.

6.2 Correlation Analysis with Human Scores

Table 1 displays the correlation between the metrics and the mean human scores. The results were analyzed at a criteria level by examining correlations between each criteria's scores with our metric which targets that criteria. We also analyze the *Overall* scores by summing up the 3 criteria scores and measuring its correlation with RoViST which represents the sum of the scores produced by RoViST-VG, RoViST-C and RoViST-NR.

With the grounding correlations, RoViST-VG outperforms the baselines for Kendall's correlation. However, it is slightly outperformed by TIGEr when comparing Spearman's correlation and by TIGEr and WMD when comparing Pearson's correlation. We note that all baseline metrics are reference-based and therefore, a likely explanation for the moderate correlations for even simple metrics like METEOR is that human references can already provide a good guideline when assessing text-to-image relatedness. Moreover, we hypothesize that image captioning metrics will perform well for the visual grounding aspect in the case when the model happens to output a sentence that sounds like an image caption. However, unlike image captioning, we emphasize that just having high correlation between image objects and text descriptions does not necessarily mean a good story as we highlighted in the previous section. Examining the coherence and non-redundancy aspect, we observe that a majority of the baselines correlate poorly. Conversely, our RoViST-C and RoViST-NR metric designed to specifically target these criteria generated significantly higher correlations. When comparing at the *Overall* level, we also achieved noticeably better results in terms of ρ, r and τ.

6.3 Changing Number of References

Figure 4 shows how the Spearman and Kendall correlations for some of the metrics vary with different number of human-written references versus our reference-less metric. The stories selected for our analysis each have a different number of reference stories ranging from 1 to 4. As there were not many stories with 4 references, we select those stories that had 3 references, resulting in 60 stories with 300 sentences for analysis. We then compute the correlations with the human judgement across the metrics using 1,2, and 3 references.

It is evident that the results from the reference-based metrics fluctuate significantly according to the number of references. However, the trend is unclear. Increasing the number of references from

Model	Input Image Sequence: 	Coherence Scores
AREL	1. I went to visit the old church. 2. This is the house we stayed at. 3. Then we went to the market to get some food . 4. We had a great time there. 5. The view from the porch was beautiful.	Sent 1-2: 0.956 Sent 2-3: 0.900 Sent 3-4: 0.942 Sent 4-5: 0.337 **Mean: 0.783**
MCSM + BART	1. We found an old looking house . 2. We had an apartment near our home. 3. The decor around the building was very old. 4. We saw people on the street with their dogs. 5. The houses are very old now .	Sent 1-2: 0.058 Sent 2-3: 0.999 Sent 3-4: 0.707 Sent 4-5: 0.460 **Mean: 0.556**
KG-Story	1. We visited a small town. 2. There were many buildings. 3. The dog was very old. 4. This is my home. 5. I also saw some really cool house .	Sent 1-2: 0.999 Sent 2-3: 0.387 Sent 3-4: 0.522 Sent 4-5: 0.149 **Mean: 0.514**
GLACNet	1. The house was very big. 2. It was a lot of work . 3. There was a lot of snow. 4. I had to go back home. 5. I was not happy.	Sent 1-2: 0.128 Sent 2-3: 0.212 Sent 3-4: 0.957 Sent 4-5: 0.101 **Mean: 0.349**

Figure 5: Predicted coherence probabilities from RoViST-C for 4 VST models.

1 to 2 appears to improve the correlations for some of the metrics like CIDEr, SPICE and ROUGE-L. This may be because having more references can better capture allowable variations in storytelling compared to a single reference. However, increasing from 2 to 3 references actually worsens the performance for many of the metrics (BLEU-1/4, CIDEr, METEOR and ROUGE-L). A possible explanation could be that the additional reference added may have caused bias for some metrics. In particular, n-gram based metrics like BLEU and ROUGE focus on n-gram overlap. Thus, it is possible that the additional reference introduced may have a high n-gram overlap with the candidate but for unimportant filler words like '*the*' or '*and*'. Our metric on the other hand, alleviates this issue by first being a reference-free metric and secondly, by only focusing on important words (nouns) in the candidate story via RoViST-VG.

It is also noted that examining more amount of references could potentially reveal a better trend. However, this is challenging as the maximum amount of references in the VIST dataset is 5 with 82.50% of the stories having 3 or less. Moreover, collecting multiple human reference stories is an expensive process in most cases.

6.4 Qualitative Analysis

We conduct qualitative analysis on our visual grounding scorer (RoViST-VG) and coherence scorer (RoViST-C).

RoViST-VG Figure 6 in Appendix A displays an example gold story with noun mentions highlighted in blue, followed by the corresponding bounding box regions that gave the highest similarity score retrieved by our RoViST-VG model. We observe that the model performs well at matching a majority of the nouns. However, words that are less visually grounding like '*corner*' or intangible nouns such as '*visit*' are extremely challenging to ground. Consequently, RoViST-VG can sometimes retrieve a region that is not closely related for these types of words. This also occurs for words that are mentioned in the story but not explicitly shown in the images like the word '*photos*' in Example Story 2. A potential problem of this may be the presence of false positives if a story tends to mention many non-visual entities. This could lead to a higher grounding score compared to a story that only mentions a few entities that are visually grounded. Nevertheless, our model still serves as guidance for analyzing how visually detailed a story is and can also reflect how many related entities are mentioned.

RoViST-C The qualititive results for 4 example machine stories is displayed in Figure 5. Noticeably, RoViST-C tends to assign higher probabilities to sentences that flow. These sentences do not necessarily need to be about the same topic. For instance, sentence 2 and 3 in AREL's story each have a different topic focus but the sentence transition is given a 0.90 coherence score as they follow a narrative style. Conversely, consecutive sentences with similar topics but are incoherent can be given low scores such as sentences 4-5 from KG-Story. It is clear that training ALBERT with sentence order prediction allows the model to capture inter-sentence coherence and is not just limited to modelling topic similarity across sentences.

7 Conclusion

We propose RoViST, a metric for evaluating VST tasks on 3 aspects: visual grounding, coherence and non-redundancy. RoViST correlates well with human judgement, outperforming other metrics when comparing the coherence and non-redundancy criteria as well as when combining all 3 criteria. While some existing metrics slightly outperform our method on visual grounding, we note that image-to-text similarity is just one aspect of VST and this aspect alone is insufficient in defining a good story. Unlike other metrics, RoViST is reference-free and hence, robust to the number of references which are costly to obtain for VST. It is also interpretable and can be used to gauge out where the model is underperforming. We hope that RoViST provides preliminary insight into future work on developing VST models and evaluations.

A RoViST-VG Example Output

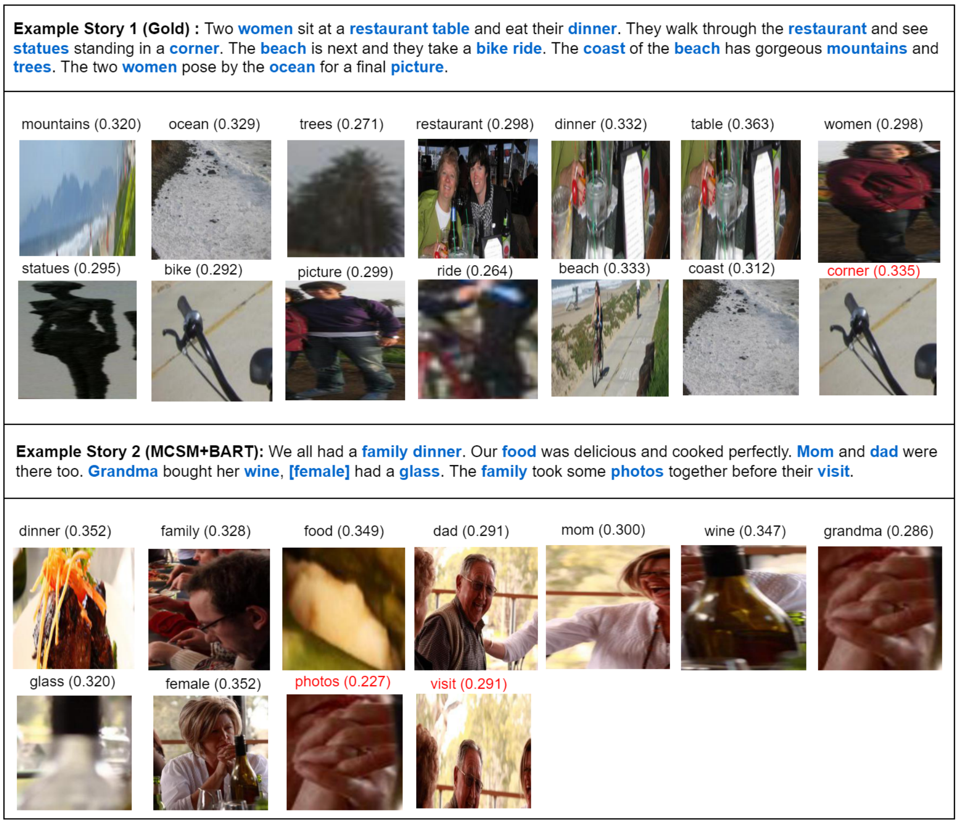
Figure 6 shows the retrieved regions from the RoViST-VG model for an example gold story (top) and a machine-story generated from the MCSM+BART model (bottom). The blue highlighted words are the nouns while red highlighted words indicate words that do not explicitly appear in the image sequence or are less visually grounding words.

B Implementation Details

RoViST-VG We use the Adam optimizer (Kingma and Ba, 2014) with a 0.00001 weight decay. The learning rate was initially set to 0.00005 and was reduced by 5% with each consecutive epoch. For the ViT model, we use the '*vit-base-patch16-224*' style configuration which outputs image features as a 768 dimensional vector. Further, the linear layer used to project the text and embedding features to the joint embedding space (of dimension 1024) uses a $tanh$ activation function. No normalization of the image and text embeddings was done during the training process as we did not find any benefit from doing this. Finally, we set the mini-batch size to 64 and use early stopping to cease training after the validation loss fails to improve for 3 consecutive epochs. We note that 85% and 15% of the data was used in the training and validation set respectively. The model converged in 3 epochs, taking approximately 12 hours with a Nvidia Tesla P100 GPU.

RoViST-C For ALBERT, we use the '*albert-large-v1*' configuration and the Adam optimizer with a 0.00001 weight decay for training. The learning rate was 0.00001 which we schedule to reduce by 5% every epoch. Additionally, the batch size was 32 and early stopping was employed after the validation loss failed to improve for 5 epochs. We note that 85% and 15% of the data was used in the training and validation set respectively. In total, we trained the model for 5 epochs, taking 14 hours with a Nvidia Tesla P100 GPU.

RoViST-NR For assessing intra-sentence non-redundancy, n-grams of size 4 were used as we found that repetition of words within sentences usually occurred in fours.



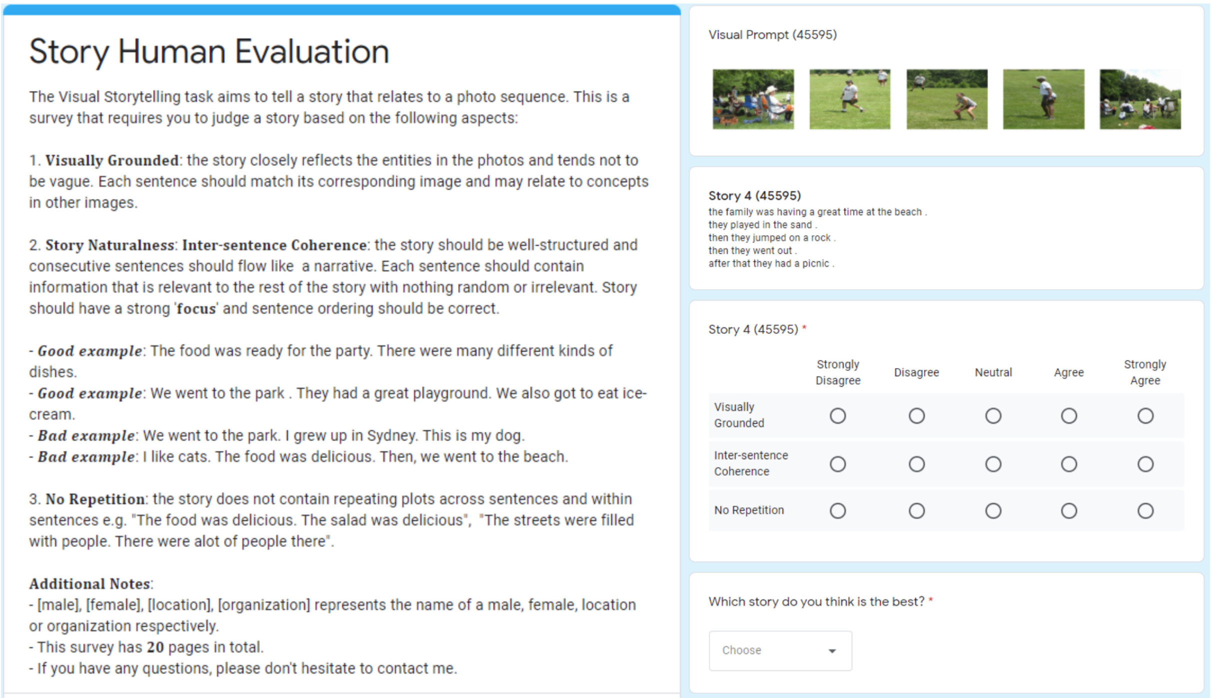
Example Story 1 (Gold) : Two **women** sit at a **restaurant table** and eat their **dinner**. They walk through the **restaurant** and see **statues** standing in a **corner**. The **beach** is next and they take a **bike ride**. The **coast** of the **beach** has gorgeous **mountains** and **trees**. The two **women** pose by the **ocean** for a final **picture**.

Example Story 2 (MCSM+BART): We all had a **family dinner**. Our **food** was delicious and cooked perfectly. **Mom** and **dad** were there too. **Grandma** bought her **wine**, **[female]** had a **glass**. The **family** took some **photos** together before their **visit**.

Figure 6: Retrieved regions from RoViST-VG for an example gold story (top) and machine generated story (bottom).

C Human Evaluation Survey

Figure 7 shows the survey instructions used in the human evaluation study and the format of the survey questions. Participants recruited were volunteers from a variety of age groups (20-60 years old), education level and gender (10 female, 16 male).



Story Human Evaluation

The Visual Storytelling task aims to tell a story that relates to a photo sequence. This is a survey that requires you to judge a story based on the following aspects:

1. **Visually Grounded**: the story closely reflects the entities in the photos and tends not to be vague. Each sentence should match its corresponding image and may relate to concepts in other images.

2. **Story Naturalness**: **Inter-sentence Coherence**: the story should be well-structured and consecutive sentences should flow like a narrative. Each sentence should contain information that is relevant to the rest of the story with nothing random or irrelevant. Story should have a strong '**focus**' and sentence ordering should be correct.

- ***Good example***: The food was ready for the party. There were many different kinds of dishes.
- ***Good example***: We went to the park . They had a great playground. We also got to eat ice-cream.
- ***Bad example***: We went to the park. I grew up in Sydney. This is my dog.
- ***Bad example***: I like cats. The food was delicious. Then, we went to the beach.

3. **No Repetition**: the story does not contain repeating plots across sentences and within sentences e.g. "The food was delicious. The salad was delicious", "The streets were filled with people. There were alot of people there".

Additional Notes:
- [male], [female], [location], [organization] represents the name of a male, female, location or organization respectively.
- This survey has **20** pages in total.
- If you have any questions, please don't hesitate to contact me.

Visual Prompt (45595)

Story 4 (45595)
the family was having a great time at the beach .
they played in the sand .
then they jumped on a rock .
then they went out .
after that they had a picnic .

Story 4 (45595) *

	Strongly Disagree	Disagree	Neutral	Agree	Strongly Agree
Visually Grounded	○	○	○	○	○
Inter-sentence Coherence	○	○	○	○	○
No Repetition	○	○	○	○	○

Which story do you think is the best? *

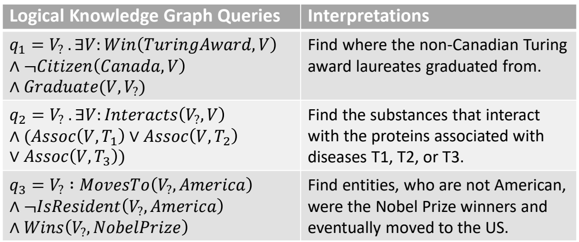
Abstract

Answering complex logical queries on incomplete knowledge graphs (KGs) with missing edges is a fundamental and important task for knowledge graph reasoning. The query embedding method is proposed to answer these queries by jointly encoding queries and entities to the same embedding space. Then the answer entities are selected according to the similarities between the entity embeddings and the query embedding. As the answers to a complex query are obtained from a combination of logical operations over sub-queries, the embeddings of the answer entities may not always follow a uni-modal distribution in the embedding space. Thus, it is challenging to simultaneously retrieve a set of diverse answers from the embedding space using a single and concentrated query representation such as a vector or a hyper-rectangle. To better cope with queries with diversified answers, we propose Query2Particles (Q2P), a complex KG query answering method. Q2P encodes each query into multiple vectors, named particle embeddings. By doing so, the candidate answers can be retrieved from different areas over the embedding space using the maximal similarities between the entity embeddings and any of the particle embeddings. Meanwhile, the corresponding neural logic operations are defined to support its reasoning over arbitrary first-order logic queries. The experiments show that Query2Particles achieves state-of-the-art performance on the complex query answering tasks on FB15k, FB15K-237, and NELL knowledge graphs.

1 Introduction

Reasoning over a factual knowledge graph (KG) is the process of deriving new knowledge or conclusions from the existing data in the knowledge graph (Chen et al., 2020). A recently developed sub-task of knowledge graph reasoning is complex query answering, which aims to answer complex queries over large knowledge graphs (Hamilton et al., 2018; Ren et al., 2020; Ren and Leskovec, 2020). Compared to KG completion tasks (Liu et al., 2016; West et al., 2014), complex query answering requires reasoning over multi-hop relations and logical operations. As shown in Figure 1, complex KG queries are defined in predicate logic forms with relation projection operations, existential quantifiers ∃, logical conjunctions ∧, disjunctions ∨, and negation ¬. Answering these queries is challenging because real-world knowledge graphs (KG), such as Freebase (Bollacker et al., 2008), NELL (Carlson et al., 2010), and DBPedia (Bizer et al., 2009), are incomplete. Consequently, sub-graph matching methods cannot be used to find the answers.



Logical Knowledge Graph Queries	Interpretations
$q_1 = V_? \,.\, \exists V: Win(TuringAward, V)$ $\wedge \neg Citizen(Canada, V)$ $\wedge\, Graduate(V, V_?)$	Find where the non-Canadian Turing award laureates graduated from.
$q_2 = V_? \,.\, \exists V: Interacts(V_?, V)$ $\wedge\, (Assoc(V, T_1) \vee Assoc(V, T_2)$ $\vee\, Assoc(V, T_3))$	Find the substances that interact with the proteins associated with diseases T1, T2, or T3.
$q_3 = V_? : MovesTo(V_?, America)$ $\wedge \neg IsResident(V_?, America)$ $\wedge\, Wins(V_?, NobelPrize)$	Find entities, who are not American, were the Nobel Prize winners and eventually moved to the US.

Figure 1: The example logical knowledge graph queries and their interpretations in natural language.

To address the challenge raised from the incompleteness of knowledge graphs, the query embedding methods are proposed (Hamilton et al., 2018; Ren et al., 2020; Ren and Leskovec, 2020; Sun et al., 2020). In this line of research, the queries and entities are jointly encoded into the same embedding space, and the answers are retrieved based on similarities between the query embedding and entity embeddings. In general, there are two steps in encoding a query to the vector space. First, a query is parsed into a computational graph with a directed acyclic graph (DAG) structure, as shown in Figure 2 (A). Then, the query representation is iteratively computed following the neural logic operations and relation projections in the DAG.

Although the query embedding methods are robust for dealing with the incompleteness of KGs,

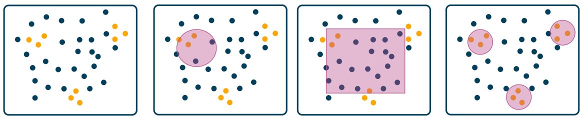
(A) Computation Graph

(B) 2-Dimensional Illustration of Query2Particles Approach

Figure 2: An example of answering a knowledge graph query by using the Query2Particles method. (A) The computational graph corresponds to the query "where did the non-Canadian Turing award laureates graduate from." (B) The Query2Particles encodes each query into a set of vectors, called particle embeddings. The logical operations iteratively compute particle embeddings following the computational graph. The answers are determined by using the maximum similarities between the entity embeddings and any one of the resulting particle embeddings.

the embedding structure used for encoding the queries can be improved. Because of the multi-hop and compositional nature of complex KG queries, a single query may contain multiple sufficiently diverse answers. Thus, the ideal query embedding may follow a multi-modal distribution[1] in the embedding space. For example, the answers to the query, "*Find entities, who are not American, were the Nobel Prize winners and eventually moved to the US,*" involve intermediate entities with different attributes, such as gender, nationality, research fields, etc. It is difficult to use a single embedding vector to find all final answer embeddings. Box embedding (Ren et al., 2020) partially solved this problem, but for complicated attributes, a single box may be too coarse, and intermediate entities are distributed far away from each other, so they are more like several disjoint clusters rather than a single big region in the embedding space. So for the query embedding methods, the capability to simultaneously encode a set of answers from different areas is necessary.

To better address the diversity of answers, we propose Query2Particles, a new query embedding method for complex query answering. In this approach, each query is encoded into a set of vectors in the embedding space, called particle embeddings. The particle embeddings of a query are iteratively computed by following the computational graph parsed from the query. Then the answers to this query are determined by using the maximum similarities between the entity embeddings and any one of the resulting particle embeddings. Experimental results show that Query2Particle achieves state-of-the-art performance on complex query answering over three standard knowledge graphs: FB15K, FB15k-237, and NELL. Meanwhile, the inference speed of Query2Particles is comparable to other query embedding methods and is higher than query decomposition methods on multi-hop queries. Further analysis indicates that the optimal numbers of particles for different query types depend on the structures of the queries. Our experimental code is released on github[2].



(A) (B) (C) (D)

Figure 3: In the example embedding space, the yellow dots are the answer entities, and the blue dots are the non-answer entities. The purple areas in (B), (C), and (D) demonstrate the neighborhoods of the vector embedding, the box embedding, and the particle embeddings respectively. In this case, the particle embeddings are more suitable for finding the answers clustered in different areas in the embedding space.

2 Related Work

Other query embedding approaches are closely related to our work. These query embedding methods leverage different structures to encode logical KG queries, and they can answer various scopes of logical queries. The GQE method proposed by Hamilton et al. (2018) can answer the conjunctive queries by representing queries as vector representations. Ren et al. (2020) used hyper-rectangles to encode and answer existential positive first-order (EPFO) queries. At the same time, Sun et al. (2020) proposed to improve the faithfulness of the query embedding method by using centroid-sketch representations on EPFO queries. The conjunctive queries and EPFO queries are both subsets of first-order logic (FOL) queries. The Beta Embedding (Ren and Leskovec, 2020) is the first query embed-

---

[1] A multi-modal distribution is a distribution with two or more distinct peaks in the probability density function.

[2] https://github.com/HKUST-KnowComp/query2particles

ding method that supports a full set of operations in FOL by encoding entities and queries into probabilistic Beta distributions. In a contemporaneous work, Zhang et al. (2021) uses cone embeddings to encode the FOL queries. As shown in Figure 3, compared to these query embedding approaches, the Q2P method can encode the FOL queries to address the diversity of answers. Note that, Ren et al. (2020) proposed to use the disjunctive normal form (DNF) to address the answer diversities resulting from the union operations. This partly solve the problem, but the diversity of the answers is not solely caused by the union operation, but a joint effort of multi-hop projections, intersection, and complement. As a result, using particle embeddings is a more general solution.

Query decomposition (Arakelyan et al., 2020) is another approach to answering complex knowledge graph queries. In this line of research, a complex query is decomposed into atomic queries, and the probabilities of atomic queries are modeled by link predictors. In the inference process, continuous optimization and beam search are used for finding the answers. Meanwhile, the rule and path-based methods (Guo et al., 2016; Xiong et al., 2017; Lin et al., 2018; Guo et al., 2018; Chen et al., 2019) use pre-defined or learned rules to do multi-hop KG reasoning. These methods explicitly model the intermediate entities in the query. Instead, the query embedding methods directly embed the complex query and retrieve the answers without explicit modeling intermediate entities. So the query embedding methods are more scalable to large knowledge graphs and complex query structures.

Neural link predictors (Wang et al., 2014; Trouillon et al., 2016; Dettmers et al., 2018; Sun et al., 2018) are also related to this work. The link predictors learn the distributed representations of entities and relations in embedding space and use different neural structures to classify whether there exists a certain relation between two entities. The link predictors can be used for one-hop queries, but cannot be directly used for answering complex queries.

3 Preliminaries

In this section, we formally define the complex logical knowledge graph queries and the corresponding computational graphs. The knowledge graph reasoning is conducted on a multi-relational knowledge graph $\mathcal{G} = (\mathcal{V}, \mathcal{R})$, where each vertex $v \in \mathcal{V}$ represents an entity, and each relation $r \in \mathcal{R}$ is a binary function defined as $r : \mathcal{V} \times \mathcal{V} \rightarrow \{0, 1\}$. For any $r \in \mathcal{R}$, and $u, v \in \mathcal{V}$, there is a relation r between entities u and v if and only if $r(u, v) = 1$.

3.1 First-Order Logic Query

The complex knowledge graph query is defined in first-order logic form with logical operators such as existential quantifiers $\exists$, conjunctions $\wedge$, disjunctions $\vee$, and negations $\neg$. In a first-order logic query, there is a set of anchor entities $V_a \in \mathcal{V}$, existential quantified variables $V_1, V_2, ...V_k \in \mathcal{V}$, and a unique target variable $V_? \in \mathcal{V}$. The query intends to find the answers $V_? \in \mathcal{V}$, such that there simultaneously exist $V_1, V_2, ...V_k \in \mathcal{V}$ satisfying the logical expression in the query. For each FOL query, it can be converted to a disjunctive normal form, where the query is expressed as a disjunction of several conjunctive expressions:

$$q[V_?] = V_?.\exists V_1, ..., V_k : c_1 \vee c_2 \vee ... \vee c_n, \quad (1)$$

$$c_i = e_{i1} \wedge e_{i2} \wedge ... \wedge e_{im}. \quad (2)$$

Each c_i represents a conjunctive expression of several literals e_{ij}, and each e_{ij} is an atomic or the negation of an atomic expression expressed by any of the following expressions: $e_{ij} = r(v_a, V)$, $e_{ij} = \neg r(v_a, V)$, $e_{ij} = r(V, V')$, or $e_{ij} = \neg r(V, V')$. Here $v_a \in V_a$ is one of the anchor entities, and $V, V' \in \{V_1, V_2, ..., V_k, V_?\}$ are distinct variables satisfying $V \neq V'$.

3.2 Computational Graph and Operations

As shown in Figure 2 (A), for a first-order query, there is a corresponding computational graph. In the computational graph, each node corresponds to an intermediate query embedding, and each edge corresponds to a neural logic operation to be defined in the following section. Both the input and output of these operations are query embeddings. These operations are used for implicitly modeling different set operations over the intermediate answer sets. These set operations include relational projection, intersection, union, and complement: (1) *Relational Projection*: Given a set of entities A and a relation $r \in R$, the relational projection will return all entities having relation r with at least one of entity $e \in A$. Namely, $P_r(A) = \{v \in \mathcal{V} | \exists v' \in A, r(v', v) = 1\}$; (2) *Intersection*: Given sets of entities $A_1, ...A_n \subset \mathcal{V}$, this operation computes their intersection $\cap_{i=1}^{n} A_i$; (3) *Union*: Given several sets of entities $A_1, ...A_n \subset \mathcal{V}$, the union operation calculates their union $\cup_{i=1}^{n} A_i$; (4) *Complement*:

Given a set of entities A, the complement operation calculates its absolute complement $\mathcal{V} - A$.

4 Query2Particles

In this section, we first introduce the particle embeddings structure and the neural logic operations, and then we present the learning of the model.

4.1 Particles Representations of Queries

In Query2Particles, each query is represented as a set of vectors, called particles. For simplicity, a set of particles $\{p^{(k)}\}_{k=1}^{K}$ are represented as a matrix P. All the operations discussed in the following sections are invariant to the permutations of the particle vectors in the matrix. Formally, the particle embeddings $P \in R^{d \times K}$ are

$$P = [p^{(1)}, p^{(2)}, ..., p^{(K)}], \tag{3}$$

where each vector $p^{(k)} \in R^d$ is a particle vector. As shown in Figure 2, the computations along the computation graph start with the anchor entities, such as "Turing Award". Suppose the entity embedding of an anchor entity v is denoted as $e_v \in R^d$. Then, the initial particle embeddings are computed as the sum of e_v and a learnable offset matrix $M \in R^{d \times K}$,

$$P_0 = e_v + M. \tag{4}$$

Here and in the following sections, the addition between the matrix M and the vector e_v is defined as the broadcasted element-wise addition.

4.2 Logical Operations

In this sub-section, we define and parameterize four types of neural logic operations: projection, intersection, negation, and union.

4.2.1 Projection

Suppose the $e_l \in R^d$ is the embedding vector of the relation l. The relation projection f_P is expressed as $P_{i+1} = f_P(P_i, e_l)$, where the P_i and P_{i+1} are input and output particle embeddings. Instead of directly adding the same relation embedding e_l to all particles in P_i to model the relation projection following (Bordes et al., 2013), we incorporate multiple neuralized gates (Chung et al., 2014) to individually adjust the relation transition for each particle in P_i, which are expressed as follows:

$$Z = \sigma(W_z^P e_l + U_z P_i + b_z), \tag{5}$$

$$R = \sigma(W_r^P e_l + U_r P_i + b_r), \tag{6}$$

$$T = \phi(W_h^P e_l + U_h (R \odot P_i) + b_h), \tag{7}$$

$$A_i = (1 - Z) \odot P_i + Z \odot T. \tag{8}$$

Here, σ and ϕ are the sigmoid and hyperbolic tangent functions, and $\odot$ is the Hadamard product. Also, $W_z^P, W_r^P, W_h^P, U_z, U_r, U_h$ are parameter matrices. T is interpreted as the relation transitions for each of the particles given the relation embedding e_l, and Z and R are the update gate and the reset gate used for customizing the relation transitions for each particle. Meanwhile, the relation projection result for each particle should also depend on the positions of other input particles. To allow information exchange among different particles, a scaled dot-product self-attention (Vaswani et al., 2017) module is also incorporated,

$$P_{i+1} = \texttt{Attn}(W_q^P A_i^T, W_k^P A_i^T, W_v^P A_i^T)^T. \tag{9}$$

The $W_q^P, W_k^P, W_v^P \in R^{d \times d}$ are parameters used for modeling the input Query, Key, and Value for the self-attention module `Attn`. The `Attn` represents the scaled dot-product self-attention,

$$\texttt{Attn}(Q, K, V) = \texttt{Softmax}(\frac{QK^T}{\sqrt{d}})V. \tag{10}$$

Here, the Q, K, and V represent the input Query, Key, and Value for this attention layer.

4.2.2 Intersection

The intersection operation f_I is defined on multiple sets of particle embeddings $\{P_i^{(n)}\}_{n=1}^{N}$. It outputs a single set of particle embeddings $P_{i+1} = f_I(\{P_i^{(n)}\}_{n=1}^{N})$. The particles from the $\{P_i^{(n)}\}_{n=1}^{N}$ are first merged into a new matrix $P_i = [P_i^{(1)}, P_i^{(2)}, ..., P_i^{(N)}] \in R^{d \times NK}$, and this matrix P_i serves as the input of the intersection operation. The operation updates the position of each particle according to the positions of other input particles in $\{P_i^{(n)}\}_{n=1}^{N}$. This process is modeled by the scaled dot-product self-attention followed by a multi-layer perceptron (MLP) layer,

$$A_i = \texttt{Attn}(W_q^I P_i^T, W_k^I P_i^T, W_v^I P_i^T)^T, \tag{11}$$

$$P_{i+1} = \texttt{MLP}(A_i). \tag{12}$$

Here $W_q^I, W_k^I, W_v^I \in R^{d \times d}$ are parameters for the self-attention layer. The `MLP` here denotes a multi-layer proceptron layer with `ReLU` activation, and the parameters in the `MLP` layers in different operations are not shared. To keep the number of particles unchanged, we uniformly sub-sample K particles out of the NK particles in P_{i+1} as the final output of the intersection operation.

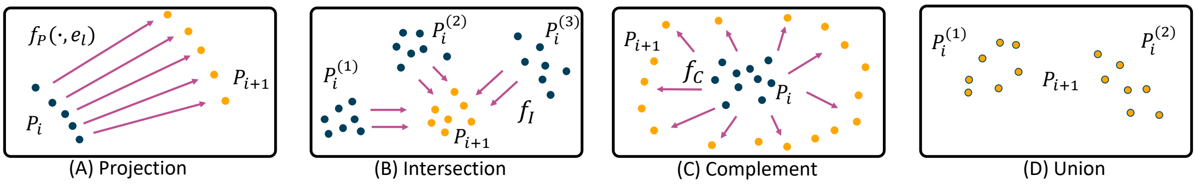


Figure 4: The P_i in blue and the P_{i+1} in yellow are the input and output particles respectively. (A) The embeddings P_i are projected to P_{i+1} by the relation l. (B) The resulting embeddings P_{i+1} are computed from three sets of particles P_i by the intersection f_I. (C) The output P_{i+1} are computed from the input P_i by the complement f_C. (D) The P_{i+1} are directly taken from the all input particles in P_i without any additional parameterization.

4.2.3 Complement

The input of the complement operation is a single set of particle embeddings P_i, and the operation f_C is formulated as $P_{i+1} = f_C(P_i)$. The complement operation updates the position of each particle based on the distributions of other input particles. The operation is then modeled by scaled dot-product attention followed by an MLP layer, and this can be formulated by

$$A_i = \texttt{Attn}(W_q^C P_i^T, W_k^C P_i^T, W_v^C P_i^T)^T, \quad (13)$$

$$P_{i+1} = \texttt{MLP}(A_i). \quad (14)$$

Here, the $P_{i+1} \in R^{d\times K}$ are the resulting particle embeddings for the complement operation, and the values in $W_q^C, W_k^C, W_v^C \in R^{d\times d}$ are parameters. Intuitively speaking, the proposed structure can model the complement operation by encouraging the particles to move towards the areas that are not occupied by any of the input particles.

4.2.4 Union

The union operation is directly modeled by all the input particles without extra parameterization. In detail, the particles from the input particle embeddings are directly merged into a new set of particles,

$$f_U(\{P_i^{(n)}\}_{n=1}^N) = [P_i^{(1)}, ..., P_i^{(N)}]. \quad (15)$$

4.3 Scoring

After the particle embeddings $P_T \in R^{d\times K}$ for the target variable of the query q are computed, the scoring function ϕ between the particle embeddings P_T and each entity embedding e_v is used for calculating the maximal similarities between each particle vectors in $\{p_T^{(k)}\}_{k=1}^K$ and entity embedding vector. Here, the inner product is used to compute the similarity scores between vectors, and the overall scoring function is expressed by

$$\phi(P_T, e_v) = \max_{k\in\{1,2,...,K\}} < p_T^{(k)}, e_v > . \quad (16)$$

4.4 Learning Query2Particles

To train the Query2Particles model, we compute the normalized probability of the entity v being the correct answer of query q by using the `softmax` function on all similarity scores,

$$p(v, q) = \frac{\phi(P_T, e_v)}{\sum_{v'\in V} \phi(P_T, e_{v'})}. \quad (17)$$

Then we construct the cross-entropy loss from the given probabilities to maximize the log probabilities of all correct query-answer pairs:

$$L = -\frac{1}{N}\sum_i \log p(v^{(i)}, q^{(i)}). \quad (18)$$

The $(v^{(i)}, q^{(i)})$ denotes is one of the positive query-answer pairs, and in total there are N such pairs.

5 Experiments

The experiments in this section demonstrate the effectiveness and efficiency of Query2Particles.

5.1 Experimental Setup

The Query2Particles method is evaluated on three commonly used knowledge graphs, FB15K (Bordes et al., 2013), FB15K-237 (Toutanova and Chen, 2015), and NELL995 (Carlson et al., 2010) with the standard training, validation, and testing edges separations. For each of these graphs, the corresponding training graph G_{train}, validation graph G_{valid}, and testing graph G_{test} are created from training edges, training + validation edges, and training + validation + testing edges respectively.

There are two sets of complex logical queries sampled from these knowledge graphs, and the existing methods evaluate their performance on either of them. Specifically, Ren et al. (2020) sample nine different types of existential positive first-order (EPFO) queries. For these queries, five types of them (`1p`, `2p`, `3p`, `2i`, `3i`) are used for training and evaluation in a supervised setting. For the rest of four types of queries (`2u`, `up`, `ip`, `pi`), they

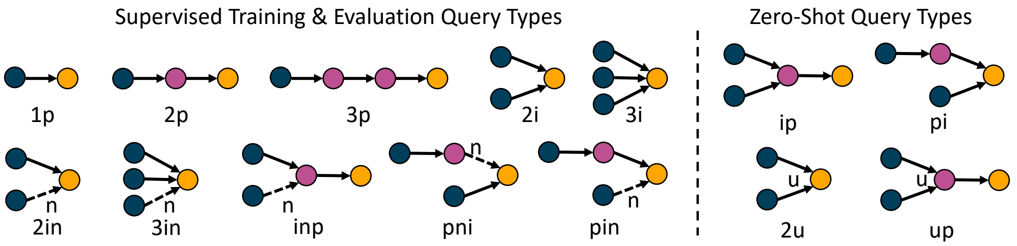

Figure 5: The query structures used for training and evaluation. For brevity, the p, i, n, and u represent the projection, intersection, negation, and union operations respectively. The query types on the left are trained and evaluated under supervised settings. There are not training queries for the four types of queries on the right, and they are directly evaluated at the test time to measure the generalization capability of the models to unseen query types.

do not appear in the training set and are directly evaluated in a zero-shot way. In another work, Ren and Leskovec (2020) refine these queries by raising the difficulties of the existing nine types of queries. They also include five types of complement queries (`2in`, `3in`, `inp`, `pni`, `pin`) for general first-order logic (FOL) queries. These complement queries are also trained and evaluated in the supervised setting, but their training samples are fewer than other types. More details about the knowledge graphs and sampled queries are shown in the appendix. To demonstrate the performance of Query2Particles, it is evaluated on both sets of queries. Note that, the query-answer pairs used for training are only from the training graph G_{train}. For validation and testing, only the hard answers from validation graph G_{valid} and testing graph G_{test} are evaluated.

5.2 Baselines

The Query2Particles model is compared with the following baselines in the following sections.

Graph Query Embedding (GQE) answers conjunctive logic queries by encoding the logical queries into vectors (Hamilton et al., 2018).

Query2Box (Q2B) answers existential positive first-order logic queries by encoding them into boxes in the embedding space (Ren et al., 2020).

Beta Embedding (BetaE) answers first-order logic queries by modeling them as Beta Distributions (Ren and Leskovec, 2020). This is the current state-of-the-art model on first-order logic queries.

The reported mean reciprocal rank (MRR) scores of these baselines are used by the BetaE paper (Ren and Leskovec, 2020), and Query2Particles (Q2P) is evaluated following with the same metrics under the filtered setting, in which the rankings of answers are computed excluding all other correct answers. Meanwhile, the Q2P method is also compared with other methods on EPFO queries with the queries used by Ren et al. (2020).

Continuous Query Decomposition (CQD) decomposes the complex queries to multiple atomic queries that can be solved by link predictors (Arakelyan et al., 2020) .

Embedding Query Language (EmQL) improves the faithfulness in the reasoning process by encoding EPFO queries into centroid-sketch representations (Sun et al., 2020).

The reported Hit@3 results of these two baselines are used by Arakelyan et al. (2020); Sun et al. (2020). Our model is evaluated on FB15K, FB15K-237, and NELL in the same setting.

5.3 Implementation Details

The Query2Particles model is trained on the queries in an end-to-end manner. To fairly compare with previous methods, we set the same size of embedding vectors as four hundred. We use the validation queries to tune hyperparameters for our model by using grid search. In the grid search, we consider the batch size from $\{1024, 2048, 4096, 8192\}$, dropout rate from $\{0.1, 0.2, 0.3\}$, learning rate

from $\{10^{-4}, 3 * 10^{-4}, 10^{-3}\}$, and label smoothing from $\{0.3, 0.5, 0.7\}$. The final hyperparameters are shown in the supplementary materials. Our experiments are conducted on Titan Xp with PyTorch 1.8, and they are repeated three times.

5.4 Comparison with Baselines

First, we compare Query2Particles (Q2P) with GQE, Q2B, and BetaE on the first-order logic queries used by Ren and Leskovec (2020). The results on all fourteen types of queries are reported in Table 1 and Table 2. To fairly compare with the baseline methods, we keep the same number of parameters used in each type of query embedding.

As shown in Tables 1 and 2, the Q2P model can achieve more accurate results than GQE, Q2B, and BetaE on all types of queries except `2u`. As we keep the number of query embedding parameters the same, it indicates that the structure of particle embeddings is more suitable for encoding complex queries than boxes or Beta distributions.

Though it is slightly less accurate on the `2u` queries, Q2P is more efficient in encoding the queries that include union operations. This is because Q2P is the first embedding method that directly models the union operation. To avoid direct modeling of the union operation, all previous embedding methods pre-process the queries by converting them to DNF forms. However, the DNF forms can be exponentially larger than the original queries, and the conversion also takes exponential time. Meanwhile, BetaE proposes to use De Morgan's law to replace one union operation with one intersection and three complements, but this substitution still largely increases the query complexity. Instead, Q2P directly models the union operation without any pre-processing or additional parameterization, while achieving the state-of-the-art performance on `up`, which is more complicated and involving the Union operation.

We also compare our model with EmQL and CQD methods on the queries used by Ren et al. (2020). On average, our model has better Hit@3 scores on all datasets[3]. Compared to the CQD method, the Q2P method is better at answering multi-hop queries. encodes the complex queries into centroid-sketch representations, which cannot compactly encode sufficiently diverse answers. The Q2P method specifically addresses the diversity of answers, so it has higher empirical performance. CQD performs better on shorter queries like `1p`, `2p`, and `2u`, because it can use the state-of-the-art link predictors. Also, as shown in Figure 6, the Q2P method demonstrates a faster inference

---

[3] In this paper, we only focus on the inductive setting, so we skip the comparison with EmQL under the entailment setting, in which the test graph is used for both training and testing.

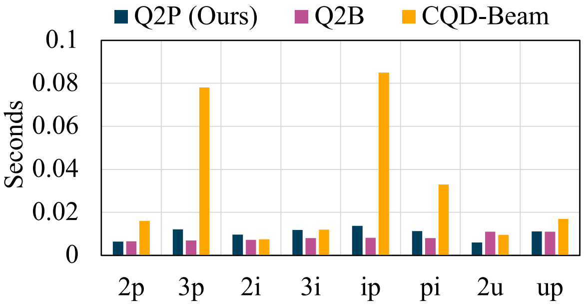

Figure 6: The inference time of different types of queries on FB15k, which has the largest number of edges among three graphs.

speed than the CQD method on multi-hop queries, because CQD uses inference time optimization, which is either a continuous optimization or a beam search. The inference time optimization simplifies the learning of CQD but also slows down the inference efficiency on large graphs.

5.5 The Improvement of Q2P-KP

Experiments show that the performance of the diversified queries can be largely improved by using more particles. To demonstrate the effects, we conduct additional evaluations on the most diversified 10% queries for each query type, as shown in the DIVR columns in Table 4. In doing so, we use the number of answers to measure the diversity of each query. In the same table, we also present the original results in the FULL columns as a comparison.

We can observe that there is a significant performance gap between the FULL and DIVR results, which demonstrates that the diversified queries are harder to answer. Meanwhile, it is also observed that comparing to Q2P-1P, Q2P-KP (K>1) significantly improves the MRR of DIVR queries by 7.8 points. From this perspective, the improvement of Q2P-KP (K>1) over Q2P-1P is significant on those challenging queries.

5.6 Further Ablation Study for Q2P-1P

To better explain the superior performance of Q2P-1P over the baseline models, we conduct further ablations studies in Table 5.

First, we remove all the self-attention layers `Attn`. Then the performance of intersection operations largely decreased. This can be explained that the self-attention structure is important for aggregating the information from multiple sub-queries.

Then, we remove all the neural network structures, including all `MLP` and `Attn` from all operations, and replace them with the operations defined in the GQE model (Hamilton et al., 2018). Then the performance of Q2P is also reduced. This indicates that the neural structures in the particle operations are also important to the overall improvement. Thus, we infer that the baseline model underfit the complex queries in the training set, and the performance can be improved by introducing more parameters and non-linearity. This conclusion is also aligned with Sun et al. (2020), in which they found the baselines cannot faithfully answer the queries that are observed in the training time.

MODELS	1P		2I		2U		2IN		AVERAGE	
	FULL	DIVR	FULL	DIVR	FULL	DIVR	FULL	DIVR	FULL	DIVR
Q2P-1P	81.8	44.8	63.4	28.8	33.4	11.3	18.9	15.0	49.4	25.0
Q2P-2P	82.6	49.4	**65.1**	35.5	32.1	13.3	**21.9**	20.7	50.4	29.7

MODELS	1P	2P	2I	2U	2IN
Q2P-KP	**83.4**	**31.5**	**66.0**	**38.9**	**22.3**
Q2P-1P	81.8	30.7	63.4	33.4	18.9
− SELF ATTENTION	78.5	28.5	30.9	30.3	15.2
− ALL NNS + GQE OPS	56.7	16.1	39.2	20.1	–
Q2P	68.0	21.0	55.1	35.1	–
GQE	54.6	15.3	39.7	22.1	–

Table 5: The ablation study on the Q2P neural networks. The Q2P-KP result shows the highest result when K is ranged from 2 to 6.

However, solely using more complex structures cannot address the problem raised from the diversity of the answers. As shown in Table 4, on the top of Q2P-1P, Q2P-KP (K>1) can still largely improve the performance on the diversified queries.

6 Conclusion

In this paper, we proposed Query2Particles, a query embedding method for answering complex logical knowledge graph queries over incomplete knowledge graphs. The Query2Particle method supports a full set of FOL operations. Specifically, the Q2P method is the first query embedding method that can directly model the union operation without any preprocessing. Experimental results show that the Q2P method achieves state-of-the-art performances on answering FOL queries on three different knowledge graphs while using comparable inference time as the previous methods.

7 Ethical Impacts

This paper introduces a knowledge graph reasoning method, and the experiments are on several publicly available benchmark datasets. As a result, there is no data privacy concern. Meanwhile, this paper does not involve human annotations, and there is no related ethical concerns.

Abstract

Idioms are phrases which present a figurative meaning that cannot be (completely) derived by looking at the meaning of their individual components. Identifying and understanding idioms in context is a crucial goal and a key challenge in a wide range of Natural Language Understanding tasks. Although efforts have been undertaken in this direction, the automatic identification and understanding of idioms is still a largely under-investigated area, especially when operating in a multilingual scenario. In this paper, we address such limitations and put forward several new contributions: we propose a novel multilingual Transformer-based system for the identification of idioms; we produce a high-quality automatically-created training dataset in 10 languages, along with a novel manually-curated evaluation benchmark; finally, we carry out a thorough performance analysis and release our evaluation suite at `https://github.com/Babelscape/ID10M`.

1 Introduction

Idioms pertain to a wider family of linguistic phenomena referred to as multi-word expressions (MWEs). Broadly speaking, an MWE can be defined as a combination of two or more words, behaving as a complex lexical unit and showing idiosyncratic properties (Baldwin and Kim, 2010). Over the course of the last few years, several attempts have been made to classify MWEs based on specific dimensions such as polylexicality, fixedness, compositionality and idiomaticity (Sailer and Markantonatou, 2018). According to Sag et al. (2002), MWEs can be divided into lexicalized and institutionalized phrases. While the former show syntactic or semantic idiosyncrasies, e.g. *kingdom come* and *spill the beans*, the latter are compositional from a syntactic and semantic perspective, but statistically idiosyncratic, e.g. *traffic light* and *telephone booth*.

Among lexicalized phrases, idioms are of particular interest in that their meaning cannot be obtained by compositionally interpreting their word constituents. These include non-compositional phrases, e.g. *kick the bucket*, and partially-compositional phrases, e.g. *rain cats and dogs* (Nunberg et al., 1994).

Given their complex nature, idioms are hard to be automatically identified and pose a crucial challenge to the entire field of Natural Language Understanding (NLU). Although research in this field has recently achieved great advancements, the current formulation of many tasks tends to overlook the idiomatic usage of language. Instead, idioms ought to be playing an important role in NLU as they are a frequent phenomenon which can be observed in all languages. The correct identification of idioms in context is crucial for tasks such as Word Sense Disambiguation (Bevilacqua et al., 2021) and Entity Linking (Sevgili et al., 2020), but also for many downstream applications. For instance, in Question Answering or dialog, a system must be able to understand *"It was a piece of cake"* in relation to the question *"How was the test?"* (Jhamtani et al., 2021; Mishra and Jain, 2016). Similarly, if the idiom *kick the bucket* is identified, then a Text Summarization system would be able to summarize all its occurrences within a text with "die" (Chu and Wang, 2018; Gambhir and Gupta, 2017). Finally, once an idiom is identified, a Machine Translation system would then be able to avoid its compositional translation, and treat it as a whole (Anastasiou, 2010). Furthermore, idioms are widely studied in linguistics and psycholinguistics (Cacciari and Tabossi, 1988; Gibbs Jr, 1992; Nunberg et al., 1994; Cacciari and Tabossi, 2014; Liu, 2017), hence a system capable of effectively identifying idioms in texts would significantly improve many research areas, far beyond NLU.

Most of the past idiom extraction strategies focused on specific domains and on a limited number

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2715 - 2726
July 10-15, 2022

of languages. In our work, we tackle these shortcomings and, taking inspiration from the Named Entity Recognition (NER) task (Yadav and Bethard, 2018), we reformulate the identification of idioms as a sequence labeling task. Specifically, we propose the following new contributions:

- We design a novel multilingual Transformer-based system for the identification of idioms;
- We release a high-quality silver training dataset in 10 languages and a novel manually-curated evaluation benchmark in 4 languages;
- We measure the quality of the data produced and of our system design through an extensive evaluation.

We hope that this work will provide a stepping stone for further studies regarding idiomatic expressions and their applications, and encourage further work on the identification of idioms in multiple languages. We release the produced datasets and software at `https://github.com/Babelscape/ID10M`.

2 Related Work

Systems Over the course of the past two decades, several approaches have been put forward to address the idiom identification task. To this end, two main properties of idioms have been leveraged, namely their syntactic and semantic idiosyncrasies. While the former refers to the peculiar syntactic behaviour of idioms, the latter indicates the linguistic property in which the meaning of an idiomatic expression cannot be completely derived from the meaning of its individual components.

Initial studies regarding idiom identification focused on syntactic idiosyncrasy, concentrating on verb/noun idioms, e.g. *shoot the breeze* (Fazly and Stevenson, 2006; Cook et al., 2007; Diab and Bhutada, 2009), on verb/particle idioms, e.g. *call off* (Ramisch et al., 2008) or on idioms satisfying specific restrictions, i.e. subject/verb such as *tension mounted* and verb/direct-object, e.g. *break the ice* (Shutova et al., 2010).

Subsequent approaches exploited semantic idiosyncrasies. This property implies that idiomatic expressions often occur in contexts typically unrelated to the meaning of their individual constituents, thus providing a key feature to be exploited in an automatic approach. In particular, Muzny and Zettlemoyer (2013) introduced new lexical and graph-based features that use WordNet[1] and Wiktionary[2], and proposed a simple yet efficient binary Perceptron classifier to distinguish between idiomatic and non-idiomatic expressions by exploiting their components and dictionary definitions. A similar, but unsupervised approach was adopted by Verma and Vuppuluri (2015) which relied on the dictionary definitions of each component of a given idiom.

These latter methods have more recently been superseded by approaches making use of distributional similarity in the form of both static and contextualized word embeddings (Gharbieh et al., 2016; Ehren, 2017; Senaldi et al., 2019; Hashempour and Villavicencio, 2020; Fakharian, 2021; Garcia et al., 2021; Nedumpozhimana and Kelleher, 2021), while keeping the underlying assumption unchanged: the vector representation of the component words should be distant from the vector representation of the context or of the expression as a whole.

Notwithstanding the recent improvements, to the best of our knowledge, the identification of idiomatic expressions in multiple languages is largely under-investigated.

Datasets In the early 2000s, several datasets for idiom identification were created. For instance, Cook et al. (2008) and Sporleder et al. (2010) manually selected a limited number of idioms, and then extracted sentences containing such idioms from the British National Corpus (BNC, Consortium et al., 2007). Similarly, Sporleder and Li (2009) extracted a dataset from the Gigaword corpus (Graff and Christopher, 2003). Street et al. (2010), instead, used multiple annotators to validate sentences from the American National Corpus (ANC, Ide and Macleod, 2001). Additionally, Muzny and Zettlemoyer (2013) created a dataset by applying the aforementioned classifier on Wiktionary entries, more than doubling the number of idiomatic expressions in Wiktionary.

Furthermore, Korkontzelos et al. (2013) introduced Task 5b at SemEval-2013 regarding the detection of semantic compositionality in context. The authors selected idioms from Wiktionary, and extracted instances from the ukWaC corpus (Ferraresi et al., 2008). Schneider et al. (2016), instead, proposed the DiMSUM dataset for Task 10 at SemEval-2016, and extracted annotations from reviews, tweets and TED talks. However, this work

---

[1] `https://wordnet.princeton.edu/`

[2] `https://www.wiktionary.org/`

did not categorise MWEs into subtypes, making it difficult to quantify the number of idioms in the corpus.

Finally, Peng et al. (2015) expanded the dataset introduced by Cook et al. (2008) by retrieving further sentences from the BNC corpus, while more recently Gong et al. (2017) introduced a small-scale dataset derived from Google Books[3] for English and Chinese.

Unfortunately, almost all the aforementioned approaches focused on English. The first concrete attempt to scale to multiple languages was made by Madabushi et al. (2021) who also proposed a SemEval-2022 task on idiom identification. Nevertheless, their datasets are limited in size and they only cover three languages, namely English, Portuguese and Galician.

3 ID10M

In what follows, we first describe the creation process of our training datasets (Section 3.1) and the manually-curated test sets (Section 3.2). Then, we introduce our new task formulation and illustrate the architecture of our idiom identification system (Section 3.3).

3.1 Silver-Standard Data Creation

Automatic Annotation In order to create our training data, we exploit Wiktionary[4] as the main source, as it provides access to a large number of MWEs along with usage examples in multiple languages. However, since such examples are provided for a limited number of MWEs, we search for further textual contexts in a large external source, namely WikiMatrix[5] (Schwenk et al., 2021), a multilingual corpus that covers 83 languages and contains parallel sentences extracted from Wikipedia[6].

We perform data extraction as follows. Let E_l be the set of MWEs available in Wiktionary in the language l, with $|E_l| = n$, and let us define the function $L(p)$ that, given a phrase p, outputs its lemma. Then, we apply a heuristic which allows us, for each expression $e_i \in E_l$, to search for a sentence in WikiMatrix such that there exists at least a span of tokens S_{k-j} starting at index k and ending at index j, where $e_i = S_{k-j} \vee e_i = L(S_{k-j}) \vee L(e_i) = S_{k-j} \vee L(e_i) = L(S_{k-j})$. By applying this heuristic, not only do we obtain a large set of sentences containing potentially idiomatic expressions (PIEs), but – thanks to the lemmatization step – we also collect several morphological variations of the original expressions in E_l, e.g. starting from '*kick the bucket*', we also obtain '*kicked the bucket*' and '*kicks the bucket*'. In particular, if an MWE is marked as idiomatic in Wiktionary, we mark all its occurrences as idiomatic too. Similarly, if an MWE is not marked as idiomatic in Wiktionary, we mark all its occurrences as literal. However, this has a limitation: if an MWE is labeled as idiomatic (or literal) in Wiktionary, it will not necessarily always also be idiomatic (or literal) in the WikiMatrix sentences in which it appears.

We adopt the above-described procedure to create datasets in the following 10 languages: Chinese, Dutch, English, French, German, Italian, Japanese, Polish, Portuguese and Spanish.

Automatic Validation Since the data derived from Wiktionary and WikiMatrix may contain errors, we aim at automatically improving their quality. To achieve this goal, we exploit the semantic idiosyncrasy property of idiomatic expressions, and the consequent fact that the meaning of the individual constituents of idiomatic expressions are unrelated to the surrounding context. Specifically, following this intuition, and by taking inspiration from recent advances in the main disambiguation tasks (Blevins and Zettlemoyer, 2020; Botha et al., 2020; Tedeschi et al., 2021), we design a dual-encoder architecture (Figure 1) to produce a vector representation for both the expression and its context, and then, based on their cosine similarity, label the expression as idiomatic or literal.

More formally, let us define an expression encoder Ψ and a context encoder Ω. Then, given an expression-context pair $\langle e, c \rangle$, the output of the dual-encoder architecture Φ is defined as follows:

$$\Phi(e, c) = \begin{cases} 1, & \text{if } \dfrac{\Psi(e)^T \Omega(c)}{\|\Psi(e)\| \, \|\Omega(c)\|} \leq \delta \\ 0, & \text{otherwise} \end{cases}$$

where $\Phi(e, c) = 1$ means that e is idiomatic in c, while $\Phi(e, c) = 0$ if e has a literal meaning

---

[3] https://books.google.com/

[4] We employ the Wiktextract library to collect the necessary data from Wiktionary. WikiExtract (https://pypi.org/project/wiktextract/) provides a preprocessed version of the Wiktionary dump together with useful APIs.

[5] https://github.com/facebookresearch/LASER/tree/main/tasks/WikiMatrix

[6] The encyclopedia-style prose of Wikipedia could have a lower idiom density compared to other textual sources, but the large size of WikiMatrix should balance this lower density.

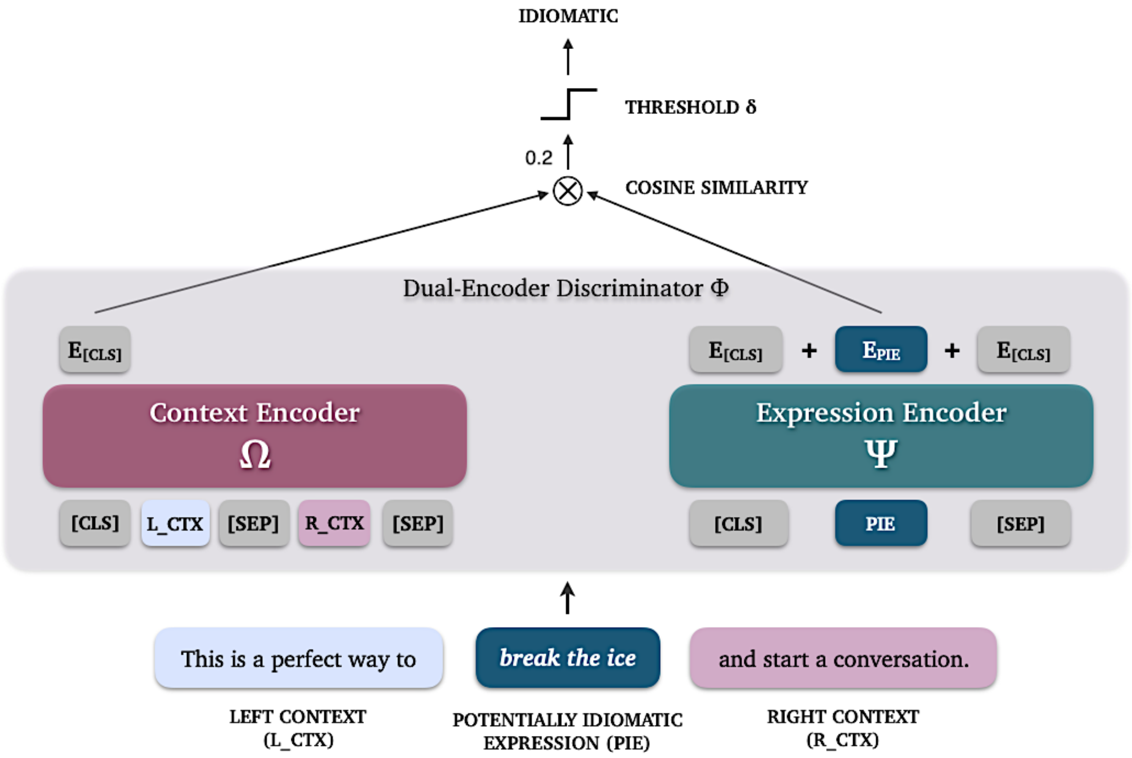

Figure 1: Graphical representation of the dual-encoder architecture given as input an example sentence. “E" stands for Embedding. A potentially idiomatic expression e is labeled as idiomatic when the cosine similarity score between the representations $\Omega(c)$ and $\Psi(e)$, where c is the surrounding context, is lower than the threshold δ.

in c. δ is a manually-tuned threshold. Both encoders are `bert-base-multilingual-cased` architectures that take as input the tokenized versions of expressions and their contexts, respectively, surrounded by the special tokens [CLS] and [SEP]. To encode an expression, we take the sum of the individual representations of all its subwords. Instead, for the representation of the context we take the representation of the [CLS] token. We evaluate the quality of our dual encoder in Section 4.3.

Additionally, to further improve the quality of the annotations produced, we follow the recent findings of Tedeschi and Navigli (2022) which demonstrated how NER can be exploited to better discriminate between idiomatic and literal usages of potentially idiomatic expressions.

3.2 Gold-Standard Data Creation

To evaluate the performance of our idiom identification system, we manually create a novel evaluation benchmark in 4 languages, i.e. English, German, Italian and Spanish. As explained in Section 3.1, we start by producing a set of sentences containing PIEs. Then, to properly label the expressions, depending on the context in which they occur, we ask professional annotators[7] to perform the following binary classification task: given a context-expression pair $\langle e, c\rangle$, the goal is to tag this pair with a label $y \in \{Idiomatic, Literal\}$. In order to make our gold standard more challenging, and better evaluate the system performance, we also ask annotators to include unseen idioms, i.e. idioms that do not appear in the training set.

3.3 Idiom Identification

Task Formulation Current and past approaches to idiom identification typically take expressions-context pairs $\langle e, c\rangle$ as input and limit themselves to determining whether e is used with a figurative meaning or not in c (Madabushi et al., 2021; Muzny and Zettlemoyer, 2013). However, this formulation has a major drawback: potentially idiomatic expressions need to be pre-identified. Importantly, we drop this requirement and reformulate the task as a sequence-labeling task, by employing the well-known BIO tagging scheme[8].

---

[7] We hired a mother-tongue professional annotator for each language.

[8] The BIO tagging scheme (short for Beginning, Intermediate, Out) is a popular tagging scheme where the B label indicates that the corresponding token is the first token of a

Table 1: Statistics concerning the automatically-created (Silver Data) training sets and our manually-curated test sets (Gold Data). "# Seen" represents the number of expressions in the test set already encountered in the training set, whereas "# Unseen" is the number of expressions never encountered. In the count of individual idioms (# Idioms), morphological variations of a certain idiom are mapped to the same idiom.

More formally, given as input a raw text sequence X of n tokens $x_1, \ldots, x_n$, each x_i must be labeled by the system with a tag $y_i \in \{B, I, O\}$ for each $i \in [1, n]$. This formulation also allows us to easily handle multiple idiomatic expressions within the same text.

In order to use our new formulation, we convert all the datasets constructed in Section 3.1 and Section 3.2 in BIO format. Table 2 shows an example of instance labeled using the BIO tagging scheme.

Our System Our model for idiom identification is inspired by the BERT-based neural architecture of Mueller et al. (2020) used for Named Entity Recognition, however, rather than encoding a word with the first contextualized subword representation as indicated by Devlin et al. (2019), we take the mean of its subwords, as suggested by recent literature (Ács et al., 2021). Then, the resulting vectors are passed through a multi-layer sentence-level BiLSTM network, whose logits are finally fed into a CRF model, trained to maximize the log-likelihood of the span-based gold label sequences (Huang et al., 2015).

4 Experiments

In this Section, we describe our experimental setup (Section 4.1), the datasets we use to train and evaluate our idiom identification system (Section 4.2), and the results obtained (Section 4.3).

bullet	I-IDIOM
.	O

Table 2: Example of instance labeled according to the BIO tagging scheme.

4.1 Experimental Setup

We implement our idiom identification system (Section 3.3) and our dual-encoder discriminator (Section 3.1) with PyTorch (Paszke et al., 2019), using the Transformers library (Wolf et al., 2019) to load the weights of `BERT-base-multilingual-cased` (mBERT). We fine-tune our idiom identification system for 30 epochs with a Cross-Entropy loss criterion, adopting an early stopping strategy with a patience value of 5, Adam (Kingma and Ba, 2015) optimizer and a learning rate of 10^{-5}, as standard when fine-tuning the weights of a pretrained language model. For our dual-encoder discriminator, instead, we use mBERT as feature extractor since no training data for the task were available.

---

span, in this case an idiomatic expression, the I label denotes an intermediate token of a span, and O means out of a span.

Italian	82.74
Spanish	82.55
Avg.	**82.85**

Table 4: Accuracy of the annotations produced by our automatic system compared to those provided by the human annotators on the 4 languages covered by our gold-standard test sets.

The entire model training is carried out on a NVIDIA GeForce RTX 3090. Each training (i.e. for each language) requires ∼8min/epoch on average, for a mean of ∼20 epochs. Table 3 shows the full list of hyperparameters.

4.2 Training, Validation and Test Data

The training and validation sets that we use in our experiments are those obtained by applying the methodology described in Section 3.1, with $\delta = 0.4$[9]. Although we automatically produce training data in 10 languages, we report results only on the 4 languages for which manually-curated test sets are available (see Section 3.2). However, since the training data has been created with the same procedure for each of the 10 languages, similar results are expected on non-tested languages. Statistics are provided in Table 1.

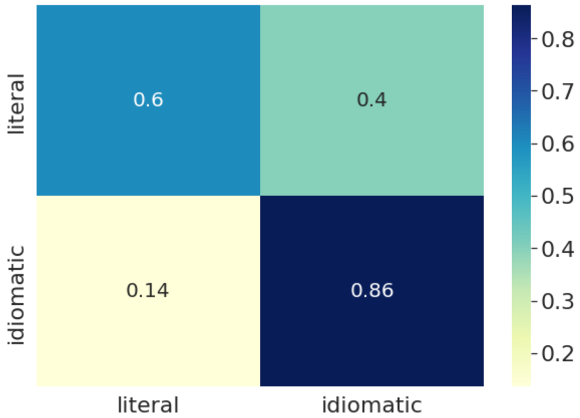

Figure 2: Confusion matrix of the predictions of our automatic system (X-axis) compared to the corresponding ground truth values (Y-axis). Results are averaged over the 4 languages covered by the test sets.

4.3 Results

In what follows, we measure both the quality of our automatic annotation methodology (Section 3.1) and of our idiom identification system (Section 3.3) by means of accuracy and token-level macro F_1-score metrics, respectively. In the latter case, we rely on the macro-F_1 metric due to the high class imbalance in the datasets, i.e. the number of O tags is much higher than the sum of the number of B and I tags, see Table 1.

Silver-Data Quality Evaluation We first aim at providing an empirical evaluation of the effectiveness of the proposed automatic strategy for producing idiom-related[10] sentences. To do so, for each language, we apply our dual-encoder discriminator $\Phi(e, c)$ to the expression-context pairs $\langle e, c\rangle$ available in our manually-curated test set, and we measure the accuracy score by comparing the predictions produced by the system with the human annotations in the gold-standard test sets. The accuracy results obtained are reported in Table 4.

With this being a binary-classification task, we can observe that the performance achieved by our dual encoder is much higher than the 50% baseline of a random classifier, hence implying that the system is able to distinguish between idiomatic and literal usages of PIEs based on the surrounding contexts.

However, the accuracy is not sufficient for us to determine the strengths and the weaknesses of our system. Therefore, we group both the predic-

---

[9] We use the English validation set to manually search for the best value of δ by choosing from the following set of possible values: $\delta = \{0.2, 0.25, 0.3, 0.35, 0.4, 0.45, 0.5, 0.55, 0.6, 0.65, 0.7\}$

[10] With the term “idiom-related sentences" we refer to sentences containing potentially idiomatic expressions.

	No	58.3	+ 6.1

Table 7: Comparison of the results obtained by training the system on the silver-standard data validated by our dual encoder (Yes) and non validated ones (No).

tions and the labels coming from the 4 languages, and construct a confusion matrix in order to better analyze the system behavior. From the confusion matrix in Figure 2, we can observe that the system is able to (almost always) identify idiomatic expressions as such, mainly thanks to their semantic distance from the meaning of the surrounding words. On the other hand, when dealing with literal expressions, the system again correctly predicts the majority of these, but it makes more errors. We attribute this to the fact that the context is often not sufficiently rich to find a strong similarity (i.e. higher than the threshold δ) with the meaning of the individual constituents of the idiomatic expression, and hence to label the expression as literal. Indeed, the lower the value of δ, the higher the number of literal expressions discovered, but the system inevitably classifies more idiomatic expressions as literal.

Multilingual Idiomatic Expression Identification In the previous paragraph we evaluated the performance of our dual-encoder architecture on the binary *literal or idiomatic* classification task, where the PIE was pre-identified. In this paragraph, instead, we use the refined silver-data produced by the aforementioned dual encoder, and measure the identification capabilities of our idiom identification system on the sequence-labeling task we introduced (Section 3.3) by comparing the BIO tags produced with the corresponding gold labels. The results obtained are reported in Table 5 (further results are provided in Appendix A).

The first thing that catches the eye is that the performances on the O tags are much higher than those on the B and I tags, on all tested languages. However, this is not surprising, owing to the fact that there is a high class imbalance. An interesting result, instead, is that the system achieves an average score of about 76 F1 points, while the percentage of seen entities[11] is only 48.7% on average. This implies that the system is able to generalize, and consequently also to correctly predict unseen idioms. This phenomenon is particularly evident on English and Spanish, where the percentage of seen idioms is very low.

To better highlight the capability of the system to go beyond idioms already seen during training, we also analyze the system performance on the "seen" and "unseen" subsets independently, and report the results in Table 6. As we can observe, the

---

[11] Seen entities are entities in the test set which have already been encountered in the training set.

	Type	Prediction
DE	Correct ✔	Ich bin nur der Typ, der ***ihr die Stange hält***.
	Correct ✔	Wir haben dieses Geschäft ***von Grund auf*** aufgebaut.
	Wrong ✘	***Durch den Wind*** wurden 27 Häuser in der Region zerstört.
	Wrong ✘	Sei nicht so'ne beleidigte Leberwurst!
EN	Correct ✔	The old horse finally ***kicked the bucket***.
	Correct ✔	Written tests are his ***Achilles' heel***...
	Wrong ✘	Her aunt is a great cook, do you want a ***piece of cake***?
	Wrong ✘	It is difficult, but possible to quit smoking cold turkey.

	Wrong ✘	¿Has visto alguna vez a tu gato ***meter la pata*** en su bebedero?
	Wrong ✘	El agente tiene vista de lince.

Table 8: Examples of idioms correctly and wrongly identified by our idiom identification system. Underline represents the target idiomatic expression (if any), while bold + italic represents the predicted idiomatic expression.

system is able to correctly predict the majority of unseen idioms on all tested languages, achieving an F1 score of 59.6 points, on average. Moreover, on seen idioms, the system behaves almost perfectly reaching an average score of 91.5 points. We underline that morphological variations of idioms encountered in the training sets are considered as seen idioms. Table 1 provides dimensions of the "seen" and "unseen" subsets, for each language.

Then, to further demonstrate the effectiveness of our dual-encoder architecture (Section 3.1), we compare the results obtained by training the system on the data produced with and without the validation performed by our dual encoder. The results reported in Table 7 highlight an average gap of 4.3 F1-score points between the refined version of the data and the original one, showing how the validation step is fundamental for improving the quality of the annotations, consequently leading the system to a better understanding of idioms.

Finally, the high results in Table 5 also prove that, thanks to our renewed task formulation (Section 3.3), common sequence-labeling architectures (e.g. those used for NER) can be successfully imported into the idiom identification task, thus enabling knowledge transfer from other research areas.

5 Qualitative Analysis

Together with the quantitative evaluation provided in Section 4.3, we now perform a qualitative analysis of our system. More specifically, in Table 8, we provide 4 examples of system predictions (2 correct and 2 wrong) for each tested language. Although our system proves to be robust over literal PIEs (see Figure 2), its most common mistake consists in classifying a PIE used with its literal meaning as idiomatic. This is mainly due to the system bias towards the labels associated to such PIEs during training, e.g. if more than 90% of occurrences of a certain PIE are labeled as idiomatic in the training set, then the system will tend to classify as idiomatic any other of its occurrences in the test set. This result suggests that improvements over the distribution of labels of PIEs are possible. In Table 8 we provide an example of one such wrongly labeled PIE for each language. Another commonly observed error, again highlighted in Table 8, is that in which unseen idiomatic expressions are not identified by the system. However, as previously demonstrated in Table 6, the system is nevertheless able to correctly handle the majority of such cases.

On the other hand, we observe that the system is able to correctly identify both lemmatized and inflected forms of idiomatic expressions, for both seen and unseen ones.

6 Conclusions and Future work

In this work, we introduced ID10M, an innovative framework for idiom identification consisting of i) a new multilingual Transformer-based architecture, ii) a novel automatic annotation pipeline for creating high-quality silver-data in 10 languages, and iii) a challenging manually-curated benchmark in 4 languages. Moreover, while the majority of current approaches to idiom identification need pre-identified potentially idiomatic expressions, we, instead, dropped this requirement and proposed a new formulation for the idiom identification task that lets systems be directly applicable to raw texts. Finally, our experiments showed that our system is able to generalize beyond idioms seen during training, hence achieving up to 85.4 macro F1-score on the idiom identification task.

As future work, we plan to scale our system to a greater number of languages and textual sources, but, most importantly, investigate the benefits derived from our work in key tasks such as Word Sense Disambiguation, Machine Translation and Question Answering.

robust architecture for the idiom identification task, we compared various sequence tagging architectures. Specifically, we evaluated the performance of several alternative systems: Bidirectional LSTM (Bi-LSTM), Bi-LSTM + CRF, Multilingual BERT (mBERT), mBERT + Bi-LSTM, mBERT + Bi-LSTM + CRF, XLM-RoBERTa (XLM-R, Conneau et al., 2020), XLM-R + Bi-LSTM, XLM-R + Bi-LSTM + CRF. Results are reported in Table 9. Surprisingly, mBERT achieved performance slightly higher than XLM-R. Moreover, the addition of Bi-LSTM and CRF modules provided further improvements.

Cross-Domain Classification of Moral Values

Abstract

Moral values influence how we interpret and act upon the information we receive. Identifying human moral values is essential for artificially intelligent agents to co-exist with humans. Recent progress in natural language processing allows the identification of moral values in textual discourse. However, domain-specific moral rhetoric poses challenges for transferring knowledge from one domain to another.

We provide the first extensive investigation on the effects of cross-domain classification of moral values from text. We compare a state-of-the-art deep learning model (BERT) in seven domains and four cross-domain settings. We show that a value classifier can generalize and transfer knowledge to novel domains, but it can introduce catastrophic forgetting. We also highlight the typical classification errors in cross-domain value classification and compare the model predictions to the annotators agreement. Our results provide insights to computer and social scientists that seek to identify moral rhetoric specific to a domain of discourse.

1 Introduction

Morality helps humans discern right from wrong. Pluralist moral philosophers argue that human morality can be represented, understood, and explained by a finite number of irreducible basic elements, referred to as *moral values* (Graham et al., 2013). The difference in our preferences over moral values explains how and why we think differently. For instance, both conservatives and liberals may agree that individual welfare is important. However, a conservative, who cherishes the values of freedom and independence, may believe that taxes should be decreased to attain more individual welfare. In contrast, a liberal, who cherishes the values of community and care, may believe that taxes should be increased to obtain welfare (Graham et al., 2009).

It is crucial to understand human morality to develop beneficial AI (Russell et al., 2015; Soares and Fallenstein, 2017). To operate among humans, artificial agents must be able to comprehend and recognize the moral values that drive the differences in human behavior (Akata et al., 2020; Gabriel, 2020). The ability to understand moral rhetoric can be instrumental for, e.g., facilitating human-agent trust (Chhogyal et al., 2019; Mehrotra et al., 2021) and engineering value-aligned socio-technical systems (Ajmeri et al., 2020; Murukannaiah et al., 2020; Serramia et al., 2021; Montes and Sierra, 2021).

There are survey instruments to estimate individual value profiles (Schwartz, 2012; Graham et al., 2013). However, reasoning about moral values is challenging for humans (Le Dantec et al., 2009; Pommeranz et al., 2012). Further, in practical applications, e.g., to conduct meaningful conversations (Tigunova et al., 2019) or to identify online trends (Mooijman et al., 2018), artificial agents should be able to understand moral rhetoric on the fly.

The growing capabilities of natural language processing (NLP) enable the estimation of moral rhetoric from textual discourse (Hoover et al., 2020; Araque et al., 2020; Alshomary et al., 2022; Kiesel et al., 2022). Specifically, a value classifier can be used to identify the moral values underlying a piece of text on the fly. For instance, Mooijman et al. (2018) show that detecting moral values from tweets can predict violent protests.

Existing value classifiers are evaluated on a specific dataset, without re-training or testing the classifier on a different dataset. This shows the ability of the classifier to predict values from text, but not the ability to transfer the learned knowledge across datasets. A critical aspect of moral values is that they are intrinsically linked to the domain under discussion (Pommeranz et al., 2012; Liscio et al., 2021, 2022). Moral value expressions may take different forms in different domains. For example, in the driving domain, the value of safety concerns

Findings of the Association for Computational Linguistics: NAACL 2022, pages 2727 - 2745
July 10-15, 2022

speed limits and seat belts, but in the COVID-19 domain, safety concerns social distancing and face masks. Further, a word (broadly, language) may trigger different moral rhetoric in different domains. For example, in a libertarian blog, the word ‘taxes’ may be linked to the authority value, but in a socialist blog it may be linked to the community value. Thus, it is crucial for a value classifier to recognize domain-specific connotations of moral rhetoric.

Collecting and annotating a sufficient amount of training examples in each domain is expensive and time consuming. To reduce the need for new annotated examples, we can pretrain classifiers with similar available annotated data and transfer the acquired knowledge to a novel task—a practice known as *transfer learning* (Ruder, 2019). Despite the benefits, transfer learning poses well-known challenges, including: (1) *generalizability*: how well does a classifier perform on novel data? (2) *transferability*: how well is knowledge transferred from one domain to another? and (3) *catastrophic forgetting*: to what extent is knowledge of a previous domain lost after training in a new domain? These challenges are crucial for value classification because of its domain-specific nature.

We perform the first comprehensive cross-domain evaluation of a value classifier. We employ the Moral Foundation Twitter Corpus (Hoover et al., 2020), consisting of seven datasets spanning different socio-political areas, annotated with the value taxonomy of the Moral Foundation Theory (Graham et al., 2013). Treating each dataset as a domain, we train a deep learning model, BERT (Devlin et al., 2019), in four training settings to evaluate the value classifier’s generalizability, transferability, and catastrophic forgetting.

Our experiments show that (1) a value classifier can generalize to novel domains, especially when trained on a variety of domains; (2) initializing a classifier with examples from different domains improves performance in novel domains even when little training data is available in the novel domains; (3) catastrophic forgetting occurs even when training on a small portion of data from the novel domain, and its impact must be considered when training on a novel domain; and (4) in the large majority of cases, in all considered training settings, at least one annotator agrees with the model predictions.

Our investigation is significant because moral rhetoric is seldom explicit in language, but often lies in subtle domain-dependent cues. Understanding whether a classifier can recognize and transfer such hidden patterns across domains is instrumental for the practical use. By unveiling the successes and mistakes of value classifiers in cross-domain settings, we hope to inspire researchers and practitioners to employ value classification responsibly.

2 Background and Data

We introduce the Moral Foundation Theory (MFT) (Graham et al., 2013) and the Moral Foundation Twitter Corpus (MFTC) (Hoover et al., 2020) used in our experiments.

The MFT is a well-established theory of moral values developed by social and cultural psychologists. It argues that human morality is composed of a finite set of innate moral foundations, similar to how the five taste receptors (for sweet, sour, salt, bitter, and umami) combine to yield the tastes we experience. The MFT includes five foundations, each composed of a vice–virtue duality, resulting in the 10 moral values shown in Table 1.

Table 1: The five moral foundations in the MFT

Foundation	**Definition**
Care/ Harm	Support for care for others/ Refrain from harming others
Fairness/ Cheating	Support for fairness and equality/ Refrain from cheating or exploiting others
Loyalty/ Betrayal	Support for prioritizing one’s inner circle/ Refrain from betraying the inner circle
Authority/ Subversion	Support for respecting authority and tradition/ Refrain from subverting authority or tradition
Purity/ Degradation	Support for the purity of sacred entities/ Refrain from corrupting such entities

The MFTC is composed of 35,108 tweets, divided into seven datasets, each corresponding to a topic: All Lives Matter (**ALM**), Baltimore protests (**BLT**), Black Lives Matter (**BLM**), hate speech and offensive language (**DAV**) (Davidson et al., 2017), 2016 presidential election (**ELE**), MeToo movement (**MT**), and hurricane Sandy (**SND**). These datasets from complex and diverse socio-political issues allow us to evaluate the transferability by treating each dataset as belonging to a domain.

The tweets were annotated by multiple annotators with the MFT taxonomy. Hoover et al. (2020) provide additional details on the annotation process. They recognize that the vice and the virtue constituting one moral foundation are expressed differently in natural language. For example, an utterance describing a care concern (e.g., taking care of one's offspring) does not necessarily also contain harm expressions. For this reason, each tweet was annotated with all 10 individual moral values plus an additional *nonmoral* label, resulting in 11 possible labels per tweet. Due to the subjective nature of moral values, different annotators may label the same tweet differently. For this reason, Hoover et al. (2020) apply a majority vote to select the definitive label(s) of each tweet. Tweets with no majority label are labeled as nonmoral. Table 2 shows three examples of annotated tweets.

Table 2: Examples of labeled tweets in MFTC

Tweet	**Dataset**	**Labels**
Police lives matter, all lives matter, peace and love people	ALM	care
Which oppression is worse, sexism or racism?	BLM	harm, cheating
Baltimore Police will deliver an update on the #FreddieGray investigation. Listen live on WBAL	BLT	nonmoral

Table 3 shows the distribution of labels. The MeanIR is a measure of imbalance in a dataset (Charte et al., 2015). MeanIR is the mean of IR_l for each label l, where IR_l is the ratio of the number of instances having the majority (i.e., nonmoral) label and the number of instances having label l. The degree of imbalance varies largely across datasets, which is realistic since different domains are likely to have different distributions of moral content.

Table 3: Distribution of labels per dataset of the MFTC

3 Experimental Setup

Predicting moral values is a multi-label classification problem. Given a set of textual documents, $\mathcal{T}$, and a set of moral value labels, $\mathcal{L} = (l_1, l_2, \ldots, l_n)$, we wish to learn a mapping $\mathcal{C} : \mathcal{T} \mapsto \mathcal{P}(\mathcal{L})$. Each element in $\mathcal{P}(\mathcal{L})$ is a binary vector, $y = (y_1, y_2, \ldots, y_n)$, where $y_i = 1$ if the corresponding text is labeled with l_i. The mapping $\mathcal{C}$ is learned via BERT (Devlin et al., 2019), a language representation model based on the Transformer architecture (Vaswani et al., 2017). We choose BERT as it represents the state-of-the-art for several NLP tasks, including value classification (Kobbe et al., 2020; Alshomary et al., 2022; Kiesel et al., 2022). We provide additional details, including hyperparameters, in the Appendix. The code is available on GitHub[1].

3.1 Cross-Domain Evaluation

To perform cross-domain evaluation, we partition the MFTC datasets into $\mathcal{T}_{source}$ and $\mathcal{T}_{target}$. We treat $\mathcal{T}_{source}$ as available data and $\mathcal{T}_{target}$ as an incoming dataset from a novel domain. In our experiments, $\mathcal{T}_{target}$ is always composed of one MFTC dataset. We experiment with $\mathcal{T}_{source}$ composed of one, three, and six datasets. We present the results for the setting with six datasets as $\mathcal{T}_{source}$ in Section 4 and the other settings in the Appendix.

For each partition, we train a value classifier, $\mathcal{C}$, in each of the four scenarios shown in Figure 1. These scenarios differ in how the classifier is trained. (1) In the $source$ scenario, $\mathcal{T}_{source}$ is the training set. (2) In the $target$ scenario, $\mathcal{T}_{target}$ is the training set. (3) In the $finetune$ scenario, the classifier is first trained on $\mathcal{T}_{source}$ and then continued to train (i.e., finetuned) on $\mathcal{T}_{target}$. (4) In the all scenario, the training set includes both $\mathcal{T}_{source}$ and $\mathcal{T}_{target}$.

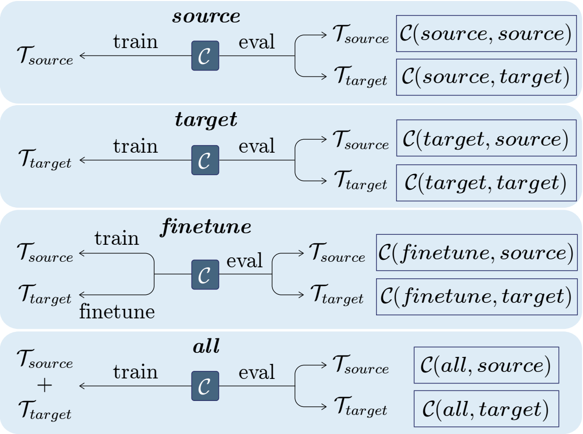

Figure 1: The cross-domain evaluation setting

---

[1] `https://github.com/adondera/transferability-of-values`

In each scenario, the classifier is evaluated on both $\mathcal{T}_{source}$ and $\mathcal{T}_{target}$, resulting in eight settings (combinations of training scenario and evaluation set) as shown in Figure 1. For example, $\mathcal{C}(source, target)$ indicates that $\mathcal{C}$ is trained in the $source$ scenario (i.e., on $\mathcal{T}_{source}$) and evaluated on $\mathcal{T}_{target}$.

As we have seven partitions and four scenarios, we train 28 unique models. We evaluate the models on both $\mathcal{T}_{source}$ and $\mathcal{T}_{target}$, covering 56 settings.

3.2 Comparisons

Our experimental setting (partitioning, training scenarios, and evaluation settings) enables a comprehensive cross-domain evaluation of the value classifiers as described below.

Baseline $\mathcal{C}(source, source)$ and $\mathcal{C}(target, target)$ show the performances of a value classifier on the training domain, when no cross-domain training is performed.

Topline $\mathcal{C}(all, source)$ and $\mathcal{C}(all, target)$ represent the ideal scenario, where all data is simultaneously available for training.

Generalizability $\mathcal{C}(source, target)$ and $\mathcal{C}(target, source)$ reflect the ability of a value classifier to generalize to a new domain.

Transferability Comparing $\mathcal{C}(finetune, target)$ and $\mathcal{C}(target, target)$ shows whether the knowledge learned by pretraining on $\mathcal{T}_{source}$ ($finetune$ scenario) has an advantage over the absence of pretraining ($target$ scenario).

Catastrophic Forgetting Comparing $\mathcal{C}(finetune, source)$ and $\mathcal{C}(source, source)$ shows the extent to which the knowledge learned by training on $\mathcal{T}_{source}$ is lost when finetuned on $\mathcal{T}_{target}$.

3.3 Metrics

Since the imbalance in our datasets varies greatly, we report both the micro F_1-score and the macro F_1-score in each setting. The micro F_1-score, m, is the weighted (by class size) mean of the per-label F_1-scores. The macro F_1-score, M, is the unweighted mean of the per-label F_1-scores.

When training and testing on the same set, we use 10-fold cross-validation with fixed splits into training and test data, and report the average F_1-scores over the 10 runs. For consistency, when testing on a set different from the training set, we test on 10 splits of the set (i.e., ultimately on the whole set) and report average F_1-scores.

4 Results and Discussion

We evaluate the performance of the model in four training scenarios ($source$, $target$, $finetune$, all). Table 4 reports the micro and macro F_1-scores of the eight evaluation settings. The columns indicate the dataset used as $\mathcal{T}_{target}$ (e.g., in the BLT column, BLT is $\mathcal{T}_{target}$ and the remaining six datasets compose $\mathcal{T}_{source}$). The final column reports the average F_1-scores over the seven datasets. We also report the results of the majority classifier which labels all tweets as nonmoral (the majority class in all datasets), for both $\mathcal{T}_{source}$ and $\mathcal{T}_{target}$.

We perform Wilcoxon's ranksum test (Hollander and Wolfe, 1999) to evaluate whether two results significantly differ or not. In each column (and in the top-half or the bottom-half), we choose the setting with the highest F_1-score and perform a pair-wise comparison with each of the other settings in that (half) column. We highlight, in bold, the best result and the results that are not significantly different ($p > 0.05$) from the best.

4.1 General Trends

Before cross-domain analysis, we observe some general trends. First, the topline training scenario (all) leads to the best results when evaluating on both $\mathcal{T}_{source}$ and $\mathcal{T}_{target}$ (Table 4). However, all is the ideal scenario. In the top half of the table, $\mathcal{C}(source, source)$ has comparable results to $\mathcal{C}(all, source)$, which is to be expected, since the two models are trained on similar data (six out of seven datasets in the $source$ scenario, all seven in the all scenario). Analogously, in the bottom half of the table, the $\mathcal{C}(finetune, target)$ setting leads to results comparable to $\mathcal{C}(all, target)$. We analyze this result further in Section 4.3.

Second, the results are rather consistent across datasets when evaluating on $\mathcal{T}_{source}$ (top half of Table 4), but have large differences when evaluating on $\mathcal{T}_{target}$ (bottom half of Table 4). These differences can be attributed to BLT and DAV, two highly-imbalanced datasets (Table 3). The class imbalance also justifies the large difference between micro and macro F_1-scores for these two datasets.

4.2 Generalizability

To evaluate generalizability, we analyze the results for the $\mathcal{C}(source, target)$ and $\mathcal{C}(target, source)$ settings. In $\mathcal{C}(source, target)$, $\mathcal{T}_{source}$ includes six datasets and $\mathcal{T}_{target}$ includes one dataset. In contrast, in $\mathcal{C}(target, source)$, $\mathcal{T}_{source}$ includes

Table 4: Results of the four training scenarios evaluated on $\mathcal{T}_{source}$ and $\mathcal{T}_{target}$. The columns indicate the dataset used as $\mathcal{T}_{target}$. We report both micro F_1-score (m, left column) and macro F_1-score (M, right column).

Majority ($target$)	37.9	5.1	64.8	7.4	28.3	4.2	**92.2**	8.7	44.5	5.7	27.9	4.4	26.4	4.0	46.0	5.6

one dataset and $\mathcal{T}_{target}$ includes six datasets. Thus, $\mathcal{C}(target, source)$ is a more challenging setting for generalization than $\mathcal{C}(source, target)$.

First, we observe that the model achieves better average F_1-scores in the $\mathcal{C}(source, target)$ setting than the majority ($target$) baseline. This indicates that the moral rhetoric learned on a varied array of domains is generalizable to a novel domain to some extent, in spite of the domain-specific nature of moral values. However, the performances in $\mathcal{C}(source, target)$ are not on par with the best results on $\mathcal{T}_{target}$, as we discuss in Section 4.3.

Second, we observe that the model achieves better average F_1-scores in the $\mathcal{C}(target, source)$ setting than the majority ($source$) baseline, despite the more challenging setting. However, the results are just marginally better than the majority ($source$) baseline, showing the difficulty in generalizing from one to multiple domains.

Finally, in both cases, when we look at the results for individual datasets, the generalizability result does not hold for BLT and DAV, which highlights the challenge of generalizing to domains with a skewed distribution of moral values.

4.3 Transferability

Recall that, in the $target$ scenario, a model is only trained on $\mathcal{T}_{target}$, but in the $finetune$ scenario, the model is first trained on $\mathcal{T}_{source}$ and then finetuned on $\mathcal{T}_{target}$. Thus, to evaluate transferability, we compare the $\mathcal{C}(finetune, target)$ and $\mathcal{C}(target, target)$ settings.

From the average F_1-scores in Table 4, we observe that $\mathcal{C}(finetune, target)$ performs better than or on par with $\mathcal{C}(target, target)$—precisely, similar m and 8% increase of M. Thus, the benefits of finetuning are larger for the macro than the micro F_1-scores. This suggests that pretraining on $\mathcal{T}_{source}$, which contains a more varied distribution of labels than $\mathcal{T}_{target}$, improves the prediction of the minority labels in $\mathcal{T}_{target}$.

To transfer knowledge from $\mathcal{T}_{source}$ to $\mathcal{T}_{target}$, typically, we need some labeled data in $\mathcal{T}_{target}$. For the results in Table 4, we used 90% of $\mathcal{T}_{target}$ for training, and the leftover 10% for evaluating at each fold. However, in practice, such a large amount of training data may not be available in the target domain. Thus, we perform an additional experiment to compare $\mathcal{C}(target, target)$ and $\mathcal{C}(finetune, target)$, when trained or finetuned, respectively, on a smaller portion of $\mathcal{T}_{target}$ (10%, 25%, and 50%) and tested on a fixed, randomly selected, 10% of $\mathcal{T}_{target}$. Figure 2 shows this comparison. We report the average results of 10-fold cross-validations performed on each of the seven datasets.

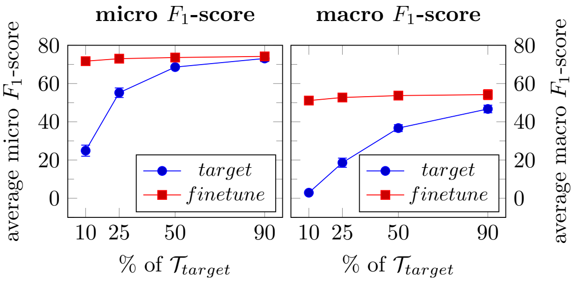

Figure 2: $\mathcal{C}(target, target)$ and $\mathcal{C}(finetune, target)$ results trained with increasing portions of $\mathcal{T}_{target}$

We make an important observation from Figure 2. The finetuning paradigm does not require a large portion of $\mathcal{T}_{target}$ to perform well in the target domain. In contrast, the performance of $\mathcal{C}(target, target)$ increases (but does not surpass

$\mathcal{C}(finetune, target)$) as training data from $\mathcal{T}_{target}$ increases. Indeed, $\mathcal{C}(finetune, target)$ with 10% of $\mathcal{T}_{target}$ performs on par with $\mathcal{C}(target, target)$ trained on 90% of $\mathcal{T}_{target}$. This result shows that transferring the knowledge of values from source domains to a target domain is valuable especially when the target domain has little training data.

4.4 Catastrophic Forgetting

Recall that, in the *source* scenario, a model is only trained on $\mathcal{T}_{source}$, but in the *finetune* scenario, the model is first trained on $\mathcal{T}_{source}$ and then finetuned on $\mathcal{T}_{target}$. Thus, comparing $\mathcal{C}(finetune, source)$ and $\mathcal{C}(source, source)$ provides insight on the extent to which a model forgot about $\mathcal{T}_{source}$ because of finetuning on $\mathcal{T}_{target}$.

We observe that the model suffers from catastrophic forgetting since finetuning on $\mathcal{T}_{target}$ reduces the performance on $\mathcal{T}_{source}$. The forgetting is most evident when finetuning on unbalanced datasets such as DAV than balanced datasets such as BLM. In fact, $\mathcal{C}(finetune, source)$ leads to only slightly worse results than $\mathcal{C}(source, source)$ in BLM (decrease of 2% in m and 7% in M), with the difference being largest in DAV (decrease of 15% in m and 25% in M).

Figure 2 shows that the finetuning paradigm ensures good performances on $\mathcal{T}_{target}$ even when the model is trained on a small portion of $\mathcal{T}_{target}$. Next, we evaluate catastrophic forgetting in the same setting, comparing $\mathcal{C}(source, source)$ and $\mathcal{C}(finetune, source)$ when the model is trained with increasing portions of $\mathcal{T}_{target}$ (10%, 25%, and 50%) as shown in Figure 3.

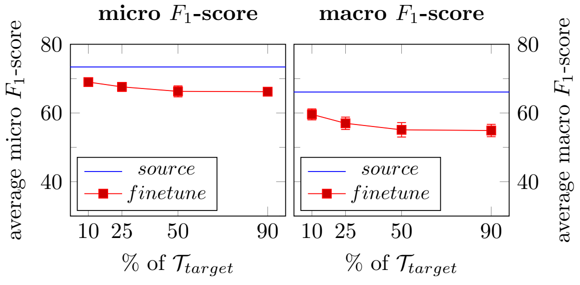

Figure 3: $\mathcal{C}(source, source)$ and $\mathcal{C}(finetune, source)$ results trained with increasing portions of $\mathcal{T}_{target}$

Figure 3 indicates that catastrophic forgetting worsens as the model is trained with a larger portion of $\mathcal{T}_{target}$. $\mathcal{C}(finetune, source)$ trained with 10% of $\mathcal{T}_{target}$ leads to a decrease of 4% in m and 7% in M compared to $\mathcal{C}(source, source)$ (evident by comparing the *source* flat blue line to the first red *finetune* square in Figure 3). Further, $\mathcal{C}(finetune, target)$ trained with 10% of $\mathcal{T}_{target}$ leads to an increase of 7% in m and 6% in M compared to $\mathcal{C}(source, target)$ (evident by comparing the average $\mathcal{C}(source, target)$ in Table 4 to the first red *finetune* square in Figure 2). These results show the tradeoff between the advantage of transfer learning and the impact of forgetting, even when finetuning with a small portion of $\mathcal{T}_{target}$.

4.5 Misclassification Errors

We reported F_1-scores to provide an overview of the model performance in different training settings. Next, we investigate the behavior of the model through the lens of the MFT. We inspect (1) the confusion between morally loaded and nonmoral tweets, and, (2) the mistakes among and within moral foundations since moral foundations are differentially manifested in language (Kennedy et al., 2021). We highlight the following four types of misclassification errors (which add up to 100%):

Error I A tweet labeled with one (or more) values is classified (by the model) as nonmoral.

Error II A tweet labeled as nonmoral is classified with one (or more) values.

Error III A tweet labeled with a value is classified with values from other foundations.

Error IV A tweet labeled as a vice/virtue is classified as the opposite virtue/vice of the foundation.

Table 5 shows the distribution of errors, averaged over the seven datasets.

Table 5: Distribution of errors per setting (in percentage)

Setting	Err. I	Err. II	Err. III	Err. IV
$\mathcal{C}(source, source)$	25.8	34.3	36.3	3.5
$\mathcal{C}(target, source)$	41.8	24.4	32.0	1.8
$\mathcal{C}(finetune, source)$	38.7	27.5	31.3	2.5
$\mathcal{C}(all, source)$	25.9	34.3	36.3	3.4
$\mathcal{C}(source, target)$	34.7	32.3	30.2	2.8
$\mathcal{C}(target, target)$	31.5	27.6	38.5	2.4
$\mathcal{C}(finetune, target)$	36.0	28.6	32.6	2.8
$\mathcal{C}(all, target)$	30.8	33.0	33.1	3.1

Generalizability In $\mathcal{C}(target, source)$, Error I occurs largely more often than the other errors, indicating that, when generalizing from one to several domains, labeling value-laden tweets as nonmoral is the most common mistake. In contrast, in $\mathcal{C}(source, target)$, when generalizing from several to one domain, Error I is less prominent, indicating that the model attempts to classify moral rhetoric in the novel domain.

Transferability Error III is more prevalent in $\mathcal{C}(target, target)$ than $\mathcal{C}(finetune, target)$. Thus, the confusion among moral values reduces when a model is pretrained on the source domain.

Catastrophic Forgetting Error I occurs largely more often in $\mathcal{C}(finetune, source)$ than $\mathcal{C}(source, source)$, indicating that the major type of catastrophic forgetting is missing moral rhetoric in the source dataset.

Finally, Error IV occurs seldom, suggesting that the models generally learn to not confuse between virtues and vices of the same moral foundation.

4.6 Annotators Agreement

We analyze the correspondence between the model predictions and the annotators agreement. Each tweet in the MFTC was annotated by at least three and at most eight different annotators (Hoover et al., 2020, Table 1). More than 99% of the tweets were annotated by three to five annotators and 84% by three or four annotators. As described in Section 2, the majority agreement was selected for training and evaluation—that is, only values annotated by at least 50% of the annotators were retained as correct labels. However, given the subjectivity in value annotation, values labeled by a minority of annotators ought to be considered too.

Tables 6 and 7 show the percentage of annotators that agree with the model predictions considered as errors and accurate, respectively, averaged over the seven datasets. The columns indicate the percentage of annotators agreeing with the model prediction. For instance, if one out of the four workers who annotated a tweet agrees with the model prediction, we record a 25% agreement.

Table 6: Distribution (in percentage) of classification errors and annotators agreement percentage

Setting	$\mathbf{0}$	$\mathbf{(0, 25]}$	$\mathbf{(25, 34]}$	$\mathbf{(34, 50)}$
$\mathcal{C}(source, source)$	26.1	22.3	45.0	6.6
$\mathcal{C}(target, source)$	49.5	18.0	28.5	3.9
$\mathcal{C}(finetune, source)$	38.5	20.2	36.1	5.2
$\mathcal{C}(all, source)$	26.3	22.2	45.0	6.5
$\mathcal{C}(source, target)$	40.2	23.2	30.4	6.2
$\mathcal{C}(target, target)$	19.7	30.7	40.6	8.9
$\mathcal{C}(finetune, target)$	21.2	30.5	39.9	8.4
$\mathcal{C}(all, target)$	25.6	27.5	39.0	7.9

Table 7: Distribution (in percentage) of correct predictions and annotators agreement percentage

Setting	$\mathbf{[50, 66)}$	$\mathbf{[66, 75)}$	$\mathbf{[75, 100)}$	$\mathbf{100}$
$\mathcal{C}(source, source)$	16.9	24.4	20.9	37.7
$\mathcal{C}(target, source)$	16.8	20.0	20.2	43.1
$\mathcal{C}(finetune, source)$	17.0	22.7	20.9	39.4
$\mathcal{C}(all, source)$	17.0	24.5	20.9	37.7
$\mathcal{C}(source, target)$	15.0	27.5	18.5	39.0
$\mathcal{C}(target, target)$	15.0	27.7	18.8	38.5
$\mathcal{C}(finetune, target)$	15.8	28.5	18.7	37.0
$\mathcal{C}(all, target)$	15.7	28.4	18.8	37.2

First, we analyze the classification errors in Table 6. We observe that the sum of the last three columns is always larger than 50%. This indicates that, in all settings, more than half of the model classification errors are not severe in that at least one human annotator agrees with the model prediction. Then, we notice that the settings with the highest incidence of 'bad' classification errors (i.e., where no annotators agree with the model prediction) are those employed to evaluate generalizability ($\mathcal{C}(target, source)$ and $\mathcal{C}(source, target)$) and catastrophic forgetting ($\mathcal{C}(finetune, source)$). These results are explained by the harder challenge represented in these settings (refer to Sections 4.2 and 4.4 for a more in-depth discussion). Finally, we observe that there is a small percentage of errors with agreement between 34% and 50%. For the agreement to be in this range, a tweet must have been annotated by at least 5 annotators. However, 84% of the tweets in the MFTC have been annotated by four annotators or less, thus resulting in a smaller agreement in the last column.

Second, we analyze the correct predictions in Table 7. We notice, in all settings, a high correspondence between 100% agreement among annotators and correct model predictions—that is, tweets annotated with consistent agreement reliably lead to correct predictions. Further, we observe that the distributions of agreement and correct predictions are consistent across different settings.

5 Related Work

We review closely related works on value estimation from text, and on cross-domain classification in NLP subfields relevant to value classification.

5.1 Value Estimation from Text

Value estimation has been addressed from both unsupervised and supervised approaches. Unsupervised methods exploit value lexicons to identify values in text. Value lexicons are generated manually (Graham et al., 2009), via semi-automated methods (Wilson et al., 2018; Rezapour et al., 2019; Araque et al., 2020; Hopp et al., 2021), or expanded from an initial seed via NLP techniques (Ponizovskiy et al., 2020; Araque et al., 2021). Value lexicons are used to identify values in text through word count software (Pennebaker et al., 2001) or similarity in embedding space (Garten et al., 2018; Shen et al., 2019; Bahgat et al., 2020). However, adapting a lexicon to a novel domain is a significant additional effort as it requires identifying words that are relevant and removing words that are not relevant in the novel domain.

Supervised methods employ the classification paradigm (Lin et al., 2018; Mooijman et al., 2018; Hoover et al., 2020; Alshomary et al., 2022; Kiesel et al., 2022). A textual dataset is annotated with values belonging to a value taxonomy, and the labels are used to train a supervised model. This approach is akin to the one we use in this paper. However, in the reviewed literature, no emphasis is put on the effect of cross-domain training. Further, several of the works mentioned above (Lin et al., 2018; Mooijman et al., 2018; Hoover et al., 2020) use binary classification to independently predict the presence of a value in text. That is, given N values, N classifiers are employed (one per value). However, it has been shown that modeling relationships among values (and additional contextualizing information such as actors) helps improve downstream performances (Johnson and Goldwasser, 2018; Roy et al., 2021). Thus, we train a multi-label value classifier, similarly to Alshomary et al. (2022) and Kiesel et al. (2022). Furthermore, our objective is not to compare binary and multi-label value classification but to evaluate the cross-domain capabilities (generalizability, transferability, and catastrophic forgetting) of a multi-label value classifier.

5.2 Datasets with Moral Content

The recent success of NLP models has sparked a surge of research in constructs akin to moral values, e.g., moral norms, ethical judgments, and social biases. Researchers have collected large datasets annotated with the related implicit components of human language similar to the MFTC (Section 2). Forbes et al. (2020) introduced SOCIAL-CHEM-101, a corpus of almost 300,000 rules-of-thumb aimed at learning social and moral norms. Sap et al. (2020) collected the Social Bias Inference Corpus with the intent of modeling the way in which people project social biases onto each others. Hendrycks et al. (2021) proposed the ETHICS dataset to assess basic knowledge of ethics through well-studied theories of normative ethics (such as deontology and utilitarianism). Lourie et al. (2021) introduced SCRUPLES, a dataset composed of 625,000 ethical judgments over 32,000 real-life anecdotes. Finally, Emelin et al. (2021) presented *Moral Stories*, a crowd-sourced collection of contextualized narratives with the intent of investigating grounded, goal-oriented social reasoning.

These datasets offer an unprecedented opportunity for studying the social and moral aspects of language. In our research we employ the MFTC as the same moral value theory is used to annotate data in seven different domains, allowing for a direct cross-domain comparison.

5.3 Cross-Domain NLP Classification

Cross-domain classification is gaining attention (Aji et al., 2020; Nguyen et al., 2021; Rongali et al., 2021; Bornea et al., 2021; Markov and Daelemans, 2021). Ruder (2019) provides an overview of the basic terminology, including generalizability, transferability, and catastrophic forgetting.

Cross-domain classification has been investigated in NLP tasks such as sentiment analysis (Al-Moslmi et al., 2017; Qu et al., 2019; Du et al., 2020), fake news detection (Fung et al., 2021; Silva et al., 2021; Yuan et al., 2021), and argument mining (Al-Khatib et al., 2016; Daxenberger et al., 2017; Thorn Jakobsen et al., 2021). These tasks are similar to value classification in that they aim to classify high-level constructs (such as sentiments and arguments). However, value classification stands out for its multi-label and domain-specific nature. Also, cross-domain classification is particularly important for values because reasoning about values (Pommeranz et al., 2012) and generating value-annotated datasets is very difficult.

6 Conclusions and Directions

We perform a comprehensive cross-domain evaluation of a multi-label value classifier, by comparing a deep learning model (BERT) in seven domains with four cross-domain training scenarios. Our aim is to support practical applications of moral rhetoric classification, e.g., the detection of radicalism through the study of moral homogeneity (Atari et al., 2021), the prediction of violent protests (Mooijman et al., 2018), the identification of moral concerns of citizens (Mouter et al., 2021; Siebert et al., 2022), and the extraction of moral rhetoric supporting both stances and arguments (Draws et al., 2022; van der Meer et al., 2022). Our findings inform both computer scientists and social scientists on training value classifiers. However, we do not provide a fixed recipe since the right model and approach depend on the time, resources, and data available.

We show that a value classifier generally exhibits the ability to classify moral values across domains. However, the results are highly dependent on the distribution of moral rhetoric in a domain.

Our experiments support the following key findings. First, a value classifier can generalize to novel domains, especially when trained on multiple domains. However, its performance on the novel domain improves even when trained with a small portion of data from the novel domain. Second, pretraining a value classifier with data from different domains has three benefits when finetuning the classifier. It yields (1) better performances on the novel domain than other settings, (2) good performances even when little training data is available in the novel domain, and (3) smaller confusion among moral values, especially among those less frequent in the novel domain. Third, finetuning on a novel domain causes catastrophic forgetting of the domain it was pretrained with, even when finetuning on a small portion of data from the novel domain. Thus, the tradeoff between benefits of transferability and adverse effects of forgetting must be considered in choosing the extent of finetuning. Finally, despite the challenging nature of cross-domain value classification, the majority of classification errors are not severe in that, in all evaluation settings, at least one annotator agrees with the model prediction.

Our investigation opens avenues for additional experiments with advanced methods to improve transfer learning (Howard and Ruder, 2018; Jiang et al., 2020; Nguyen et al., 2021) and mitigate catastrophic forgetting (Kirkpatrick et al., 2017; Li and Hoiem, 2018; Thompson et al., 2019). Further, based on the analysis of classification errors, we suggest incorporating the annotators (dis-) agreement into the training of the model, e.g., by employing the full distributions of annotations, as opposed to the current majority approach (Uma et al., 2021).

7 Ethical Considerations

We discuss three ethical considerations relevant to our work. First, the MFTC is composed of monolingual tweets about US-centric topics. Whether or not our conclusions hold for results across different languages and cultures is yet to be evaluated. This limitation may cause the perpetuation of Western biases and values (Mehrabi et al., 2021). However, we believe that our experimental setup offers a systematic approach to studying such cultural influences when pertinent data is available.

Second, the MFTC has low annotator agreement (Hoover et al., 2020, Table 6), potentially caused by the subjectivity and complexity of annotating values. Selecting the majority label as golden label may perpetuate the 'tyranny' of the majority, which is especially dangerous when dealing with values. We expose the impact of the annotator agreement in Section 4.6 and identify an avenue for addressing it as a future direction in Section 6.

Finally, the importance of understanding moral values has been recognized by computer scientists (Russell et al., 2015) and designers (Friedman et al., 2008). However, we recognize that value classification can be misused, especially, when sensitive attributes such as gender and race are attached to the data. For instance, authorities could use it to automatically identify and suppress liberal minorities in non-liberal countries. Additional research is necessary for addressing such problems, e.g., by devising techniques that mitigate bias and unfairness by design (Kleinberg et al., 2018; Dinan et al., 2020; Vargas and Cotterell, 2020).

Acknowledgments

This research was (partially) funded by the Hybrid Intelligence Center, a 10-year programme funded by the Dutch Ministry of Education, Culture and Science through the Netherlands Organisation for Scientific Research. Furthermore, we thank Florentin Arsene for his contribution in previous iterations of the project.

A Experimental Details

As we train deep learning models, reproducibility is an issue due to the inherent randomness of the training procedure. Nevertheless, we seek to provide all possible tools for reproducing our experimental results. To do so, we attach our code and the complete set of results. Furthermore, the following sections describe our data preprocessing, the hyperparameters, the computing infrastructure, and the random seeds used in our experiments.

A.1 Data Preprocessing

We choose to use the datasets as they are, despite their imbalanced label distribution (Table 3), since such imbalance is representative of realistic applications. We preprocess the tweets by removing URLs, emails, usernames and mentions. Next, we employ the Ekphrasis package[2] to correct common spelling mistakes and unpack contractions. Finally, emojis are transformed into their respective words using the Python Emoji package[3].

A.2 Hyperparameters

To select the hyperparameters, we trained and evaluated the model on the entire MFTC corpus with 10-fold cross-validation. Table A1 shows the hyperparameters that were compared in this setting, highlighting in bold the best performing option that we then used in the experiments described in the paper. If a parameter is not present in the table, the default value supplied by the framework was used.

Table A1: Hyperparameters tested and selected

Hyperparameters	**Options**
Model name	**bert-base-uncased**
Number of parameters	**110M**
Max sequence length	**64**
Epochs	2, **3**, 5
Batch size	**16**, 32, 64
Dropout	0.05, **0.1**, 0.02
Optimizer	**AdamW**
Learning Rate	**$5*10^{-5}$**
Loss function	**Binary Cross Entropy**

A.3 Computing Infrastructure

The following are the main libraries and computing environment used in our experiments.

- PyTorch: 1.8.1
- TensorFlow: 2.5.0
- FastText: 0.8.22
- Hugginface's Transformers: 4.6.0
- NVIDIA GeForce RTX 2080 Ti GPU
- CUDA: 11.2
- cuDNN: 8.1.1.33

Refer to the code base for a detailed list of the libraries we used, and their versions.

The following list details the amount of GPU hours spent for obtaining our results:

- Tables 4, B1, and B2: 44 hours
- Figures 2 and 3: 33 hours
- Tables B3, B4, and B5: 24 hours
- Table B7: 26 hours

The error analysis (Tables 5, 6, and 7) did not require additional GPU time.

A.4 Random Seeds

In our experiments, we ensured that the same train-test splits are used across different runs of each experiment. Further, to control for randomness, we fixed the random seeds in the following libraries:

- Python (`random.seed`);
- NumPy (`numpy.random.seed`);
- PyTorch (`torch.manual_seed`);
- Tensorflow (`tensorflow.random.set_seed`).

A.5 Artifacts Usage

We have mainly used two artifacts in this research: the MFTC and BERT.

The MFTC was collected with the intent of facilitating NLP research on moral values (Hoover et al., 2020). It can be downloaded[4] and used under the Creative Commons Attribution 4.0 license.

BERT (Devlin et al., 2019) was created with the intent of performing, among others, text classification. Thus, we are using it as originally intended, under its Apache 2.0 distribution license[5].

B Extended Results

In this Appendix we extend the results presented in the paper. The following results are not crucial for supporting our conclusions. Nevertheless, they provide additional details on our experiments.

B.1 Model Comparison

We have presented the results of the transferability analysis with the BERT model. In order to evaluate whether our conclusions generalize to other model architectures, we repeat the experiment conducted in the paper (see Sections 3 and 4) with the following two additional models:

- Long Short Term Memory (**LSTM**), a category of Recurrent Neural Networks (RNN). We choose LSTM as a baseline model since it is commonly used in moral value classification (Lin et al., 2018; Mooijman et al., 2018; Rezapour et al., 2019; Hoover et al., 2020).
- **fastText**, a machine learning approach that learns character-level information, in contrast to the whole word representations LSTM employs. This flexibility makes fastText a good candidate for transfer learning. Further, we choose fastText as it attains performances on par with state-of-the-art deep learning methods, but is considerably faster.

Tables B1 and B2 present the results of the transferability analysis, performed and presented analogously to Table 4, for LSTM, fastText, and BERT. We observe that BERT outperforms fastText and LSTM in most settings. This is not surprising, since BERT is state-of-the-art for text classification. Both BERT and fastText outperform LSTM, the model extensively used for predicting moral values. Further, we notice that the general trends observed in Section 4.1 hold for all three models.

Generalizability All three models achieve better average F_1-scores in the $\mathcal{C}(source, target)$ setting than the majority ($target$) baseline. However, compared to the majority ($source$) baseline, $\mathcal{C}(target, source)$ performs worse with LSTM, comparably with fastText, and much better with BERT. This suggests that a contextualized representation, as in BERT, is necessary for value classification in novel domains, especially for the novel domains with a large moral vocabulary as is the case in $\mathcal{C}(target, source)$.

Transferability From the average F_1-scores in Table B2, we observe that $\mathcal{C}(finetune, target)$ performs better than or on par with $\mathcal{C}(target, target)$ across all three models. The benefits of finetuning are most evident for LSTM (7% increase in the average m and 17% increase in M). The benefits can also be observed for fastText (similar m and 8% increase of M) and BERT (similar m and 8% increase of M), but to a lesser degree than LSTM.

Catastrophic Forgetting We observe that all three models suffer from catastrophic forgetting since finetuning on $\mathcal{T}_{target}$ reduces the performance on $\mathcal{T}_{source}$. As mentioned in the paper, the degree of catastrophic forgetting is most evident when finetuning on unbalanced datasets such as DAV than balanced datasets such as BLM.

B.1.1 Training Time

In some applications, e.g., estimating value trends on Twitter, value classifiers need to be re-trained frequently since the trends can shift fast. Similarly, to employ techniques such as active learning for value annotation requires training a classifier at every iteration to prompt for new labels. In such cases, training time is an important factor for selecting an approach and model. Figure B1 shows the average training time in logarithmic scale, for different models and scenarios (Appendix A.3 describes our computing infrastructure).

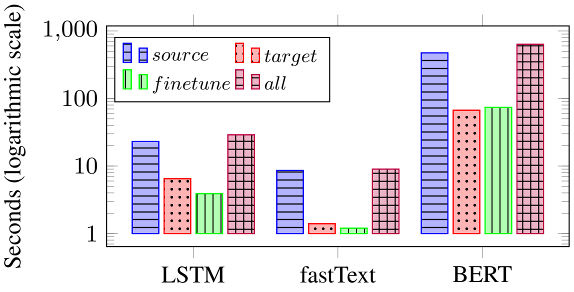

Figure B1: Average training time per model and scenario

Two considerations are evident. First, fastText trains significantly faster than the other two models. Second, for all three models, the training time is approximately proportional to the amount of data in the training set—the $target$ and $finetune$ scenarios employ a similar amount of data, which is roughly six times smaller than in the $source$ and all scenarios.

Table B1: Results of the four training scenarios and three models evaluated on $\mathcal{T}_{source}$. The columns indicate the dataset used as $\mathcal{T}_{target}$. For each experiment we report micro F_1-score (m, left-hand column) and macro F_1-score (M, right-hand column).

B.2 Composition of $\mathcal{T}_{source}$

In Section 3.1, we mention that in our experiments $\mathcal{T}_{target}$ is always composed of one dataset of the MFTC, while we test with $\mathcal{T}_{source}$ being composed of one, three, or six datasets. In the main paper we present the results where $\mathcal{T}_{source}$ is composed of six datasets. Here, we present the results where it is composed of one or three datasets, using BERT.

B.2.1 One Dataset as $\mathcal{T}_{source}$

Not all the settings described in Section 3.1 can be meaningfully replicated when $\mathcal{T}_{source}$ is composed of just one dataset. For instance, $\mathcal{C}(source, source)$ and $\mathcal{C}(target, target)$ would coincide, as well as $\mathcal{C}(source, target)$ and $\mathcal{C}(target, source)$. Thus, in Tables B3, B4, and B5 we present the results along the lines of generalizability, transferability, and catastrophic forgetting, respectively. When possible, we compare the results to the results pre-

Table B3: Generalizability: the model is trained on $\mathcal{T}_{source}$ and evaluated on $\mathcal{T}_{target}$.

sented in the paper (where $\mathcal{T}_{source}$ is composed of six datasets). As in the paper, we highlight in bold the best result and the results that are not significantly different from it.

Generalizability To evaluate generalizability (Table B3), the model is trained on $\mathcal{T}_{source}$ and evaluated on $\mathcal{T}_{target}$, akin to the $\mathcal{C}(source, target)$ setting described in the paper. Thus, at the end of the table, we append the results of $\mathcal{C}(source, target)$ from Table 4 (where $\mathcal{T}_{source}$ is composed of six datasets). First, we notice that the results are generally better when $\mathcal{T}_{source}$ is composed of six datasets. Further, there is no dataset that stands out as clearly better than the other six in generalizability.

Transferability To evaluate transferability (Table B4), the model is trained on $\mathcal{T}_{source}$, retrained on $\mathcal{T}_{target}$, and evaluated on $\mathcal{T}_{target}$, akin to the $\mathcal{C}(finetune, target)$ setting described in the paper. Thus, at the end of the table, we append the results of $\mathcal{C}(finetune, target)$ from Table 4 (where $\mathcal{T}_{source}$ is composed of six datasets). First, we notice that the results are generally better or on par to the results where $\mathcal{T}_{source}$ is composed of six datasets. Further, there is no dataset that stands out as clearly better than the other six in transferability. These two aspects suggest that a combination of the six datasets as $\mathcal{T}_{source}$ consistently leads to better transferability results.

Catastrophic Forgetting To evaluate catastrophic forgetting (Table B5), the model is trained on $\mathcal{T}_{source}$, retrained on $\mathcal{T}_{target}$, and evaluated on $\mathcal{T}_{source}$, akin to the $\mathcal{C}(finetune, source)$ setting described in the paper. However, we cannot compare the results with the $\mathcal{C}(finetune, source)$

setting, as the evaluation sets differ (one dataset in Table B5, six datasets in $\mathcal{C}(finetune, source)$ in Table 4). However, we compare to the case where the model is only trained on $\mathcal{T}_{source}$. Differently from the previous tables, the evaluation sets (i.e., $\mathcal{T}_{source}$) are consistent in every row, not in every column. Thus, we highlight the best results per row. It is evident that catastrophic forgetting happens even when $\mathcal{T}_{source}$ is composed of one dataset. Further, there is no dataset that stands out as better than the other six in mitigating forgetting.

B.2.2 Three Datasets as $\mathcal{T}_{source}$

When employing three datasets as $\mathcal{T}_{source}$, the settings described in Section 3.1 can be meaningfully reproduced. However, the selection of the three datasets (out of the six available at each experiment) that compose $\mathcal{T}_{source}$ is not trivial. Experimenting with all possible combinations would result in $\frac{6!}{3!(6-3)!} = 20$ experiments per setting. In order to simplify the experiments, we decide to test with only one combination of three datasets, selected as the best performing combination from the experiments in Section B.2.1. We average the results of Tables B3, B4, and B5, and for each dataset used as $\mathcal{T}_{target}$, we select the three datasets that led to the best average performance. Due to the class imbalance of all datasets, one of the biggest challenges is to achieve good performances across all values. Thus, we decide to consider only the average macro F_1-scores. We report the best resulting datasets in Table B6—for each dataset that we use as $\mathcal{T}_{target}$ in the following experiments, we use the indicated three datasets as $\mathcal{T}_{source}$.

Table B6: The three datasets used as $\mathcal{T}_{source}$ in Table B7

Table B7 reports the complete cross-domain evaluation results, analogously to Table 4. For further comparison, we add the results from Table 4 (where $\mathcal{T}_{source}$ is composed of six datasets). The results in the bottom half of the table can be directly compared, as in each column the model is evaluated on the same test set. However, the results on the top half cannot be directly compared, as the model is evaluated on different test sets (three and six datasets, respectively).

It is evident that the results are consistent with the results presented in the main paper. In the top half of the table, the best performing settings are $\mathcal{C}(source, source)$ and $\mathcal{C}(all, source)$, both when $\mathcal{T}_{source}$ is composed of three and six datasets. In the bottom half, where the results can be directly compared, we notice that the best performing settings are consistent, and lead to comparable results.

We conclude that selecting the three best performing datasets as $\mathcal{T}_{source}$ has neither advantage nor disadvantage over selecting all six datasets. However, selecting all six allows for a consistent evaluation, where all MFTC datasets are used in all evaluation settings, thus avoiding the arbitrary choice of datasets to be used as $\mathcal{T}_{source}$ that we described at the beginning of this section.

Table B7: Results of the four training scenarios evaluated on $\mathcal{T}_{source}$ and $\mathcal{T}_{target}$, when $\mathcal{T}_{source}$ is composed of three or six datasets. The columns indicate the dataset used as $\mathcal{T}_{target}$. We report both micro F_1-score (m, left column) and macro F_1-score (M, right column).
