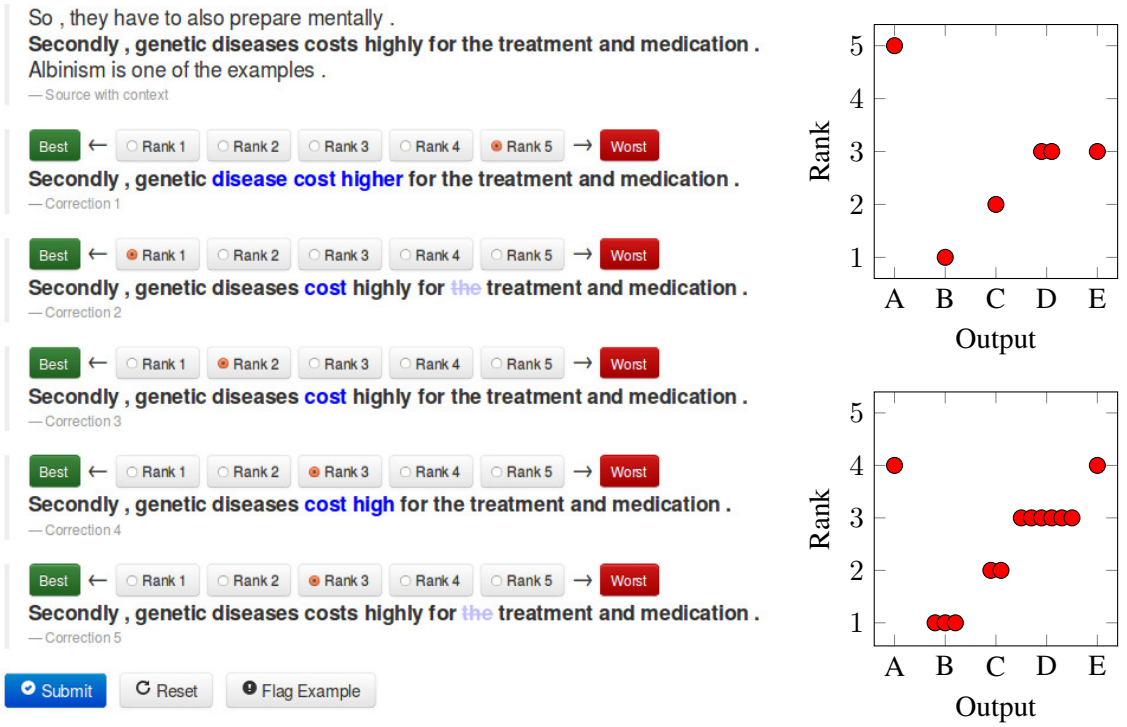
$$C_i = \frac{\sum_{j=M}^{N} c_i(j) \cdot j}{\sum_{j=M}^{N} c_i(j)}.$$

The pseudo-probability p'_i of sampling the i-th sentence is defined as

$$p'_i = \frac{\binom{M}{2}}{\binom{C_i}{2}} \quad \text{where} \quad \binom{C_i}{2} = \frac{C_i(C_i - 1)}{2}$$

which is the ratio of pairwise comparisons of M versus C_i different systems. By normalizing over



(a) Screenshot of Appraise modified for GEC judgment.

(b) Overlapping rankings.

Figure 2: Displayed ranking and corresponding overlapping rankings.

the entire set of output sets we obtain the probability p_i of sampling the i-th set of outputs as

$$p_i = \frac{p'_i}{\sum_{j=1}^{|E|} p'_j}.$$

4.2 Collecting system rankings

The sets of outputs sampled with the described method have been prepared for Appraise (Federmann, 2010) and presented to the judges. Judges were asked to rank sentences from best to worse. Ties are allowed. Judges were aware that the absolute ranks bear no relevance as ranks are later turned into relative pairwise judgments. No notion of "better" or "worse" was imposed by the authors, we relied on the judges to develop their own intuition. All eight judges are English native speakers and have extensive backgrounds in linguistics.

Figure 2a displays a screen shot of Appraise with a judged sentence. Several modifications to the Appraise framework[2] were implemented to account for the specific nature of GEC:

Only the input sentence is displayed (top, bold), no reference correction is given. The input sentence is surrounded by one preceding and one following sentence. Identical corrections are collapsed into one output, system names with the same output are recorded internally. Edited fragments are highlighted, blue for insertions and substitutions, pale blue and crossed-out for deletions.

4.3 Pairwise judgments

As conducted during the WMT campaigns, we turn rankings into sets of relative judgments of the form `A>B`, `A=B`, `A<B` where the lower ranked system scores a win. Absolute ranks and differences are lost. As mentioned above, due to the collapsing of identical outputs we obtain significantly more data than the usual 10 pairs from one ranking with five sentences. Figure 2a contains a ranking with overlapping outputs as displayed in the top graph of Figure 2b. Pairs from within overlaps result in ties, pairs between overlaps are expanded as products, $\binom{6}{2} = 15$ pairwise judgments can be extracted. Greater overlap leads to more pairwise judgments (bottom, $\binom{13}{2} = 78$).

Table 1 lists the full statistics for collected rankings by individual annotators. Unexpanded pairs are WMT-style pairwise judgments before an output `A` gets split into overlapping systems $\texttt{A}_1$, $\texttt{A}_2$, $\texttt{A}_3$, etc. The large number of ties for expanded pairs is to be expected due to the high overlap

[2] A fork of the original source code with can be found at `https://github.com/snukky/Appraise`

Judge	Ranks	Unexpanded	Expanded
1	400	3525 (1022)	18400 (10166)
2	299	2684 (1099)	13657 (8429)
3	400	3523 (914)	18912 (9684)
4	201	1750 (550)	9478 (5539)
5	349	3099 (766)	17107 (8972)
6	400	3474 (517)	19313 (9209)
7	70	646 (145)	3383 (1593)
8	200	1815 (681)	8848 (5525)
Total	2319	20516 (5694)	109098 (59117)

Table 1: Statistics for collected rankings (Ranks), unexpanded and expanded pairwise judgments, numbers for ties are given in parentheses.

between systems (on average there are only 5.7 unique outputs among 13 systems).

4.4 Inter- and intra-annotator agreement

Again inspired by the WMT evaluation campaigns, we compute annotator agreement as a measure of reliability of the pairwise judgments with Cohen's kappa coefficient (Cohen, 1960):

$$\kappa = \frac{P(A) - P(E)}{1 - P(E)}.$$

where $P(A)$ is the proportion of times that annotators agree, and $P(E)$ is the proportion of times that they would agree by chance. κ assumes values from 0 (no agreement) to 1 (perfect agreement).

All probabilities are computed as ratios of empirically counted pairwise judgments. As the judges worked on collapsed outputs, we calculate agreement scores for unexpanded pairs; otherwise, the high overlap would unfairly increase agreement.

$P(A)$ is calculated by examining all pairs of outputs which have been judged by two or more judges, and counting the proportion of times that they agreed that A<B, A=B, or A>B.

$P(E) = P(\texttt{A<B})^2 + P(\texttt{A=B})^2 + P(\texttt{A>B})^2$ is the probability that two judges agree randomly. Intra-annotator agreement as a measure of consistency is calculated for output sets that have been judged more than one time by the same annotator.

The agreement numbers in Table 2 are in the lower range of values reported during WMT. However, it should be noted that judges never saw the repeated outputs within one ranking which probably decreases agreement compared to the MT-specific task.

Agreement	Value	Degree
Inter-annotator	0.29	Weak
Intra-annotator	0.46	Moderate

(a) Inter-annotator and intra-annotator agreement for all judges

	1	2	3	4	5	6	7	8
1	.42	.26	.30	.37	.34	.26	.31	.24

8	–	–	–	–	–	–	–	.48

(b) Pairwise inter-annotator and intra-annotator agreement per judge. Stars indicate too few overlapping judgements.

Table 2: Inter-annotator and intra-annotator agreement (Cohen's κ) on unexpanded pairwise judgments.

5 Computing ranks

In this section, it is our aim to produce a system ranking from best to worse by computing the average number of times each system was judged better than other systems based on the collected pairwise rankings. While previously introduced methods for producing rankings, total orderings, as well as partial orderings at chosen confidence-levels, can be directly applied to our data, determining which ranking is more accurate turns out to be methodologically and computationally more involved due to the specific nature of GEC outputs.

5.1 Ranking methods

We adapt two ranking methods applied during WMT13 and WMT14 to GEC evaluation: the Expected Wins method and a version of TrueSkill.

Expected Wins. Expected Wins (EW) has been introduced for WMT13 (Bojar et al., 2013) and is based on an underlying model of "relative ability" proposed in Koehn (2012). One advantage of this method is its intuitiveness; the scores reflect the probability that a system S_i will be ranked better than another system that has been randomly chosen from a pool of opponents $\{S_j : j \neq i\}$. Defining the function $\text{win}(A, B)$ as the number of times system A is ranked better than system B, Bojar et

Table 3: Comparison of official CoNLL-2014 ranking and human rankings. Ranges and clusters have been calculated with bootstrap resampling at $p \leq 0.05$.

al. (2013) calculate EW scores as follows:

$$\text{score}_{\text{EW}}(S_i) = \frac{1}{|\{S_j\}|} \sum_{j,j \neq i} \frac{\text{win}(S_i, S_j)}{\text{win}(S_i, S_j) + \text{win}(S_j, S_i)}.$$

TrueSkill. The TrueSkill ranking system (Herbrich et al., 2007) is a skill based ranking system for Xbox Live developed at Microsoft Research. It is used to identify and model player (GEC systems in our case) ability in a game to assign players to competitive matches. The TrueSkill ranking system models each player S_i by two parameters: the average relative ability μ_{S_i} and the degree of uncertainty in the player's ability $\sigma^2_{S_i}$. Maintaining uncertainty allows TS to make greater changes to the ability estimates at the beginning and smaller changes after a number of consistent matches has been played. Due to that TS can identify the ability of individual players from a smaller number of pairwise comparisons.

A modification of this approach to the WMT manual evaluation procedure by Sakaguchi et al. (2014) has been adopted as the official ranking method during WMT14 replacing EW. The TrueSkill scores are calculated as inferred means:

$$\text{score}_{TS}(S_i) = \mu_{S_i}.$$

5.2 Rank clusters

Both ranking methods produce total orderings without information on the statistical significance of the obtained ranks. Bojar et al. (2014) notice that the similarity of the participants in terms of methods and training data causes some of them to be very similar and group systems into equivalence classes as proposed by Koehn (2012).

Although the methods and training data among the systems examined in this paper are quite diverse, a great similarity of produced outputs is an inherent property of GEC. Therefore, in this section, for each system S_j placed on rank r_j we also try to determine the true systems rank ranges $[r'_j, \ldots, r''_j]$ at a confidence-level of 95% and clusters of equivalent systems by following the procedure outlined by Koehn (2012).

This is accomplished by applying bootstrap resampling. Pairwise rankings are drawn from the set of judgments with multiple drawings. Based on this sample a new ranking is produced. After repeating this process a 1000 times the obtained 1000 ranks for S_j are sorted, with the top 25 and bottom 25 ranks being discarded. The interval of the remaining ranks serves as the final rank range. Next, these rank ranges are used to produce clusters of overlapping rank ranges. This is the last step required to produce the rankings in Tables 3b and 3c for both methods, EW and TS, respectively.

5.3 Choosing the final ranking

Now, we face the question which ranking should be presented as the final result of the human evaluation task. Again, we turn to Bojar et al. (2014) who choose their rankings based on the ranking model's ability to predict pairwise rankings. Accuracy is computed by 100-fold cross-validation. For each fold a new ranking is trained from 99 parts with the left-over part serving as test data.

In a first step, we calculate the accuracy of the unclustered total orderings discarding ties. A ranking based on model scores alone cannot predict ties, this requires equivalence classes. Bojar et al. (2014) define a draw radius r such that systems whose scores differ by less than r are assigned to one cluster, r is tuned to maximize accuracy.

In our case, due to the large number of ties, their method of tuning r is trapped in local maxima and assigns all systems to a single cluster. Alternatively, we propose to calculate clusters according to the method described in the previous section.

Method	EW	TS
Total ordering (non-ties)	58.18	58.15
Bootstrapped clusters	40.12	39.48

Table 4: Accuracy for ranking-based prediction of pairwise judgments.

By fixing $p \leq 0.05$ we directly evaluate rankings of the form given in Table 3. The absolute values of scores and their different interpretations between methods become irrelevant which makes it unnecessary to tune a parameter like r. The main drawback of this approach is its computational cost. For each of the 100 folds we bootstrap another 100 rankings with EW and TS, fix $p \leq 0.05$ and calculate rank clusters. The single clustered ranking for each fold is then used to calculate accuracy for the held-out test data.

For our data, contrary to the MT-specific results from Bojar et al. (2014), EW beats TS in both cases (Table 4). We therefore present the ExpectedWins-based ranking (Table 3b) as the final result of the human evaluation effort described in this work and refer to it in the remainder of the paper when the human ranking is mentioned.

5.4 Analysis

The final human-created ranking (Table 3b) consists of four non-overlapping rank clusters. Rank ranges have been calculated at a confidence level of 95%. Comparing the official CoNLL-2014 ranking (Table 3a) with the manually created ExpectedWins ranking shows interesting differences.

The AMU system is judged to be a clear leader by human judges in its own rank cluster. For six out of eight judges, AMU has the highest score (Table 7). The officially winning system CAMB occupies third place in terms of EW scores and is placed in the second cluster with four systems. Only one judge put CAMB in first place. RAC, a middling system, is elevated to second place occupying a rank cluster with three other systems. NTHU, another middling system that based on M^2 should be similar to RAC, is put in the second to last position. Two systems are judged to be worse than INPUT. The rank cluster that includes INPUT is the largest among the four clusters.

We also include pairwise comparisons between all systems according to EW in Table 3d. Each cell contains the percentage of times the system in that column was judged to be better than the system in

that row. Bold values mark the winner. We applied the Sign Test to measure statistically significant differences, $\star$ indicates statistical significance at $p \leq 0.10$, † at $p \leq 0.05$, and ‡ at $p \leq 0.01$.

6 Correlation with GEC metrics

Since WMT08 (Callison-Burch et al., 2008) the "metrics task" has been part of the WMT. The aim of the metrics task is to assess the quality of automatic evaluation metrics for MT in terms of correlation with the collected human judgments. We attempt the same in the context of GEC.

6.1 Measures of correlation

Based on Macháček and Bojar (2013), we use Spearman's rank correlation ρ and Pearson's r to compare the similarity of rankings produced by various metrics to the manual ranking from the previous section.

Spearman's rank correlation ρ. Spearman's ρ for rankings with no ties is defined as

$$\rho = 1 - \frac{6 \sum d_i^2}{n(n^2-1)}$$

where d_i is the distance between human and metric rank for system i, n is the number of systems.

Pearson's r. Macháček and Bojar (2013) find that Spearman's ρ is too harsh and propose to also use Pearson's r, calculated as

$$r = \frac{\sum_{i=1}^{n}(H_i - \bar{H})(M_i - \bar{M})}{\sqrt{\sum_{i=1}^{n}(H_i - \bar{H})^2}\sqrt{\sum_{i=1}^{n}(M_i - \bar{M})^2}}$$

where H and M are the vectors of human and metric scores, $\bar{H}$ and $\bar{M}$ are corresponding means.

6.2 Metrics

The inventory of evaluation metrics for GEC is significantly smaller than for MT. We hope that making our data available will fuel the interest in this area. The following metrics are assessed:

MaxMatch (M^2). Due to its adoption as the main evaluation metric of the CoNLL shared tasks and the QALB shared tasks (Mohit et al., 2014), the M^2 metric (Dahlmeier and Ng, 2012) can be seen as a *de facto* standard. Being an F_β-score, M^2 results are most influenced by the choice of β. Between the CoNLL-2013 and CoNLL-2014 shared tasks, the organizers changed β from 1.0 to 0.5, and motivate this with intuition alone. The QALB shared tasks for Arabic continue to use $\beta = 1.0$.

Metric	Spearman's ρ	Pearson's r
M^2 $F_{1.0}$	0.648	0.610
M^2 $F_{0.5}$*	0.692	0.627
M^2 $F_{0.25}$	0.720	0.680
M^2 $F_{0.18}$	**0.758**	**0.701**
M^2 $F_{0.1}$	0.670	0.652
I-WAcc	-0.154	-0.098
BLEU	-0.346	-0.240
METEOR	-0.374	-0.241

Table 5: Correlation results for various metrics and human ranking.

	1	2	3	4	5	6	7	8	ρ	$\bar{\rho}$
1	–	.70	.31	.76	.74	.19	.62	.48	.70	
2	.72	–	.77	.84	.90	.57	.59	.64	.93	
3	.53	.89	–	.66	.70	.58	.42	.64	.63	
4	.82	.79	.69	–	.91	.42	.67	.54	.91	.72
5	.65	.85	.82	.87	–	.63	.63	.51	.93	
6	.32	.71	.67	.56	.86	–	.63	.39	.42	
7	.72	.74	.57	.76	.72	.63	–	.63	.76	
8	.64	.85	.86	.69	.72	.57	.75	–	.60	
r	.67	.93	.82	.87	.92	.66	.80	.82	–	
$\bar{r}$				.80						

Table 6: Inter-annotator correlation (Spearman's ρ above the diagonal, Pearson's r below).

I-measure/Weighted Accuracy (I-WAcc). The recently proposed I-WAcc metric (Felice and Briscoe, 2015) tries to address the shortcomings of M^2. The inclusion of true negatives into the formula makes this a very conservative metric; quite similar to the MT metrics described below. The metric assigns negative weights to systems that are harmful with regard to the input text, values from the range $[1, -1]$ are possible. The reported correlation values have been calculated for the ranking presented in Felice and Briscoe (2015).

Machine translation evaluation metrics. Basing most of our results on findings from MT, we also take a look at two machine translation evaluation metrics, BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2011). In order to use the CoNLL-2014 gold standard with these metrics, the edit-based annotation has been converted into two plain text files, one per annotator.

6.3 Analysis

The correlation results are collected in table 5. The M^2 metric is generally moderately correlated with

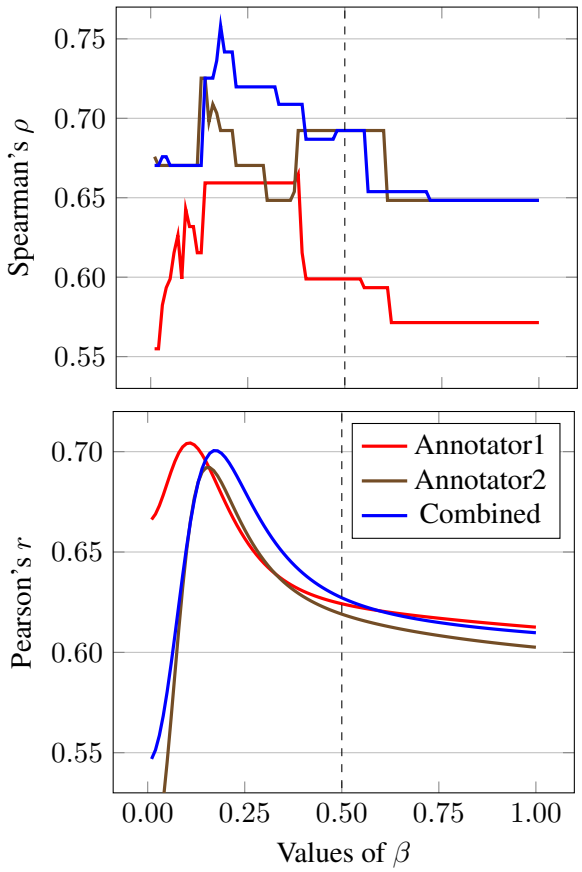

Figure 3: Spearman's ρ and Pearson's r correlation of M^2 with human judgment w.r.t. β. Dashed line marks official CoNLL-2014 choice $\beta = 0.5$.

human judgment and is on the brink of high correlation for values of β closer to 0.2. Compared to M^2, the other metrics are weakly or moderately inversely correlated to human judgment. Inverse correlation with human judgments for metrics that all assign higher scores to better systems seems problematic. In the case of I-WAcc, we would go as far as to state an absence of correlation. It seems the conservative approach adopted for I-WAcc does not correspond to the notion of quality that our judges worked out for themselves. The switch to $\beta = 0.5$ from $\beta = 1.0$ for the CoNLL-2014 shared task was a good choice, but a higher correlation can be achieved for $\beta = 0.25$, the maximum is reached for $\beta = 0.18$. Correlation drops sharply for $\beta = 0.1$. The lack of positive correlation for the MT-metrics is interesting in the light of improvement that results from a shift towards precision for M^2 as BLEU is based on precision.

Figure 3 contains detailed plots of ρ and r with regard to β within the $[0, 1]$ range. As the CoNLL-2014 test data included edits from two annotators, we plot curves for both annotators separately and for the combined gold standard. In the case of Spearman's ρ having alternative error annotations, this leads to higher correlation values. Based on the plots we would recommend setting $0.2 \leq \beta \leq 0.3$ instead of 0.5 or even 1.0.

Inter-annotator correlations of rankings computed for individual judges (Table 6) can be treated as human-level upper bounds for metric correlation. The penultimate column and row contain correlations of rankings for individual judges with rankings computed from all judges minus the respective judge. The last column and row contain the respective weighted (w.r.t. judgments per judge) average of these correlations.

7 Conclusions and future work

We have successfully adapted methods from the WMT human evaluation campaigns to automatic grammatical error correction. The collected and produced data has been made available and should be useful for other researchers. Although we set out to provide answers, we probably ended up with more questions. The following (and more) might be investigated in the future: What makes the winning system special and why do the standard metrics fail at identifying this system? Can we come up with better system-level metrics? Can meaningful sentence-level metrics be developed?

Outside the scope of the particular data, we need to wonder if our results generalize to other shared tasks and other languages. The CoNLL-2014 data concerns ESL learners only and may not be transferable to systems for native speakers. This would be in line with the ideas developed by Chodorow et al. (2012). We would hope to see similar endeavors for the other shared tasks as this would enable the field to draw more general conclusions.

Obtaining the data

The presented data and tools are available from: `https://github.com/grammatical/evaluation`

Learning a Deep Hybrid Model for Semi-Supervised Text Classification

Alexander G. Ororbia II, C. Lee Giles, David Reitter

{ago109, giles, reitter}@psu.edu

Abstract

We present a novel fine-tuning algorithm in a deep hybrid architecture for semi-supervised text classification. During each increment of the online learning process, the fine-tuning algorithm serves as a top-down mechanism for pseudo-jointly modifying model parameters following a bottom-up generative learning pass. The resulting model, trained under what we call the *Bottom-Up-Top-Down* learning algorithm, is shown to outperform a variety of competitive models and baselines trained across a wide range of splits between supervised and unsupervised training data.

1 Introduction

Recent breakthroughs in learning expressive neural architectures have addressed challenging problems in domains such as computer vision, speech recognition, and natural language processing. This success is owed to the representational power afforded by deeper architectures supported by long-standing theoretical arguments (Hastad, 1987). These architectures efficiently model complex, highly varying functions via multiple layers of non-linearities, which would otherwise require very "wide" shallow models that need large quantities of samples (Bengio, 2012). However, many of these deeper models have relied on mini-batch training on large-scale, labeled data-sets, either using unsupervised pre-training (Bengio et al., 2007) or improved architectural components (such as activation functions) (Schmidhuber, 2015).

In an online learning problem, samples are presented to the learning architecture at a given rate (usually with one-time access to these data points), and, as in the case of a web crawling agent, most of these are unlabeled. Given this, batch training and supervised learning frameworks are no longer applicable. While incremental approaches such as co-training have been employed to help these models learn in a more update-able fashion (Blum and Mitchell, 1998; Gollapalli et al., 2013), neural architectures can naturally be trained in an online manner through the use of stochastic gradient descent (SGD).

Semi-supervised online learning does not only address practical applications, but it also reflects some challenges of human category acquisition (Tomasello, 2001). Consider the case of a child learning to discriminate between object categories and mapping them to words, given only a small amount of explicitly labeled data (the mother pointing to the object), and a large portion of unsupervised learning, where the child comprehends an adult's speech or experiences positive feedback for his or her own utterances regardless of their correctness. The original argument in this respect applied to grammar (e.g., Chomsky, 1980; Pullum & Scholz, 2002). While neural networks are not necessarily models of actual cognitive processes, semi-supervised models can show learnability and illustrate possible constraints inherent to the learning process.

The contribution of this paper is the development of the *Bottom-Up-Top-Down* learning algorithm for training a Stacked Boltzmann Experts Network (SBEN) (Ororbia II et al., 2015) hybrid architecture. This procedure combines our proposed top-down fine-tuning procedure for jointly modifying the parameters of a SBEN with a modified form of the model's original layer-wise bottom-up learning pass (Ororbia II et al., 2015). We investigate the performance of the constructed deep model when applied to semi-supervised text classification problems and find that our hybrid architecture outperforms all baselines.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 471–481,
Lisbon, Portugal, 17-21 September 2015.

2 Related Work

Recent successes in the domain of connectionist learning stem from the expressive power afforded by models, such as the Deep Belief Network (DBN) (Hinton et al., 2006; Bengio et al., 2007) or Stacked Denoising Autoencoder (Vincent et al., 2010), that greedily learn layers of stacked non-linear feature detectors, equivalent to levels of abstraction of the original representation. In a variety of language-based problems, deep architectures have outperformed popular shallow models and classifiers (Salakhutdinov and Hinton, 2009; Liu, 2010; Socher et al., 2011; Glorot et al., 2011b; Lu and Li, 2013; Lu et al., 2014). However, these architectures often operate in a multi-stage learning process, where a generative architecture is pre-trained and then used to initialize parameters of a second architecture that can be discriminatively fine-tuned (using back-propagation of errors or *drop-out*: Hinton et al., 2012). Several ideas have been proposed to help deep models deal with potentially uncooperative input distributions or encourage learning of discriminative information earlier in the process, many leveraging auxiliary models in various ways (Bengio et al., 2007; Zhang et al., 2014; Lee et al., 2014). A few methods for adapting deep architecture construction to an incremental learning setting have also been proposed (Calandra et al., 2012; Zhou et al., 2012). Recently, it was shown in (Ororbia II et al., 2015) that deep hybrid architectures, or multi-level models that integrate discriminative and generative learning objectives, offer a strong viable alternative to multi-stage learners and are readily usable for categorization tasks.

For text-based classification, a dominating model is the support vector machine (SVM) (Cortes and Vapnik, 1995) with many useful innovations to yet further improve its discriminative performance (Subramanya and Bilmes, 2008). When used in tandem with prior human knowledge to hand-craft good features, this simple architecture has proven effective in solving practical text-based tasks, such as academic document classification (Caragea et al., 2014). However, while model construction may be fast (especially when using a linear kernel), this process is costly in that it requires a great deal of human labor to annotate the training corpus. Our approach, which builds on that of (Ororbia II et al., 2015), provides a means for improving classification performance when labeled data is in scarce supply, learning structure and regularity within the text to reduce classification error incrementally.

3 A Deep Hybrid Model for Semi-Supervised Learning

To directly handle the problem of discriminative learning when labeled data is scarce, (Ororbia II et al., 2015) proposed deep hybrid architectures that could effectively leverage small amounts of labeled and large amounts of unlabeled data. In particular, the best-performing architecture was the Stacked Boltzmann Experts Network (SBEN), which is a variant of the DBN. In its construction and training, the SBEN design borrows many recent insights from efficiently learning good DBN models (Hinton et al., 2006) and is essentially a stack of building block models where each layer of model parameters is greedily modified while freezing the parameters of all others. In contrast to the DBN, which stacks restricted Boltzmann machines (RBM's) and is often used to initialize a deep multi-layer perceptron (MLP), the SBEN model is constructed by composing hybrid restricted Boltzmann machines and can be directly applied to the discriminative task in a single learning phase.

The hybrid restricted Boltzmann machine (HRBM) (Schmah et al., 2008; Larochelle and Bengio, 2008; Larochelle et al., 2012) building block of the SBEN is itself an extension of the RBM meant to ultimately perform classification. The HRBM graphical model is defined via parameters $\Theta = (\mathbf{W}, \mathbf{U}, \mathbf{b}, \mathbf{c}, \mathbf{d})$ (where $\mathbf{W}$ is the input-to-hidden weight matrix, $\mathbf{U}$ the hidden-to-class weight matrix, $\mathbf{b}$ is the visible bias vector, $\mathbf{c}$ is the hidden unit bias vector, and $\mathbf{d}$ is the class unit bias vector), and is a model of the joint distribution of a binary feature vector $\mathbf{x} = (x_1, \cdots, x_D)$ and its label $y \in \{1, \cdots, C\}$ that makes use of a latent variable set $\mathbf{h} = (h_1, \cdots, h_H)$. The model assigns a probability to the triplet (y,$\mathbf{x}$,$\mathbf{h}$) using:

$$p(y, \mathbf{x}, \mathbf{h}) = \frac{e^{-E(y,\mathbf{x},\mathbf{h})}}{Z}, \tag{1}$$

$$p(y, \mathbf{x}) = \frac{1}{Z} \sum_{\mathbf{h}} e^{-E(y,\mathbf{x},\mathbf{h})} \tag{2}$$

where Z is known as the partition function. The model's energy function is defined as

$$E(y, \mathbf{x}, \mathbf{h}) = -\mathbf{h}^T\mathbf{W}\mathbf{x} - \mathbf{b}^T\mathbf{x} - \mathbf{c}^T\mathbf{h} - \mathbf{d}^T\mathbf{e}_y - \mathbf{h}^T\mathbf{U}\mathbf{e}_y. \tag{3}$$

where $\mathbf{e}_y = (\mathbf{1}_{i=y})_{i=1}^{C}$ is the one-hot vector encoding of y. It is often not possible to compute $p(y, \mathbf{x}, \mathbf{h})$ or the marginal $p(y, \mathbf{x})$ due to the intractable normalization constant. However, exploiting the model's lack of intra-layer connections, block Gibbs sampling may be used to draw samples of the HRBM's latent variable layer given the current state of the visible layer and vice versa. This yields the following equations:

$$\begin{aligned} p(\mathbf{h}|y, \mathbf{x}) &= \prod_j p(h_j|y, \mathbf{x}), \\ p(h_j = 1|y, \mathbf{x}) &= \sigma(c_j + U_{jy} + \sum_i W_{ji}x_i) \end{aligned} \tag{4}$$

$$\begin{aligned} p(\mathbf{x}|\mathbf{h}) &= \prod_i p(x_i|\mathbf{h}), \\ p(x_i = 1|\mathbf{h}) &= \sigma(b_i + \sum_j W_{ji}h_j) \end{aligned} \tag{5}$$

$$p(y|\mathbf{h}) = \frac{e^{d_y + \sum_j U_{jy}h_j}}{\sum_{y^\star} e^{d_{y^\star} + \sum_j U_{jy^\star}h_j}} \tag{6}$$

where $\sigma(v) = 1/(1 + e^{-v})$. Classification may be performed directly with the HRBM by using its free energy function $F(y, \mathbf{x})$ to compute the conditional distribution

$$p(y|\mathbf{x}) = \frac{e^{-F(y,\mathbf{x})}}{\sum_{y^\star \in \{1,\cdots,C\}} e^{-F(y^\star,\mathbf{x})}} \tag{7}$$

where the free energy is formally defined as

$$-F(y, \mathbf{x}) = (d_y + \sum_j \psi(c_j + U_{jy} + \sum W_{ji}x_i)) \tag{8}$$

and ψ is the softplus activation function $\psi(v) = \log(1 + e^v)$.

To construct an *N*-layer SBEN (or *N*-SBEN), as was shown in (Ororbia II et al., 2015), one may learn a stack of HRBMs in one of two ways: (1) in a strict greedy, layer-wise manner, where layers are each trained in isolation on all of the data samples one at a time from the bottom-up; or (2) in a more relaxed disjoint fashion, where all layers are trained together on all of the data but still in a layer-wise bottom-up pass. To properly compute intermediate data representations during training and prediction in the SBEN, one must combine Equations 4 and 7. (The specific procedure for doing this can be found in the *computeLayerwiseStatistics* sub-routine in Algorithm 1.) This gives rise to the full SBEN architecture, which is depicted in Figure 1.

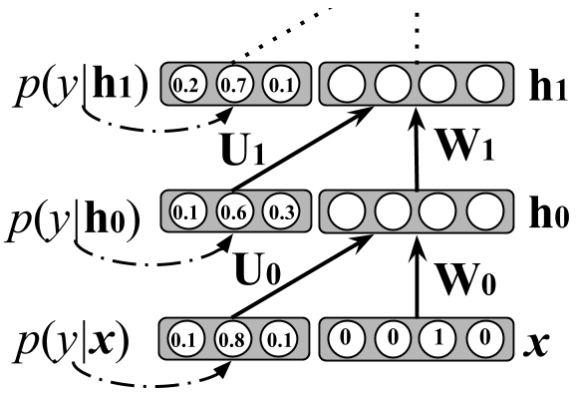

Figure 1: Architecture of the SBEN model. The model in feedforward mode can be viewed as a directed model, however, during training, connections are bi-directional.

3.1 Ensembling of Layer-Wise Experts

The SBEN may be viewed as a natural vertical ensemble of layer-wise "experts", where each layer maps latent representations to predictions, which differs from standard methods such as boosting (Schapire, 1990). Traditional feedforward neural models propagate data through the final network to obtain an output prediction y_t from a penultimate layer for a given $\mathbf{x}_t$. In contrast, this hybrid model is capable of a producing a label y_t^n at each level *n* for $\mathbf{x}_t$.

To vertically aggregate layer-wise expert outputs, we compute a simple mean predictor, $p(y|\mathbf{x})_{ensemble}$, as follows:

$$p(y|\mathbf{x})_{ensemble} = \frac{1}{N}\sum_{n=1}^{N} p(y|\mathbf{x})_n \tag{9}$$

This ensembling scheme provides a simple way to incorporate acquired discriminative knowledge of different levels of abstraction into the model's final prediction. We note that the SBEN's inherent layer-wise discriminative ability stands as an alternative to coupling helper classifiers (Bengio et al., 2007) or the "companion objectives" (Lee et al., 2014).

3.2 The Bottom-Up-Top-Down Learning Algorithm

With the SBEN architecture defined, we next present its simple two-step training algorithm, or the *Bottom-Up-Top-Down* procedure (*BUTD*), which combines a greedy, bottom-up pass with a subsequent top-down fine-tuning step. At every iteration of training, the model makes use of a single labeled sample (taken from an available, small labeled data subset) and an example from either a large unlabeled pool or a data-stream. We describe each of the two phases in Sections 3.2.1 and 3.2.2.

3.2.1 Bottom-Up Layer-wise Learning (BU)

The first phase of *N*-SBEN learning consists of a bottom-up pass where each layerwise HRBM can be trained using a compound objective function. Data samples are propagated up the model to the layer targeted for layer-wise training using the feedforward schema described above. Each HRBM layer of the SBEN is greedily trained using the frozen latent representations of the one below, which are generated by using the lower level expert's input and prediction. The loss function for each layer balances a discriminative objective $\mathcal{L}_{disc}$, a supervised generative objective $\mathcal{L}_{gen}$, and an unsupervised generative objective $\mathcal{L}_{unsup}$, fully defined as follows:

$$\begin{aligned}\mathcal{L}_{semi}(\mathcal{D}_{train}, \mathcal{D}_{unlab}) = \gamma\mathcal{L}_{disc}(\mathcal{D}_{train}) \\ +\alpha\mathcal{L}_{gen}(\mathcal{D}_{train}) \\ +\beta\mathcal{L}_{unsup}(\mathcal{D}_{unlab})\end{aligned} \quad (10)$$

Unlike generative pre-training of neural architectures (Bengio et al., 2007), the additional free parameters γ, α, and β offer explicit control over the extent to which the final parameters discovered are influenced by generative learning (Larochelle et al., 2012; Ororbia II et al., 2015). More importantly, the generative objectives may be viewed as providing data-dependent regularization on the discriminative learning gradient of each layer.

The objectives themselves are defined as:

$$\mathcal{L}_{disc}(\mathcal{D}_{train}) = -\sum_{t=1}^{|\mathcal{D}_{train}|} \log p(y|\mathbf{x}_t), \quad (11)$$

$$\mathcal{L}_{gen}(\mathcal{D}_{train}) = -\sum_{t=1}^{|\mathcal{D}_{train}|} \log p(y_t, \mathbf{x}_t), \text{ and} \quad (12)$$

$$\mathcal{L}_{unsup}(\mathcal{D}_{unlab}) = -\sum_{t=1}^{|\mathcal{D}_{unlab}|} \log p(\mathbf{x}_t) \quad (13)$$

where $\mathcal{D}_{train} = \{(\mathbf{x}_t, y)\}$ is the labeled training data-set and $\mathcal{D}_{unlab} = \{(\mathbf{u}_t)\}$ is the unlabeled training data-set. The gradient for $\mathcal{L}_{disc}$ may be computed directly, which follows the general form

$$\begin{aligned}\frac{\partial \log p(y_t|\mathbf{x})}{\partial\theta} = -\mathbb{E}_{\mathbf{h}|y_t,\mathbf{x}_t}\left[\frac{\partial}{\partial\theta}\left(\mathbb{E}(y_t, \mathbf{x}_t, \mathbf{h})\right)\right] \\ +\mathbb{E}_{y,\mathbf{h}|,\mathbf{x}}\left[\frac{\partial}{\partial\theta}\left(\mathbb{E}(y, \mathbf{x}, \mathbf{h})\right)\right]\end{aligned} \quad (14)$$

and can be calculated directly (see Larochelle et al., 2012 , for details) or through a form of *Dropping*, such as *Drop-Out* or *Drop-Connect* (Tomczak, 2013). The generative gradients themselves follow the form

$$\begin{aligned}\frac{\partial \log p(y_t, \mathbf{x})}{\partial\theta} = -\mathbb{E}_{\mathbf{h}|y_t,\mathbf{x}_t}\left[\frac{\partial}{\partial\theta}\left(\mathbb{E}(y_t, \mathbf{x}_t, \mathbf{h})\right)\right] \\ +\mathbb{E}_{y,\mathbf{x},\mathbf{h}}\left[\frac{\partial}{\partial\theta}\left(\mathbb{E}(y, \mathbf{x}, \mathbf{h})\right)\right]\end{aligned} \quad (15)$$

and, despite being intractable for any sample $(\mathbf{x}_t, y_t)$, may be approximated via the contrastive divergence procedure (Hinton, 2002). The intractable second expectation is replaced with a point estimate using a single Gibbs sampling step. To calculate the generative gradient for an unlabeled sample $\mathbf{u}$, a pseudo-label must be obtained by using a layer-wise HRBM's current estimate of $p(y|\mathbf{u})$, which can be viewed as a form of self-training or *Entropy Regularization* (Lee, 2013). The online procedure for computing the generative gradient (either labeled or unlabeled example) for a single HRBM can be found in Ororbia et al., (2015).

Setting the coefficients that control learning objective influences can lead to different model configurations (especially with respect to γ) as well as impact the gradient-based training of each model layer (i.e., α and β). In this paper, we shall explore two particular configurations, namely 1) by setting $\gamma = 0$ and $\alpha = 1$, which leads to constructing a purely generative model of $\mathcal{D}_{train}$ and

Algorithm 1 Top-down fine-tuning of an *N*-SBEN (*ensemble back-propagation*). Note that "$\cdot$" indicates a Hadamard product, ξ is an error signal vector, the prime superscript indicates a derivative (i.e., σ' means derivative function of the sigmoid), and $\widehat{\mathbf{z}}$ is the symbol for linear pre-activation values.

$\mathcal{D}_{unsup}$, and 2) by setting $\gamma = 1$ with α freely varying (which recovers the model of Ororbia et al., 2015). In both scenarios, β is allowed to vary as a user-defined hyper-parameter. The second setting of γ allows for training the SBEN directly with only the bottom-up phase defined in this section. However, if the first setting is used, a second phase may be used to incorporate a top-down fine-tuning phase. A bottom-up pass simply entails computing this compound gradient for each layer of the model for 1 or 2 samples per training iteration. Notice that the first scenario reduces the number of hyper-parameters to explore in model selection, requiring only an appropriate value for β to be found.

3.2.2 Top-Down Fine-tuning (TD)

Although efficient, the bottom-up procedure described above is greedy, which means that the gradients are computed for each layer-wise HRBM independent of gradient information from other layers of the model. One way we propose to introduce a degree of joint training of parameters is to incorporate a second phase that adjusts the SBEN parameters via a modified form of back-propagation. Such a routine can further exploit the SBEN's multiple predictors (or entry points) where additional error signals may be computed and aggregated while signals are reverse-propagated down the network. We hypothesize that holistic fine-tuning ensures that discriminative information is incorporated into the generative

features being constructed in the bottom-up learning step. Furthermore, errors from experts above are propagated down to lower layers, which were initially frozen during the greedy, bottom-up training phase.

Fine-tuning in the context of training an SBEN is different from using a pre-trained MLP that is subsequently fine-tuned with back-propagation. First, since the SBEN is a more complex architecture than an MLP, pre-initializing an MLP would be insufficient given that one would be tossing potentially useful information stored in the SBEN's class filters (and corresponding class bias vectors) of each layer-wise expert (i.e., U and $\mathbf{d}$). Second, merely using the SBEN as an intermediate model ignores the fact the SBEN can already perform classification directly. To avoid losing such information and to fully exploit the model's predictive ability, we adapt the back-propagation algorithm for training MLP's to operate on the SBEN, which we shall call *ensemble back-propagation* since the fine-tuning method propagates error derivatives down the network from many points of entry. Ensemble back-propagation is described in Algorithm 1.

With this second online training step, the *Bottom-Up-Top-Down* (*BUTD*) training algorithm for fully training an SBEN proceeds with a single bottom-up modification step followed by a single top-down joint fine-tuning step using the *ensemble back-propagation* procedure defined in Algorithm 1 for each training time step. A full top-down phase can consist of up to two calls to the *ensemble back-propagation* procedure. One is used to jointly modify the SBEN's parameters with respect to the sample taken from $\mathcal{D}_{train}$. A second one is potentially needed to tune parameters with respect to the sample drawn from $\mathcal{D}_{unlab}$. For the unlabeled sample, if the highest class probability assigned by the SBEN (using Equation 9) is greater than a pre-set threshold (i.e., $max[p_{ensemble}(y|\mathbf{u})] > \bar{p}$), a pseudo-label is created for that sample by converting the model's mean vector to a 1-hot encoding. The probability threshold $\bar{p}$ for the potential second call to the *ensemble back-propagation* routine allows us to incorporate a tunable form of pseudo-labeling (Lee, 2013) into the *Bottom-Up-Top-Down* learning algorithm.

The high-level view of the *BUTD* learning algorithm is depicted in Algorithm 2.

4 Experimental Results

We investigate the viability of our deep hybrid architecture for semi-supervised text categorization. Model performance was evaluated on the WebKB data-set [1] and a small-scale version of the 20NewsGroup data-set [2].

The original WebKB collection contains pages from a variety of universities (Cornell, Texas, Washington, and Wisconsin as well as miscellaneous pages from others). The 4-class classification problem we defined using this data-set was to determine if a web-page could be identified as one belonging to a Student, Faculty, Course, or a Project, yielding a subset of usable 4,199 samples. We applied simple pre-processing to the text, namely stop-word removal and stemming, chose to leverage only the k most frequently occurring terms (this varied across the two experiments), and binarized the document low-level representation (only 1 page vector was discarded due to presence of 0 terms). The 20NewsGroup data-set, on the other hand, contained 16242 total samples and was already pre-processed, containing 100 terms, binary-occurrence low-level representation, with

[1] The exact data-set we used can be found and downloaded at http://www.cs.cmu.edu/afs/cs/project/theo-20/www/data/

[2] The exact data-set we used can be found and downloaded at http://www.cs.nyu.edu/roweis/data.html.

tags for the four top-most highest level domains or meta-topics in the newsgroups array.

For both data-sets, we evaluated model generalization performance using a stratified 5-fold cross-validation (CV) scheme. For each possible train/test split, we automatically partitioned the training fold into separate labeled, unlabeled, and validation subsets using stratified random sampling without replacement. Generalization performance was evaluated by estimating classification error, average precision, average recall, and average F-Measure, where F-Measure was chosen to be the harmonic mean of precision and recall, $F1 = 2(\text{precision} \cdot \text{recall})/(\text{precision} + \text{recall})$.

4.1 Model Designs

We evaluated the BUTD version of our model, the *3-SBEN,BUTD*, as described in Algorithm 2. For simplicity, the number of latent variables at each level of the SBEN was held equal to the dimensionality of the data (i.e., a complete representation). We compared this model trained with *BUTD* against a version utilizing only the bottom-up phase (*3-SBEN,BU*) as in Ororbia et al. (2015). Both SBEN models contained 3 layers of latent variables.

We compared against an array of baseline classifiers. We used our implementation of an incremental version of Maximum Entropy, or *MaxEnt-ST* (which, as explained in Sarikaya et al., 2014, is equivalent to a softmax classifier). Furthermore, we used our implementation of the Pegasos algorithm (*SVM-ST*) (Shalev-Shwartz et al., 2011) which was extended to follow a proper multi-class scheme (Crammer and Singer, 2002). This is the online formulation of the SVM, trained via sub-gradient descent on the primal objective followed by a projection step (for simplicity, we opted to using a linear-kernel). Additionally, we implemented a semi-supervised Bernoulli Naive Bayes classifier (*NB-EM*) trained via Expectation-Maximization as in (Nigam et al., 1999). We also compared our model against the HRBM (Larochelle and Bengio, 2008) (effectively a single layer SBEN), which serves as a powerful, non-linear shallow classifier in of itself, as well as a 3-layer sparse deep Rectifier Network (Glorot et al., 2011a), or *Rect*, composed of leaky rectifier units.

All shallow classifiers (except *NB-EM* and the HRBM) were extended to the semi-supervised setting by leveraging a simple self-training scheme in order to learn from unlabeled data samples. The self-training scheme entailed using a classifier's estimate of $p(y|\mathbf{u})$ for an unlabeled sample and, if $max[p(y|\mathbf{u})] > \bar{p}$, we created a 1-hot proxy encoding using the *argmax* of model's predictor, where $\bar{p}$ is a threshold meta-parameter. Since we found this simple pseudo-labeling approach, similar in spirit to (Lee, 2013), to improve the results for all classifiers, and thus we report all results utilizing this scheme. [3] All classes of models (*SBEN*, *HRBM*, *Rect*, *SVM-ST*, *MaxEnt-ST*, *NB-ST*) were subject to the same model selection procedure described in the next section.

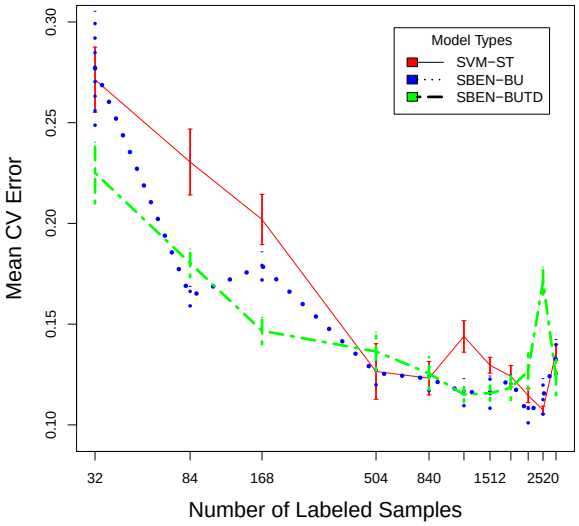

Figure 2: Mean CV generalization performance as a function of labeled sample subset size (using 200 features).

4.2 Model Selection

Model selection was conducted using a parallelized multi-setting scheme, where a configuration file for each model was specified, describing a set of hyper-parameter combinations to explore (this is akin to a course-grained grid search, where the points of model evaluation are set manually a priori). For the SBEN's, we varied the learning rate ($[0.01, 0.25]$) and β coefficient ($[0.1, 1.0]$) and

[3] All model implementations were computationally verified for correctness when applicable. Since most discriminative objectives followed a gradient descent optimization scheme and could be realized in an automatic differentiation framework, we checked gradient validity via finite difference approximation.

experimented with stochastic and mean-field versions of the models [4] (we found that mean-field did slightly better for this experiment and thus report the performance of this model in this paper). The HRBM's meta-parameters were tuned using a similar set-up to (Larochelle et al., 2012) with learning rate varied in ($[0.01, 0.25]$), α in ($[0.1, 0.5]$), and β in ($\{0.01, 0.1\}$). For the *SVM-ST* algorithm, we tuned its slack variable λ, searching in the interval $[0.0001, 0.5]$, for *MaxEnt-ST* its learning rate in $[0.0001, 0.1]$, and for $\bar{p}$ of all models (shallow and deep) that used pseudo-labeling we searched the interval $[0.1, 1.0]$. All models of all configurations were trained for a 10,000 iteration sweep incrementally on the data and the model state with lowest validation error for that particular run was used. The *SBEN*, *HRBM*, and *Rect* models were also set to use a momentum term of 0.9 (linearly increased from 0.1 in the first 1000 training iterations) and the *Rect* model made use of a small *L1* regularization penalty to encourage additional hidden sparsity. For a data-set like the 20NewsGroup, which contained a number of unlabeled samples greater than training iterations, we view our schema as simulating access to a data-stream, since all models had access to any given unlabeled example only once during a training run.

[4] Mean-field simply means no sampling steps were taken after computing probability vectors, or "means" in any stage of the computation.

4.3 Model Performance

We first conducted an experiment, using the WebKB data-set, exploring classification error as a function of labeled data subset cardinality (Figure 2). In this setup, we repeated the stratified cross-fold scheme for each possible labeled data subset size, comparing the performance of the SVM model against 3-SBEN,BU (blue dotted curve) and 3-SBEN,*BUTD* (green dash-dotted curve). We see that as the number of labeled examples increases (which entails greater human annotation effort) all models improve, nearly reaching 90% accuracy. However, while the performance difference between models becomes negligible as the training set becomes more supervised, as expected, it is in the less scarce regions of the plot we are interested in. We see that for small proportions, both variants of the SBEN outperform the SVM, and furthermore, the SBEN trained via full *BUTD* can reach lower error, especially for the most extreme scenario where only 8 labeled examples per class are available. We notice a bump in the performance of *BUTD* as nearly the whole training set becomes labeled and posit that since the *BUTD* involves additional pseudo-

Table 3: Top-most words that the SBEN (*BUTD*) model associates with the 4 NewsGroup meta-topics.

Meta-Topic	Associated Terms
*comp.**	$windows, graphics, card, driver, scsi, dos, files, display$
*rec.**	$players, hockey, season, nhl, team, league, baseball, games$
*sci.**	$orbit, shuttle, space, earth, mission, nasa, moon, doctor$
*talk.**	$jews, christian, religion, jesus, bible, war, israel, president$

labeling steps (as in the top-down phase), there is greater risk of reinforcing incorrect predictions in the pseudo-joint [5] tuning of layerwise expert parameters. For text collections where most of the data is labeled and unlabeled data is minimal, only a simple bottom-up pass is needed to learn a good hybrid model of the data.

The next set of experiments was conducted with only 1% of the training sets labeled. We observe (Tables 1 and 2) that our deep hybrid architecture trained via *BUTD* outperforms all other models with respect to all performance metrics. While the SBEN trained with simply an online bottom-up performs significantly better than the SVM model, we note a further reduction of error using our proposed *BUTD* training procedure. The additional top-down phase serves as a mechanism for unifying the layer-wise experts, where error signals for both labeled and pseudo-labeled examples increase agreement among all model layer experts.

For the 20NewsGroup data-set, we conducted a simple experiment to uncover some of the knowledge acquired by our model with respect to the target categorization task. We applied the mechanism from (Larochelle et al., 2012) to extract the variables that are most strongly associated with each of the clamped target variables in the lowest layer of a *BUTD*-trained SBEN. The top-scored terms associated with each class variable are shown in Table 3, using the 10 hidden nodes most highly triggered by the clamped class node, in a model trained on all of the 20NewsGroup data using a model configuration determined from CV results for the 20NewsGroup data-set reported in the paper. Since the SBEN is a composition of layer-wise experts each capable of classification, we note that this procedure could be applied to each level to uncover which unobserved variables are most strongly associated with each class target. We speculate that this could serve the basis for uncovering the model's underlying learnt hierarchy of the data and be potentially used for knowledge extraction, a subject for future work in analyzing black box neural models such as our own.

[5] We use the phrase "pseudo-joint" to differentiate a model that has all its parameters trained jointly from our own, where only the top-down phase of *BUTD* introduces any form of joint parameter modification.

5 Conclusions

We presented the *Bottom-Up-Top-Down* procedure for training the Stacked Boltzmann Experts Network, a hybrid architecture that balances both discriminative and generative learning goals, in the context of semi-supervised text categorization. It combines a greedy, layer-wise bottom-up approach with a top-down fine-tuning method for pseudo-joint modification of parameters.

Models were evaluated using two text corpora: WebKB and 20NewsGroup. We compared results against several baseline models and found that our hybrid architecture outperformed the others in all settings investigated. We found that the SBEN, especially when trained with the full *Bottom-Up-Top-Down* learning procedure could in some cases improve classification error by as much 39% over the Pegasos SVM, and nearly 17% over the HRBM, especially when data is in very limited supply. While we were able to demonstrate the viability of our hybrid model when using only simple surface statistics of text, future work shall include application of our models to more semantic-oriented representations, such as those leveraged in building log-linear language models (Mikolov et al., 2013).

Abstract

Sponsored search is at the center of a multibillion dollar market established by search technology. Accurate ad click prediction is a key component for this market to function since the pricing mechanism heavily relies on the estimation of click probabilities. Lexical features derived from the text of both the query and ads play a significant role, complementing features based on historical click information. The purpose of this paper is to explore the use of word embedding techniques to generate effective text features that can capture not only lexical similarity between query and ads but also the latent user intents. We identify several potential weaknesses of the plain application of conventional word embedding methodologies for ad click prediction. These observations motivated us to propose a set of novel joint word embedding methods by leveraging implicit click feedback. We verify the effectiveness of these new word embedding models by adding features derived from the new models to the click prediction system of a commercial search engine. Our evaluation results clearly demonstrate the effectiveness of the proposed methods. To the best of our knowledge this work is the first successful application of word embedding techniques for the task of click prediction in sponsored search.

1 Introduction

Sponsored search is a multibillion dollar market (Easley and Kleinberg, 2010) that makes most search engine revenue and is one of the most successful ways for advertisers to reach their intended audiences. When search engines deliver results to a user, sponsored advertisement impressions (ads) are shown alongside the organic search results (Figure 1). Typically the advertiser pays the search engine based on the *pay-per-click* model. In this model the advertiser pays only if the impression that accompanies the search results is clicked. The price is usually set by a *generalized second-price* (GSP) auction (Edelman et al., 2005) that encourages advertisers to bid truthfully. An advertiser wins if the expected revenue for this advertiser, which is the bid price times the expected click probability (also know as *click through rate*, or CTR), is ranked the highest. The price the advertiser pays, known as *cost-per-click* (CPC), is the bid price for the second ranked advertiser times the ratio of the expected CTR between the second and first ranked advertisers. From this discussion it should be clear that CTR plays a key role in deciding both the ranking and the pricing of the ads. Therefore it is very important to predict CTR accurately.

Figure 1: Sponsored ads when "pizza" was searched at Yahoo! (*www.yahoo.com*).

The state of the art search engine typically uses a machine learning model to predict CTR by exploiting various features that have been found useful in practice. These include historical click performance features such as historical click probability for the query, the ad, the user, and a combination of these; contextual features such as temporal and geographical information; and text-based features such as query keywords or ad title and description. Among these, historical click performance features often have the most predictive power for queries, ads and users that have registered many impressions. For queries, ads and users that have not registered many impressions, however, historical CTR may have too high a variance to be useful. Hillard *et al.* (2011) observed that the number of impressions and clicks recorded on query-ad pairs have a very long tail: only 61% of queries has greater than three clicks. They also reported a drastic drop in the accuracy of the click prediction model when fewer historical observations are available. Furthermore, fine-grained historical CTR information takes a huge amount of space, which

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 482–491,
Lisbon, Portugal, 17-21 September 2015.

makes it costly to maintain. On the other hand, text features are always readily available, and thus are particularly useful for those cases for which there is insufficient historical information.

Multiple researchers, for example (Richardson, 2007; Cheng and Cantú-Paz, 2010), reported the usage of text features including simple lexical similarity scores between the query and ads, word or phrase overlaps and the number of overlapping words and characters. Such features rely on the assumption that query-ad overlap is correlated with perceived relevance. While this is true to a certain extent, the use of simple lexical similarity cannot capture semantic information such as synonyms, entities of the same type and strong relationships between entities (e.g. CEO-company, brand-model, part-of). Recently a host of studies on word embedding have been conducted; all map words into a vector space such that semantically relevant words are placed near each other in the space (Mikolov et al., 2013a; Pennington et al., 2014; Baroni et al., 2014). The use of continuous word vectors has been shown to be helpful for a wide range of NLP tasks by better capturing both syntactic and semantic information than simple lexical features (Socher et al., 2012a).

No previous research on sponsored search has successfully used word embeddings to generate text features. In this paper, we explore the use of word embeddings for click prediction. However, it is clear that conventional word embeddings (which solely rely on word co-occurrence in a context window) can only offer limited discriminative power because queries and ad text are typically very short. In addition, conventional word embeddings cannot capture user intents, preferences and desires. Wang et al. (2013) showed that specific frequently occurring lexical patterns, e.g., *x% off*, *guaranteed return in x days* and *official site*, are effective in triggering users desires, and thus lead to significant differences in CTR. Conventional word embeddings cannot capture these phenomena since they do not incorporate the implicit feedback users provide through clicks and non-clicks. These observations naturally lead us to leverage click feedback to infuse users' intentions and desires into the vector space.

The simplest way to harness click feedback is to train conventional word embedding models on a corpus that only includes clicked impressions, where each "sentence" is constructed by mixing the query and ad text. Having trained a word embedding model, we simply take the average of word vectors of the query and ads respectively to obtain sentence (or paragraph) vectors, which in turn are used to compute the similarity scores between the query and ads. Our experiments show that this method does improve click prediction performance. However, this method has several potential weaknesses. First, the use of only clicked impressions ignores the large amount of negative signals contained in the non-clicked ad impressions. Second, the use of indirect signals (word co-occurrences) can be noisy or even harmful to our ultimate goal (accurate click prediction) when it is combined with direct signals (impressions with click feedback). Third, without explicit consideration about the averaging step in the training process of word embedding models, a simple averaging scheme across word vectors may be a suboptimal. We therefore propose several joint word embedding models; all of these aim to put query vectors close to relevant ad vectors by explicitly utilizing both positive and negative click feedback. We evaluate all these models against a large sponsored search data set from a commercial search engine, and demonstrate that our proposed models significantly improve click prediction performance.

The rest of this paper is organized as follows. In Section 2 we present a brief summary of related work. In Section 3 we give some background information on ad click prediction in sponsored search. In Section 4 we describe our methods. In Section 5 we discuss our experiments. We finish with some conclusions and future directions in Section 6.

2 Related Work

Text features for predicting click probability There have been many studies on the use of text features for click prediction. For example, Dembczynski et al. (2008) used a decision rule-based approach involving such lexical features as the number of words in ad title and description, the number of segments and length of the ad URL, and individual words and terms in ad title and description. Cheng et al. (2010) used a logistic regression model that used both historical click performance features and simple lexical features such as word or phrase overlap between query and ad title and description. Trofimov et al. (2012) used a variant of boosted decision trees with similar features. Richardson et al. (2007) specifically considered new ads (which lack historical click prediction data) and proposed to use the CTR for ad terms, the frequency of certain unigrams (e.g., dollar signs) and general English usage patterns, and simple lexical distance between the query and ads. In all this previous work, text features consisted only of surface-level text features. To the best of our knowledge, there is no previous work adopting semantic-level text features for the purpose of click prediction, in particular word embeddings to measure query-ad relevance. In a similar vein of research, Grbovic et al. (2015) adopted word embeddings to the task of query rewriting for a better match between queries and keywords that advertisers entered into an auction. Using the embeddings, semantically similar queries are mapped into vectors close in the embedding space, which allows expansion of a query via K-nearest neighbor search.

Word embeddings for language processing Recently many NLP systems have obtained improved performance with less human engineering by adopting distributed word representations (Socher et al., 2012a).

In particular, neural word embedding techniques are now known to be effective in capturing syntactic and semantic relationships, and more computationally efficient than many other competitors (Mikolov et al., 2013a; Pennington et al., 2014; Baroni et al., 2014). On top of word embeddings, a new stream of research on sentence and paragraph embeddings has also emerged to tackle higher level tasks such as sentiment analysis, machine translation and semantic relatedness tasks. *Recursive Neural Networks* (RNNs) have been used for syntactic parsing (Socher et al., 2012b; Socher et al., 2013; Socher et al., 2014; Irsoy and Cardie, 2014). *Long Short-Term Memory* (LSTM) networks have been applied to machine translation (Bahdanau et al., 2014; Sutskever et al., 2014) and semantic processing (Tai et al., 2015). Interestingly *Convolutional Neural Networks* (CNNs), widely used for image processing, have recently emerged as a strong class of models for NLP tasks (Kim, 2014; Blunsom et al., 2014). As apposed to the models above, *PhraseVector* (Le and Mikolov, 2014) takes a less structured but unsupervised approach by treating a piece of text as a token and performing word embedding-like training with an unlimited context window. None of this previous work exactly fits the click prediction task. Since queries and ads are much less structured than usual text, it is not attractive to use models with complex structures, such as RNNs, at the cost of speed and scalability. *PhraseVector* is less structured but it does not support compositionality, suffering from sparseness or requiring to train new vectors for each unseen query and ad. Interestingly, as reported in (Tai et al., 2015), a simple averaging scheme (*mean vector*) was found to be very competitive to more complex models for high level semantic tasks despite its simplicity. These observations lead us to one of our models that aims to improve the *mean vector* method by directly optimizing mean vectors instead of word vectors.

Joint embedding to bridge multiple views. Multiple studies have explored the task of bringing multiple views into the same vector space. For example, there is now a large body of research on joint modeling of text and image information (Frome et al., 2013; Karpathy and Fei-Fei, 2014; Socher et al., 2014). The multimodal embedding space helps find appropriate alignments between image regions and corresponding pieces of text description. Joint embedding has also been applied to question answering (Wang et al., 2014) and semantic understanding (Yang et al., 2014). In contrast to the tasks above, there is no natural component-wise correspondence between queries and ads; instead the relationship is more implicit and pragmatic. Because of this, our methods rely on global rather than component-level signals for model training.

3 Baseline Click Prediction Model

We first present a high-level description of sponsored search. The process consists of several stages. First, given a user query, a list of candidate ads are retrieved, either by exactly matching query terms to the bid terms of the advertiser, or by first using query term expansion to obtain a longer list of matched ads. Some candidate ads may be filtered out based on metrics such as ad quality. Then, a *click prediction model* scores the candidate ads to estimate how likely it is that each will be clicked. This *click probability* serves a crucial role both in the user experience and in the revenue for the search engine. The ads with the highest click probabilities are placed in the search results page. The price-per-click for each ad shown is determined based on the click probabilities and the GSP auction.

Our baseline click prediction model is formulated as a supervised learning problem. Specifically we use *Logistic Regression* (LR) since LR is well suited for probability estimation. Given a variety of features, the probability of a click is expressed as:

$$p(c|q,a,u) = \frac{1}{1+exp\{\sum_i w_i f_i(q,a,u)\}}, \quad (1)$$

where $c \in \{1,0\}$ is the label (1: click or 0: non-click), $f_i(q,a,u)$ is the ith feature derived for query-ad-user triple (q,a,u) and w_i is the associated weight. The model is trained using a stochastic gradient descent algorithm on a per impression basis with l_1 regularization to avoid overfitting.

An accurate LR model relies greatly on the effectiveness of its features. Our baseline model is furnished with a rich set of features that are typically used in commercial search engines. The first feature type is based on the historical CTR of user, query, ad triples (if there is enough historical information on this). We use two groups of features of this type: COEC based features and user factor features. The second feature type is based on query and ad text.

Due to the significant decrease of CTR depending on the ad position, it has become common practice to use position-normalized CTR (a.k.a. *Clicks Over Expected Clicks*):

$$COEC = \frac{\sum_p c_p}{\sum_p i_p * CTR_p}, \quad (2)$$

where the numerator is the total number of clicks received by the configuration of interest; the denominator is the *expected clicks* (ECs) that an average ad would receive after i_p times impressions at position p, and CTR_p is the average CTR at position p, calculated over all queries, ads and users. We use user-independent features derived from COEC statistics for specific query-ad pairs. However, many impressions are needed for these statistics to be reliable and therefore data for specific query-ad pairs can be sparse and noisy (only around 70% of queries and about 50% of query-URL, query-bid term pairs have historical CTR). To alleviate this problem, additional COEC statistics over aggregations of queries or ads are also used. The exact description of these aggregations is beyond the

scope of this paper, but briefly we exploit the categorization of the ads in ad groups, campaigns, and accounts defined by advertisers.

Since it is well known that personalization features are crucial to obtain accurate click prediction models (Cheng and Cantú-Paz, 2010), we also use features that measure user factors relating to CTR. The user click feedback features capture the inclination of individual users to click on ads in general. The user-query click feedback features indicate the propensity of users to click for certain queries or groups of queries. Finally user-ad features dictate the user preferences on certain ads or advertisers. However the data sparseness problem becomes even more serious when it comes to user-specific features (we use a threshold of 100 for statistical confidence). For example, only about 5% of user-URL pairs and 1% of user, query, URL triples have historical CTR information. Therefore a set of segment-level features can be extracted as back-off features where users, queries and ads are clustered into groups, and group level historical CTRs are collected.

Our second major feature type involves the lexical similarity between query and ad text. These text features assume that users are more likely to click on ads that seem to be relevant to the query, and that perceived relevance is correlated with the degree of query-ad overlap. These features include the number of overlapping words and characters in query-ad URL, query-ad title, and query-ad description, and the number of words and characters in the query. The discrimination power of simple lexical features is relatively limited because query and ad text are typically very short.

Finally, we use other contextual features that are helpful in predicting the click probabilities.; for example, time of day, day of week, and geographic information. To model interactions among features, some features are selected by domain knowledge to be conjoined. All together, our baseline model utilize a comprehensive set of historical CTR, lexical, and contextual features (over a hundred features in total). The fact that this baseline model is highly optimized makes the subsequent performance improvement from our proposed algorithm meaningful. This baseline model is used in production in part of a major search platform.

4 Joint Embedding for Click Prediction

We now describe several methods that jointly embed words in both the query and the ads into the same vector space. In our experiments, we incorporate these methods as features in our click prediction model. We start by defining the notation used in this section. A sponsored search dataset $\mathcal{D}$ is a set of tuples for each ad impression (q, t, d, y) where $q \equiv \{q_j\}$ is a multiword query string, $t \equiv \{t_k\}$, $d \equiv \{d_l\}$ are multiword ad title and description strings, and y is a binary indicator for whether the ad is clicked. We have two choices in defining the vocabulary $\mathcal{V}$ from which words are drawn: we can use a unified vocabulary for both query and ads or define a separate vocabulary for each – $\mathcal{V} \equiv \mathcal{V}_q \oplus \mathcal{V}_a$. In our initial experiments the unified vocabulary constantly yielded better performances, thus we always use the unified vocabulary here. We use bold letters $\mathbf{q}_j, \mathbf{t}_k, \mathbf{d}_l$ to denote the corresponding embedding representations of $\{q_j, t_k, d_l\}$. Finally we use W to represent the vocabulary matrix; in W each column is a word vector.

4.1 Exploiting word2vec embedding

Typically word embeddings are learned from a given text corpus through implicit supervision of predicting the current word given a window of its surrounding text or predicting each word in the window of the current word. The former approach is known as *continuous bag-of-words* (CBOW) and the latter *Skip-gram*. For simplicity's sake we use negative-sampling for training word embedding models (Mikolov et al., 2013b). More formally we define the binary conditional probability for a pair of words (v, w): [1]

$$p(\mathbf{v}, \mathbf{w}) = \frac{1}{1 + \exp(-\mathbf{v}^T \mathbf{w})}, \tag{3}$$

The CBOW algorithm learns word embeddings by minimizing the following *logloss* of each impression i with regard to W:

$$\begin{aligned} CB_i(W) = &- \log p(\mathbf{w}_i, \boldsymbol{\mu}_C) \\ &- \sum_{v \in N(w_i)} \log\left(1 - p(\mathbf{v}, \boldsymbol{\mu}_C)\right), \end{aligned} \tag{4}$$

where the context C of a word w_i comes from a window of size k around the word in a sentence of n words $w_1,\ldots,w_n$: $C = w_{i-k},\ldots,w_{i-1},w_{i+1},\ldots,w_{i+k}$. $\boldsymbol{\mu}_C$ is the averaged context vector of w_i; $\boldsymbol{\mu}_C = \frac{1}{|C|}\sum_{v \in C} \mathbf{v}$. $N(w_i)$ is the set of negative examples which is drawn according to the unigram distribution of the corpus raised to the 3/4th power. Similarly to (Mikolov et al., 2013b), we adopt a dynamic window size – for each word the actual window size is sampled uniformly from $1, \ldots, k$.

Similarly the Skip-gram algorithm minimizes the *logloss* of each impression i with regard to W:

$$\begin{aligned} SK_i(W) = &- \sum_{v \in C} \log p(\mathbf{w}_i, \mathbf{v}) \\ &- \sum_{v \in N(w_i)} \log\left(1 - p(\mathbf{w}_i, \mathbf{v})\right). \end{aligned} \tag{5}$$

In our first word embedding model that incorporates click feedback, we construct a corpus by taking only clicked impressions from $\mathcal{D}$ and then mixing (q, t, d) of each impression into a sentence. Then we simply train CBOW and Skip-gram models on the corpus.

[1] We use only a single vector for a word unlike (Mikolov et al., 2013b) where two vectors ("input" and "output") for a word are used. This halves the required space to store vectors without performance loss.

4.2 Joint word embedding using click feedback

Although the CBOW and Skip-gram models trained on a specially constructed corpus can capture signals from both click feedback and word co-occurrence, they have a couple of drawbacks. First, by ingesting only clicked impressions we "waste" the large amount of negative signals contained in the non-clicked impressions. Second, the incorporation of indirect signals such as word co-occurrences can be rather harmful for achieving accurate click prediction as these are very noisy compared to direct signals such as click feedback.

For our second word embedding model that incorporates click feedback, we define a joint word embedding model that minimizes the following *weighted logloss*:

$$JW_i(W) = \eta(y_i)\Big\{l(y_i, q_i, t_i) + l(y_i, q_i, d_i)\Big\}, \quad (6)$$

where the component loss function $l(\cdot,\cdot,\cdot)$ is defined as follows:

$$l(y,a,b) = \sum_{k}^{|a|}\sum_{l}^{|b|} - y \log p(\mathbf{a}_k, \mathbf{b}_l) - (1-y)\log\left(1 - p(\mathbf{a}_k, \mathbf{b}_l)\right). \quad (7)$$

Here $\eta(y_i)$ is a function that returns a small weight η only to negative examples:

$$\eta(y_i) = \begin{cases} \eta, & \text{if } y_i = 0, \\ 1, & \text{otherwise.} \end{cases} \quad (8)$$

The fact that the user did not click on an ad does not necessarily mean that the ad is not what the user wanted; it often means that the ad is just less favored than the clicked ads (Rendle et al., 2009). Since the scope of this work is restricted to estimating click probability on a per-impression basis, we adopt a weighting scheme rather than optimizing rank-based loss over a set of related impressions.

4.3 Joint mean vector optimization

The joint word embedding models defined in the previous sections do not define how to aggregate a variable length sequence of word vectors into a sentence (or paragraph) vector to facilitate the computation of sentence-level similarity scores. One approach to this aggregation task is *mean vector*: simply average the word-level embeddings across the sentence or paragraph. As noted by (Tai et al., 2015), this approach is a strong competitor to more complex models such as RNNs or LSTMs despite its simple composition method. However, this method may generate suboptimal sentence vectors. With *weight logloss*, we aim to optimize sentence vectors instead of individual word vectors:

$$JM_i(W) = \eta(y_i)\Big\{\bar{l}(y_i, q_i, t_i) + \bar{l}(y_i, q_i, d_i)\Big\}, \quad (9)$$

where the component loss function $\bar{l}(\cdot,\cdot,\cdot)$ is defined as follows:

$$\bar{l}(y,a,b) = - y \log p(\boldsymbol{\mu}_a, \boldsymbol{\mu}_b) - (1-y)\log\left(1 - p(\boldsymbol{\mu}_a, \boldsymbol{\mu}_b)\right), \quad (10)$$

where $\boldsymbol{\mu}_s$ returns the average vector for the multiword string s, i.e. $\boldsymbol{\mu}_s = \frac{1}{|s|}\sum_k^{|s|} \mathbf{s}_k$.

5 Experiments

Data The data used in our experiments were collected from a random bucket of the Yahoo! sponsored search traffic logs for a period of 4 weeks in October 2014. In the data there are approximately 65 million unique users, 150 million unique queries and 12 million unique ads. There are approximately 985 million ad impression events in total. We split the data into 3 partitions with respect to time: the first 14 days' data are used for training word embedding models, the next 7 days' data for training click prediction models, and the last 7 days' data for testing. Table 1 presents more detailed statistics for the data.

Models We are interested in evaluating the usefulness of different word embedding models as features for click prediction, and already have a very good baseline system for this task. Consequently, in all experiments below, we used the same personalized historical CTRs, contextual and lexical features as the baseline system described in Section 3. We tested models with the following additional features derived from word embeddings:

1. cosine similarity between the mean vectors of the query and ad title
2. cosine similarity between the mean vectors of the query and ad description
3. sum of 1 and 2
4. sigmoid function value for the dot product of the mean vectors of the query and ad title
5. sigmoid function value for the dot product of the query and ad description
6. sum of 4 and 5

All these continuous features are quantized into 50 bins. We compared five different word embedding algorithms:

1. Skip-gram trained on Wikipedia (SK-WIKI)
2. Skip-gram trained on clicked impressions (SK-CI), see Section 4.1
3. CBOW trained on clicked impressions (CB-CI), see Section 4.1
4. Joint individual word vector embedding (JIWV), see Section 4.2

	Embedding	Train	Test	Total
Number of impressions	489M	252M	244M	985M
Number of unique queries	82M	46M	45M	150M
Number of unique ads	8M	6M	6M	12M
Number of unique users	40M	25M	25M	65M
Number of unique words in query	6757K	6039K	5774K	16028K
Number of unique words in ad title	3371K	2586K	2557K	4598K
Number of unique words in ad description	1993K	1583K	1589K	2628K
Number of words in query	1600M	830M	800M	3230M
Number of words in ad title	3260M	1690M	1635M	6585M
Number of words in ad description	4311M	2206M	2131M	8650M
Average number of words in query per impression	3.275	3.284	3.289	3.281
Average number of words in ad title per impression	6.667	6.708	6.706	6.687
Average number of words in ad description per impression	8.818	8.759	8.741	8.784

Table 1: Data description

5. Joint mean vector embedding (JMV), see Section 4.3

We used the skip-gram mode of word2vec [2] with a window size of 5 and negative sampling to train the SK-WIKI model. For all other models we used in-house implementation which employs *AdagradRDA* (Duchi et al., 2011) to minimize the loss functions introduced in Section 4. The dimension of a word vector is set to 100 for all algorithms[3]. We removed a set of prefixed stop-words and all words occurring fewer than 100 times; the resulting vocabulary comprised 126K unique words. To process our web-scale data, we implemented a multithread program where each thread randomly traverses over a partition of the data $\mathcal{D}$ to compute gradients and update the matrix W stored in a shared memory. For computational efficiency, the hogwild lock-free approach (Recht et al., 2011) is used. We set η in Eq. 8 and Eq. 9 to 0.2 through grid search based on two-fold cross-validation. This small value indeed verifies the idea of weak negative feedback for unclicked impressions.

In order to circumvent the severe influence of ad position on the click prediction model, only the impressions that are placed at the top position were used for training the click prediction model. Note that CTR at other positions can be derived from that of the ad at the top position through scaling. Dembczynski et al. (2008) showed that CTR can be decomposed as a product of the probability of an ad getting clicked given its being seen and the probability of an ad being seen at a particular position.

Results We ordered query-ad pairs by the predicted score to compute *AucLoss* (i.e. 1 - AUC where AUC is the area under the *Receiver Operating Characteristic* (ROC) curve). The ROC AUC is known to have a correlation with the quality of ranking by the predicted score (Fawcett, 2006); thus is one of the most important metrics for click prediction (McMahan et al., 2013).

	AucLoss Reduction (%)
Baseline + SK-WIKI	0.530
Baseline + SK-CI	0.595
Baseline + CB-CI	0.656
Baseline + JIWV	2.276
Baseline + JMV	**4.114**

Table 2: Comparative evaluation results in AucLoss reduction from the baseline system

Our experimental results (Table 2) show that the use of features derived from our proposed word embedding models significantly reduce AucLoss by up to 4.1%. For commercial search engines which have a very strong baseline *AucLoss*, a reduction of 1% can be considered large (McMahan et al., 2013). Moreover, as expected, the more issues (as identified in Section 4) an algorithm addresses, the better performance it achieves. From the comparison between the SK-WIKI model and the rest, we can recognize the importance of word embedding models specialized to domain text and supervision signals. Also the difference between the CB-CI (SK-CI) model and the JIWV model indicates the noisiness of indirect signals such as word co-occurrence compared to direct signals like click feedback. Finally the gap between the JIWV and JWV models highlights the significance of considering compositionality in the word embedding training process.

Eyeballing the most similar words to several queries in the vector space is often helpful for getting some sense about how different methods influence the resulting vector spaces. Table 3 lists the top 20 most similar words to the query "metal watch." The top words for the SK-WIKI model are not semantically interesting in terms of capturing the intent or desires. This clearly shows the limitation of word embedding methods that only rely on indirect signals (i.e. word co-occurrences) from a generic text corpus (e.g. Wikipedia) for sponsored search click prediction. Noticeably the methods

Table 4: Top 20 most similar words to "princess costumes"

that incorporate click feedback find more words related to products, services or websites instead of just conceptuatlly related words. Given that real products or services can be regarded as the best possible surrogates to user intents and desires, this demonstrates the effectiveness of our methods. This tendency gets stronger as a method takes into account both positive and negative click feedback.

Another very interesting observation comes from the fact that none of the methods except JMV successfully captures the composite meaning of "metal watch"; they tend to either find related words separately for each query word (e.g. "watch" is strongly associated to the sense of watching something like movie or other types of video) or find totally unrelated words (particularly SK-WIKI). This demonstrates that it is crucial to address compositionality in the very process of learning word vectors.

Table 4 shows the top 20 most similar words to the query "princess costumes." In this example we can spot another surprising result. The JMV model pushes a lot of price related expressions to the top[4]. This may imply that many parents search for lower cost costumes, clearly showing a clear psychological desire in the financial dimension. This observation confirms the findings in (Wang et al., 2013) about the significant role of certain ad expressions in triggering users' psychological desires. We also note that the CB-CI model returns a lot of misspells for "costume(s)", which would not be possible with simple lexical features of the baseline system. A close look at this example generally confirms the observations we made for the previous ex-

ample. Finally Table 5 shows top the 20 most similar words for the query "game for kids." Once again we found the same analysis holds for this case.

6 Conclusions

In this paper we explored the use of word embedding techniques to overcome the shortcomings of traditional lexical features for ad click prediction in sponsored search. We identified several potential weaknesses of the plain application of conventional word embedding methodologies: the lack of the right machinery to harness both positive and negative click feedback, the limited utility of pure word co-occurrence signals, and no consideration of vector composition in the word embedding training process. We proposed a set of new implicit feedback-based joint word embedding methods to address those issues. We evaluated the new word embedding methods in the context of a very good baseline click prediction system, on a large scale data set collected from Yahoo! search engine logs. Our experimental results clearly demonstrate the effectiveness of the proposed methods. We also presented several examples for qualitative analysis to advance our understanding on how each algorithm really contributes to the improved performance. To the best of our knowledge this work is the first successful application of word embedding techniques for the sponsored search task.

There are multiple interesting research directions for future work. One of these directions is to extend the vocabulary by identifying significant phrases (as well as words) before training word vectors. Hillard et al. (2011) employed *Conditional Random Fields* to divide queries with multiple words into segments and collected historical CTR on the segment level. We also like to investigate more structured embedding methods such as RNNs (probably for ad descriptions). In case the computational cost of such methods are too high to be practical for sponsored search, we can employ them only for a small fraction of ads filtered by faster methods.

It may be possible to deal with the implicit negative feedback of unclicked ad impressions in a more principled way by adopting ranking-based loss functions. However, this is only possible with the extra cost of identifying and aggregating related ads into a single transaction.

Though not directly related to NLP, yet another promising direction is to jointly embed not only text data but also a variety of user activities (e.g., organic search results, mobile app usages, other daily activities) all together in the same vector space. Since many of the different sources contain their own unique information, we might be able to obtain a much better understanding about the user state and intent through this rich joint embedding space. Joint embedding with rich information can also help us to perform automatic clustering of users, eventually leading to powerful smoothing methods for personalized historical CTR statistics.

Abstract

The prevalence of temporal references across all types of natural language utterances makes temporal analysis a key issue in Natural Language Processing. This work adresses three research questions: 1/is temporal expression recognition specific to a particular domain? 2/if so, can we characterize domain specificity? and 3/how can subdomain specificity be integrated in a single tool for unified temporal expression extraction? Herein, we assess temporal expression recognition from documents written in French covering three domains. We present a new corpus of clinical narratives annotated for temporal expressions, and also use existing corpora in the newswire and historical domains. We show that temporal expressions can be extracted with high performance across domains (best F-measure 0.96 obtained with a CRF model on clinical narratives). We argue that domain adaptation for the extraction of temporal expressions can be done with limited efforts and should cover pre-processing as well as temporal specific tasks.

1 Introduction

References to phenomena occurring in the world and their temporal characterization can be found in natural language utterances across domains, genres and languages. Temporal analysis is a key issue in natural language processing that has been receiving increasing attention in recent years. Many efforts in this direction focused on newswire text in English. The focus on this language and domain was in part guided by the availability of the TimeBank corpus (Pustejovsky et al., 2003) used in evaluation campaigns such as TempEval (Verhagen et al., 2007). More recent efforts have extended the initial work on English and addressed other languages such as Chinese (Li et al., 2014), French (Moriceau and Tannier, 2014), Arabic, Italian, Spanish, and Vietnamese (Strötgen et al., 2014a). A study of three domain corpora in English in addition to the newswire domain (SMS, historical narratives and clinical trial abstracts) yielded interesting insight to extend the normalized representation of temporal expressions (Strötgen and Gertz, 2012). This work was then applied to cover historical narratives in an additional seven languages. One key finding was that domain specificity could differ between languages (Strötgen et al., 2014b). This prompts the need to study temporal analysis across domains in a variety of languages in order to adequately characterize each domain and language pairs.

The clinical domain has been addressed during the 2012 i2b2 challenge (Sun et al., 2013b), with a task on temporal relation extraction from clinical narratives. This task used a corpus of clinical notes in English annotated with temporal information (Sun et al., 2013a) based on ISO-TimeML (Pustejovsky et al., 2010). It prompted further work in this domain in English (Jindal and Roth, 2013) and Swedish (Velupillai, 2014), including the release of detailed guidelines for creating temporal annotations of clinical text and a discussion of the clinical domain specificity related to temporal aspects (Styler IV et al., 2014). Finally, clinical TempEval 2015 brought the temporal information extraction tasks of past TempEval campaigns to the clinical domain (Bethard et al., 2015).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 492–498,
Lisbon, Portugal, 17-21 September 2015.

In this paper, we continue to explore temporal expression identification across domains, with a focus on French narratives. We introduce a new corpus of French clinical narratives annotated with normalized time expressions. We characterize temporal expression recognition in three domains and discuss how the development of an automated temporal expression identification tool may be impacted.

2 Temporal Expression Extraction and Normalization

Rule-based methods were shown to be very efficient for the extraction and normalization of time expressions from news narratives in several languages[1]. In the latest SemEval campaign (UzZaman et al., 2013), the rule-based HeidelTime (Strötgen and Gertz, 2010) out performed machine-learning and hybrid counterparts by a large margin. However, statistical systems obtained promising results with respect to temporal entity extraction.

Based on these results, we chose to use the state-of-the-art rule-based system HeidelTime as well as an in-house statistical tool relying on the Wapiti (Lavergne et al., 2010) implementation of Conditional Random Fields (CRFs) (Lafferty et al., 2001).

Existing HeidelTime settings were used to customize it for the analysis of news and historical narratives in French. In addition, we developed a set of 14 rules to provide additional customization for the analysis of clinical narratives in French.

The CRF model was developed using part of the clinical corpus as a training set, with domain independant surface and lexical features for the text tokens:

- The original token from the text (word form);
- Surface features: capitalization of the token (all in upper/lower case, combination of both), presence of digit (YES, NO) and punctuation mark in the token (PUNCT, NO_PUNCT), temporal type of token according to HeidelTime;
- Lexical features: *n*-grams , number of words, number of digits, number of consecutive repeats. Token frequency was computed based on the entire training corpus.

For clinical text analysis, we experimented with standard tokenization (provided by TreeTagger (Schmid, 1994)) and a custom tokenization where punctuation marks are always considered as token separators, even in dates such as "10-02-2010" or "10.04.10".[2]

3 French Corpora with Temporal Annotations

For this study, we used two available French corpora with TIMEX3 annotations: the French TimeBank corpus (FTB called *news* in this paper) (Bittar et al., 2011) which covers the news domain and the AncientTimes corpus (ATC, called *historical* in this paper) (Strötgen et al., 2014b) which covers the historical domain.

To cover a third domain, we developed a corpus using a set of clinical notes where personal identifying information (PII) had been marked and replaced by surrogates (Grouin and Névéol, 2014). This included marking some temporal expressions such as dates, which were replaced by surrogate dates obtained by substracting a fixed number of days to the original dates. Manual review ensured that there were no format or other errors in the reintroduced surrogate dates. For compatibility with the sources that were already available, including our study corpora and HeidelTime, we chose the TIMEX3 standard for creating temporal annotations.

Three annotators (the authors of this paper) contributed towards the creation of gold-standard annotations for time expressions in the corpus. The annotation of time expressions was carried out in two phases: first, the time expressions and their values were annotated, and second the time expressions were normalized. At the beginning of the first phase, two initial samples of twenty documents were selected for all three annotators to work on. These documents were pre-annotated using the French version of HeidelTime and dates marked as PII. The annotators' task was then to revise the pre-annotations independently. This phase of the annotation process contributed to refining annotation guidelines and creating additional rules to improve on the pre-annotation. Subsequently, the rest of the corpus was divided between annotators, so that each document was annotated independently by two annotators. Final

[1] Normalization is the process of turning any reference to a date into an absolute, formated date.

[2] This tokenization script, adapted from TreeTagger, is available upon request.

gold standard annotations were created by adjudicating any disagreements during meetings between the pair of contributing annotators. Two annotators contributed to the second phase of annotations (normalization). A small sample of 20 documents was annotated independently by the two annotators. Inter-annotator agreement was then computed and found to be sufficiently high to allow for the rest of the corpus to be distributed between annotators.

The phasing of annotations allowed having all corpus documents reviewed several times, so that time expressions that might have been missed during the first phase could be identified and added to the gold standard in the second phase.

To visualize and create annotations, we used the BRAT Rapid Annotation Tool (Stenetorp et al., 2012). Inter-annotator agreement was computed in terms of F-measure, using the companion brateval tool (Verspoor et al., 2013), which we extended to compute inter-annotator agreement on normalized entities.

Table 1 shows the distribution of time expressions according to types in the three corpora used in our study. It suggests that domain specificity is reflected by the types of temporal expressions found in each of the corpora. While *Dates* are prevalent across domains, the news corpus stands out with a high proportion of *Times*, the clinical corpus with a high proportion of *Set* and the historical corpus with almost none of either type. Additional statistics on the clinical corpus are provided in section 4.

	FTB (news)		**ATC (hist.)**		**Clinical**	
	#	%	#	%	#	%

4 Results

4.1 French Clinical Corpus with Temporal Annotations

Figure 1 shows an excerpt of the training corpus annotated with temporal expressions. The blue boxes show the normalized value associated with each temporal expression. Due to the confidential nature of the corpus, we are currenlty not able to release it.

Table 2 presents detailed statistics on the clinical corpus. Inter-annotator agreement was .91 F-measure for temporal entity annotation (averaged over the three annotator pairs on the training corpus) and .99 F-measure for temporal normalization (computed on a sample of 20 documents from the training corpus).

TIME	19	32	51

Table 2: Description of the gold standard clinical corpus

4.2 Extraction of Temporal Expressions across Domains

Table 3 presents the results of temporal expression extraction in French narratives across the three domains in our study. The model configurations used are either HeidelTime (H) or statistical (S), adapted to one of the three domains. For HeidelTime models, the adaptation consisted in selecting a domain specific set of rules. We also report results by Strötgen et al. (2014b) showing the difference between HeidelTime 1.5 and the improvements obtained by their new rules for historical French texts. For statistical models, the adaptation consisted in training the model on a corpus of the relevant domain. We studied the effect of corpus size by training a model using a portion of the clinical training data equivalent in size to that of FTB (marked *clin-* in Table 3). However, the ATC corpus was too small to train any usable models (results not shown). Experiments with our adapted, in-house tokenization tool are marked with a + in the models.

The results of the evaluation are reported in terms of precision, recall and F1-measure. We evaluate the extraction of temporal expressions associated to the correct TIMEX3 attribute type (DATE, DURATION, TIME, SET), with the 'strict' measure (only exact match is correct) and the 'relaxed' measures (overlaps are allowed).

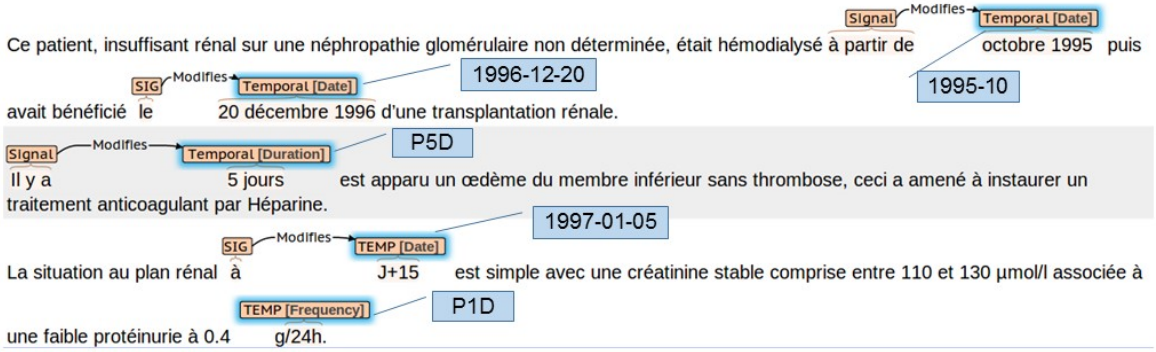

Figure 1: Excerpt from a sample document annotated with temporal expressions; dates and personal health information were replaced by plausible surrogates.

5 Discussion

Overall, our results show that while good performance can be achieved for the extraction of temporal expression on many specific domains, the task of automatically extracting temporal expressions is not solved across the board. Methods that are successfully developed for one specific domain do not carry very well over to other domains without any adaptation work. In our experiments, rule-based methods seem to fare somewhat better in terms of generalizability, but statistical methods can be better optimized for a particular domain, given enough training data. Similar insight resulted from a recent study of negation detection in the clinical domain (Wu et al., 2014). One additional issue highlighted in the negation study was that the definition of the entities that could fall under the scope of negation varied from domain to domain in the available negation corpora. This pitfall is avoided with the temporal task thanks to the use of the TimeML standard. The challenges of extracting temporal expressions across domains that we identified in this study on French correlate well with those described by (Strötgen and Gertz, 2012) on English. The performance of statistical models trained on in-domain data was significantly higher compared to out-domain data: *S-news+* yielded the highest performance on the News corpus (strict F-measure 0.74), and *S-clin+* yielded the highest performance on the Clinical corpus (strict F-measure 0.94).

Adaptation burden. The amount of effort to adapt to new domains was overall limited for the rule-based system: only a few rules needed to be added to the news-oriented HeidelTime (2 for historical, 14 for clinical) to reach comparable performance on other domains. The adaptation effort for the statistical model relies mostly on the availability of annotated corpora in the relevant domains. A competitive CRF model can be trained without using domain specific features. However, we find that adaptation effort can cover pre-processing: for clinical documents, using domain-specific tokenization yielded improved temporal expression extraction for both rule-based and statistical systems. This is in line with previous findings that pre-processing is essential for making experiments reproducible, and variations in pre-processing methods can result in significant difference in performance for different NLP tasks (Fokkens et al., 2013).

Finally, we can note that the difference between HeidelTime and CRFs is much bigger on the strict measure than on the relaxed measure, which may suggest that small variations could be better handled with more covering rules.

Impact of pre-processing, training corpus type and size. Tokenization had a real impact on the performance of statistical models. Using a baseline tokenization method can reduce the performance by several points in F-measure (strict F-measure of 0.68 for *S-news* vs. 0.74 for *S-news+* on the News corpus, strict F-measure of 0.88 for *S-clin* vs. 0.94 for *S-clin+* on the Clinical corpus – see Table 3). Corpus size had a comparably smaller impact. The training dataset used for *S-clin* is 10 times larger than that used for *S-clin-*, and yet it provides an improvement of about 4 points in F-measure for in-domain application. Conversely, for out-domain application, using the larger model is detrimental. Using in-domain training data (or more generally, training

Table 3: Evaluation of temporal expression extraction in French narratives across three domains. Values from models with a '*' come from Strötgen et al. (2014b). Models with a '+' used custom tokenization. Models with a '-' used the reduced training set.

data that is as close as possible to in-domain, such as News vs. Clinical for Historical) of any reasonable size yields better performance, even if still under the rule-based approach.

Limitations of this study. Size imbalance in the corpora used in our study was a limitation; the clinical corpus is much larger than the other two and the Historical corpus is really small, which limits the applicabiblity of statistical methods. In our work with the clinical corpus, more time was spent on annotating data and implementing statistical models vs. developping rules. Arguably, devoting additional efforts to rule development might improve the rule-based performance.

6 Conclusion and Future Work

This study contributes to a better understanding of temporal expression recognition accross domains. We found that an important part of domain specificity lies in the distribution of the types of temporal expressions accross domains. We also noticed that specific mentions of temporal expressions can be categorized as different types from one domain to another (e.g. *le soir* was generally considered a set in our clinical corpus – as in *every night* – and a time in the news corpus – as in *in the evening*). The results of our domain adaptation experiments suggest that the performance of temporal expression recognition is improved when domain specificity is taken into account by using in-domain training data or domain-specific rules.

In terms of adaptation strategy, our experiments show that the addition of a limited number of rules to the default (news-oriented) HeidelTime leads to matching the expected performance of HeidelTime on a new domain corpus. Furthermore, we show that more substantial efforts spent on annotating data can result in training data that will support a statistical model that outperforms simple rule adaptation. We can hypothesize that devoting equivalent efforts towards rule development may also result in increased performance. We believe that some amount of corpus annotation is necessary to gain adequate corpus knowledge to craft such rules.

Overall, we show that domain adaptation for the extraction of temporal expressions can be done with limited efforts, provided that an adequate corpus is available. We found that the tokenization method used in pre-processing was instrumental for improving statistical model performance across domains.

In future work, we will address the task of temporal expression normalization.

Semi-Supervised Bootstrapping of Relationship Extractors with Distributional Semantics

Abstract

Semi-supervised bootstrapping techniques for relationship extraction from text iteratively expand a set of initial seed relationships while limiting the semantic drift. We research bootstrapping for relationship extraction using word embeddings to find similar relationships. Experimental results show that relying on word embeddings achieves a better performance on the task of extracting four types of relationships from a collection of newswire documents when compared with a baseline using TF-IDF to find similar relationships.

1 Introduction

Relationship Extraction (RE) transforms unstructured text into relational triples, each representing a relationship between two named-entities. A bootstrapping system for RE starts with a collection of documents and a few seed instances. The system scans the document collection, collecting occurrence contexts for the seed instances. Then, based on these contexts, the system generates extraction patterns. The documents are scanned again using the patterns to match new relationship instances. These newly extracted instances are then added to the seed set, and the process is repeated until a certain stop criteria is met.

The objective of bootstrapping is thus to expand the seed set with new relationship instances, while limiting the semantic drift, i.e. the progressive deviation of the semantics for the extracted relationships from the semantics of the seed relationships.

State-of-the-art approaches rely on word vector representations with TF-IDF weights (Salton and Buckley, 1988). However expanding the seed set by relying on TF-IDF representations to find similar instances has limitations, since the similarity between any two relationship instance vectors of TF-IDF weights is only positive when the instances share at least one term. For instance, the phrases *was founded by* and *is the co-founder of* do not have any common words, but they have the same semantics. Stemming techniques can aid in these cases, but only for variations of the same root word (Porter, 1980).

We propose to address this challenge with an approach based on word embeddings (Mikolov et al., 2013a). By relying on word embeddings, the similarity of two phrases can be captured even if no common words exist. The word embeddings for *co-founder* and *founded* should be similar, since these words tend to occur in the same contexts. Word embeddings can nonetheless also introduce semantic drift. When using word embeddings, phrases like *studied history at* can, for instance, have a high similarity with phrases like *history professor at*. In our approach, we control the semantic drift by ranking the extracted relationship instances, and by scoring the generated extraction patterns.

We implemented these ideas in BREDS, a bootstrapping system for RE based on word embeddings. BREDS was evaluated with a collection of 1.2 million sentences from news articles. The experimental results show that our method outperforms a baseline bootstrapping system based on the ideas of Agichtein and Gravano (2000) which relies on TF-IDF representations.

2 Bootstrapping Relationship Extractors

Brin (1999) developed DIPRE, the first system to apply bootstrapping for RE, which represents the occurrences of seeds as three contexts of strings: words before the first entity (BEF), words between the two entities (BET), and words after the second entity (AFT). DIPRE generates extraction patterns by grouping contexts based on string matching, and controls semantic drift by limiting the number of instances a pattern can extract.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 499–504,
Lisbon, Portugal, 17-21 September 2015.

Agichtein and Gravano (2000) developed Snowball, which is inspired on DIPRE's method of collecting three contexts for each occurrence, but computing a TF-IDF representation for each context. The seed contexts are clustered with a single-pass algorithm based on the cosine similarity between contexts using the three vector representations:

$$\begin{aligned}\text{Sim}(S_n, S_j) = \alpha \cdot \cos(BEF_i, BEF_j) \\ + \beta \cdot \cos(BET_i, BET_j) \\ + \gamma \cdot \cos(AFT_i, AFT_j)\end{aligned} \quad (1)$$

In the formula, the parameters α, β and γ weight each vector. An extraction pattern is represented by the centroid of the vectors that form a cluster. The patterns are used to scan the text again, and for each segment of text where any pair of entities with the same semantic types as the seeds co-occur, three vectors are generated. If the similarity from the context vectors towards an extraction pattern is greater than a threshold τ_{sim}, the instance is extracted.

Snowball scores the patterns and ranks the extracted instances to control the semantic drift. A pattern is scored based on the instances that it extracted, which can be included in three sets: P, N, and U. If an extracted instance contains an entity e_1, which is part of a seed, and if the associated entity e_2 in the instance is the same as in in the seed, then the extraction is considered positive (included in set P). If the relationship contradicts a relationship in the seed set (i.e., e_2 does not match), then the extraction is considered negative (included in a set N). If the relationship is not part of the seed set, the extraction is considered unknown (included in a set U). A score is assigned to each pattern p according to:

$$\text{Conf}_\rho(p) = \frac{|P|}{|P| + W_{ngt} \cdot |N| + W_{unk} \cdot |U|} \quad (2)$$

W_{ngt} and W_{unk} are weights associated to the negative and unknown extractions, respectively. The confidence of an instance is calculated based on the similarity scores towards the patterns that extracted it, weighted by the pattern's confidence:

$$\text{Conf}_\iota(i) = 1 - \prod_{j=0}^{|\xi|} (1 - \text{Conf}_\rho(\xi_j) \times \text{Sim}(C_i, \xi_j)) \quad (3)$$

where, ξ is the set of patterns that extracted i, and C_i is the textual context where i occurred. Instances with a confidence above a threshold τ_t are used as seeds in the next iteration.

3 Bootstrapping Relationship Extractors with Word Embeddings

BREDS follows the architecture of Snowball, having the same processing phases: find seed matches, generating extraction patterns, finding relationship instances, and detecting semantic drift. It differs, however, in that it attempts to find similar relationships using word embeddings, instead of relying on TF-IDF representations.

3.1 Find Seed Matches

BREDS scans the document collection and, if both entities of a seed instance co-occur in a text segment within a sentence, then that segment is considered and BREDS extracts the three textual contexts as in Snowball: BEF, BET, and AFT.

In the BET context, BREDS tries to identify a relational pattern based on a shallow heuristic originally proposed in ReVerb (Fader et al., 2011). The pattern limits a relation context to a verb (e.g., *invented*), a verb followed by a preposition (e.g., *located in*), or a verb followed by nouns, adjectives, or adverbs ending in a preposition (e.g., *has atomic weight of*). These patterns will nonetheless only consider verb mediated relationships. If no verbs exist between two entities, BREDS extracts all the words between the two entities, to build the representations for the BET context.

Each context is transformed into a single vector by a simple compositional function that starts by removing stop-words and adjectives and then sums the word embedding vectors of each individual word. Representing small phrases by summing each individual word's embedding results in good representations for the semantics in small phrases (Mikolov et al., 2013b).

A relationship instance i is represented by three embedding vectors: V_{BEF}, V_{BET}, and V_{AFT}. Considering the sentence:

The tech company Soundcloud *is based in* Berlin, *capital of Germany.*

BREDS generates the relationship instance with:

$$V_{BEF} = \text{E}(\text{“tech”}) + \text{E}(\text{“company”})$$
$$V_{BET} = \text{E}(\text{“is”}) + \text{E}(\text{“based”})$$
$$V_{AFT} = \text{E}(\text{“capital”})$$

where, E(x) is the word embedding for word x.

BREDS also tries to identify the passive voice using part-of-speech (PoS) tags, which can help to detect the correct order of the entities in a relational triple. BREDS identifies the presence of the passive voice by considering any form of the verb *to be*, followed by a verb in the past tense or the past participle, and ending in the word *by*.

For instance, the seed <Google, owns, DoubleClick> states that the organisation Google owns the organisation DoubleClick. Using this seed, if BREDS detects a pattern like *agreed to be acquired by* it will swap the order of the entities when producing a relational triple, outputting the triple <ORG$_2$, *owns*, ORG$_1$>, instead of the triple <ORG$_1$, *owns*, ORG$_2$>.

3.2 Extraction Patterns Generation

As Snowball, BREDS generates extraction patterns by applying a single-pass clustering algorithm to the relationship instances gathered in the previous step. Each resulting cluster contains a set of relationship instances, represented by their three context vectors.

Algorithm 1 describes the clustering approach taken by BREDS, which takes as input a list of relationship instances and assigns the first instance to a new empty cluster. Next, it iterates through the list of instances, computing the similarity between an instance i_n and every cluster Cl_j. The instance i_n is assigned to the first cluster whose similarity is higher or equal to a threshold τ_{sim}. If all the clusters have a similarity lower than a threshold τ_{sim}, a new cluster C_m is created, containing the instance i_n.

The similarity function Sim(i_n, Cl_j), between an instance i_n and a cluster Cl_j, returns the maximum of the similarities between an instance i_n and any of the instances in a cluster Cl_j, if the majority of the similarity scores is higher than a threshold τ_{sim}. A value of zero is returned otherwise. The similarity between two instances is computed according to Formula (1). As a result, clustering in Algorithm 1 differs from the original Snowball method, which instead computes similarities towards cluster centroids.

3.3 Find Relationship Instances

After the generation of extraction patterns, BREDS finds relationship instances with Algorithm 2. It scans the documents once again, collecting all segments of text containing entity pairs whose semantic types are the same as those in the seed instances. For each segment, an instance i is generated as described in Section 3.1, and the similarity towards all previously generated extraction patterns (i.e., clusters) is computed. If the similarity between i and a pattern Cl_j is equal or above τ_{sim}, then i is considered a candidate instance, and the confidence score of the pattern is updated, according to Formula (2). The pattern which has the highest similarity ($pattern_{best}$) is associated with i, along with the corresponding similarity score (sim_{best}). This information is kept in a history of $Candidates$. Note that the histories of $Candidates$ and $Patterns$ are kept through all the bootstrap iterations, and new patterns or instances can be added, or the scores of existing patterns or instances can change.

Algorithm 1: Single-Pass Clustering.

Input: $Instances = \{i_1, i_2, i_3, ..., i_n\}$
Output: $Patterns = \{\}$
$Cl_1 = \{i_1\}$
$Patterns = \{Cl_1\}$
for $i_n \in Instances$ **do**
  for $Cl_j \in Patterns$ **do**
    if $Sim(i_n, Cl_j) >= \tau_{sim}$ **then**
      $Cl_j = Cl_j \cup \{i_n\}$
    else
      $Cl_m = \{i_n\}$
      $Patterns = Patterns \cup \{Cl_m\}$

Algorithm 2: Find Relationship Instances.

Input: $Sentences = \{s_1, s_2, s_3, ..., s_n\}$
Input: $Patterns = \{Cl_1, Cl_2, ..., Cl_n\}$
Output: $Candidates$
for $s_i \in Sentences$ **do**
  $i = create\_instance(s_i)$
  $sim_{best} = 0$
  $p_{best} = None$
  for $Cl_i \in Patterns$ **do**
    $sim = \text{Sim}(i, Cl_i)$
    if $sim >= \tau_{sim}$ **then**
      $\text{Conf}_\rho(C_i)$
      if $sim >= sim_{best}$ **then**
        $sim_{best} = sim$
        $P_{best} = Cl_i$
  $Candidates[i].patterns[p_{best}] = sim_{best}$

3.4 Semantic Drift Detection

As Snowball, BREDS ranks the candidate instances at the end of each iteration, based on the scores computed with Formula (3). Instances with a score equal or above the threshold τ_t are added to the seed set, for use in the next iteration of the bootstrapping algorithm.

4 Evaluation

In our evaluation we used a set of 5.5 million news articles from AFP and APW (Parker et al., 2011).

Our pre-processing pipeline is based on the models provided by the NLTK toolkit (Bird et al., 2009): sentence segmentation[1], tokenisation[2], PoS-tagging[3] and named-entity recognition (NER). The NER module in NLTK is a wrapper over the Stanford NER toolkit (Finkel et al., 2005).

We performed weak entity-linking by matching entity names in sentences with FreebaseEasy (Bast et al., 2014). FreebaseEasy is a processed version of Freebase (Bollacker et al., 2008), which contains a unique meaningful name for every entity, together with canonical binary relations. For our experiments, we selected only the sentences containing at least two entities linked to FreebaseEasy, which corresponded to 1.2 million sentences.

With the full articles set, we computed word embeddings with the skip-gram model[4] using the *word2vec*[5] implementation from Mikolov et. al. (2013a). The TF-IDF representations used by Snowball were calculated over the same articles set. We adopted a previously proposed framework for the evaluation of large-scale RE systems by Bronzi et al. (2012), to estimate precision and recall, using FreebaseEasy as the knowledge base.

We considered entity pairs no further away than 6 tokens, and a window of 2 tokens for the BEF and AFT contexts, ignoring the remaining of the sentence. We discarded the clusters with only one relationship instances, and ran a maximum of 4 bootstrapping iterations. The W_{unk} and W_{ngt} parameters were set to 0.1 and 2, respectively, based on the results reported by Yu et al. (2003).

We compared BREDS against Snowball in four relationship types, shown in Table 1. For each relationship type we considered several bootstrapping configurations by combining different values for the τ_{sim} and τ_t thresholds, all within the interval [0.5,1.0].

Table 1: Relationship types and used seeds.

We bootstrapped each relationship with two context weighting configurations in Formula (1):

- Conf_1: $\alpha = 0.0$, $\beta = 1.0$, $\gamma = 0.0$
- Conf_2: $\alpha = 0.2$, $\beta = 0.6$, $\gamma = 0.2$

where Conf_1 only considers the BET context and Conf_2 uses the three contexts, while giving more importance to the BET context.

Table 2 shows, for each relationship type, the best F_1 score and the corresponding precision and recall, for all combinations of τ_{sim} and τ_t values, and considering only extracted relationship instances with confidence scores equal or above 0.5. Table 2a shows the results for the BREDS system, while Table 2b shows the results for Snowball (ReVerb), a modified Snowball in which a relational pattern based on ReVerb is used to select the words for the BET context. Finally, Table 2c shows the results for Snowball, implemented as described in the original paper.

Overall, BREDS achieves better F_1 scores than both versions of Snowball. The F_1 score of BREDS is higher, mainly as a consequence of much higher recall scores, which we believe to be due to the relaxed semantic matching caused by using the word embeddings. For some relationship types, the recall more than doubles when using word embeddings instead of TF-IDF. For the *acquired* relationship, when considering Conf_1, the precision of BREDS drops compared with the other versions of Snowball, but without affecting the F_1 score, since the higher recall compensates for the small loss in precision.

Regarding the context weighting configurations, Conf_2 produces a lower recall when compared to Conf_1. This might be caused by the

sparsity of both BEF and AFT, which contain many different words that do not contribute to capture the relationship between the two entities. Although, sometimes, the phrase or word that indicates a relationship occurs on the BEF or AFT contexts, it is more often the case that these phrases or words occur in the BET context.

The performance results of Snowball (Classic) and Snowball (ReVerb) suggest that selecting words based on a relational pattern to represent the BET context, instead of using all the words, works better for TF-IDF representations.

The results also show that word embeddings can generate more extraction patterns. For instance, for the *founder-of* relationship, BREDS learns patterns based on words such as *founder, co-founder, co-founders* or *founded*, while Snowball only learns patterns that have the word *founder*, like *CEO and founder* or *founder and chairman*.

The implementations of BREDS and Snowball, as described in this paper, are available on-line[6].

5 Conclusions and Future Work

This paper reports on a novel bootstrapping system for relation extraction based on word embeddings. In our experiments, bootstrapped RE achieved better results when using word embeddings to find similar relationships than with similarities between TF-IDF weighted vectors.

We have identified two main sources of errors: NER problems and incorrect relational patterns extraction due to the use of a shallow heuristic that only captures local relationships.

In future work, more robust entity-linking approaches, as proposed by Hoffart et al. (2011), could be included in our pre-processing pipeline. This could alleviate NER errors and enable experimentation with other relationship types.

Gabbard et al. (2011) have shown that coreference resolution can increase bootstrapping RE performance, and the method of Durrett and Klein (2014) could also be included in our preprocessing pipeline.

Finally, we could explore richer compositional functions, combining word embeddings with syntactic dependencies (SD) (Yu et al., 2014). The shortest path between two entities in an SD tree supports the extraction of local and long-distance relationships (Bunescu and Mooney, 2005).

Extraction and generalisation of variables from scientific publications

Erwin Marsi, Pinar Öztürk
Department of Computer and Information Science

{emarsi,pinar}@idi.ntnu.no

Abstract

Scientific theories and models in Earth science typically involve changing *variables* and their complex interactions, including correlations, causal relations and chains of positive/negative feedback loops. Variables tend to be complex rather than atomic entities and expressed as noun phrases containing multiple modifiers, e.g. *oxygen depletion in the upper 500 m of the ocean or timing* and *magnitude of surface temperature evolution in the Southern Hemisphere in deglacial proxy records*. Text mining from Earth science literature is therefore significantly different from biomedical text mining and requires different approaches and methods. Our approach aims at automatically locating and extracting variables and their direction of variation: *increasing*, *decreasing* or just *changing*. Variables are initially extracted by matching tree patterns onto the syntax trees of the source texts. Next, variables are generalised in order to enhance their similarity, facilitating hierarchical search and inference. This generalisation is accomplished by progressive pruning of syntax trees using a set of tree transformation operations. Text mining results are presented as a browsable variable hierarchy which allows users to inspect all mentions of a particular variable type in the text as well as any generalisations or specialisations. The approach is demonstrated on a corpus of 10k abstracts of Nature publications in the field of Marine science. We discuss experiences with this early prototype and outline a number of possible improvements and directions for future research.

1 Introduction

Text mining of scientific literature originates from efforts to cope with the ever growing flood of publications in biomedicine (Swanson, 1986; Swanson, 1988; Swanson and Smalheiser, 1997; Hearst, 1999; Ananiadou et al., 2006; Zweigenbaum et al., 2007; Cohen and Hersh, 2005; Krallinger et al., 2008; Rodriguez-Esteban, 2009; Zweigenbaum and Demner-Fushman, 2009; Ananiadou et al., 2010; Simpson and Demner-Fushman, 2012; Ananiadou et al., 2014). Consequently the resulting approaches, methods, tools and applications – as well as data, corpora and evaluation tasks – are rooted in the paradigm of biomedical research and its conceptual framework. Typical source text consists of abstracts from PubMed or full-text articles from PubMed Central. Standard tasks include recognition, normalisation and mapping of biological entities (e.g., genes, proteins, drugs, symptoms and diseases), extraction of biological relations (e.g., protein-protein interaction, disease-gene associations or drug-drug interaction) or bio-event extraction (e.g., regulation or inhibition events and their participants). There are extensive ontologies like the Gene Ontology (Consortium, 2001), annotated corpora like the GENIA (Kim et al., 2003) and BioInfer (Pyysalo et al., 2007) corpora and dedicated shared tasks including BioCreative (Hirschman et al., 2005) and BioNLP (Pyysalo et al., 2012). In short, there is a whole infrastructure supporting biomedical text mining (Cohen and Hunter, 2008).

Text mining is now spreading out to other scientific disciplines, notably in the humanities and social sciences (O'Connor et al., 2011), holding the promise for knowledge discovery from large text collections. Our own research targets text mining in the field of Earth science, more specifically in Oceanography or Marine science, with a focus on climate change. As text mining efforts in this

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 505–511,
Lisbon, Portugal, 17-21 September 2015.

area are extremely rare (Ekstrom and Lau, 2008; Vossen et al., 2010; Zhang et al., 2013; Marsi et al., 2014; Aamot, 2014), it is not surprising that a corresponding infrastructure is mostly lacking. In addition, however, we found that due to significant differences between the conceptual frameworks of biomedicine and marine science, simply "porting" the biomedical text mining infrastructure to another domain will not suffice.

One major difference is that the biomedical entities of interest are relatively well defined – genes, proteins, organisms, species, drugs, diseases, etc. – and typically expressed as proper nouns. In contrast, defining the entities of interest in marine science turns out to be much harder. Not only does it seem to be more open-ended in nature, the entities themselves tend to be complex and expressed as noun phrases containing multiple modifiers, giving rise to examples like *oxygen depletion in the upper 500 m of the ocean* or *timing and magnitude of surface temperature evolution in the Southern Hemisphere in deglacial proxy records*.

Given the difficulties with entities, we propose to concentrate first on text mining of events, leaving entities underspecified for the time being. Theories and models in marine science are characterised by changing variables and their complex interactions, including correlations, causal relations and chains of positive/negative feedback loops. Many marine scientists are interested in finding evidence – or counter-evidence – in the literature for events of change and their relations. Here we present ongoing work to automatically locate and extract *variables* and their direction of variation: *increasing*, *decreasing* or just *changing*. Examples are given in Table 1.

Since many of these changing variables are long and complex expressions, their frequency of occurrence tends to be low, making the discovery of relations among different variables harder. As a partial solution to this problem, we propose progressive pruning of syntax trees using a set of tree transformation operations. For example, generalising *oxygen depletion in the upper 500 m of the ocean* to *oxygen depletion in the ocean* and subsequently to the much more frequent *oxygen depletion*. Text mining results are then presented as a browsable variable hierarchy which allows users to inspect all mentions of a particular variable type in the text as well as any generalisations or specialisations.

2 Variable extraction

Our text material consists of 10k abstracts from journals published by Nature Publishing Group. Search terms obtained from domain experts were used to query Nature's OpenSearch API[1] for publications in a limited range of relevant journals, after 1997, retrieving records including title and abstract. The top-10k abstracts matching most search terms were selected for further processing with CoreNLP (Manning et al., 2014), including tokenisation, sentence splitting, POS tagging, lemmatisation and parsing. Lemmatised parse trees were obtained by substituting terminals with their lemmas. The resulting new corpus contains 9,586 article abstracts, 59,787 sentences and approximately 4M tokens.

Methods for information extraction broadly rely on either knowledge-based pattern matching or supervised machine learning (Sarawagi, 2008). Although ML approaches are currently dominant in IE research, rule-based systems have several advantages, including: (a) the rules are interpretable and thus suitable for rapid development and domain transfer; and (b) humans and machines can contribute to the same model (Valenzuela-Escárcega et al., 2015). In our case, patterns offered more flexibility in exploring the domain, whereas the manual annotation required for ML demands more commitment to a precise definition of entities, relations and events, which we found hard to achieve at this stage. Tree pattern matching is applied to lemmatised syntax trees using the Tregex engine (Levy and Andrew, 2006), which supports a compact language for writing regular expressions over trees; see Table 1 for examples of patterns and matching phrases. For instance, the pattern for a decreasing variable is defined as a noun phrase (NP) that is immediately dominated (>) by a verb phrase (VP), which in turn is headed by (<<#) the lemma *reduce*. Similarly, the pattern for increase describes an NP dominated by a prepositional phrase (PP) that is headed by the preposition *in* or *of*; in addition, this PP must be preceded by an NP sister node (`$,`) headed by the lemma *increase*.

Patterns were generated by instantiating a small set of hand-written pattern templates, drawing from manually created lists of verbs and nouns ex-

[1] `http://www.nature.com/developers/documentation/api-references/opensearch-api`

Table 1: Examples of tree patterns and matching variables

Direction:	**Tree pattern:**	**Matched variable in sentence:**
Change	`NP <- (/NN/=d1 < variability $ /NN/) !$. PP`	Thus **the annual, Milankovitch and continuum temperature variability** together represent the response to deterministic insolation forcing.
Increase	`NP > (PP <<# (in|of) $, (NP <<# increase))`	The record reveals a linear increase in **annual temperature between 1958 and 2010** by 2.4 +/-1.2 degreesC ...
Decrease	`NP > (VP <<# reduce )`	Some researchers have observed that abundant natural gas substituting for coal could reduce **carbon dioxide (CO2) emissions**.

pressing change, increase or decrease. The patterns cover expression as a main verb (*X increases, something increases X)*, attributive use of verbs (*increasing temperature, temperature is increasing*), head of NP (*a temperature increase*) or NP with PP modifier (*increase in temperature*). The total number of patterns is 320: 90 for change, 122 for increase, 108 for decrease (see supplements for a full list). The total number of matched variables in the corpus is 21,817: 9,352 for change, 7,400 for increase and 5,065 for decrease.

Some variables do not exactly correspond to a node, i.e., not every variable is a valid syntactic phrase. For instance, the pattern for Change in Table 1 matches the NP *the annual, Milankovitch and continuum temperature variability*, whereas the actual variable is *the annual, Milankovitch and continuum temperature*. This is corrected in a post-processing step that deletes the *variability* node from the extracted subtree and substring. For this purpose, the pattern contains an assignment of the name d1 to the node directly dominating the lemma *variability* (`/NN/=d1 < variability`)), allowing a corresponding tree operation to delete this node, which is implemented using the Tsurgeon counterpart of Tregex.

3 Variable generalisation

Since many of the extracted variables are long and complex expressions, their frequency is low. The most frequent variables are generic terms (*climate* 1207, *temperature* 156, *global climate* 73), but over 66% is unique. This evidently impedes the discovery of relations among variables. As a partial solution to this problem, variables are generalised by progressive pruning of syntax trees using a set of tree transformation operations.

Figure 1 shows an example of generalisation by iterative tree pruning. The first transformation STRIP INIT DT strips the initial determiner from the NP. Next, COORD 3.1 deletes everything but the first conjunct from a coordinated structure of three NPs, resulting in *annual temperature* , which is finally reduced to just *temperature* by stripping the premodifier (STRIP PREMOD 1). An analogous procedure is applied to the other two conjuncts of the coordinated structure.

Tree transformations are implemented using Tsurgeon (Levy and Andrew, 2006): Tregex patterns match the syntactic structures of interest, whereas an associated Tsurgeon operation deletes selected nodes (see supplements for details). The transformations are ordered in four groups. The first group handles coordination of two to four conjuncts (cf. Figure 1) – at the phrase level or the lexical level – as well as cases of ellipsis (e.g. *hailstorm frequency and intensity* into *hailstorm frequency* and *hailstorm intensity*). The second group strips bracketed material in parenthetical and list structures. The third group deletes non-restrictive relative clauses and other non-restrictive modifiers preceded by a comma. The final group progressively strips premodifiers (mainly adjectives) from left to right and postmodifiers (PPs, relative clauses) from right to left . Since different transformation may arrive at the same generalisation (e.g. *temperature* in Figure 1), duplicates are filtered out. After filtering, 150,716 variables remained, which is 4.86 times the number of originally extracted variables.

As mentioned, the point of generalisation is to find relations among variables. In Table 1, for example, both *the annual, Milankovitch and continuum temperature variability* and *annual temperature between 1958 and 2010* are generalised to *annual temperature*. However, many generalised variables are unique and thus serve no purpose in relating variables. Retaining only original variables and generalised variables with at least two mentions yields a total of 17,613 variable types.

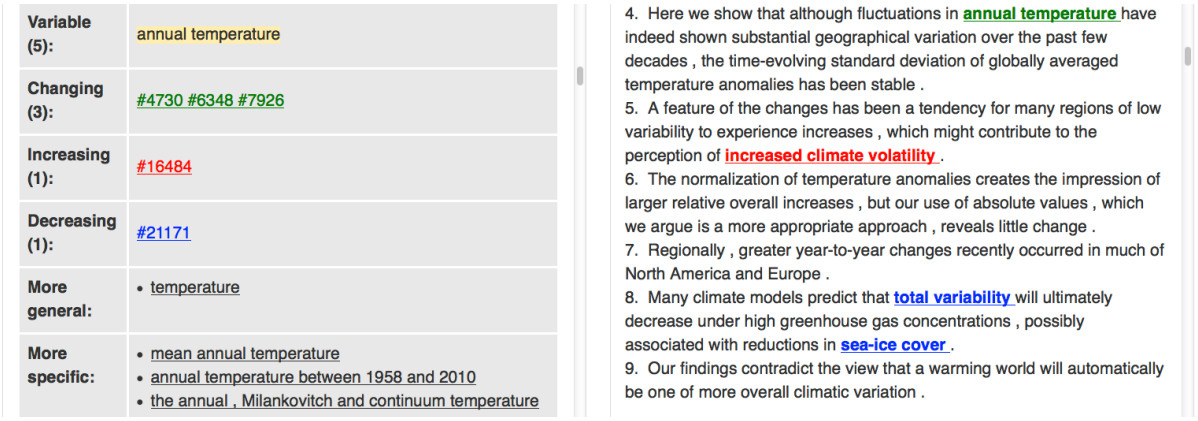

Figure 2: Partial screenshot of user interface showing variable type hierarchy (left) and linked variable mentions in text (right) where colour encodes change (green), increase (red) or decrease (blue)

the annual , Milankovitch and continuum temperature
  STRIP INIT DT → annual , Milankovitch and continuum temperature
    COORD 3.1 → annual temperature
      STRIP PREMOD 1 → temperature
    COORDI 3.2 → Milankovitch temperature
      STRIP PREMOD 1 → temperature
    COORD 3.3 → continuum temperature
      STRIP PREMOD 1 → temperature

Figure 1: Example of generalisation by iterative tree pruning

4 User interface

The output of the text mining step can be regarded as a directed graph where the nodes are variable *types* and the edges point from a more specific variable to a more general variable (as a result of a particular tree transformation). Each variable type is also linked to a set of tokens, i.e. variable mentions in the text which are either changing, increasing or decreasing. Figure 2 shows how this information is presented to the user in a browser (see supplements for full version). The left panel lists the variable types, ordered from most general to most specific and, secondary, on decreasing token frequency. Links point to more specific/general variables types, as well as to changing/increasing/decreasing variable mentions in the text. The right panel shows the source text, where colour encodes changing (green), increasing (red) or decreasing (blue) variable mentions, which are linked to their most specific variable type. This setup allows users to quickly explore variables, for example, finding abstracts containing a variable of interest and from there to related variables.

5 Discussion

We have argued that the paradigm established in biomedical text mining does not transfer directly to other scientific domains like Earth science. A new approach was proposed for extracting variables and their direction of variation (increasing, decreasing or just changing), focusing on events rather than entities. A generic system based on syntactic pattern matching and tree transformations was described for extraction and subsequent generalisation of variable events. Text mining results are presented in an innovative way as a browsable hierarchy ranging from most general to most specific variables, with links to their textual instances. In addition, a first text corpus in marine science was produced, including automatically annotated change events. Our corpus as well as the extracted variables are publicly available[2]. We think our approach to extraction is generalisable to other domains where the entities of interest are common nouns or complex noun phrases rather the proper nouns, e.g. in nanotechnology & nanoscience (Kostoff et al., 2007).

To the best of our knowledge, there are currently no other systems for text mining in Earth science which we can compare our results with, nor are there any benchmark data sets for our task. Most related is (Marsi et al., 2014), but their definition of variables is more restricted and their pilot corpus is too small for evaluation purposes. Reporting on our ongoing work now, future work will include an evaluation by asking domain exports to judge the correctness of extracted variables as well

[2] https://dl.dropboxusercontent.com/u/2370516/emnlp15_corpus.zip

as their generalisations in the given context.

Preliminary observations indicate that most problems originate from syntactic parsing errors, in particular well-known ambiguities in coordination and PP-attachment. As a result, patterns may either fail to match or match unintentionally, yielding incomplete or incoherent variables. Since many sentences are long, complex and domain-specific, it comes as no surprise that the parser often fails to correctly resolve well-known ambiguities in coordination and PP-attachment. However, with pattern matching on strings and/or POS tags instead of syntax trees, determining boundaries of variables would be problematic. False positives also occur because of different semantics of the same pattern, e.g. *change in western Europe* is unlikely to mean literally that the European continent is changing, neither does *changes in less than a few thousand years* imply that past years are changing.

At the same time, certain false negatives are beyond the power of pattern matching. For instance, variation may be entailed rather than explicitly stated: *ocean acidification* entails increasing acidity of ocean water and *Arctic warming* entails increasing temperature in the Arctic region. This is closely related to textual entailment (Androutsopoulos and Malakasiotis, 2010; Dagan et al., 2006), requiring inference in combination with domain knowledge. A related matter is negation (*no increase in global temperature*), which can even be expressed in non-trivial ways (*temperature remained constant*) (Morante and Daelemans, 2009). Variables were also found to be recursive or embedded, expressing "a change of a change". For example, *reduce subseasonal temperature variance* implies both a change in temperature as well as a decrease of this temperature change. The current visualisation falls short in these cases, as HTML browsers cannot render a link in a link.

Generalisation by tree pruning appears to work quite well as long as the parse is correct. However, pruning by itself is insufficient and should be supplemented with other methods. For instance, linking named entities like species, chemicals or locations to unique concepts in appropriate ontologies/taxonomies would support generalisations such as *iron* is a *metal* or a *diatom* is a *plankton*. Generalisation also bears a strong resemblance to other text-to-text generation tasks such as paraphrasing (Androutsopoulos and Malakasiotis, 2010), sentence compression (Jing, 2000) and sentence simplification (Shardlow, 2014). Given suitable training data, ML approaches may therefore be applied, e.g. (Knight and Marcu, 2002; Cohn and Lapata, 2009).

The most general variables are probably too generic to be of much help to a user, e.g. *concentration*, *rate*, *level*, etc. Likewise, *climate* is by far the most frequent changing variable due to the frequently occurring collocation *climate change*. In addition, variables often contain references to previously mentioned entities – anaphoric *it* being the ultimate example of this – suggesting a need for co-reference resolution (Miwa et al., 2012).

Yet another future direction is to structurally model variables as opposed to a possibly over-simplified generalisation. Similar to nominal SRL, one can define relevant arguments including frequency (e.g. annual), temporal scope (between 1958 and 2010), location, etc. The most generic variables mentioned earlier in fact provide a good basis for such modelling.

Extraction and generalisation of variables provides a basis for building systems supporting knowledge discovery. One approach is mining associations between variables frequently co-occurring in the same sentence or abstract (Jenssen et al., 2001; Hashimoto et al., 2012)) More precise results can be expected by extracting causal relations between change events (Chang and Choi, 2005; Blanco et al., 2008; Raja et al., 2013). Pairs of change events – causally or otherwise associated – obtained from different publications can be chained together, possibly in combination with domain knowledge, in order to generate new hypotheses, as pioneered in the work on literature-based knowledge discovery (Swanson, 1986; Swanson, 1988; Swanson and Smalheiser, 1997). Automatic extraction and generalisation of variables from scientific publications thus paves the way for future research on text mining in Earth science.

Named entity recognition with document-specific KB tag gazetteers

Abstract

We consider a novel setting for Named Entity Recognition (NER) where we have access to *document-specific knowledge base tags*. These tags consist of a canonical name from a knowledge base (KB) and entity type, but are not aligned to the text. We explore how to use KB tags to create document-specific gazetteers at inference time to improve NER. We find that this kind of supervision helps recognise organisations more than standard wide-coverage gazetteers. Moreover, augmenting document-specific gazetteers with KB information lets users specify fewer tags for the same performance, reducing cost.

1 Introduction

NER is the task of identifying names in text and assigning them a type (e.g. person, location, organisation, miscellaneous). State-of-the-art supervised approaches use models that incorporate a name's form, its linguistic context and its compatibility with known names. These models rely on large manually-annotated corpora, specifying name spans and types. These are vital for training models, but it is laborious and expensive to label every occurrence of a name in a document.

We consider a non-standard setting where, for each document, we have metadata in the form of *document-specific knowledge base tags*. A KB tag is a canonical name, that is an identifier in a KB (e.g. a Wikipedia title), and an entity type. While these tags have a correct type assigned for at least one context, they are not aligned to phrases in the text, and may not share the same form as all of their mentions (e.g. we may see the tag `United Nations` for the mention UN). We also assume that each tag matches at least one mention in the document, but do not specify where in the document the mention is.

There are many sources of KB tags, such as manual entity indexing for news stories or data extracted from personalised knowledge stores. For example, the New York Times Annotated Corpus (Sandhaus, 2008) contains more than 1.5M articles "manually tagged by library scientists with tags drawn from a normalized indexing vocabulary of people, organizations, locations and topic descriptors". Names and types are also present in large quantities of financial news stories from Bloomberg (Bradesko et al., 2015), in the form of linked names of companies and people.

Document-level tags may be quicker for annotators to apply than the usual method of marking spans in text, and are thus a cheap form of supervision. It is hard to make strong comparisons to the standard NER task, as KB tags can be considered partial, unaligned gold-standard supervision – so fully supervised models *should* perform better, the question is by how much and why.

This paper explores effective ways to use KB tags for improving NER. We use the CoNLL 2003 English NER dataset (Tjong Kim Sang and De Meulder, 2003), annotated with Wikipedia links (Hoffart et al., 2011). This allows us to simulate a set of KB tags for each document in the TRAIN, TESTA and TESTB splits of the dataset. We use a document's KB tags to build a document-specific gazetteers which we use in addition to standard features for a conditional random field (CRF) model (Lafferty et al., 2001).

We compare against wide-coverage gazetteers, which score 89.85% F-score on TESTA. Assuming access to all possible KB tags, the upper bound for KB tag models is substantially better at 92.85% F-score. KB tags help NER accuracy across all entity types, but provide relatively better supervision for organisation entities than wide-coverage gazetteers. The benefit of KB tags comes from their type information, which is required for good performance. We also examine how performance

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 512–517,
Lisbon, Portugal, 17-21 September 2015.

degrades as we use fewer KB tags, simulating the use-case where a busy knowledge worker spends less time annotating. We find that KB augmentation means we require fewer tags to reach the same performance, which reduces the cost of obtaining KB tags. We show how KB tags can be exploited as a useful complement to traditional NER supervision.

2 Background

Gazetteers have long been used to augment statistical NER models, adding general evidence of tokens used in names (Nadeau and Sekine, 2007). These are usually drawn from wide-coverage sources like Wikipedia and census lists (Ratinov and Roth, 2009) and can be incorporated into sequence models by designing binary features that indicate whether a token appears in a gazetteer entry. Features can be refined by specifying which part of an entry a token matches using tag encoding schemes such as IOB (Kazama and Torisawa, 2007). Using multiple gazetteers allows feature weights to capture different name types and sources. Given their purpose to increase coverage beyond names included in training data, gazetteers are usually large, general and static, remaining the same during training and prediction time.

Beyond their use as sources for gazetteers, the link structure in and around KBs has been used to create training data. A prominent technique is to follow links back from KB articles to documents that mention the subject of the article, heuristically labelling high-precision matches to create training data. This has been used for genetic KBs (Morgan et al., 2003; Vlachos and Gasperin, 2006), and Wikipedia (Kazama and Torisawa, 2007; Richman and Schone, 2008; Nothman et al., 2013). These works do not consider our setting where gold-standard entities are given at inference time as their goal is to generate training data.

KBs have also been used to help other natural language processing tasks such as coreference resolution (Rahman and Ng, 2011), topic modelling (Kataria et al., 2011) and named entity linking (Cucerzan, 2007; Ratinov et al., 2011). Finally, it may be that supervised data is only available in some circumstances, for example in the case of personalising NER models. Jung et al. (2015) query a user's smartphone data services to create user-specific gazetteers of personal information. The background NER model is initially trained without access to the user-specific information and later adapted on the users's smartphone.

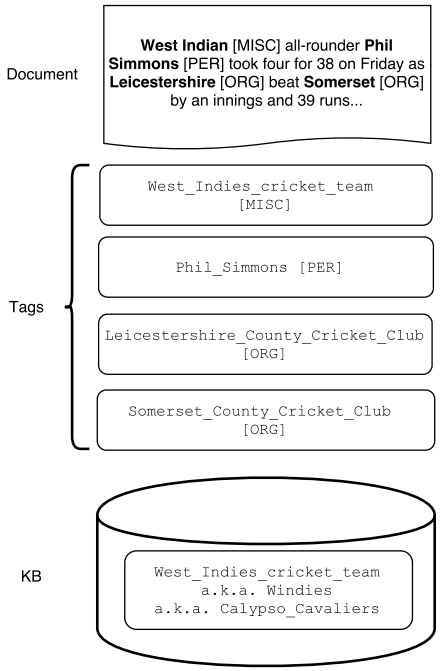

Figure 1: An entity-tagged document, KB tags with canonical name and type and KB with aliases.

3 Document-level KB tags

We incorporate information from KB tags by building document-specific gazetteers. Figure 1 shows an example with a document in which the **names** need to be recognised and typed (in square brackets). We are also given a list of KB tags, each of which is a canonical name and a type. These are linked to a KB which we use to extract aliases, in our case each canonical name is a Wikipedia article, and redirects to that article are considered aliases. Our goal is that knowing that a document mentions the entity `West Indies cricket team` can help us identify Windies or Calypso Cavaliers.

To create gazetteers from a document's KB tags, we preprocess the canonical name from each KB tag, tokenising by underscore, lowercasing and removing parenthesised suffixes (e.g. `Chris_Lewis_(cricketer)` becomes chris lewis). We use an encoding scheme to incorporate the type information from the KB tag. Inspired by Kazama and Torisawa (2007), who applied IOB encoding to gazetteers, we apply the BMEOW (a.k.a. BILOU), a scheme that also distinguishes between **b**eginning, **m**iddle, **e**nd, **o**utside

and single word positions.[1] For example, this allows us to map chris lewis to B-PER E-PER, and we can aggregate gazetteers of tokens for each encoded type, such that the gazetteer for B-PER contains chris.

Our CRF gazetteer features are calculated from an input token from the text that we wish to label. Having created a document's KB tag gazetteers, we can define binary features that are active if an input token matches (case-insensitively) with a particular gazetteer. This models both the part of the KB tag name that the token matched, and its type. The input token Chris thus activates the feature fB-PER and the token cricket would activate the fI-MISC and fI-ORG, as it matches inside entries of the two types.

4 Methodology

We define several configurations to investigate KB tags. The first four baselines either do not use KB tags, or do not integrate them into the CRF. The second four configurations use KB tag features in the CRF model.

4.1 Baselines

KB tag matching (MATCH) We find the longest full match from the document gazetteer and apply the known type. This will not match partial or non-canonical names, but should be high-precision. This is similar to the CoNLL 2003 baseline system (Tjong Kim Sang and De Meulder, 2003).

Baseline (CRF) We train a CRF model using CRFsuite (Okazaki, 2007) with a standard set of features that encode lexical context, token shape, but no external knowledge features such as gazetteers. All following configurations build on the CRF with standard features.

KB tag repair ($\text{CRF}_{+\text{REPAIR}}$) We label the text using the baseline CRF, then find the longest full match from the document gazetteer and assign the known type. When a gazetteer match overlaps with a CRF match, we prefer the gazetteer and remove the latter. Although we do not consider partial matches, this may recognise longer names that can be difficult for CRF models.

Wide-coverage gazetteers ($\text{CRF}_{+\text{WIDE}}$) This uses gazetteers distributed with the Illinois NER system (Ratinov and Roth, 2009). We encode each phrase using the BMEOW scheme described above, and use the filename of each gazetteer as its type. There are 33 gazetteers drawn from many sources with approximately 2 million entries.

4.2 Using KB tags as CRF features

KB tag names ($\text{CRF}_{+\text{NAME}}$) We generate document-specific gazetteer features, but use the same type for each entry.

KB tag names and types ($\text{CRF}_{+\text{NAME+TYPE}}$) This is equivalent to $\text{CRF}_{+\text{NAME}}$, but includes known types. Since type varies with context, this may not be correct, but is hopefully informative.

KB tag names, types and KB aliases ($\text{CRF}_{+\text{NAME+TYPE+AKA}}$) This builds on the above, but uses the KB to augment the document-specific gazetteer with known aliases of the KB tags, for example adding UN for United_Nations with the known type.

KB tag names, types, KB aliases and large gazetteers ($\text{CRF}_{+\text{NAME+TYPE+AKA+WIDE}}$) This combines all KB tag features with the wide-coverage gazetteers.

We fetch and cache KB information using a Wikipedia API client.[2] We assume the tag set of person (PER), organisation (ORG), location (LOC) and miscellaneous (MISC), and report precision, recall and F-score from the conlleval evaluation script. The median proportion of mentions in a document that are linked to the KB is 81% in TRAIN and TESTB, and 85% in TESTA. Augmenting the gazetteer with aliases produces, on average, 26 times the number of gazetteer entries than KB tags alone in TESTA, and 23 times in TESTB.

5 Results

Table 1 shows the performance of different configurations – we focus first on TESTA overall F-scores. Matching against KB tag names results in high-precision but low recall with an F-score of 55.35%, far worse than the baseline CRF at 87.68%. Despite its naïve assumptions, repairing the CRF tags using longest matches in the document gazetteer performs surprisingly well at 89.76%, just lower than using wide coverage gazetteers, with an F-score of 89.85%.

The first setting that uses KB tags as CRF features is $\text{CRF}_{+\text{NAME}}$, which includes typeless names

[1] We omit the O tag as all gazetteer tokens are inside.

+NAME+TYPE+AKA+WIDE	93.13	92.01	92.57	95.48	88.34	87.96	94.97	89.86	88.85	89.35

Table 1: Results for CoNLL 2003 TESTA and TESTB. We report P/R/F for all tags and per-type F-scores. Methods starting with "+" build on the standard CRF by repairing or adding features.

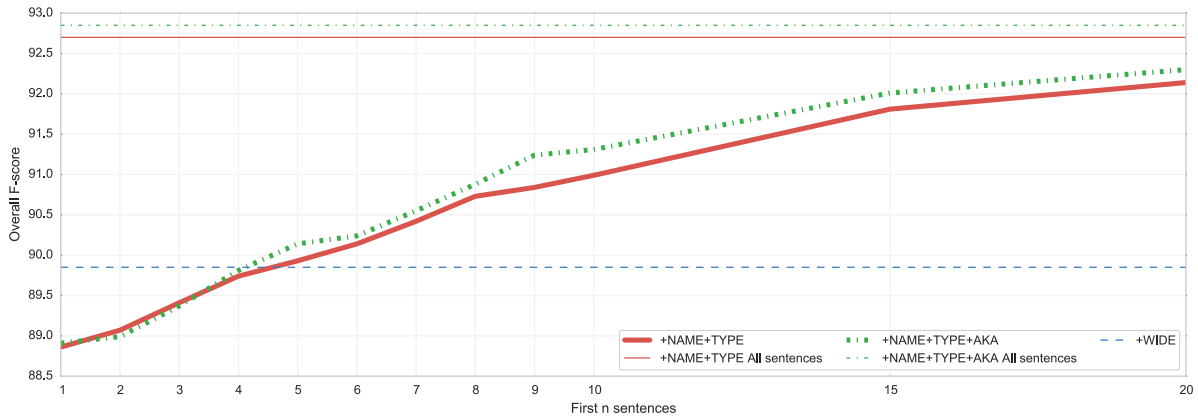

Figure 2: How many sentences should an annotator check for KB tags? TESTA results for $CRF_{+NAME+TYPE}$ and $CRF_{+NAME+TYPE+AKA}$ where KB tags are drawn from the first n sentences. This is compared to the F-score for CRF_{+WIDE} and versions of the models with access to all sentences in the document (horizontal, thin lines).

and has an F-score of 89.29%. Precision and recall are lower than wide coverage gazetteers, suggesting that, without type information, bigger gazetteers are better. Adding type features ($CRF_{+NAME+TYPE}$) results in better performance than either CRF or CRF_{+WIDE} at 92.7% F-score.[3] Augmenting the document gazetteers using aliases from the KB further improves F-score for aliases (92.85%). Adding wide-coverage gazetteers to KB tags slightly decreases F-score at 92.57%. These results indicate that type information is critical and, to confirm this, we ran experiments that used only name and alias information from KB tags. This scores 89.45% F-score on TESTA and 83.62% F-score on TESTB. While aliases help, type information is required to improve performance beyond wide coverage gazetteers.

To give some insight into why KB tag types are effective, consider the name West Indian. This appears 65 times across 11 of the 33 wide-coverage gazetteers, including those that also contain people, locations, organisations, songs. A document-specific gazetteer is able to constrain this type ambiguity, producing a cleaner signal for the model. Aliases, on the other hand, allow the model to capture non-canonical variants of a name, but this depends on type information for good NER performance.

We also examine the per-tag F-scores for TESTA to investigate whether KB tags help some types of entities more than others. Using $CRF_{+NAME+TYPE+AKA}$ we obtain around 95.5% F-score for PER and LOC entities. As with CRF_{+WIDE}, MISC entities remain hard to tag correctly. However, if we consider the percentage F-score gain by type over the CRF baseline, CRF_{+WIDE} gazetteers improve performance most for PER (+2.94%), then ORG (2.77%) entities. The top two are reversed for $CRF_{+NAME+TYPE+AKA}$, with ORG (+6.83%), then PER (+5.48%). This suggests that KB tags are particularly well-suited for helping recognise organisations names.

[3]We tried to manually map the 33 gazetteer filenames to the 4 NER types, but this reduced performance on TESTA.

We see similar trends in TESTB, except KB tags and $\text{CRF}_{+\text{WIDE}}$ are complementary. The experiments illustrate that if we are lucky enough to have KB tags, they improve NER. However, the models use all possible KB tags and should be considered an upper bound. To better model busy workers, we restrict the gazetteers to only KB tags from mentions in the first n sentences. This matches asking an annotator to only bother looking at the first n sentences. Figure 2 shows how the KB tag models perform on TESTA as we increase n. To achieve better performance than $\text{CRF}_{+\text{WIDE}}$, one should view the first 5 sentences for $\text{CRF}_{+\text{NAME+TYPE}}$. Aliases ($\text{CRF}_{+\text{NAME+TYPE+AKA}}$) reduce performance slightly when only using a few sentences, but with more than 4 sentences, aliases are consistently useful. This trend is also apparent in TESTB, showing that augmenting tags with KB information improves NER, especially when only a few tags are available.

6 Discussion and conclusion

There are several avenues to explore further. Asking annotators to specify types is not ideal and it would be better to predict them from the KB. We only use the KB to collect aliases, but we could use it to harvest related entities. Another challenge is appropriately modelling the interaction between a sentence-level task and document-level constraints. A KB tag might match a mention in one sentence and this should influence predictions there. However, its evidence should be less important elsewhere since that constraint has already been satisfied. This would improve robustness, however global constraints are hard to model in sentence-unit CRF models.

This paper presents a novel NER setting whereby we have access to some number of KB tags – canonical names and types – at training and inference time. We explore how best to use this information, finding that CRF models can indeed take advantage of this non-standard supervision. Moreover, models benefit from integration with the KB, in our case augmenting document gazetteers to maximise the benefit of KB tags.

Abstract

Learning to determine when the time-varying facts of a Knowledge Base (KB) have to be updated is a challenging task. We propose to learn state changing verbs from Wikipedia edit history. When a state-changing event, such as a marriage or death, happens to an entity, the infobox on the entity's Wikipedia page usually gets updated. At the same time, the article text may be updated with verbs either being added or deleted to reflect the changes made to the infobox. We use Wikipedia edit history to distantly supervise a method for automatically learning verbs and state changes. Additionally, our method uses constraints to effectively map verbs to infobox changes. We observe in our experiments that when state-changing verbs are added or deleted from an entity's Wikipedia page text, we can predict the entity's infobox updates with 88% precision and 76% recall. One compelling application of our verbs is to incorporate them as triggers in methods for updating existing KBs, which are currently mostly static.

1 Introduction

Extracting relational facts between entities and storing them in knowledge bases (KBs) has been a topic of active research in recent years. The resulting KBs are generally static and are not updated as the facts change (Suchanek et al., 2007; Carlson et al., 2010; Fader et al., 2011; Mitchell et al., 2015). One possible approach to updating KBs is to extract facts from dynamic Web content such as news (Nakashole and Weikum, 2012). In this paper, we propose to predict state changes caused by verbs acting on entities in text. This is different from simply applying the same text extraction pipeline, that created the original KB, to dynamic Web content.

In particular, our approach has the following advantages: (1) Consider for example the SPOUSE relation, both *marry* and *divorce* are good patterns for extracting this relation. In our work, we wish to learn that they cause different state changes. Thus, we can update the entity's fact *and* its temporal scope (Wijaya et al., 2014a). (2) Learning state changing verbs can pave the way for learning the ordering of verbs in terms of their pre- and post-conditions.

Our approach learns state changing verbs from Wikipedia revision history. In particular, we seek to establish a correspondence between infobox edits and verbs edits in the same article. The infobox of a Wikipedia article is a structured box that summarizes an entity as a set of facts (attribute-value pairs) . Our assumption is that when a state-changing event happens to an entity e.g., a marriage, its Wikipedia infobox is updated by adding a new SPOUSE value. At approximately the same time, the article text might be updated with verbs that express the event, e.g., *X is now **married** to Y*. Figure 1 is an example of an infobox of an entity changing at the same time as the article's main text to reflect a marriage event.

Wikipedia revision history of many articles can act as distant supervision data for learning the correspondence between text and infobox changes. However, these revisions are very *noisy*. Many infobox slots can be updated when a single event happens. For example, when a death happens, slots regarding birth e.g., *birthdate*, *birthplace*, may also be updated or added if they were missing before. Therefore, our method has to handle these sources of noise. We leverage logical constraints to rule out meaningless mappings between

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 518–523,
Lisbon, Portugal, 17-21 September 2015.

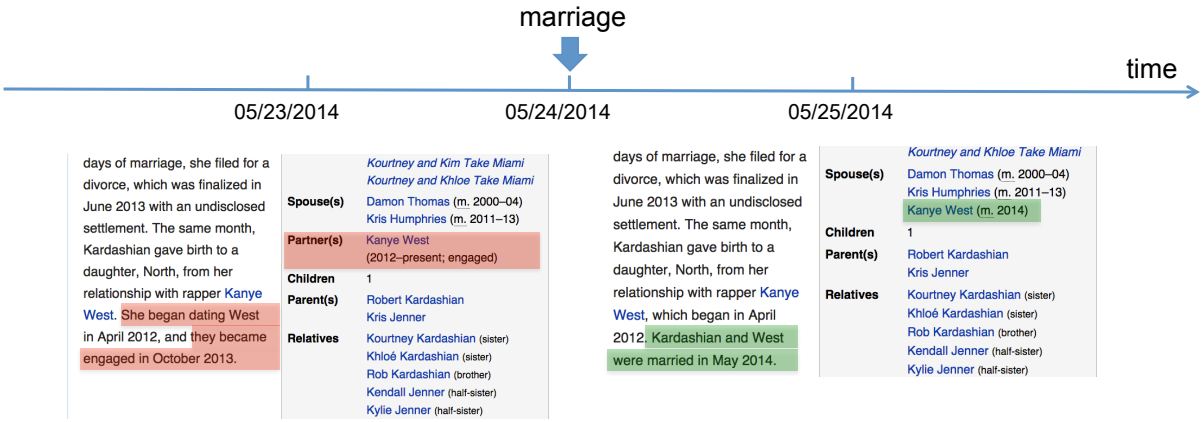

Figure 1: A snapshot of Kim Kardashian's Wikipedia revision history, highlighting text and infobox changes. In red (and green) are the differences between the page on 05/25/2014 and 05/23/2014: things that are deleted from (and added to) the page.

infobox and text changes.

In summary, our contributions are as follows: (1) we present an algorithm that uses Wikipedia edit histories as distantly labeled data to learn which verbs result in which state changes to entities, and experimentally demonstrate its success, (2) we make available this set of distantly labeled training data on our website[1], and (3) we also make available our learned mappings from verbs to state changes, as a resource for other researchers, on the same website.

2 Method

2.1 Data Construction

We construct a dataset from Wikipedia edit histories of person entities whose facts change between the year 2007 and 2012 (i.e., have at least one fact in YAGO KB (Suchanek et al., 2007) with a start or end time in this period). We obtain Wikipedia URLs of this set of entities P from YAGO and crawl their article's revision history. Given a person p, his/her Wikipedia revision history R_p has a set of ordered dates T_p on which revisions are made to his/her Wikipedia page (we consider date granularity). Each revision $r_{p,t} \in R_p$ is his/her Wikipedia page at date t where $t \in T_p$.

Each Wikipedia revision $r_{p,t}$ is a set of infobox slots $S_{p,t}$ and textual content $C_{p,t}$. Each infobox slot $s \in S_{p,t}$ is a quadruple, $\langle s_{att}, s_{value}, s_{start}, s_{end} \rangle$ containing the attribute name (non-empty), the attribute value, and the start and end time for which this attribute-value pair holds in reality.

A document $d_{p,t}$ in our data set is the *difference*[2] between any two consecutive revisions separated by more than 24 hours i.e., $d_{p,t} = r_{p,t+2} - r_{p,t}$, where $r_{p,t+2}$ is the *first* revision on date $t+2$ and $r_{p,t}$ is the *last* revision on date t (as a page can be revised many times in a day).

A document $d_{p,t}$ is therefore a set of infobox changes $\Delta S_{p,t}$ and textual changes $\Delta C_{p,t}$. Each slot change $\delta s \in \Delta S_{p,t} = \langle s_{att}, \delta s_{value}, \delta s_{start}, \delta s_{end} \rangle$ is prefixed with $+$ or $-$ to indicate whether they are added or deleted in $r_{p,t+2}$. Similarly, each text change $\delta c \in \Delta C_{p,t}$ is prefixed with $+$ or $-$ to indicate whether they are added or deleted.

For example, in Figure 1, a document $d_{kim,\ 05/23/2014} = r_{kim,05/25/2014} - r_{kim,05/23/2014}$ is a set of slot changes: $\langle$SPOUSE, $+$"Kanye West", $+$"2014", " "$\rangle$, $\langle$PARTNER, $-$"Kanye West", $-$"2012-present; engaged", " "$\rangle$ and a set of text changes: $+$"Kardashian and West were married in May 2014", $-$"She began dating West", $-$"they became engaged in October 2013".

For each $d_{p,t}$, we use $\Delta S_{p,t}$ to label the document and $\Delta C_{p,t}$ to extract features for the document. We label $d_{p,t}$ that has a new value or start time added to its infobox: $\langle s_{att}, +\delta s_{value}, *, * \rangle \in \Delta S_{p,t}$ or $\langle s_{att}, *, +\delta s_{start}, * \rangle \in \Delta S_{p,t}$ with the label *begin-*s_{att} and label $d_{p,t}$ that has a new end time added to its infobox: $\langle s_{att}, *, *, +\delta s_{end} \rangle \in \Delta S_{p,t}$ with the label *end-*s_{att}.

The label represents the state change that

[1] http://www.cs.cmu.edu/ dwijaya/postcondition.html

[2] a HTML document obtained by "compare selected revisions" functionality in Wikipedia

happens in $d_{p,t}$. For example, in Figure 1, $d_{kim,\ 05/23/2014}$ is labeled with *begin-spouse*.

The revision history dataset that we make available for future research consists of all documents $d_{p,t}$, labeled and unlabeled, $\forall t \in T_p,\ t \in [01/01/2007,\ 12/31/2012]$, and $\forall p \in P$; a total of 288,184 documents from revision histories of 16,909 Wikipedia entities. Using our labeling process, we find that out of 288,184 documents, only 41,139 have labels (i.e., have their infobox updated with new values/start/end time). The distribution of labels in the dataset is skewed towards birth and death events as these are life events that happen to almost all person entities in Wikipedia. The distribution of labels in the dataset that we release can be seen in Figure 2. We show only labels that we evaluate in our task.

For our task of learning state changing verbs from this revision history dataset, for each labeled $d_{p,t}$, we extract as features, verbs (or verbs+prepositions) $v \in \Delta C_{p,t}$ of which its subject (or object) matches the Wikipedia entity p *and* its object (or subject resp.) matches an infobox value, start or end time: $(v_{subject}, v_{object}) = (_{arg1}, _{arg2})$ or $(v_{subject}, v_{object}) = (_{arg2}, _{arg1})$, where $_{arg1}= p$ and $\langle s_{att},_{arg2}, *, * \rangle$ or $\langle s_{att}, *,_{arg2}, * \rangle$ or $\langle s_{att}, *, *,_{arg2} \rangle \in \Delta S_{p,t}$. We use Stanford CoreNLP (Manning et al., 2014) to dependency parse sentences and extract the subjects and objects of verbs. We find that 27,044 out of the 41,139 *labeled* documents contain verb edits, but only 4,735 contain verb edits with two arguments, where one argument matches the entity and another matches the value of the infobox change. We use the latter for our task, to improve the chance that the verb edits used as features are related to the infobox change.

2.2 Model

We use a Maximum Entropy (MAXENT) classifier[3] given a set of training data = $\{(\mathbf{v}_{d_\ell},\ y)\}$ where $\mathbf{v}_{d_\ell} = (v_1,\ v_2,\ ...\ v_{|V|}) \in R^{|V|}$ is the $|V|$-dimensional representation of a labeled document d_ℓ where V is the set of all verbs in our training data, and y is the label of d_ℓ as defined in 2.1.

These training documents are used to estimate a set of weight vectors $\mathbf{w} = \{\mathbf{w}_1,\ \mathbf{w}_2,\ ...\ \mathbf{w}_{|Y|}\}$, $\mathbf{w}_y \in R^{|V|}$, one for each label $y \in Y$, the set of all labels in our training data. The classifier can then be applied to classify an unlabeled document d_u using:

$$p(y|\mathbf{v}_{d_u}) = \frac{\exp(\mathbf{w}_y \cdot \mathbf{v}_{d_u})}{\sum_{y'} \exp(\mathbf{w}_{y'} \cdot \mathbf{v}_{d_u})} \quad (1)$$

2.3 Feature Selection using Constraints

While feature weights from the MAXENT model allow us to identify verbs that are good features for predicting a particular state change label, our distantly supervised training data is inherently noisy. Changes to multiple infoboxes can happen within our revision. We therefore utilize constraints among state changes to select consistent verb features for each type of state change.

We use two types of constraints: (1) mutual exclusion (*Mutex*) which indicate that mutex state changes do not happen at the same time e.g., update on *birthdate* should not *typically* happen with update on *deathcause*. Hence, their state changing verbs should be different. (2) Simultaneous (*Sim*) constraints which indicate that simultaneous state changes should *typically* happen at the same time e.g., update on *birthdate* should *typically* happen with other birth-related updates such as *birthplace*, *birthname*, etc. We manually specified these two types of constraints to all pairs infoboxes where they apply. We have 10 mutex constraints and 23 simultaneously updated constraints. The full list of constraints can be found in our website.

Given a set of constraints, a set of labels Y, and a set of base verbs[4] B in our training data, we solve a Mixed-Integer Program (MIP) for each base verb $b \in B$ to estimate whether b should be a feature for state change $y \in Y$.

We obtain label membership probabilities $\{P(y|b) = count(y,b)/\sum_{y'} count(y',b)\}$ from our training data. The MIP takes the scores $P(y|b)$ and constraints as input and produces a bit vector of labels $\mathbf{a}_b$ as output, each bit $a_b^y \in \{0,\ 1\}$ represents whether or not b should be a feature for y.

The MIP formulation for a base verb b is presented by Equation 2. For each b, this method tries to maximize the sum of scores of selected labels, after penalizing for violation of label constraints. Let $\zeta_{y,y'}$ be slack variables for *Sim* constraints, and $\xi_{y,y'}$ be slack variables for *Mutex* constraints.

[3]We use MALLET implementation of MAXENT: http://mallet.cs.umass.edu/

[4]The verb root or base form of a verb (after removing preposition)

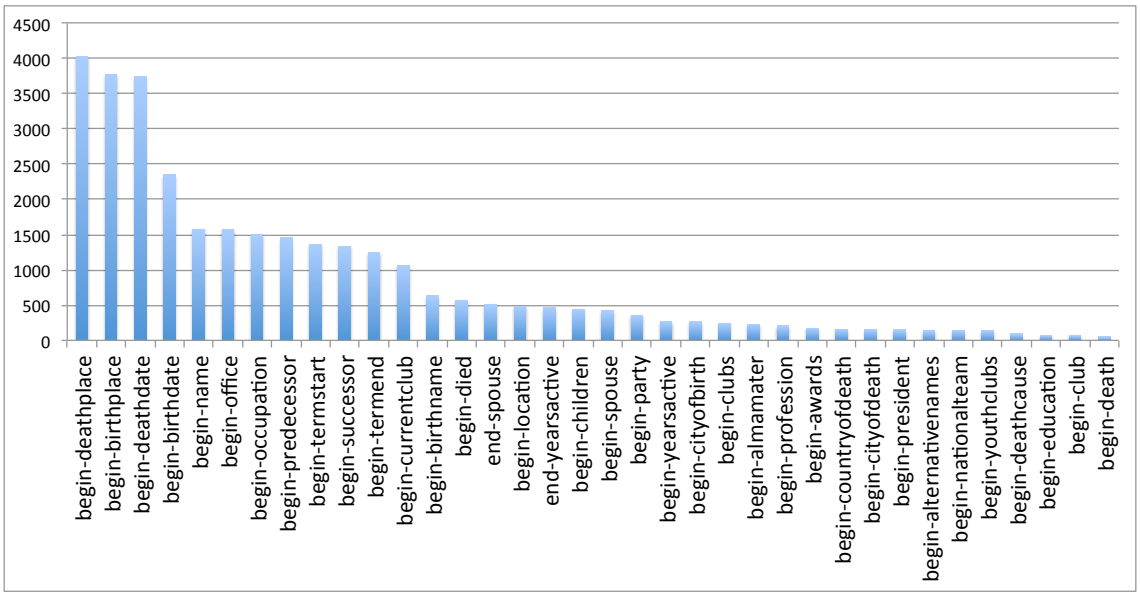

Figure 2: Distribution of labels we evaluate in our task in the revision history dataset.

Solving MIP per base verb is fast; we reduce the number of labels considered per base verb i.e., we only consider a label y to be a candidate for b if $\exists\, v_i \in V$ s.t. $w_y^i > 0$ and b = base form of v_i.

After we output $\mathbf{a}_b$ for each b, we select features for each label. We only select a verb v_i to be a feature for y if the learned weight $w_y^i > 0$ and $a_b^y = 1$, where b = the base form of v_i. Essentially for each label, we select verb features that have positive weights and are consistent for the label.

$$\begin{aligned} \underset{\mathbf{a}_b,\, \zeta_{y,y'},\, \xi_{y,y'}}{\text{maximize}} \quad & \Big(\sum_y a_b^y * P(y|b) - \sum_{\langle y,y' \rangle \in Sim} \zeta_{y,y'} - \\ & \sum_{\langle y,y' \rangle \in Mutex} \xi_{y,y'} \Big) \\ \text{subject to} \quad & (a_b^y - a_b^{y'})^2 \leq \zeta_{y,y'}, \quad \forall \langle y, y' \rangle \in Sim \\ & a_b^y + a_b^{y'} \leq 1 + \xi_{y,y'}, \quad \forall \langle y, y' \rangle \in Mutex \\ & \zeta_{y,y'},\, \xi_{y,y'} \geq 0,\; a_b^y \in \{0, 1\}, \quad \forall y, y' \end{aligned} \tag{2}$$

3 Experiments

We use 90% of our labeled documents that have verb edits as features (section 2.1) as training data and test on the remaining 10%. Since revision history data is noisy, we manually go through our test data to discard documents that have incorrect infobox labels by looking the text that changed. The task is to predict for each document (revision), the label (infobox slot change) of the document given its verbs features. We compute precision, recall, and F1 values of our predictions and compare the values before and after feature selection (Fig. 3).

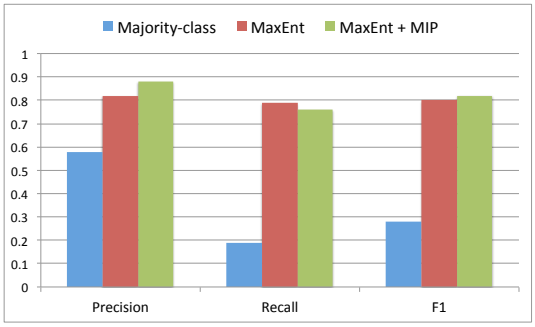

Figure 3: Results of predicting state change labels (infobox types) using verb features.

To the best of our knowledge, the task to learn state-changing verbs in terms of states defined in existing knowledge bases and learning it from Wikipedia edit histories is novel. There is no previous approach that can be used as baseline; therefore we have compared our structured prediction using MIP and MaxEnt with a majority class baseline. Both our approaches (MaxEnt and MaxEnt + MIP) perform better than the majority class baseline (Figure 3).

We observe the value of doing feature selection by asserting constraints in an MIP formulation. Feature selection improves precision; resulting in a better F1. By asserting constraints, some of the inconsistent verb features for the la-

bels were removed. For example, before feature selection, the verbs: "marry", and "be married to" were high-weighted features for both *begin-spouse* and *end-spouse*. After asserting constraints that *begin-spouse* is mutex with *end-spouse*, these verbs (whose base form is "marry") are filtered out from the features of *end-spouse*. We show some of the learned verb features (after feature selection) for some of the labels in (Table 1). In average, we have about 18 verbs per infobox state change in our state changing verb resource that we make available for future research.

4 Related Work

Learning from Wikipedia Revision History. Wikipedia edit history has been exploited in a number of problems. A popular task in this regard is that of Wikipedia edit history categorization (Daxenberger and Gurevych, 2013). This task involves characterizing a given edit instance as one of many possible categories such as spelling error correction, paraphrasing, vandalism, and textual entailment (Nelken and Yamangil, 2008; Cahill et al., 2013; Zanzotto and Pennacchiotti, 2010; Recasens et al., 2013). Prior methods target various tasks different from ours.

Learning State Changing Verbs. Very few works have studied the problem of learning state changing verbs. (Hosseini et al., 2014) learned state changing verbs in the context of solving arithmetic word problems. They learned the effect of words such as *add, subtract* on the current state. The VerbOcean resource was automatically generated from the Web (Chklovski and Pantel, 2004). The authors studied the problem of fine-grained semantic relationships between verbs. They learn relations such as if someone has bought an item, they may sell it at a later time. This then involves capturing empirical regularities such as "X buys Y" happens before "X sells Y". Unlike the work we present here, the methods of (Chklovski and Pantel, 2004; Hosseini et al., 2014) do not make a connection to KB relations such as Wikipedia infoboxes. In a vision paper, (Wijaya et al., 2014b) give high level descriptions of a number of possible methods for learning state changing methods. They did not implement any of them.

5 Conclusion

In this paper we presented a method that learns state changing verb phrases from Wikipedia revision history. We first constructed and curated a novel dataset from Wikipedia revision history that is tailored to our task. We showed that this dataset is useful for learning verb phrase features that are effective for predicting state changes in the knowledge base (KB), where we considered the KB to be infoboxes and their values. As future work we wish to explore the usefulness of our verb resource to other KBs to improve KB freshness. This is important because existing KBs are mostly static. We wish to also explore the application of the learned verb resource to domains other than Wikipedia infobox and text e.g., for predicting state changes in the knowledge base from news text.

In this paper, we learned post-conditions of verbs: state changes that occur when an event expressed by a verb happens. As future work we would also explore the feasibility of learning preconditions of verbs from Wikipedia revisions. Additionally, most Wikipedia revisions only have text changes without the associated infobox change. Therefore, another line of future work is to also learn from these unlabeled documents.

Abstract

Because of polysemy, distant labeling for information extraction leads to noisy training data. We describe a procedure for reducing this noise by using label propagation on a graph in which the nodes are entity mentions, and mentions are coupled when they occur in coordinate list structures. We show that this labeling approach leads to good performance even when off-the-shelf classifiers are used on the distantly-labeled data.

1 Introduction

In distantly-supervised information extraction (IE), a knowledge base (KB) of relation or concept instances is used to train an IE system. For instance, a set of facts like *adverseEffectOf(meloxicam, stomachBleeding)*, *interactsWith(meloxicam, ibuprofen)*, might be used to train an IE system that extracts these relations from documents. In distant supervision, instances are first matched against a corpus, and the matching sentences are then used to generate training data consisting of labeled entity mentions. For instance, matching the KB above might lead to labeling passage 1 from Table 1 as support for the fact *adverseEffectOf(, stomachBleeding)*.

A weakness of distant supervision is that it produces noisy training data: for instance, matching the adverse effect *weakness* might lead to incorrectly-labeled mention examples. Distant supervision is often coupled with learning methods that allow for this sort of noise by introducing latent variables for each entity mention (e.g., (Hoffmann et al., 2011; Riedel et al., 2010; Surdeanu et al., 2012)); by carefully selecting the entity mentions from contexts likely to include specific KB facts (Wu and Weld, 2010); by careful filtering of the KB strings used as seeds (Movshovitz-Attias and Cohen, 2012); or by making use of named-entity linking methods and co-reference to improve the matching phase of distant learning (Koch et al., 2014).

1. "Avoid drinking alcohol. It may increase your risk of stomach bleeding."
2. "Get emergency medical help if you have chest pain, weakness, shortness of breath, slurred speech, or problems with vision or balance."

Table 1: Passages from a page discussing the drug meloxicam.

Here we explore an alternative approach of ***D***istant ***IE*** using coordinate-term ***L***ists (DIEL) based on detection of *lists* in text, such as the one illustrated in passage 2 in Table 1. Since list items are usually of the same type, the unambiguous mention *chest pain* here disambiguates the mention *weakness*. Label propagation methods (Zhu et al., 2003; Lin and Cohen, 2010) can be used to exploit this intuition, by propagating the low-confidence labels associated with distance supervision through an appropriate graph.

Here we describe a pipelined system which (1) identifies lists of semantically-related items using lexico-syntactic patterns (2) uses distant supervision, in combination with a label-propagation method, to find entity mentions that can be confidently labeled and (3) from this data, uses ordinary classifier learners to classify entity mentions by their semantic type. We show that this approach outperforms a naive distant-supervision approach.

2 DIEL: *D*istant *IE* Using Coordinate *L*ists

2.1 Corpus and KB

We consider extending the coverage of Freebase in the medical domain, which is currently fairly limited: e.g., a Freebase snapshot from April 2014 has (after filtering noise with simple rules such as length greater than 60 characters and containing comma) only 4,605 disease instances and 4,383 drug instances, whereas `dailymed.nlm.nih.gov` contains data on over 74k drugs, and `malacards.org` lists nearly 10k diseases. We use a corpus downloaded from `dailymed.nlm.nih.gov` which contains 28,590 XML documents, each of which describes a drug that can be legally prescribed in the United States. We focus here on extracting instances of four semantic types, without explicitly extracting relationships between them.

We used the GDep parser (Sagae and Tsujii, 2007), a dependency parser trained on the GENIA Treebank, to parse this corpus. We used a simple POS-tag based noun-phrase (NP) chunker, and extract a list for each coordinating conjunction that modifies a nominal. For each NP we extract features (described below); and for each identified coordinate-term list, we extract its items, and a similar feature set describing the list.

The extracted lists and their items, as well as entity mentions and their corresponding NPs, can be viewed as a bipartite graph, where one set of vertices are identifiers for the lists and entity mentions, and the other set of vertices are the strings that occur as items of those lists, or as NPs of those mentions. Note that list items are also NPs. A mention can be regarded as a singleton list that contains only one item, and a list can be regarded as a complexus mention that contains a few mentions. If an item is contained by a list, an edge between the item vertex and the list vertex is included in the graph. An example bipartite graph is given in Figure 1, in which there are nine symptoms from three lists and three mentions. Some symptoms are common, such as vomiting, while some others are not, such as epigastric pain.

2.2 Label Propagation

It seems intuitive to assume that if two items co-occur in a coordinate-term list, they are very likely to have the same type, so it seems plausible to use label propagation on this graph to propagate types from NPs with known types (e.g., that match entities in the KB) to lists, and then from lists to NPs, across this graph.

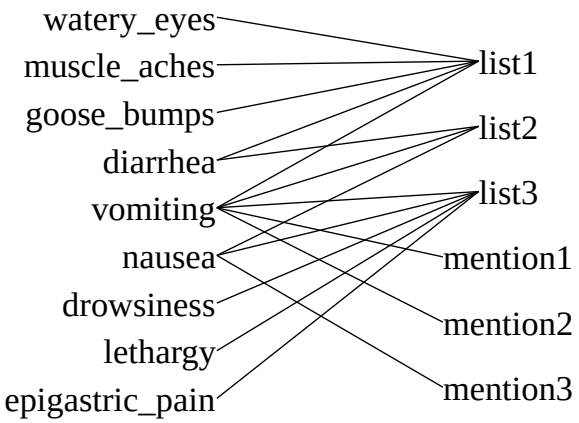

Figure 1: A bipartite graph example.

This can be viewed as semi-supervised learning (SSL) of the NPs that may denote a type (e.g., diseases or adverse effects). We adopt an existing multi-class label propagation method, namely, MultiRankWalk (MRW) (Lin and Cohen, 2010), to handle our task, which is a graph-based SSL related to personalized PageRank (PPR) (Haveliwala et al., 2003) (aka random walk with restart (Tong et al., 2006)). MRW can be described as simply computing one personalized PageRank vector for each class, where each vector is computed using a personalization vector that is uniform over the seeds, and finally assigning to each node the class associated with its highest-scoring vector. MRW's final scores depend on centrality of nodes, as well as proximity to the seeds, and in this respect MRW differs from other label propagation methods (e.g., (Zhu et al., 2003)): in particular, it will not assign identical scores to all seed examples. The MRW implementation we use is based on ProPPR (Wang et al., 2013).

2.3 Classification

One could imagine using the output of MRW to extend a KB directly. However, the process described above cannot be used conveniently to label new documents as they appear. Since this is also frequently a goal, we use the MRW output to train a classifier, which can be then used to classify the entity mentions (singleton lists) and coordinate lists in any new document.

We use the same feature generator for both entity mentions and lists. Shallow features include: tokens in the NPs, and character prefixes/suffixes of these tokens; tokens from the sentence contain-

Run	1	2	3	4	5	6	7	8	9	10	Avg.
DIEL	0.418	0.390	0.404	0.420	0.400	0.397	0.404	0.403	0.409	0.404	0.405
DS-baseline	0.394	0.342	0.400	0.373	0.342	0.297	0.326	0.332	0.330	0.352	0.349

Table 2: Recall on the held-out set.

ing the NP; and tokens and bigrams from a window around the NPs. From the dependence parse, we also find the verb which is the closest ancestor of the head of the NP, all modifiers of this verb, and the path to this verb. For a list, the dependency features are computed relative to the head of the list. We used an SVM classifier (Chang and Lin, 2001) and discard singleton features, and also the frequent 5% of all features (as a stop-wording variant). We train a binary classifier on the top N lists (including entity mentions and coordinate lists) of each type, as scored by MRW. A linear kernel and defaults for all other parameters are used. If a new list or mention is not classified as positive by all binary classifiers, it is predicted as "other".

3 Experimental Results

3.1 Results of Recovering KB

In this experiment, we examine the capability of our approach in recovering KB type instances. The targeted types are diseases, symptoms treated and adverse effects (symptom for short), drugs, and drug ingredients.

3.1.1 Baselines

We implemented a distant-supervision-based baseline (DS-baseline). It attempts to classify each NP in the input corpus into one of the four types or "other" with the training seeds as distance supervision. Each sentence is processed with the same reprocessing pipeline to detect NPs. Then, these NPs are labeled with the training seeds. The features are defined and extracted in the same way as we did for DIEL, and four binary classifiers are trained with the same method. Another baseline is developed with the output of MRW LP (LP-baseline) that contains labeled lists and mentions. Specifically, the labeled coordinate lists are broken into items each of which has the list class, and evaluation is conducted with these items together with the labeled mentions as positive predictions.

3.1.2 Settings

We extracted the seeds of these types from Freebase, and got 4,605, 1,244, 4,383, and 4,066 instances, respectively. The seeds are split into development set and held-out evaluation set. The development set is further split into a training set and a validating set in the ratio of 4:1. The validating set will be used in the next subsection to validate different parameter settings, and the training set is used in this experiment as MRW seeds and the distant supervision of DS-baseline.

For getting the development set, the polysemous instances (i.e., "headache", belonging to multiple classes: disease and symptom) are discarded since such instances will bring in ambiguity to the training examples of DS-baseline and MRW LP. After that, we randomly take half of the single-type instances as development set, and the remaining single-type instances together with the polysemous instances are used as held-out set. We report the performance of 10 runs, and each run has its own randomly generated training set (containing 1,980 diseases, 310 symptoms, 1,066 drugs, and 911 ingredients on average) and held-out set (containing 2,130 diseases, 857 symptoms, 3,051 drugs, and 2,927 ingredients on average). For DS-baseline, 35,689 training examples are collected on average for each run. For evaluation metric, we calculate recall on the instances in the held-out set.[1]

3.1.3 Results

DIEL can classify both NPs and coordinate lists, and the lists are also broken into items for recall calculation. The training examples of DIEL are prepared with the top 20,000 lists of each type, as scored by MRW with the training seeds. After removing the multiple-class ones, we obtained, on average, 58,614 training examples for each run.

The results are given in Table 2. DIEL outperforms the baselines in all runs. It shows that

[1]Because the outputs contain many correct instances that are not in Freebase, it is not suitable to calculate precision.

Upper bound	0.445	0.652	0.700	0.697

Table 3: Recall on individual types.

our result is consistently better. The reason is twofold. First, DIEL can avoid the effect of noisy training data by disambiguation with the coordinate relation in the list, so that the training examples are of high quality. Second, with label propagation, we have a larger number of training examples, which helps the recall. Compared with DS-baseline, DIEL's performance is more stable in different runs. It is because DS-baseline suffers from the noisy training data and training seed sets of different runs may bring in different levels of noisy data. Thus, its run 3 achieves 0.400, while run 6 only achieves 0.297. We also examined the upper bound recall that a system can achieve on our corpus. The results are given in the last row of Table 2. On average, the best performance of a system can achieve is 0.617.

The results for individual types are given in Table 3. DIEL and DS-baseline achieve similar results for disease and drug. Especially, both systems cover more than 80% of the held-out disease instances that exist in the corpus. DS-baseline performs poorly for symptom. The reason is that symptom instances are more ambiguous than other types, and they lead to more incorrectly-labeled mention examples. LP-baseline achieves an encouraging recall for symptom, which shows that coordinate lists are very helpful for disambiguating those symptom mentions.

3.2 Classification Results and Parameters

We present another experiment to examine the precision of the systems, and investigate the effect of training size and top N numbers on the results.

3.2.1 Setting

The evaluation data is generated with the validating set of each run. Specifically, for DIEL and LP-baseline, the evaluation data is prepared with the top 500 lists (singleton and coordinate lists) of each type, as scored by MRW with the validating instances as seeds. 2,000 testing examples are collected in total since no multiple-class ones are found. Manual checking on 200 random examples shows that 99% of them are correct. The systems are evaluated by their performance for classifying these example lists. DIEL predicts the class of a list with its feature vector, while LP-baseline determines the class of a list by checking its predicted class in the result of MRW with the corresponding training instances as seeds. For DS-baseline, the testing NP examples are obtained by distant labeling with validating instances, and on average 8,270 examples are collected for each run.

3.2.2 Results

The precision and recall are given in Table 4. For each system, different portions of the training set are used to train the system, as shown in the first row. For DIEL, the top N number varies for generating training examples, as shown in the second column. F1 values of DIEL with different settings are given in Figure 2, and F1 comparison of three systems is given in Figure 3. All results are the average of 10 runs. Each run has its own randomly generated development set, which is split into training set and validating set.

In general, for all systems, larger number of training seeds leads to better performance. For

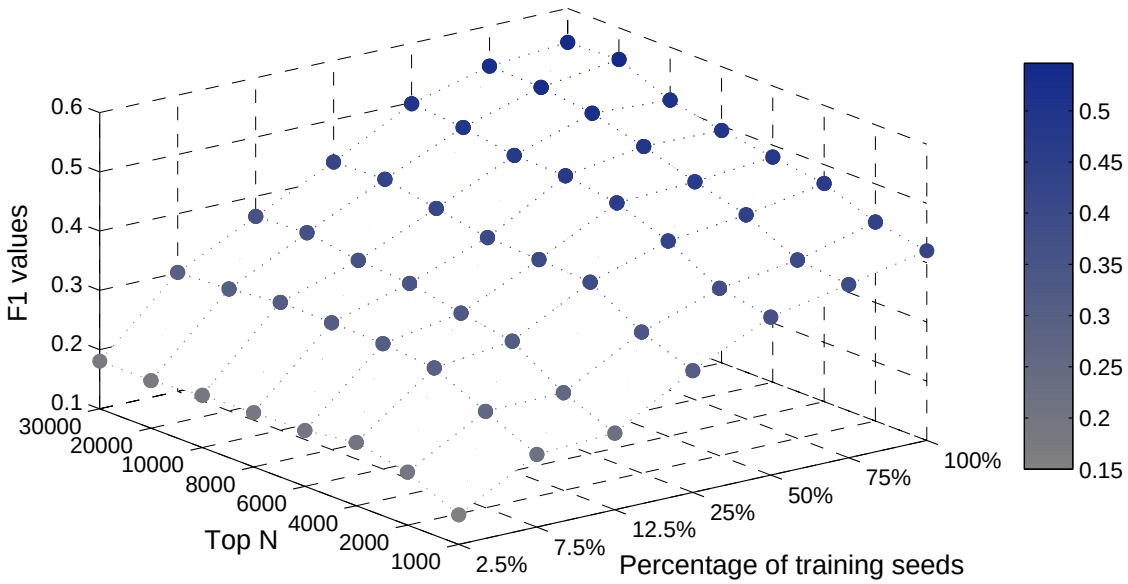

Figure 2: F1 values of DIEL under different settings.

DIEL, smaller N values achieve higher precision, but lower recall. For smaller seed numbers, the precision value is more sensitive to N. This is because the quality of training examples drops faster compared with that from larger seed numbers. For larger seeds numbers, the recall values are improved more significantly when the N value is larger. The reported results of DIEL in the previous experiment are obtained with top 20,000 examples from 100% seeds as training data, since this setting achieves the highest F1 value as shown in Figure 2.

For the DS-baseline, the number of training NPs obtained with different portions of the training set is given in the penultimate row. The recall values of this baseline are low. The reason is that it only uses the training examples that are distantly labeled with training seeds, thus, the trained classifier may not have good generalization on the testing examples labeled with validating seeds. In addition, its performance is more sensitive on the amount of training data. When the percentage is lower than 25%, its precision and recall drop significantly. Its F1 values are 0.381, 0.399 and 0.402 for 50%, 75%, and 100%, respectively. LP-baseline achieves the highest precision when using all training instances. It shows that MRW does label the testing lists very accurately in condition that the lists are traversed in the propagation with the training instances as seeds. However, its recall is much lower than DIEL. It is because, with the

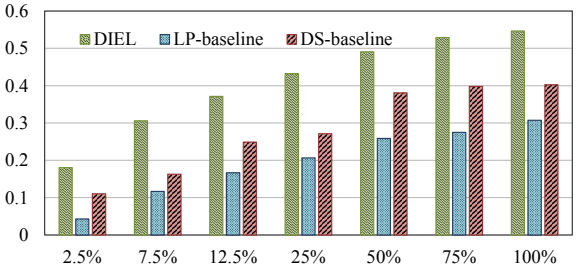

Figure 3: F1 comparison under different portions of the training seeds. For DIEL, top N = 20,000.

training seeds, MRW cannot effectively walk to testing lists that are generated with the validating set, having no intersection with the training set.

4 Conclusions

We explored an alternative approach to distant supervision, based on detection of lists in text, to overcome the weakness of distant supervision resulted by noisy training data. It uses distant supervision and label propagation to find mentions that can be confidently labeled, and uses them to train classifiers to label more entity mentions. The experimental results show that this approach consistently and significantly outperforms a naive distant-supervision approach.

An Entity-centric Approach for Overcoming Knowledge Graph Sparsity

Abstract

Automatic construction of knowledge graphs (KGs) from unstructured text has received considerable attention in recent research, resulting in the construction of several KGs with millions of entities (nodes) and facts (edges) among them. Unfortunately, such KGs tend to be severely sparse in terms of number of facts known for a *given* entity, i.e., have low *knowledge density*. For example, the NELL KG consists of only 1.34 facts per entity. Unfortunately, such low knowledge density makes it challenging to use such KGs in real-world applications. In contrast to *best-effort* extraction paradigms followed in the construction of such KGs, in this paper we argue in favor of ENTIty Centric Expansion (ENTICE), an *entity-centric* KG population framework, to alleviate the low knowledge density problem in existing KGs. By using ENTICE, we are able to increase NELL's knowledge density by a factor of 7.7 at 75.5% accuracy. Additionally, we are also able to extend the ontology discovering new relations and entities.

1 Introduction

Over the last few years, automatic construction of knowledge graphs (KGs) from web-scale text data has received considerable attention, resulting in the construction of several large KGs such as NELL (Mitchell et al., 2015), Google's Knowledge Vault (Dong et al., 2014). These KGs consist of millions of entities and facts involving them. While measuring size of the KGs in terms of number of entities and facts is helpful, they don't readily capture the volume of knowledge needed in real-world applications. When such a KG is used in an application, one is often interested in known facts for a *given* entity, and not necessarily the overall size of the KG. In particular, knowing the average number of facts per entity is quite informative. We shall refer to this as the *knowledge density* of the KG.

	Known Target **E**ntity	**N**ew Target **E**ntity
Known **R**elation	KR-KE	KR-NE
New **R**elation	NR-KE	NR-NE

Table 1: Any new fact involving a source entity from a Knowledge Graph (i.e., facts of the form *entity1-relation-entity2* where *entity1* is already in the KG) can be classified into one of the four extraction classes shown above. Most KG population techniques tend to focus on extracting facts of the KR-KE class. ENTICE, the entity-centric approach proposed in this paper, is able to extract facts of all four classes.

Low knowledge density (or high sparsity) in automatically constructed KGs has been recognized in recent research (West et al., 2014). For example, NELL KG has a knowledge density of 1.34. Such low knowledge density puts significant limitations on the utility of these KGs. Construction of such KGs tend to follow a batch paradigm: the knowledge extraction system makes a full pass over the text corpus extracting whatever knowledge it finds, and finally aggregating all extractions into a graph. Clearly, such *best-effort* extraction paradigm has proved to be inadequate to address the low knowledge density issue mentioned above. We refer to such paradigm as best-effort since its attention is divided equally among all possible entities.

Recently, a few *entity-centric* methods have

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 530–535,
Lisbon, Portugal, 17-21 September 2015.

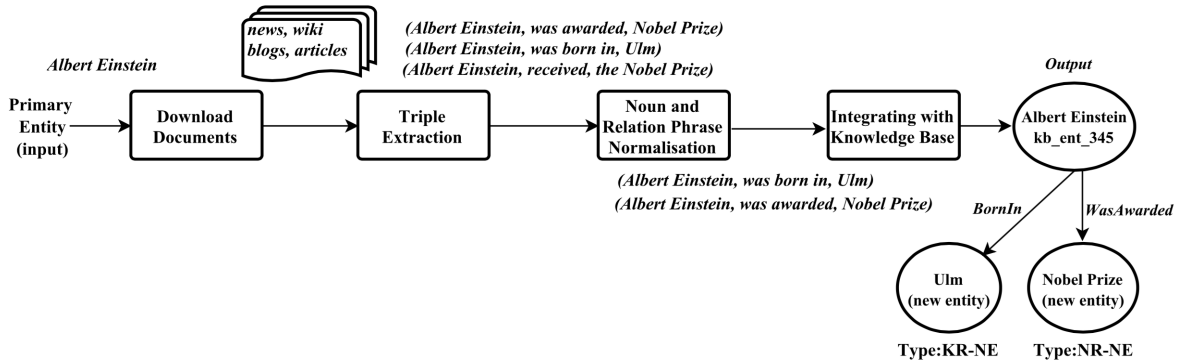

Figure 1: Dataflow and architecture and of ENTICE. See Section 3 for details.

been proposed to increase knowledge density in KGs (Gardner et al., 2013; Gardner et al., 2014). In contrast to the best-effort approaches mentioned above, these entity-centric approaches aim at increasing knowledge density for a *given* entity. A new fact involving the given entity can belong to one of the four types shown in Table 1. Unfortunately, these densifying techniques only aim at identifying instances of known relations among entities already present in the KG, i.e., they fall in the KR-KE type of Table 1.

In this paper we propose ENTIty Centric Expansion (ENTICE), an entity-centric knowledge densifying framework which, given an entity, is capable of extracting facts belonging to all the four types shown in Table 1. By using ENTICE, we are able to increase NELL's knowledge density by a factor of 7.7[1], while achieving 75.4% accuracy. Our goal here is to draw attention to the effectiveness of entity-centric approaches with bigger scope (i.e., covering all four extraction classes in Table 1) towards improving knowledge density, and that even relatively straightforward techniques can go a long way in alleviating low knowledge density in existing state-of-the-art KGs. ENTICE code is available at: `https://github.com/malllabiisc/entity-centric-kb-pop`

2 Related Work

Open Information Extraction (OIE) systems (Yates et al., 2007; Fader et al., 2011; Schmitz et al., 2012) aim at extracting textual triples of the form noun phrase-predicate-noun phrase. While such systems aim for extraction coverage, and because they operate in an ontology-free setting, they don't directly address the problem of improving knowledge density in ontological KGs such as NELL. However, OIE extractions provide a suitable starting point which is exploited by ENTICE.

(Galárraga et al., 2014) addresses the problem of normalizing (or canonicalizing) OIE extractions which can be considered as one of the components of ENTICE (see Section 3.3).

As previously mentioned, recent proposals for improving density of KGs such as those reported in (Gardner et al., 2013; Gardner et al., 2014) focus on extracting facts of one of the four extraction classes mentioned in Table 1, viz., KR-KE. The KBP challenge (Surdeanu, 2013) also focuses on extracting facts while keeping the relation set fixed, i.e., it addresses the KR-KE and KR-NE extraction classes.

A method to improve knowledge density in KGs by using search engine query logs and a question answering system is presented in (West et al., 2014). The proprietary nature of datasets and tools used in this approach limits its applicability in our setting.

ENTICE aims to improve knowledge density by extracting facts from all four extraction classes, i.e., for a given entity, it extracts facts involving known relations, identifies potentially new relations that might be relevant for this entity, establishes such relations between the given entity and other known as well as new entities – all in a single system. While various parts of this problem have been studied in isolation in the past, ENTICE is

[1]Measured with respect to the five categories experimented with in the paper. See Section 4 for details.

the first system to the best of our knowledge that addresses the complete problem as a single framework.

3 ENTIty Centric Expansion (ENTICE)

Overall architecture and dataflow within ENTICE is shown in Figure 1. We describe each of the components in the sections below.

3.1 Data Preprocessing

Given the source entity, documents relevant to it are downloaded by issues queries against Google. In order to make the query specific, especially in case of ambiguous entities, a few keywords are also added to the query. For the experiments in this paper, the category is used as the keyword. For example, for the entity *Albert Einstein* from the *scientist* category, the query will be *"Albert Einstein scientist"*. Top 20 documents returned by the search engine are downloaded and processed further. Text is extracted from the raw downloaded documents using regex patters, HTML tag matching, and by using the Boilerpipe tool[2].

3.2 Triple Extraction

Text of each document obtained in the previous step is processed through the Stanford CoreNLP toolkit (Manning et al., 2014) for tokenization, coreference resolution, and dependency parsing. Tokenized and coreference-resolved sentences are then passes through OpenIEv4 system [3] to extract *(noun phrase, predicate, noun phrase)* triples. Multiple and overlapping triples from the sentence was permitted. Length filter is applied on the noun phrase and the predicate of the triple extracted. This eliminates triples whose predicate is more than 6 tokens and noun phrase more than 7 tokens.

3.3 Noun and Relation Phrase Normalization

Noun phrases (NPs) and relation phrases obtained from the previous step are normalized (or canonicalized) in this step. Canopy clustering technique as proposed in (Galárraga et al., 2014) was used for noun phrase as well relation phrase clustering. Initial clustering is done over the *unlinked* noun phrases in the triples. Please note that since we are working in an entity-centric manner, one of the two NPs present in the triple is already connected to the knowledge graph, and hence is considered *linked*. To cluster noun phrases, we first construct canopies corresponding to each word in the noun phrase. For example, for noun phrase *Albert Einstein*, we create two canopies, viz., a canopy for *Albert* and another canopy for *Einstein*, and add *Albert Einstein* to both canopies. Grouping of noun phrases inside the canopy is the next step of clustering phase. Noun phrase similarity is calculated based on similarity of words in the noun phrases. Word similarity is either direct string matching or Gensim similarity score[4], which internally uses word2vec embeddings (Mikolov et al., 2013). After calculating pairwise similarity of noun phrases, hierarchical clustering is carried out to group noun phrases inside each canopy. A threshold score is used to stop hierarchical clustering. At the end of this process, we have canopies and groups of noun phrases inside them. A noun phrase can be in more than one canopy, hence those groups across canopies are merged if the similarity is greater than certain threshold. After this, each group will contain facts which have similar noun phrases and different (or same) relation phrase. Again the facts are clustered based on the similarity of the relation phrase. Relation phrase similarity calculation step resembles the one used for noun phrases as described above.

After this triple clustering step, the best representative triple from each cluster is selected based on a few rules. We consider the structure of POS tags in noun phrases of a triple as one of the criteria. Secondly, if both noun phrases in the triple are linked to the knowledge graph, then it makes the triple more likely to become a representative tuple of the cluster. Also, if the NPs present in the triple are frequent in the cluster, then it makes the corresponding triple more like to become a representative.

3.4 Integrating with Knowledge Graph

The set of normalized triples from the previous step are linked with the Knowledge Graph, whenever possible, in this step. For a given normalized triple, following steps are performed as part of linking. First, category of each noun phrase in the triple is obtained based on string matching. In case of no match, refinements like dropping of adjectives, considering only noun phrases are done to for rematching. Now, the relation phrase is mapped to an existing predicate in the KG based on the extraction patterns in the metadata of the target relation (e.g., NELL and many other KGs have such metadata available). Candidate predicates are chosen from the above mapped predicates based on category signature of the two noun phrases (i.e. entity1 and entity2). This is possible since the all the predicates in NELL have the type signature defined in the metadata. Frequency of the relation phrase in the metadata is used as a criteria to select a candidate from multiple predicates. If such category-signature based mapping is not possible, then the predicate is listed as a new relation, and the corresponding triple marked to belong to either NR-KE or NE-NE extraction class, depending on whether the target entity is already present in the KG or not.

4 Experiments

In order to evaluate effectiveness of ENTICE, we apply it to increase knowledge density for 100 randomly selected entities from each of the following five NELL categories: *Scientist, Universities, Books, Birds*, and *Cars*. For each category, a random subset of extractions in that category was evaluated using Mechanical Turk. To get a better accuracy of the evaluation, each fact was evaluated by 3 workers. Workers were made to classify each fact as correct, incorrect or can't say. Only those facts classified as correct by 2 or more evaluators were considered as correct facts.

Main Result: Experimental results comparing knowledge densities in NELL and after application of ENTICE, along with the accuracy of extractions, are presented in Table 2. From this, we observe that ENTICE is able to improve knowledge density in NELL by a factor of 7.7 while maintaining 75.5% accuracy. Sample extraction examples and accuracy per-extraction class are presented in Table 3 and Table 4, respectively.

Noun and Relation Phrase Normalization: We didn't perform any intrinsic evaluation of the entity and relation normalization step. However, in this section, we provide a few anecdotal examples to give a sense of the output quality from this step. We observe that the canopy clustering algorithm for entity and normalization is able to cluster together facts with somewhat different surface representations. For example, the algorithm came up with the following cluster with two facts: {*(J. Willard Milnor, was awarded, 2011 Abel Prize); (John Milnor, received, Abel Prize)*}. It is encouraging to see that the system is able to put *J. Willard Milnor* and *John Milnor* together, even though they have somewhat different surface forms (only one word overlap). Similarly, the relation phrases *was awarded* and *received* are also considered to be equivalent in the context of these beliefs.

Integrating with Knowledge Graph: Based on evaluation over a random-sampling, we find that entity linking in ENTICE is 92% accurate, while relation linking is about 70% accurate.

In the entity linking stage, adjectives present in a noun phrase (NP) were ignored while matching the noun phrase to entities in the knowledge graph (NELL KB in this case). In case the whole NP didn't find any match, part of the NP was used to retrieve its category, if any. For example, in *(Georg Waldemar Cantor, was born in, 1854)*, the NP *Georg Waldemar Cantor* was mapped to category *person* using his last name and *1854* to category *date*. The relation phrase *"was born in"* maps to many predicates in NELL relational metadata. NELL predicate *AtDate* was selected based on the rule that category signature of the predicate matches the category of the noun phrases present in the triple. It also has the highest frequency count for the relational phrase in the metadata.

We observed that relation mapping has lesser accuracy due to two reasons. Firstly, error in determining right categories of NPs present in a triple; and secondly, due to higher ambiguity involving relation phrases in general, i.e., a single relation phrase usually matches many relation predicates in the ontology.

5 Conclusion

This paper presents ENTICE, a simple but effective entity-centric framework for increasing knowledge densities in automatically constructed knowledge graphs. We find that ENTICE is able to significantly increase NELL's knowledge density by a factor of 7.7 at 75.5% accuracy. In addition to extracting new facts, ENTICE is also able to extend the ontology. Our goal in this paper is twofold: (1) to draw attention to the effectiveness of entity-centric approaches with bigger scope (i.e., covering all four extraction classes in Table 1) towards improving knowledge density; and (2) to demonstrate that even relatively straightforward techniques can go a long way in alleviating low knowledge density in existing state-of- the-art KGs. While these initial results are encouraging, we hope to apply ENTICE on other knowledge graphs, and also experiment with other normalization and entity linking algorithms as part of future work.

Abstract

Syntactic features play an essential role in identifying relationship in a sentence. Previous neural network models directly work on raw word sequences or constituent parse trees, thus often suffer from irrelevant information introduced when subjects and objects are in a long distance. In this paper, we propose to learn more robust relation representations from shortest dependency paths through a convolution neural network. We further take the relation directionality into account and propose a straightforward negative sampling strategy to improve the assignment of subjects and objects. Experimental results show that our method outperforms the state-of-the-art approaches on the SemEval-2010 Task 8 dataset.

1 Introduction

The relation extraction (RE) task can be defined as follows: given a sentence S with a pair of nominals e_1 and e_2, we aim to identify the relationship between e_1 and e_2. RE is typically investigated in a classification style, where many features have been proposed, e.g., Hendrickx et al. (2010) designed 16 types of features including POS, WordNet, FrameNet, dependency parse features, etc. Among them, syntactic features are considered to bring significant improvements in extraction accuracy (Bunescu and Mooney, 2005a). Earlier attempts to encode syntactic information are mainly kernel-based methods, such as the convolution tree kernel (Qian et al., 2008), subsequence kernel (Bunescu and Mooney, 2005b), and dependency tree kernel (Bunescu and Mooney, 2005a).

With the recent success of neural networks in natural language processing, different neural network models are proposed to learn syntactic features from raw sequences of words or constituent parse trees (Zeng et al., 2014; Socher et al., 2012), which have been proved effective, but, often suffer from irrelevant subsequences or clauses, especially when subjects and objects are in a longer distance. For example, in the sentence, "The [singer]$_{e1}$, who performed three of the nominated songs, also caused a [commotion]$_{e2}$ on the red carpet", the *who* clause is used to modify subject e_1, but is unrelated to the *Cause-Effect* relationship between *singer* and *commotion*. Incorporating such information into the model will hurt the extraction performance. We therefore propose to learn a more robust relation representation from a convolution neural network (CNN) model that works on the simple dependency path between subjects and objects, which naturally characterizes the relationship between two nominals and avoids negative effects from other irrelevant chunks or clauses.

Our second contribution is the introduction of a negative sampling strategy into the CNN models to address the relation directionality, i.e., properly assigning the subject and object within a relationship. In the above *singer* example, (*singer*, *commotion*) hold the *Cause-Effect* relation, while (*commotion*, *singer*) not. Previous works (Liu et al., 2015) do not fully investigate the differences between subjects and objects in the utterance, and simply transform a (K+1)-relation task into a ($2\times K$+1) classification task, where 1 is the *other* relation. Interestingly, we find that dependency paths naturally offer the relative positions of subjects and objects through the path directions. In this paper, we propose to model the relation directionality by exploiting the dependency path to learn the assignments of subjects and objects using a straightforward negative sampling method, which adopts the shortest dependency path from the object to the subject as a negative sample. Experimental results show that the negative sampling method significantly improves the performance,

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 536–540,
Lisbon, Portugal, 17-21 September 2015.

and our model outperforms the-state-of-the-art methods on the SemEval-2010 Task 8 dataset.

2 The Shortest Path Hypothesis

If e_1 and e_2 are two nominals mentioned in the same sentence, we assume that the shortest path between e_1 and e_2 describes their relationship. This is because (1) if e_1 and e_2 are arguments of the same predicate, then their shortest path should pass through that predicate; (2) if e_1 and e_2 belong to different predicate-argument structures, their shortest path will pass through a sequence of predicates, and any consecutive predicates will share a common argument. Note that, the order of the predicates on the path indicates the proper assignments of subjects and objects for that relation. For example, in Figure 1, the dependency path consecutively passes through *carried* and *receives*, which together implies that in the *Instrument-Agency* relation, the subject and object play a sender and receiver role, respectively.

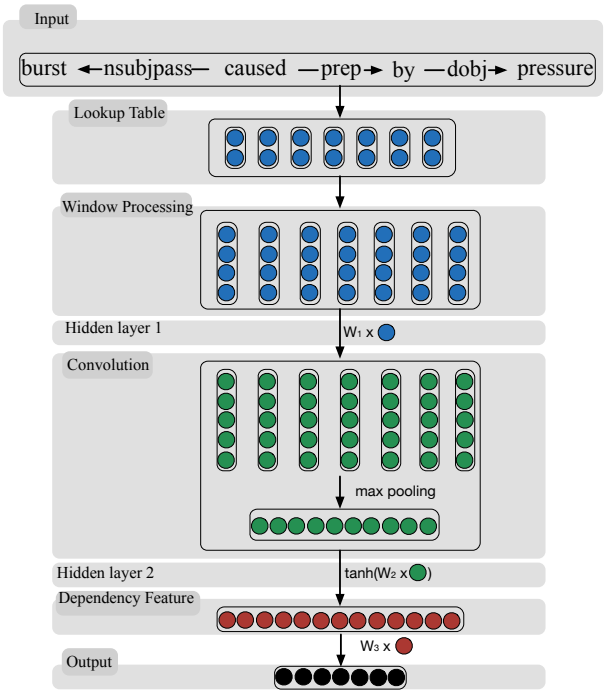

Figure 2: Architecture of the convolution neural network.

3 A Convolutional Neural Network Model

Our model successively takes the shortest dependency path (i.e, the words, dependency edge directions, and dependency labels) from the subject to the object as input, passes it through the lookup table layer, produces local features around each node on the dependency path, and combines these features into a global feature vector that are then fed to a softmax classifier. Each dimension of the output vector indicates the confidence score of the corresponding relation.

In the *lookup table* step, each node (i.e. word, label or arrow) in the dependency path is transformed into a vector by looking up the embedding matrix $W_e \in \mathbb{R}^{d \times |\mathbb{V}|}$, where d is the dimension of a vector and $\mathbb{V}$ is a set of all nodes we consider.

Convolution To capture the local features around each node of the dependency path, we consider a fixed size window of nodes around each node in the *window processing* component, producing a matrix of node features of fixed size $d_w \times 1$, where $d_w = d \times w$ and w is the window size. This matrix can be built by concatenating the vectors of nodes within the window, which are then fed to the convolutional layer.

In the convolutional layer, we use a linear transformation $W_1 \in \mathbb{R}^{n_1 \times d_w}$ to extract local features around each window of the given sequence, where n_1 is the size of hidden layer 1. The resulting matrix Z has size of $n_1 \times t$, where t is the number of nodes in the input dependency path.

We can see that Z captures local contextual information in the dependency path. However, identifying a relationship requires considerations for the *whole* dependency path. We therefore perform a max pooling over Z to produce a global feature vector in order to capture the most useful local features produced by the convolutional layer (Collobert et al., 2011), which has a fixed size of n_1, independent of the dependency path length.

Dependency based Relation Representation To extract more meaningful features, we choose hyperbolic tanh as the non-linearity function in the second hidden layer, which has the advantage of being slightly cheaper to compute, while leaving the generalization performance unchanged. $W_2 \in \mathbb{R}^{n_2 \times n_1}$ is the linear transformation matrix, where n_2 is the size of hidden layer 2. The output vector can be considered as higher level syntactic features, which is then fed to a softmax classifier.

Objective Function and Learning The softmax classifier is used to predict a K-class distribution $d(x)$, where K is the size of all possible relation types, and the transformation matrix is $W_3 \in \mathbb{R}^{K \times n_2}$. We denote $t(x) \in \mathbb{R}^{K \times 1}$ as the target

Table 1: Performances on the development set with different train and testing strategies.

distribution vector[1]: the entry $t_k(x)$ is the probability that the dependency path describes the *k*-th relation. We compute the cross entropy error between $t(x)$ and $d(x)$, and further define the objective function over all training data:

$$J(\theta) = -\sum_{x}\sum_{k=1}^{K} t_k(x)\log d_k(x) + \lambda||\theta||^2$$

where $\theta = (W_e, W_1, W_2, W_3)$ is the set of model parameters to be learned, and λ is a vector of regularization parameters. The model parameters θ can be efficiently computed via backpropagation through network structures. To minimize $J(\theta)$, we apply stochastic gradient descent (SGD) with AdaGrad (Duchi et al., 2011) in our experiments.

4 Negative Sampling

We start by presenting three pilot experiments on the development set. In the first one, we assume that the assignment of the subject and object for a relation is not given (blind), we simply extract features from e_1 to e_2, and test it in a blind setting as well. In the second one, we assume that the assignment is given (sighted) during training, but still blind in the test phase. The last one is assumed to give the assignment during both training and test steps. The results are listed in Table 1.

The third experiment can be seen as an upper bound, where we do not need to worry about the assignments of subjects and objects. By comparing the first and the second one, we can see that when adding assignment information during training, our model can be significantly improved, indicating that our dependency based representation can be used to learn the assignments of subjects/objects, and injecting better understandings of such assignments during training is crucial to the performance. We admit that models with more complex structures can better handle these considerations. However, we find that this can be achieved by simply feeding typical negative samples to the model and let the model learn from such negative examples to correctly choose the right assignments of subjects and objects. In practice, we can treat the opposite assignments of subjects and the objects as negative examples. Note that, the dependency path of the wrong assignment is different from that of the correct assignment, which essentially offers the information for the model to learn to distinguish the subject and the object.

[1]Note that, there may be more than one relation existing between two nominals. A dependency path thus may correspond to multiple relations.

5 Experimental Evaluation

We evaluate our model on the SemEval-2010 Task 8 (Hendrickx et al., 2010), which contains 10,717 annotated examples, including 8,000 instances for training and 2,717 for test. We randomly sampled 2,182 samples from the training data for validation.

Given a sentence, we first find the shortest dependency path connecting two marked nominals, resulting in two dependency paths corresponding to two opposite subject/object directions, and then make predictions for the two paths, respectively. We choose the relation *other* **if and only if** both predictions are *other*. And for the rest cases, we choose the non-*other* relation with highest confidence as the output, since ideally, for a non-*other* instance, our model will output the correct label for the right subject/object direction and an *other* label for the wrong direction. We evaluate our models by macro-averaged F1 using the official evaluation script.

We initialized W_e with 50-dimensional word vectors trained by Turian et al. (2010). We tuned the hyper parameters using the development set for each experimental setting. The hyper parameters include w, n_1, n_2, and regularization parameters

for W_e, W_1, W_2 and W_3. The best setting was obtained with the values: 3, 200, 100, 10^{-4}, 10^{-3}, 10^{-4} and 2×10^{-3}, respectively.

Results and Discussion Table 2 summarizes the performances of our model, depLCNN+NS(+), and state-of-the-art models, SVM (Hendrickx et al., 2010), RNN, MV-RNN (Socher et al., 2012), CNN (Zeng et al., 2014) and DepNN (Liu et al., 2015). For fair comparisons, we also add two types of lexical features, WordNet hypernyms and words around nominals, as part of input vector to the final `softmax` layer.

We can see that our vanilla depLCNN+NS, without extra lexical features, still outperforms, by a large margin, previously reported best systems, MVRNN+ and CNN+, both of which have taken extra lexical features into account, showing that our treatment to dependency path can learn a robust and effective relation representation. When augmented with similar lexical features, our depLCNN+NS further improves by 1.6%, significantly better than any other systems.

Let us first see the comparisons among plain versions of depLCNN (taking both dependency directions and labels into account), depCNN (considering the directions of dependency edges only), MVRNN and CNN, which all work in a $2\times K$+1 fashion. We can see that the both of our depCNN and depLCNN outperforms MVRNN and CNN by at least 2.2%, indicating that our treatment is better than previous conventions in capturing syntactic structures for relation extraction. And note that depLCNN, with extra considerations for dependency labels, performs even better than depCNN, showing that dependency labels offer more discriminative information that benefits the relation extraction task.

And when we compare plain depLCNN and depLCNN+NS (without lexical features), we can see that our Negative Sampling strategy brings an improvement of 2.1% in F1. When both of the two models are augmented with extra lexical features, our NS strategy still gives an improvement of 1.9%. These comparisons further show that our NS strategy can drive our model to learn proper assignments of subjects/objects for a relation.

Next, we will have a close look at the effect of our Negative Sampling method. We conduct additional experiments on the development set to compare two different negative sampling methods. As a baseline, we randomly sampled 8,000 negative examples from the NYT dataset (Chen et al., 2014). For our proposed NS, we create a negative example from each *non-other* instance in the training set, 6,586 in total. As shown in Table 2, it is no doubt that introducing more negative examples improves the performances. We can see that our model still benefits from the randomly sampled negative examples, which may help our model learn to refine the margin between the positive and negative examples. However, with similar amount of negative examples, treating the reversed dependency paths from objects to subjects as negative examples can achieve a better performance (85.4% F1), improving random samples by 1.9%. This again proves that dependency paths provide useful clues to reveal the assignments of subjects and objects, and a model can learn from such reversed paths as negative examples to make correct assignments. Beyond the relation extraction task, we believed the proposed Negative Sampling method has the potential to benefit other NLP tasks, which we leave for future work.

6 Conclusion

In this paper, we exploit a convolution neural network model to learn more robust and effective relation representations from shortest dependency paths for relation extraction. We further propose a simple negative sampling method to help make correct assignments for subjects and objects

within a relationship. Experimental results show that our model significantly outperforms state-of-the-art systems and our treatment to dependency paths can well capture the syntactic features for relation extraction.

A Baseline Temporal Tagger for all Languages

Jannik Strötgen and **Michael Gertz**
Institute of Computer Science, Heidelberg University
Im Neuenheimer Feld 348, 69120 Heidelberg, Germany
{stroetgen,gertz}@informatik.uni-heidelberg.de

Abstract

Temporal taggers are usually developed for a certain language. Besides English, only few languages have been addressed, and only the temporal tagger HeidelTime covers several languages. While this tool was manually extended to these languages, there have been earlier approaches for automatic extensions to a single target language. In this paper, we present an approach to extend HeidelTime to all languages in the world. Our evaluation shows promising results, in particular considering that our approach neither requires language skills nor training data, but results in a baseline tagger for 200+ languages.

1 Introduction & Related Work

Temporal tagging (the extraction and normalization of temporal expressions) is a crucial task in NLP, and many applications can benefit from temporal information, e.g., in the context of question answering and information retrieval (Campos et al., 2014). Thus, there has been a lot of research during the last years addressing temporal information extraction, as reflected by manually annotated corpora, approaches to temporal tagging, and research challenges such as the TempEval series (Verhagen et al., 2010; UzZaman et al., 2013).

While, in the meantime, the range of annotated corpora covers several languages different from English, e.g., the French, Portuguese, Italian, and Romanian TimeBank corpora (Bittar et al., 2011; Costa and Branco, 2012; Caselli et al., 2011; Forascu and Tufis, 2012), most approaches to temporal tagging focus on processing English text, e.g., DANTE (Mazur and Dale, 2009; Mazur, 2012) and SUTime (Chang and Manning, 2012). Of course, exceptions exist, e.g., TipSem for English and Spanish (Llorens et al., 2010), and HeidelTime (Strötgen and Gertz, 2013) even covers 13 languages. However, it required a lot of manual effort to extend HeidelTime, and researchers of different institutes and countries have been involved for German (Strötgen and Gertz, 2011), Dutch (van de Camp and Christiansen, 2012), Spanish (Strötgen et al., 2013), French (Moriceau and Tannier, 2014), Croatian (Skukan et al., 2014), Vietnamese and Arabic (Strötgen et al., 2014), Italian (Manfredi et al., 2014), Chinese (Li et al., 2014), Russian, Estonian, and Portuguese.

Obviously, it is possible to manually extend HeidelTime and thus a temporal tagger in general. However, each language is typically addressed separately, and the extension process is time- and labor-intensive, so that a method to automate this process is desirable. While there have been earlier approaches for automatic extensions of temporal taggers to further languages (Saquete et al., 2004; Negri et al., 2006; Spreyer and Frank, 2008), these were limited to a few languages and the results were considered less successful, in particular for the normalization subtask. In contrast, Angeli and Uszkoreit (2013) presented an approach to language-independent parsing of temporal expressions, however, addressing only the normalization and not the extraction subtask.

In this paper, we re-address the task of automatically extending a temporal tagger to further languages. In contrast to previous work, we address both subtasks of temporal tagging, i.e., the extraction and the normalization, and we do not limit our work to a few selected languages, but we aim at extending HeidelTime to cover all languages in the world. In addition of making use of automatic pattern translations based on Wiktionary,[1] we allow for fuzzy matching in the newly addressed languages. This strategy results in promising temporal tagging quality for many languages, although our evaluations show that the quality of a manually extended temporal tagger is not reached, and

[1] http://www.wiktionary.org/.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 541–547,
Lisbon, Portugal, 17-21 September 2015.

that there are open issues that need to be addressed for specific language characteristics.

By making our newly developed resources publicly available, we establish a baseline temporal tagger for basically all languages in the world – for comparison or as starting point for improvements.

2 HeidelTime

HeidelTime is a rule-based, domain-sensitive, and publicly available temporal tagger that was developed with multilinguality in mind so that the source code and language-dependent resources are strictly separated, and it can be extended to new languages without modifying its source code (Strötgen and Gertz, 2013).

2.1 Input and Output Format

As input, HeidelTime requires linguistic preprocessed documents with sentence, token, and part-of-speech (pos) information – although it is possible to create language resources not making use of pos constraints. For processing news-style documents, a publication date is additionally needed.

Temporal expressions are annotated following the temporal markup language TimeML (Pustejovsky et al., 2005) using TIMEX3 tags with normalization attributes, most importantly *type* (date, time, duration, set) and *value* to represent the main semantics of expressions in standard format.

2.2 Language-dependent Resources

Each language requires its own language resources consisting of patterns, normalization information and rules. Pattern files contain terms that are frequently used to form temporal expressions, e.g., for names of months and weekdays or numbers that may refer to a day or year. Regular expressions can be used in the pattern files, and each pattern file is interpreted as a regular expression pattern, which can be called by HeidelTime's rules.

Normalization files contain normalized information for patterns defined in the pattern files, e.g., that the value of "January" is "01" and that "3" has to be normalized to "03" in case it refers to a day or a month and to "3" in case it refers to a duration.

Finally, for the four types of temporal expressions (date, time, duration, and set), a rule file contains all rules for respective expressions. In addition to a rule name, the extraction part and the value normalization part are obligatory. The former is a regular expression that may contain any number of references to pattern files, and in the latter, normalization functions are called to normalize respective parts of the extracted expressions. In addition, part-of-speech constraints can be specified, negative rules can be formulated, and offset information can be set, e.g., if parts of the extracted patterns are required context information during the extraction process but not part of the temporal expression itself.[2]

2.3 Manual Extension to a New Language

So far, HeidelTime resources for newly supported languages have been manually created (cf. references is Section 1). For this, the following steps had to be completed: (i) linguistic preprocessing for the new language has been provided, (ii) all patterns in the pattern and normalization files have been manually translated, and (iii) rules have been developed iteratively. Starting with simple rules of the source language (typically English), rules have been adapted and added based on false negatives, false positives, partial matches and incorrect value normalizations on the training data for the new language. Then, more complex rules of the source language have been addressed step-by-step.

Note that tasks (ii) and (iii) have been carried out by language experts, and task (iii) was performed until no further improvements could be achieved on the training data. In addition to the fact that this process is time- and labor intensive, further disadvantages are that a language expert and temporally annotated training data are required. Finally, languages are typically addressed by different researchers with differing effort so that quality and completeness varies.

3 Automatic Extension to All Languages

In this section, we present the steps of our automatic extension approach in detail. A graphical summary of our approach is depicted in Figure 1.

3.1 Linguistic Preprocessing

While part-of-speech (pos) information can be helpful to write more general rules and to improve temporal tagging quality, there is no pos tagger covering all languages in the world. In addition,

[2]While these explanations are necessary to understand our automated resource development approach that will be presented in Section 3, for further details about HeidelTime and its language-dependent resources we refer to Strötgen and Gertz (2013) and `https://github.com/HeidelTime/heideltime`.

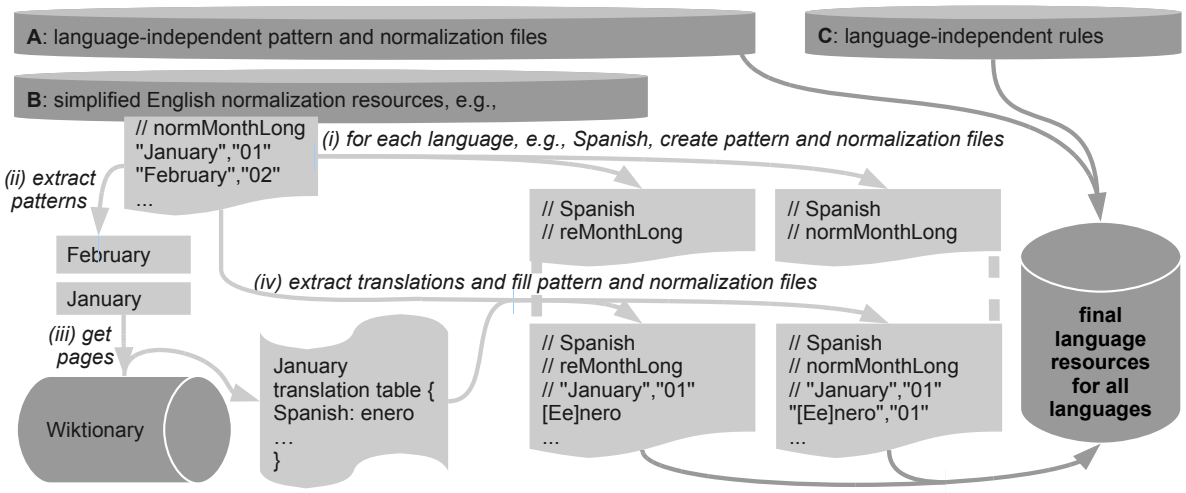

Figure 1: Graphical overview of the automated resource development process. Resources A and C are directly added to the resources of all languages; resource B is processed following steps (i) to (iv).

the only obligatory linguistic preprocessing steps are sentence splitting and tokenization. Thus, we write a simple and generic, language-independent sentence splitter and tokenizer, which we use for all languages. Note that our tokenization is based on a white-space token boundary assumption so that we have to take care of languages without such token boundaries separately (cf. Section 4).

3.2 Language-independent Resources

Some patterns and normalization information are valid for all (many) languages, e.g., numbers for days and months. For such patterns, we write language-independent pattern and normalization resources (Figure 1, A). These do not contain language-dependent terms and will be part of the resources for each of the languages in the world.

3.3 Simplified English Resources

The main goal of the simplified English resources is to make HeidelTime's original English resources amenable to automatic translation. Thus, rules are addressed in a language-independent fashion (cf. Section 3.4), and the simplified English resources (Figure 1, B) are written as normalization files, from which pattern and normalization files for all languages are derived (Figure 1, i-iv).

For terms directly occurring in English rules, new pattern files are created, and all English patterns are written without regular expressions. While this makes the resources longer (original patterns with regular expressions are expanded to many patterns), these simplified resources are necessary for a smooth translation process.

3.4 Language-independent Rules

Based on HeidelTime's English resources, we also write completely language-independent rules for date, time, duration, and set expressions. In addition, we add "creative" rules that are not necessary for English expressions but might match expressions in other languages. In particular, we allow several orderings of patterns and sometimes even random tokens in between. For instance, instead of just a "month day" pattern (e.g., to match "January 13"), we add "day month", "day X month" and "month X day", with "X" matching any token (e.g., for the Spanish translation "13 de enero").

In the extraction and normalization parts of the rules, we refer to the names of the language-independent and simplified English pattern and normalization files. Note that in contrast to the original rules, these rules do neither contain pos constraints nor any English terms to guarantee language independence. However, fuzzy pattern matching is allowed at the end of some patterns to try to take care of morphology-rich languages.

3.5 Creating Resources for All Languages

As shown in Figure 1, the patterns of the simplified English resources are translated to all languages in the world using Wiktionary as translation resource. For each normalization file, the respective pattern and normalization files for each language in Wiktionary are created (i).[3] Then,

[3]Note that Wiktionary exists in about 170 languages but contains translations to many more languages; for details, see `http://en.wiktionary.org/wiki/Wiktionary:Statistics`.

Table 1: Evaluation results for several languages on public corpora. HeidelTime 1.9 results as reported on `https://github.com/HeidelTime/heideltime/wiki/Evaluation-Results`.

the patterns are extracted from the simplified English normalization resources (ii) and the respective Wiktionary pages are accessed (iii). These contain translation information that is then added to the pattern and normalization files of the occurring languages by extracting respective translations (iv).

Note that for ambiguous words, Wiktionary contains one translation table for each meaning. For instance, there are two translation tables for "November" for the meanings "eleventh month of the Gregorian calendar" and "N in the ICAO spelling alphabet".[4] Obviously, it is crucial to use only the translations of the intended meaning. Thus, in the case of multiple meanings of English patterns, we provide the names of Wiktionary's correct translation tables to our translation script, so that only translations of the correct meaning are generated. In addition, if patterns in the new language start with a lower case character, we allow upper case and lower case for the respective character as shown in Figure 1, (iv).

Unfortunately, Wiktionary is of course not complete and does not contain translations to all languages for all English patterns. However, to allow backtracking, we add the English information to the resource files of all languages. If, at a later point, the automatically created resources are used as basis for developing better resources for specific languages, missing translations can be easily detected and manually added.

[4] `http://en.wiktionary.org/wiki/November#Translations`.

3.6 Improving and Finalizing the Resources

In particular for the rule development process, we also create the automatic resources for English. These are repeatedly evaluated on the temporally annotated English corpora TimeBank (Pustejovsky et al., 2003), TempEval-3 platinum (UzZaman et al., 2013), and WikiWars (Mazur and Dale, 2010). Analyzing the errors on these corpora, we iteratively improve the simplified English resources and the rules. In Table 1, we compare HeidelTime's original English resources (HeidelTime 1.9) with the simplified resources (HeidelTime – automatic). While details about evaluation measures will be described in Section 4, the results of the automatic approach are obviously lower, as expected due to the simplification process.

Resources for all languages are finally built by combining the language-independent resources, the automatically created pattern and normalization files, and the language-independent rules. Note that depending on the completeness of Wiktionary, the coverage of the resources – and thus also their quality – varies between languages.

4 Evaluation

For a subset of languages, temporally annotated corpora exist. Thus, we can directly evaluate our approach for these languages. For German, Spanish, Italian, French, Portuguese, Croatian, Arabic, Vietnamese, and Chinese, we compare our automatic approach with HeidelTime's manually developed resources. In addition, first results are reported for Romanian.

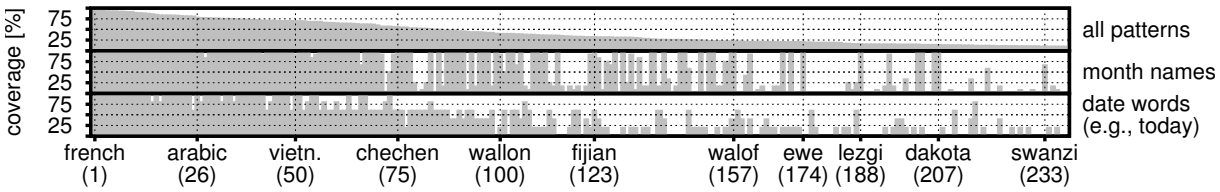

Figure 2: Language completeness statistics showing how many of the simplified English patterns have translations in Wiktionary for the 238 languages with at least 10% coverage (ordered based on "all patterns" coverage). A detailed plot with all language names is available on HeidelTime's GitHub page.

For all other languages, it is obviously difficult to judge the temporal tagging quality of the newly developed resources. However, for an estimation of the quality for languages without temporally annotated corpora, we provide completeness statistics of the pattern translations. The fewer translations are available for a language, the more likely it is that the temporal tagging quality is rather low.

4.1 Evaluation Measures

Since the task of temporal tagging is two-fold, we report precision, recall, and F1-score for the extraction task, and for the full task (relaxed extraction plus value normalization) *value F1*. Similar as the TempEval-3 organizers (UzZaman et al., 2013), we consider *value F1* with relaxed matching as most important. However, when processing large amounts of data, *value accuracy* becomes also important. Since it directly shows independent of the recall if extracted expressions are normalized correctly, it is reported, too.

4.2 Evaluation Results and Discussion

As shown in Table 1, the results of our automatically created resources are worse than those of HeidelTime with manually developed resources. For Spanish, German, French, and Portuguese, high precision, moderate recall, and good normalization results are achieved. In contrast, recall for Chinese, Croatian, and Romanian are quite low, precision is low for Romanian, and normalization accuracy for Chinese, Vietnamese and Romanian. Clearly, more work is necessary to achieve temporal tagging quality that can be considered as applicable for other applications. In particular, issues with morphology-rich languages and those without white-space tokenization have to be addressed.

Nevertheless, the results look promising for several languages taking into account that the resources are developed without any language-specific information, and that our approach has been the first step towards more sophisticated temporal tagging of all languages in the world. Note that recall is much worse than precision for all languages and that the normalization of extracted expressions works quite well (*value acc.*).

4.3 Completeness Statistics

To estimate the quality of our automatically created resources for languages without annotated corpora, we create completeness statistics. As Figure 2 shows, the completeness differs significantly between languages. However, Wiktionary translations exist for at least 75% and 50% of the patterns for 34 and 83 languages, respectively, and even for many languages with low overall coverage, important patterns such as month names and date words are well-covered. Note that even for languages with few translations, our approach can be considered as baseline since temporal tagging of most languages has not been addressed before.

5 Conclusions and Ongoing Work

In this paper, we presented our approach to automatically extend the temporal tagger HeidelTime to all languages in the world. We thus establish new temporal tagging baselines for many languages, and anyone working on any of those languages in the future can either use our resources as a starting point or as a baseline for comparison. The resources for 200+ languages are available with HeidelTime 2.0 at `http://github.com/HeidelTime/heideltime`.

Currently, we are improving the simplified English resources and the translation process by exploiting further resources such as Wikipedia. In the future, we thus plan to constantly update HeidelTime's automatically created resources.

Abstract

We consider the task of named entity recognition for Chinese social media. The long line of work in Chinese NER has focused on formal domains, and NER for social media has been largely restricted to English. We present a new corpus of Weibo messages annotated for both name and nominal mentions. Additionally, we evaluate three types of neural embeddings for representing Chinese text. Finally, we propose a joint training objective for the embeddings that makes use of both (NER) labeled and unlabeled raw text. Our methods yield a 9% improvement over a state-of-the-art baseline.

1 Introduction

Named entity recognition (NER), and more generally the task of mention detection[1], is an essential component of information extraction technologies: the first step before tasks such as relation extraction (Bunescu and Mooney, 2005) and entity linking (Dredze et al., 2010; Ratinov et al., 2011). A long line of work has focused on NER in both formal and informal domains (Collins and Singer, 1999; McCallum and Li, 2003; Nadeau and Sekine, 2007; Jin and Chen, 2008; He et al., 2012a), with recent efforts turning towards social media (Finin et al., 2010; Liu et al., 2011; Ritter et al., 2011; Fromreide et al., 2014; Li et al., 2012; Liu et al., 2012). While NER has included work on several languages, work on social media NER has largely focused on English language data.[2]

We consider NER on Chinese social media from the popular Sina Weibo service, both because of the popularity of the service (comparable in size to Twitter and previously used in NLP research (Ling et al., 2013)) and the challenges faced in processing Chinese language data. One approach is to utilize lexical embeddings to improve NER systems (Collobert and Weston, 2008; Turian et al., 2010; Passos et al., 2014), including for Twitter (Cherry and Guo, 2015). However, the use of embeddings for Chinese remains a challenge. Unlike most languages, we cannot easily assign an embedding to each Chinese word without automated segmentation, which may be unreliable, especially when we want to model informal text.[3] For this reason, state-of-the-art NER systems for Chinese do not tag words; they instead tag characters directly (Mao et al., 2008). While work has explored different embeddings for Chinese (Liu et al., 2014; Sun et al., 2014; Qiu et al., 2014; Chen et al., 2015), their inclusion in downstream tasks, such as NER, remains untested.

We explore several types of embeddings for Chinese text and their effect on Chinese social media NER. Specifically, we make the following contributions. 1) We present the first system for NER on Chinese social media using a new corpus based on Weibo messages. We consider both name and nominal mentions, with the goal of supporting downstream systems, such as coreference resolution. Notably, our results reveal that the gap between social media and traditional text for Chinese is much larger than similar corpora for English, suggesting this task as an interesting area of future work.[4] 2) We evaluate three types of embeddings for Chinese text based on their inclusion in a downstream task. We include results with and without fine-tuning. 3) We present a joint ob-

[1] Since we consider name and nominals, our work is closer to mention detection. For simplicity, we use the term NER.

[2] Etter et al. (2013) considered Spanish Twitter, which is quite similar to English from the standpoint of building models and features.

[3] Word segmentation performance is much worse on social media compared to formal text (Duan et al., 2012).

[4] Consider the overall F1 scores from Ritter et al. (2011), Cherry and Guo (2015) and Fromreide et al. (2014) compared to our best results in Table 2. This is despite the fact that Chinese NER performance on formal texts is similar to English.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 548–554,
Lisbon, Portugal, 17-21 September 2015.

jective that trains embeddings simultaneously for both NER and language modeling. Joint training yields better results than post-hoc fine-tuning.

2 NER for Chinese Social Media

Several SIGHAN shared tasks have focused on Chinese NER (Zhang et al., 2006; Jin and Chen, 2008; He et al., 2012b; Zhu et al., 2003; Fang et al., 2004; Zhang et al., 2006), though they have been restricted to formal text, e.g. news. NER for Chinese social media remains unexplored.[5]

As is the case for other languages, social media informality introduces numerous problems for NLP systems, such as spelling errors, novel words, and ungrammatical constructions. Chinese presents additional challenges, since it uses logograms instead of alphabets, and lacks many of the clues that a word is a name, e.g. capitalization and punctuation marks. The lack of explicit word boundaries further confuses NER systems. These problems are worse in social media, which has worse word segmentation. Additionally, typical Chinese corpora use exclusively traditional or simplified characters, whereas social media mixes them. Figure 1 demonstrates some challenges.

The baseline system for our task is our own implementation of Mao et al. (2008), which is the current state-of-the-art on the SIGHAN 2008 shared task (Jin and Chen, 2008). They use a CRF tagger with a BIOSE (begin, inside, outside, singleton, end) encoding that tags individual characters, not words, since word segmentation errors are especially problematic for NER (Zhang et al., 2006). Features include many common English NER features, e.g. character unigrams and bigrams, with context windows of size 5. See Mao et al. (2008) for complete details on their system.

Mao et al. (2008) use a two pass approach, training a CRF first for mention detection and using the resulting predictions as a feature for an NER system. Furthermore, they make extensive use of gazetteer features. For simplicity, we exclude the first pass mention detection and the gazetteer features, which make only small improvements to their overall performance. We note that other implementations of this system (Zhang et al., 2013) have been unable to match the performance reported in Mao et al. (2008). Similarly, our implementation yields results on SIGHAN 2008 similar

[5]Yang et al. (2014) consider a related problem of identifying product mentions in Weibo messages.

Figure 1: Examples of Weibos messages and translations with named (red) and nominal (blue) mentions.

to those reported in Zhang et al. (2013).[6] Overall, we take this tagger as representative of state-of-the-art for Chinese NER.

3 Embeddings for Chinese Text

Lexical embeddings represent words in a continuous low dimensional space, which can capture semantic or syntactic properties of the lexicon: similar words would have similar low dimensional vector representations. Embeddings have been used to gain improvements in a variety of NLP tasks. In NER specifically, several papers have shown improvements by using pre-trained neural embeddings as features in standard NER systems (Collobert and Weston, 2008; Turian et al., 2010; Passos et al., 2014). More recently, these improvements have been demonstrated on Twitter data (Cherry and Guo, 2015). Embeddings are especially helpful when there is little training data, since they can be trained on a large amount of unlabeled data. This is the case for new languages and domains, the task we face in this paper.

However, training embeddings for Chinese is not straightforward: Chinese is not word segmented, so embeddings for each word cannot be trained on a raw corpus. Additionally, the state-of-the-art systems for downstream Chinese tasks, such as NER, may not use words.

We present three types of Chinese embeddings that will be trained on a large corpus of Weibo messages. These embeddings will be used as features in the NER system by adding a (real valued) feature for each dimension of the embedding for the current word/character.

Word Embeddings We train an embedding for each word type, the standard approach in other languages. We run a Chinese word segmentation

[6]Our implementation obtains an F1 of 88.63%.

system[7] over the raw corpus of Weibo messages. To create features, we first segment the NER data, and then lookup the embedding that matches the segmented word. Since the NER system tags characters, we add the same word embedding features to each character in the word.

Character Embeddings We learn an embedding for each character in the training corpus (Sun et al., 2014; Liu et al., 2014).This removes the dependency on pre-processing the text, and better fits our intended use case: NER tagging over characters. Since there are many fewer characters than words, we learn many fewer embeddings. On the one hand, this means fewer parameters and less over-fitting. However, the reduction in parameters comes with a loss of specificity, where we may be unable to learn different behaviors of a character in different settings. We explore a compromise approach in the next section. These embeddings are directly incorporated into the NER system by adding embedding features for each character.

Character and Position Embeddings Character embeddings cannot distinguish between uses of the same character in different contexts, whereas word embeddings fail to make use of characters or character n-grams that are part of many words. A compromise is to use character embeddings that are sensitive to the character's position in the word (Chen et al., 2015). We first word segment the corpus. For each character in each word, we add a positional tag, e.g. the first/second/etc. character in the word, yielding multiple embeddings per character. We learn separate embeddings for each positionally tagged character. To use these embeddings as features, we segment the NER text, obtain position tags for each character, and add features for the corresponding embedding.

These three methods lead to 179,809 word embeddings, 10,912 character embeddings, and 24,818 character with position embeddings.

3.1 Fine Tuning

For each of the embeddings, we fine-tune pre-trained embeddings in the context of the NER task. This corresponds to initializing the embeddings parameters using a pre-trained model, and then modifying the parameters during gradient updates of the NER model by back-propogating gradients. This is a standard method that has been previously explored in sequential and structured prediction problem (Collobert et al., 2011; Zheng et al., 2013; Yao et al., 2014; Pei et al., 2014).

3.2 Joint Training Objectives

Fine-tuning has a disadvantage: it can arbitrarily deviate from the settings obtained from training on large amounts of raw text. Recent work has instead tuned embeddings for a specific task, while maintaining information learned from raw text. Yu and Dredze (2014) use multi-part objectives that include both standard unlabeled objectives, such as skip-gram models in word2vec, and task specific objectives. Jointly training the embeddings with the multi-part objectives allows the fine-tuned embeddings to further influence other embeddings, even those that do not appear in the labeled training data. This type of training can help improve OOVs (Yu and Dredze, 2015), an important aspect of improving social media NER.

We propose to jointly learn embeddings for both language models and the NER task. The modified objective function (log-likelihood) for the CRF is given by:

$$\mathcal{L}_s(\boldsymbol{\lambda}, \boldsymbol{e_w}) = \frac{1}{K} \sum_k \left[\log \frac{1}{Z(x)^k} + \sum_j \lambda_j F_j(\boldsymbol{y}^k, \boldsymbol{x}^k, \boldsymbol{e_w}) \right],$$

where K is the number of instances, $\boldsymbol{\lambda}$ is the weight vector, $\boldsymbol{x}^k$ and $\boldsymbol{y}^k$ are the words and labels sequence for each instance, $\boldsymbol{e_w}$ is the embedding for a word/character/character-position representation w, $Z(x)^k$ is the normalization factor for each instance, and $F_j(\boldsymbol{y}^k, \boldsymbol{x}^k, \boldsymbol{e_w}) = \sum_{i=1}^{n} f_j(y_{i-1}^k, y_i^k, \boldsymbol{x}^k, \boldsymbol{e_w}, i)$ represents the feature function in which j denotes different feature templates and i denotes the position index in a sentence. This differs from a traditional CRF in that the feature function depends on the additional variables $\boldsymbol{e_w}$, which are the embeddings (as defined above). As a result, the objective is no longer log-linear, but log-bilinear [8].

[7] We use Jieba for segmentation: `https://github.com/fxsjy/jieba`

[8] It is log-bilinear because the log-likelihood takes the form $f(x, y) = axy + bx + cy$, where x, y are variables and a, b, c are coefficients. In this case, x is the feature weight and y is the embedding; both of them are vectors. Taking the partial derivative with respect to any one of the variables, one gets a constant (wrt that variable). This satisfies the definition of log-bilinear functions.

The second term is the standard skip-gram language model objective (Mikolov et al., 2013):

$$\mathcal{L}_u(\boldsymbol{e_w}) = \frac{1}{T}\sum_{t=1}^{T}\sum_{-c\leq j\leq c, j\neq 0} \log p(w_{t+j}|w_t), \quad (1)$$

where

$$p(w_i|w_j) = \frac{\exp\left(\boldsymbol{e}_{\boldsymbol{w_i}}^T \boldsymbol{e}_{\boldsymbol{w_j}}\right)}{\sum_{i'} \exp\left(\boldsymbol{e}_{\boldsymbol{w_{i'}}}^T \boldsymbol{e}_{\boldsymbol{w_j}}\right)}.$$

The first objective is notated $\mathcal{L}_s$ for "supervised" (trained on labeled NER data), and the second is $\mathcal{L}_u$, "unsupervised" (trained on raw text.) Both objectives share the same variables $\boldsymbol{e_w}$. The overall goal is to maximize their weighted sum:

$$\arg\max_{e_w} = \mathcal{L}_s(\boldsymbol{\lambda}, \boldsymbol{e_w}) + C\mathcal{L}_u(\boldsymbol{e_w}) \quad (2)$$

where C is a tradeoff parameter.

3.3 Parameter Estimation

We pre-trained embeddings using word2vec (Mikolov et al., 2013) with the skip-gram training objective and NEC negative sampling. Unless otherwise stated, we used word2vec's default parameter settings. All embeddings were 100-dimensional, and we used the same embeddings for the input and output parameters in the skip-gram objective. We optimized the joint objective (2) using an alternative optimization strategy: we alternated 30 iterations of CRF training on the NE labeled data and 5 multi-threaded passes through both the labeled and unlabeled data for the skip-gram objective. We avoided over-fitting using early-stopping. For simplicity, we set $C = 1$ for (2). The CRF was trained using stochastic gradient descent with an L2 regularizer. All model hyper-parameters were tuned on dev data.

We use the off-the-shelf tool word2vec (Mikolov et al., 2013) to do skip-gram training for language model, and implement our own CRF model to modify the embeddings. We optimize (2) by alternating the optimzation of each of the two objectives.

4 Weibo NER Corpus

We constructed a corpus of Weibo messages annotated for NER. We followed the DEFT ERE (Linguistics Data Consortium, 2014) [9] annotation guidelines for entities, which includes four major semantic types: person, organization, location and geo-political entity. We annotated both name and nominal mentions. Chinese pronoun mentions can be easily recognized with a regular expression. We used Amazon Mechanical Turk, using standard methods of multiple annotators and including gold examples to ensure high quality annotations (Callison-Burch and Dredze, 2010).

	Mentions		
Entity Type	**Name**	**Nominal**	**Total**
Geo-political	243	0	243
Location	88	38	126
Organization	224	31	255
Person	721	636	1,357

Table 1: Mention statistics for the Weibo NER corpus.

Our corpus includes 1,890 messages sampled from Weibo between November 2013 and December 2014. Rather than selecting messages at random, which would yield a small number of messages with entities, we selected messages that contained three or more (segmented) words that were not in a fixed vocabulary of common Chinese words. Initial experiments showed this gave messages more likely to contain entities.

Table 1 shows statistics of the final corpus. We divided the corpus into 7 folds, each with 127 messages, where each message corresponds to a single instance. We use the first 5 folds for train, the 6th for development, and the 7th for test. We make our code and the annotated corpus available.[10]

We constructed an additional corpus of unlabeled messages for training the embeddings. We randomly selected 2,259,434 messages from the same time period as above.

5 Experiments

We evaluate our methods under two settings: training on only name mentions, and training on both name and nominal mentions. We re-train the Stanford NER system (Finkel et al., 2005) as a baseline; besides, we also evaluate our implementation of the CRF from Mao et al. (2008) as described in §2 as *Baseline Features*. To this baseline, we add each of our three embedding models: *word*, *character*, *character+position* (as described in §3), and report results on the modified

[9] See Aguilar et al. (2014) for a comparison of DEFT ERE with other common standards.

Table 2: NER results for name mentions (top) and name + nominal mentions (bottom).

CRF model with and without fine-tuning. We also report results for the joint method trained with the character+position model (cp), which performed the best on dev data for joint training.

General Results Table 2 shows results for both dev (tuned) and test (held out) splits. First, we observe that the results for the baseline are significantly below those for SIGHAN shared tasks as well as the reported results on Twitter NER, showing the difficulty of this task. In particular, recall is especially challenging. Second, all embeddings improve the baseline on test data, but the character + position model gets the best results. Fine-tuning improves embedding results, but seems to overfit on dev data. Finally, our joint model does the best in both conditions (name and name+nominal) on test data, improving over fine-tuning, yielding up to a 9% (absolute) improvement over a strong baseline.

Effect of Embeddings We expect improvements from embeddings to be larger when there is less training data. Figure 2 shows F1 on dev data for different amounts of training data, from 200 instances up to 1400, for the character + position embeddings versus the baseline model. We see that for both settings, we see larger improvements from embeddings for smaller training sets.

Error Analysis Since the results are relatively low, we conducted an error analysis by randomly sampling 150 error items and manually looking through them. Among the 150 examples, 65 are annotation errors, majorly cause by annotators neglecting some mentions, this contributes 43% of the errors. The second largest error source are the person names: Chinese person names are very flexible and nearly every character can be used in given names, this makes recognizing person names challenging and contributes to 9% of our errors. The following largest source of error are transliterated foreign names, which contributes to 7% of the errors. Other sources including boundary error, type error, name abbreviation, nicknames, etc.

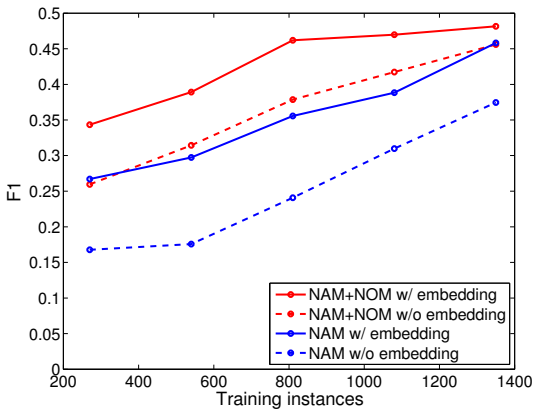

Figure 2: Dev F1 for varying number of training instances.

6 Conclusion

Our results show that NER for Chinese social media remains a challenging task, results lag behind both formal Chinese text and English Twitter. Nevertheless, our embeddings, combined with our joint training objective, provide a large improvement over a state-of-the-art model.

Acknowledgement We would like to thank the reviewers for their helpful comments and perspectives. We thank Mo Yu, Kevin Duh, Jiang Guo and Wenzhe Pei for the insightful discussions and Xuezhe Ma for help running the Stanford baseline.

Inferring Binary Relation Schemas for Open Information Extraction

Kangqi Luo[1] and **Xusheng Luo**[2] and **Kenny Q. Zhu**[3]

Abstract

This paper presents a framework to model the semantic representation of binary relations produced by open information extraction systems. For each binary relation, we infer a set of preferred types on the two arguments simultaneously, and generate a ranked list of type pairs which we call schemas. All inferred types are drawn from the Freebase type taxonomy, which are human readable. Our system collects 171,168 binary relations from ReVerb, and is able to produce top-ranking relation schemas with a mean reciprocal rank of 0.337.

1 Introduction

Open information extraction (or Open IE) is a task of extracting all sorts of relations between named entities or concepts from open-domain text corpora, without restraining itself to specific relations or patterns. State-of-the-art Open IE systems (Carlson et al., 2010; Fader et al., 2011; Schmitz et al., 2012; Nakashole et al., 2012) extract millions of binary relations with high precision from the web corpus. Each extracted relation instance is a triple of the form $\langle arg_1,\ rel,\ arg_2\rangle$, where the relation rel is a lexical or syntactic pattern, and both arguments are multi-word expressions representing the argument entities or concepts.

Whereas Open IE provides concrete relation instances, we are interested in generalizing these instances into more abstract semantic representations. In this paper, we focus on inferring the schemas of binary relations.

For example, given the binary relation "play in", an Open IE system extracts many triples of the form $\langle X,\ play\ in,\ Y\rangle$. The following relation triples are extracted in ReVerb:

$$\langle \text{Goel Grey}, played\ in, \text{Cabaret}\rangle$$
$$\langle \text{Tom Brady}, play\ in, \text{National Football League}\rangle$$

Informally, the goal of our system is to automatically infer a set of schemas such as $\langle t_1,\ play\ in,\ t_2\rangle$, where t_1 and t_2 are two semantic types drawn from a standard knowledge base such as WordNet (Miller, 1995), Yago (Suchanek et al., 2007), Freebase (Bollacker et al., 2008), and Probase (Wu et al., 2012), and each such schema can be used to represent a set of "play in" relation instances. For the above example, two possible schemas for "play in" are:

$$\langle \textbf{film actor},\ play\ in,\ \textbf{film}\rangle$$
$$\langle \textbf{athlete},\ play\ in,\ \textbf{sports league}\rangle$$

The schema of a binary relation is useful information in NLP tasks, such as context-oriented entity recognition and open domain question answering. Suppose we are to recognize the entities in the sentence "*Granger* played in *the NBA*". "*Granger*" is a highly ambiguous term, while "*the NBA*" is probably a sports league. Then with the the above relation schemas for "play in", the entity recognizer knows that "*Granger*" is more likely to be an athlete, which results in the correct linking to "Danny Granger", who is an NBA player, even though the Open IE has never extracted such fact before.

One relevant technique to achieve our goal is *selectional preference* (SP) (Resnik, 1996; Erk, 2007; Ritter et al., 2010), which computes the most appropriate types for a specific argument of a predicate. SP is based on the idea of mutual information (Erk, 2007), which tends to select types which are *unique* to the relation. In other words, common types which can be used for many different relations are less preferred. However, in Open IE, many relations are related or even similar, e.g., *play in*, *take part in* and *be involved in*. There's no reason for these relations not to share schemas. Therefore in this paper, our problem is, given a re-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 555–560,
Lisbon, Portugal, 17-21 September 2015.

lation and its instances, identify the smallest types that can cover as many instances as possible. Our approach first attempts to link the arguments in the relation instances to a set of possible entities in a knowledge base, hence generate a set of $\langle e_1, e_2 \rangle$ entity pairs. Then we select a pair of types $\langle t_1, t_2 \rangle$ that covers maximum number of entity pairs. We resolve ties by selecting the smaller (more specific) types according to a type taxonomy inferred from knowledge base.

This paper makes the following contributions: i) we defined the schema inference problem for binary relations from Open IE; ii) we developed a prototype system based on Freebase and entity linking (Lin et al., 2012; Ratinov et al., 2011; Hoffart et al., 2011; Rao et al., 2013; Cai et al., 2013), which simultaneously models the type distributions of two arguments for each binary relation; iii) our experiment on ReVerb triples showed that the top inferred schemas receive decent mean reciprocal rank (MRR) of 0.337, with respect to the human labeled ground truth.

2 Problem Definition

A knowledge base K is a 5-tuple $\langle E, Alist, T, P, IsA \rangle$, where:

- E is a finite set of entities $e \in E$,
- $Alist(e) = \{n_1, n_2, ...\}$ is a function which returns a set of names (or aliases) of an entity,
- T is a finite set of types $t \in T$,
- P is a finite set of relation instances $p(e_1, e_2)$, where p is a predicate in K.
- IsA is a finite set entity-type pairs (e, t), representing the isA relation between entities and types. An entity belongs to at least one type.

An Open IE triple set S contains all relation instances extracted by the IE system, of the form $\langle a_1,\ rel,\ a_2 \rangle$, where a_1 and a_2 are the arguments of extracted relation pattern rel. The set of argument pairs sharing the same relation pattern rel is denoted by S_{rel}.

The problem is, for each S_{rel}, return a set of type pairs (or schemas) from T, $\langle t_1, t_2 \rangle$, ordered by the number of argument pairs covered in S_{rel}. If two schemas cover the same number of argument pairs from S_{rel}, the schema covering smallest number of entities wins.

3 System

The workflow of our system is shown in Figure Figure 1. The system takes Open IE relation tuples as the input, then performs entity linking, relation grouping and schema ranking to translate them into final ranked list of schemas.

(1) Entity Linking: Relation arguments are linked to entities in the knowledge base by fuzzy string matching. Each entity in the knowledge base has a unique identifier.

(2) Relation Grouping: Linked tuples sharing similar relation patterns are grouped together. Besides, each group has a representative relation pattern, which is generated from all the patterns within the group.

(3) Schema Ranking: For each linked tuple in one relation group, argument entities are transformed into types drawn from the knowledge base. Then this procedure ranks type pairs (schemas) in terms of how much Open IE tuples a type pair can cover and how specific a type concept is.

3.1 Entity Linking

In the entity linking step, by matching arguments to entities in the knowledge base, each relation tuple is transformed into linked tuples, $ltup = \langle e_1,\ rel,\ e_2 \rangle$, with linking scores.

We aim to support fuzzy matching between arguments and entity aliases, so we take all the aliases into consideration, and build an inverted index from words to aliases. Different words in one alias cannot be treated equally. Intuitively, a word is more important if it occurs in fewer aliases (n), and vice versa. Based on the inverted index, we use inverted document frequency score to approximately model the weight of a word w:

$$idf(w) = 1 \,/\, \log(|\{n : w \in n\}|) \qquad (1)$$

Besides, stop words are removed from aliases, treating their idf scores as 0. In order to measure the probability of fuzzy matching from an argument (a) to an alias (n), we introduce the weighted overlap score:

$$overlap(a, n) = \frac{\sum_{w \in a \cap n} idf(w)}{\sum_{w \in a \cup n} idf(w)} \qquad (2)$$

We merge all the aliases of an entity together to producing a similarity score of fuzzy matching between an entity and an argument:

$$sim(e, a) = \max_{n \in Alist(e)} overlap(a, n) \qquad (3)$$

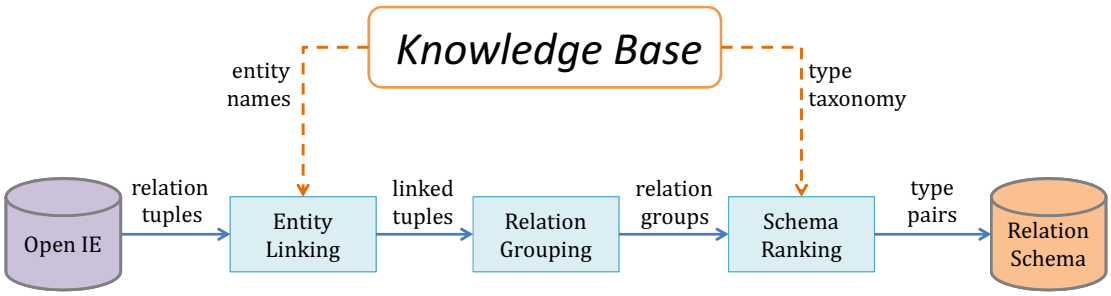

Figure 1: System Architecture

In order to control the quality of candidate entities, for an argument having m words (with stop words removed), we only keep entities that have at least one alias matching $m-1$ words in the argument, and have a similarity score larger than a threshold, τ. With similarity score computed, we generate 10 best entity candidates respectively for both the subject and the object of rel.

Next, we model the joint similarity score (F) of the relation tuple $\langle a_1, rel, a_2 \rangle$ with each entity pair combination $\langle e_1, e_2 \rangle$ in two ways. One is a **naive method** which only considers the similarity between arguments and corresponding entities:

$$F(a_1, e_1, a_2, e_2, rel) = sim(e_1, a_1) \times sim(e_2, a_2). \quad (4)$$

The other method takes predicate paths between e_1 and e_2 into consideration. Let $\vec{w}$ be the word vector of rel, and $\vec{p}$ be a path of predicates connecting e_1 and e_2 in at most 2 hops. Here we say two entities e_1 and e_2 are connected in 1 hop, if there exists a predicate p, such that $p(e_1, e_2)$ (or $p(e_2, e_1)$) is in the knowledge base.

Similarly, e_1 and e_2 are connected in 2 hops, if there exists two predicates p_1, p_2 and a transition entity e', such that $p_1(e_1, e')$ (or $p_1(e', e_1)$) and $p_2(e', e_2)$ (or $p_2(e_2, e')$) are in the knowledge base.

We hence define the relatedness between $\vec{p}$ and $\vec{w}$ in the form of a conditional probability according to the Naive Bayes model:

$$P(\vec{p}\,|\,\vec{w}) \approx \prod_p P(p\,|\,\vec{w}) \propto \prod_p P(p) \prod_w P(w\,|\,p), \quad (5)$$

and we follow the IBM alignment Model 1 (Yao and Van Durme, 2014) to calculate the conditional probability between predicates and relation words $P(\vec{p}\,|\,\vec{w})$. Based on the information above, we define a richer joint similarity score, considering all valid paths between e_1 and e_2:

$$F(a_1, e_1, a_2, e_2, rel) = sim(e_1, a_1) \times sim(e_2, a_2) \times \sum_{\vec{p}} P(\vec{p}|\vec{w}). \quad (6)$$

Due to the multiplications, the value of $P(\vec{p}|\vec{w})$ varies a lot among different entity pair candidates. The large deviation makes $P(\vec{p}|\vec{w})$ the most important term in Eq. (6), especially in the case when none of predicate paths are similar enough to the relation words. Therefore, we trust the factor of $P(\vec{p}|\vec{w})$ only when there exists a similar predicate path. In practice, we use a threshold ρ to control whether to use Eq. (6) or Eq. (4). We call this an **ensemble method**. For each case of entity linking, if there exists one candidate entity pair satisfying $P(\vec{p}\,|\,\vec{w}) > \rho$, we use the ensemble method, otherwise we fall back to the naive method for the current case.

3.2 Relation Grouping

In the step of relation grouping, linked tuples with similar relation patterns form a group. Each linked tuple belongs to one unique group.

The idea is to simplify relation patterns by syntactic transformations. If two patterns share the same simplified pattern, we treat them as being equivalent and put them into one group. First, since adjectives, adverbs and modal verbs can hardly change the type distribution of arguments in a relation, we remove these words from a pattern. Second, many relations from Open IE contain verbs, which come in different tenses. We transform all tenses into present tense. In addition, passive voice in a pattern, if any, is kept in the transformed pattern. A simple example below shows a group of relations:

⟨X, *resign from*, Y⟩
⟨X, *had resigned from*, Y⟩
⟨X, *finally resigned from*, Y⟩

All linked tuples with the same simplified pattern form a group. This pattern is selected as the representative pattern, like the pattern "*resign from*" in the above example.

3.3 Schema Ranking

Given a relation group, the step of schema ranking produces a ranked list of relation schemas with two constraints. Take "play in" as an example, the ideal schemas will contain the pair $\langle actor,\ film\rangle$ and $\langle athlete,\ sports\ league\rangle$

Each linked tuple $\langle e_1,\ rel,\ e_2\rangle$ supports the type pair $\langle t_1,\ t_2\rangle$ where $(e_1, t_1),\ (e_2, t_2) \in IsA$ in the knowledge base. We treat these pairs equally, since it's not trivial to tell which type is more related to the argument given the relation tuple as context. Combining all tuples in one group, we define the support of a type pair tp in a group (using the representative pattern r to stand for the group):

$$sup_r(\langle t_1, t_2\rangle) = \{(e_1, t_1) \in IsA,\ (e_2, t_2) \in IsA\} \quad (7)$$

A simple intuition is to rank schemas by the size of the support. Since one entity belongs to multiple types, relation schemas with general types will be ranked higher. However, two different schemas may share the same support. For instance, given the relation "*X die in Y*", suppose Open IE extractions and entity linking step returns correct results, the schema $\langle person,\ location\rangle$ and $\langle deceased\ person,\ location\rangle$ have identical supports. The latter one shows a more concrete representation of the relation, because *deceased person* covers small entities than *person* in the knowledge base.

Therefore, the schemas cannot be ranked by using the support alone. Next, we aim to extract the subsumption relations between types in the knowledge base, building the taxonomy of types.

We first define all entities in t as

$$cover(t) = \{e \mid (e, t) \in IsA\}. \quad (8)$$

Intuitively, type t_1 is subsumed in t_2, if all entities in t_1 also belong to t_2, that is, $cover(t_1) \subseteq cover(t_2)$. This uses the idea of **strict set inclusion**. For example, we can learn that the type *person* subsumes types such as *actor, politician* and *deceased person*.

However, strict set inclusion doesn't always hold in the knowledge base. For example, entities in type *award winner* are mostly *person*, but there still has some organizations in it. The strict method fails to find the subsumption relation between *award winner* and *person*, while this subsumption actually holds with a large confidence.

To resolve this problem, we use a **relaxed set inclusion**, where the set $cover(t_1)$ can be a subset of another set $cover(t_2)$ to a certain degree. We define the degree of the subsumption as the ratio between the number of entities in the two sets:

$$deg(t_1 \subseteq t_2) = \frac{|cover(t_1) \cap cover(t_2)|}{|cover(t_1)|}. \quad (9)$$

If $deg(t_1 \subseteq t_2) > \epsilon$, then t_1 is subsumed by t_2, and ϵ is a confidence parameter determined by weight tuning. By scanning all types in the knowledge base, all subsumption relations with enough confidence are extracted, forming our type taxonomy.

With a type hierarchy computed by above relaxed set inclusion, we can define a schema $\langle t_1,\ t_2\rangle$ subsumes another schema $\langle t_3,\ t_4\rangle$ if i) t_1 subsumes t_3 and t_2 subsumes t_4; ii) t_1 subsumes t_3 and $t_2 = t_4$; or iii) t_2 subsumes t_4 and $t_1 = t_3$.

If a schema (type pair) tp_1 subsumes another schema tp_2, and their supports ($|sup_r(tp)|$) are approximately equal, we give the more specific schema tp_2 a higher rank in the output list. Here two supports are roughly equal if:

$$\frac{|sup_r(tp_1)| - |sup_r(tp_2)|}{max(|sup_r(tp_1)|,\ |sup_r(tp_2)|)} < \lambda \quad (10)$$

Where λ is a threshold determined in the experiments.

4 Evaluation

Freebase (Bollacker et al., 2008) is a collaboratively generated knowledge base, which contains more than 40 million entities, and more than 1,700 real types [1]. In our experiment, We use the 16 Feb. 2014 dump of Freebase as the knowledge base.

ReVerb (Fader et al., 2011) is an Open IE system which aims to extract verb based relation instances from web corpora. The release ReVerb dataset contains more than 14 millions of relation tuples with high quality. We observed that in ReVerb, some argument is unlikely to be an entity in Freebase, for example:

$\langle Metro\ Manila,\ consists\ of,$ **12 cities**$\rangle$,

[1] Freebase types are identified by type id, for example, $sports.pro\_athlete$ stands for "professional athlete".

where the object argument is not an entity but a type. Since types are usually represented by lowercase common words, we remove the tuple if one argument is lowercase, or if it is made up completely of common words in WordNet. In addition, because date/time such as "Jan. 16th, 1981" often occurs in the object argument while Freebase does not have any such specific dates as entities, we use SUTime (Chang and Manning, 2012) to recognize dates as an virtual entity. After cleaning, the system collects 3,234,208 tuples and 171,168 relation groups.

The following parameters are tuned using a development set: $\tau = 0.667$, $\epsilon = 0.6$, $\lambda = 5\%$ and $\rho = e^{-50}$. For relation grouping, we use Stanford Parser (Klein and Manning, 2003) to perform POS tagging, lemmatizing and parsing on relations.

We first evaluate the results of entity linking. We randomly pick 200 relation instances from ReVerb, and manually labeled arguments with Freebase entities. For both naive and ensemble strategy, we evaluate the precision, recall, F1 and MRR score on the labeled set. An output entity pair is correct, if and only if both arguments are correctly linked. Experimental results are listed in Table 1.

Table 1: Entity Linking Result

Strategy	P	R	F1	MRR
Naive	0.371	0.327	0.348	0.377
Ensemble	0.386	0.340	0.361	0.381

For the evaluation of relation schema, we first randomly pick 50 binary relations with support larger than 500 from the system. For each relation, we selected top 100 type pairs with the largest support, as what we evaluated. We assigned 3 human annotators to label the fitness score of type pair for the relation. The labeled score ranges from 0 to 3. Then we merge these 3 label sets, forming 50 gold standard rankings. When evaluating a relation schema list from our system, we calculate the MRR score (Liu, 2009) by the top schemas in the gold rankings.

For comparison, we use Pointwise Mutual Information (Church and Hanks, 1990) as our baseline model, which is used in other selectional preference tasks (Resnik, 1996). We define the association score between relation and type pair as:

$$PMI(r, tp) = p(r, tp) \log \frac{p(r, tp)}{p(r, *)p(*, tp)} \quad (11)$$

Where $p(r, tp)$ is the joint probability of relation and type pair in the whole linked tuple set, and $*$ stands for any relations or type pairs.

Table 2 shows the MRR scores by using both baseline model (PMI) and our approach. As the result shows, our approach improves the MRR score by 10.1%.

Table 2: End-to-end Schema Inference Results

Approach	MRR Score
PMI Baseline	0.306
Our Approach	0.337

Finally, Table 3 shows some example binary relations, and their schemas inferred by our system. We can see that with a well-defined type hierarchy, our system is able to extract both coarse-grained and fine-grained type information from entities, resulting in a informative type lists.

Table 3: Sample Relation Schemas

Relation	Top Schemas
be find at	$\langle location,\ location\rangle$ $\langle employer,\ location\rangle$ $\langle organization,\ location\rangle$
appear on	$\langle person,\ tv\ program\rangle$ $\langle person,\ nominated\ work\rangle$ $\langle person,\ winning\ work\rangle$
be the writer of	$\langle person,\ nominated\ work\rangle$ $\langle person,\ film\rangle$ $\langle person,\ book\ subject\rangle$

5 Conclusion

In summary, our work describes a data driven approach of relation schema inference. By maximizing the support of both arguments simultaneously, our system is able to generate human-readable type pairs for a binary relation from Open IE systems. Our experiments shows that the top ranked relation schemas for each relation are accurate according to human judges. The proposed framework can be integrated with future Open IE systems.

Abstract

This paper studies Cumulative Citation Recommendation (CCR) - given an entity in Knowledge Bases, how to effectively detect its potential citations from volume text streams. Most previous approaches treated all kinds of features indifferently to build a global relevance model, in which the prior knowledge embedded in documents cannot be exploited adequately. To address this problem, we propose a latent document type discriminative model by introducing a latent layer to capture the correlations between documents and their underlying types. The model can better adjust to different types of documents and yield flexible performance when dealing with a broad range of document types. An extensive set of experiments has been conducted on TREC-KBA-2013 dataset, and the results demonstrate that this model can yield a significant performance gain in recommendation quality as compared to the state-of-the-art.

1 Introduction

Knowledge Bases (KBs), like Wikipedia, are playing increasingly important roles in numerous entity-based information retrieval tasks. Nevertheless, most KBs are hard to be up-to-date due to their manual maintenances by human editors. As reported in (Frank et al., 2012), there exists a median time lag of 356 days between the day a news article is published and the time that the news is cited in a Wikipedia article dedicated to the entity concerned by the news. The time lag would be reduced if relevant documents could be automatically detected as soon as they are published online and then recommended to the editors. This task is studied as Cumulative Citation Recommendation (CCR). Formally, given a set of KB entities, CCR is to filter relevant documents from a stream corpus and evaluate their citation-worthiness to the target entities.

A variety of supervised approaches (e.g., classification, learning to rank) have been employed and achieved promising results (Wang et al., 2013; Balog and Ramampiaro, 2013; Balog et al., 2013). Nevertheless, most of them leverage all features indiscriminately to build a global relevance model, which leads to unsatisfactory performance. The documents can offer some prior knowledge, which is named as **type** in this paper. The type is the prior knowledge embedded in the document that impacts on the probability of its being recommended to KBs. For instance, when dealing with a document on "music" topic, we would like to have less weights put on a politician entity because this document is not likely to related to it, but more often related to musicians or musical bands. Besides, the source of a document impacts on the recommendation strategies too. A document from news agencies is more reliable and citable than the one from social websites even if they state an identical story about the target KB entity. Hence we consider two kinds of document features to model the prior type knowledge: (1) topic-based features, and (2) source-based features.

This paper proposes a latent document type discriminative mixture model for CCR. We introduce an intermediate latent layer to model latent document types and define a joint distribution over the document-entity pairs and latent document-types on the observation data. The aim is to achieve a discriminative mixture model that is expected to outperform the global relevance model.

To the best of our knowledge, this is the first research work that leverages prior knowledge embedded in documents to improve CCR perfor-

mance. An extensive set of experiments conducted on TREC-KBA-2013 dataset has demonstrated the effectiveness of the proposed mixture model.

2 Discriminative Models for CCR

Given a set of KB entities $\mathcal{E} = \{e_u | u = 1, \cdots, M\}$ and a document collection $\mathcal{D} = \{d_v | v = 1, \cdots, N\}$, our objective is to estimate the conditional probability of relevance $P(r|e,d)$ with respect to an entity-document pair (e,d). Each (e,d) is represented as a feature vector $\mathbf{f}(e,d) = (f_1(e,d), \cdots, f_K(e,d))$, where K is the dimension of the entity-document feature vector. Moreover, to model the hidden document type, each document is represented as an document-type feature vector $\mathbf{g(d)} = (g_1(d), \cdots, g_L(d))$, where L indicates the dimension of the document-type feature vector.

2.1 Global Model

This paper utilizes logistic regression to estimate the conditional probability $P(r|e,d)$, where $r(r \in \{1,-1\})$ is a binary label indicating the relevance of an entity-document pair (e,d). The value of r is 1 if the document d is related to the entity e, otherwise $r = -1$. Formally, the parametric form of $P(r{=}1|e,d)$ is expressed as $P(r{=}1|e,d) = \delta(\sum_{i=1}^{K} \omega_i f_i(e,d))$, where $\delta(x)$ is the standard logistic function, ω_i is the combination parameter for the ith feature. It is easy to derive that for different values of r, the only difference in $P(r|e,d)$ is the sign within the logistic function. Therefore, we adopt the general representation of $P(r|e,d){=}\delta(r \sum_{i=1}^{K} \omega_i f_i(e,d))$. This model is denoted as **GM** in this paper. Several previous approaches can be deemed as global models adopting different classification functions such as decision trees (Wang et al., 2013) and Support Vector Machine (SVM) (Bonnefoy et al., 2013).

2.2 Latent Document Type Model

In GM, a fixed set of combination weights (i.e., ω) are learned to optimize the overall performance for all entity-document pairs. However, the best combination strategy for a given pair is not always the best for the others since both the documents and entities are heterogeneous. Therefore, we may benefit from developing a document type dependent model in which we choose the combination strategy individually for each document type to optimize the performance for specific document types. Since it is not feasible to determine the proper combination strategy for each document type, we need to classify documents into one of several types. The combination strategy is then tuned to optimize average performance for documents within the same type.

We propose a latent document type model (**LDTM**) by introducing an intermediate layer to capture the underlying type information in documents. A latent variable z is utilized to indicate which type the combination weights ω_z are drawn from. The choice of z is determined by the document d. The joint probability of relevance r and the latent variable z is represented as $P(r,z|e,d;\alpha,\omega){=}P(z|d;\alpha)P(r|e,d,z;\omega)$, where $P(z|d;\alpha)$ is the mixing coefficient, denoting the probability of choosing the hidden type z given document d, and α is the corresponding parameter. $P(r|e,d,z;\omega)$ denotes the discriminative component which takes a logistic function. By marginalizing out z, we obtain

$$P(r|e,d;\alpha,\omega) = \sum_{z}^{N_z} P(z|d;\alpha)\delta\Big(r\sum_{i=1}^{K}\omega_{zi}f_i(e,d)\Big) \quad (1)$$

where ω_{zi} is the weight for the ith entry in the feature vector under the hidden variable z. We adopt a soft-max function $\frac{1}{Z_d}\exp(\sum_{j=1}^{L}\alpha_j^z g_j(d))$ to model $P(z|d;\alpha)$, and Z_d is the normalization factor that scaled the exponential function to be a probability distribution. In this representation, each document d is denoted by a bag of document type features $(g_1(d), \cdots, g_L(d))$. By plugging the soft-max function into Equation (1), we have

$$P(r|e,d;\alpha,\omega){=} \frac{1}{Z_d}\sum_{z=1}^{N_z}\exp\Big(\sum_{j=1}^{L_z}\alpha_{zj}g_j(d)\Big)\delta\Big(r\sum_{i=1}^{K}\omega_{zi}f_i(e,d)\Big) \quad (2)$$

Suppose entity-document pairs in training set are represented as $\mathcal{T}{=}\{(d_u,e_v)\}$, and $\mathcal{R}{=}\{r_{uv}\}$ denotes the corresponding relevance judgment of (d_u,e_v), where $u = 1, \cdots, M$ and $v = 1, \cdots, N$. Assume training instances in $\mathcal{T}$ are independently generated, the conditional likelihood of training data is written as

$$P(\mathcal{R}|\mathcal{T}) = \prod_{u=1}^{M}\prod_{v=1}^{N} P(r_{uv}|e_u,d_v) \quad (3)$$

2.3 Parameter Estimation

The parameters (i.e., ω and α) can be estimated by maximizing the data log-likelihood $\mathcal{L}(\omega, \alpha)$, which is the form of logarithm of Equation (3). A typical parameter estimation method is to use Expectation-Maximization (EM) algorithm by iterating E-step and M-step continuously until convergence. The E-step is derived by computing the posterior probability of z given d_u and e_v, which is denoted as $P(z|d_u, e_v)$.

$$P(z|d_u, e_v) = \frac{\exp\Big(\sum_{j=1}^{L_z}\alpha_{zj}g_j(d_u)\Big)\delta\Big(r_{uv}\sum_{i=1}^{K}\omega_{zi}f_i(d_u, e_v)\Big)}{\sum_z \exp\Big(\sum_{j=1}^{L_z}\alpha_{zj}g_j(d_u)\Big)\delta\Big(r_{uv}\sum_{i=1}^{K}\omega_{zi}f_i(d_u, e_v)\Big)} \tag{4}$$

In M-step, we can obtain the following parameter update rules.

$$\omega_z^* = \arg\max_{\omega_z} \sum_{uv} P(z|d_u, e_v) \log\Big(\delta\Big(\sum_{i=1}^{K}\omega_{zi}f_i(d_u, e_v)\Big)\Big)$$

$$\alpha_z^* = \arg\max_{\alpha_z} \sum_u \Big(\sum_v P(z|d_u, e_v)\Big) \log\Big(\frac{1}{Z_{d_u}}\exp\Big(\sum_{j=1}^{L_z}\alpha_{zj}g_j(d_u)\Big)\Big) \tag{5}$$

To optimize Equation (5), we employ the `minFunc` toolkit[1] using Quasi-Newton strategy. We adopt Akaike Information Criteria (AIC) to determine the number of latent variables (Fang et al., 2010), which is calculated as $2m - 2\mathcal{L}(\omega, \alpha)$, where m is the number of parameters in the model.

LDTM holds two advantages over GM. (1) The combination parameters vary across various document types and hence lead to a gain of flexibility; (2) It offers probabilistic semantics for the latent document types and thus documents can be associated with multiple types.

3 Features

This section presents the two types of features used in the discriminative models. Entity-document features (i.e., $\mathbf{f}(e, d)$) are used in the discriminative components of GM and LDTM. In addition, LDTM requires document-type features (i.e., $\mathbf{g}(e)$) to learn the mixing coefficients in the mixture component.

Since our goal is not to develop new entity-document features, we adopt the identical entity-document feature set proposed in our previous work (Wang et al., 2013; Wang et al., 2015a; Wang et al., 2015b), which has been proved effective.

In terms of document-type features, we consider two kinds of prior knowledge embedded in documents to model the correlations between documents and their latent types.

Topic-based features One prior knowledge to model a document's latent type is its intrinsic topics. As we have claimed, documents with one or more obvious topics are more likely to be recommended to KB than those without any explicit topic. We capture the underlying topics in documents with word co-occurrences. After removing stop words, we represent each document as a feature vector with the bag-of-words model, where word weights are determined by TF-IDF scheme.

Source-based features The source of a document is another prior knowledge to evaluate the probability of the document's being recommended to KBs. We leverage a "bag-of-sources" model to represent each document as source-based feature vector, and term weights are determined by binary occurrence scheme. Please note that the sources are organized hierarchically. For example, *mainstream_news* is a sub-source of *news*.

4 Experiments

4.1 Dataset

We utilize TREC-KBA-2013 dataset[2] as our experimental dataset. The dataset is composed of a temporally stream corpus and a target KB entity set. The stream corpus contains nearly 1 billion documents crawled from 10 sources: **news**, **mainstream_news**, **social**, **weblog**, **linking**, **arxiv**, **classified**, **reviews**, **forum** and **memetracker**[3]. The corpus has been split with documents from October 2011 to February 2012 as training instances and the remainder for evaluation. We adopt the same training/test range setting in our experiments. The entity set is composed of 121 Wikipedia entities and 20 Twitter entities.

[1] `http://www.cs.ubc.ca/~schmidtm/Software/minFunc.html`

[2] `http://trec-kba.org/kba-stream-corpus-2013.shtml`

[3] `http://www.memetracker.org/`

Each entity-document pair is labeled as one of the 4 relevance levels: (i) **Vital**, timely information about the entity's current state, actions, or situation. This would motivate a change to an already up-to-date KB article. (ii) **Useful**, possibly citable but not timely, e.g., background biography, secondary source information. (iii) **Neural**, informative but not citable, e.g., tertiary source like Wikipedia article itself. and (iv) **Garbage**, no information about the target entity could be learned from the document, e.g., spam. Annotation details of the dataset are presented in Table 1.

	Range	Vital	Useful	Neutral	Garbage
Train	2011.10 $\sim$ 2012.02	1696	2121	1030	1702
Test	2012.03 $\sim$ 2013.02	5630	11579	3379	10543

Table 1: Annotation details of TREC-KBA-2013 dataset.

4.2 Evaluation Scenarios

According to different granularity settings, we evaluate the proposed models in two scenarios: (i) **Vital Only**. Only vital entity-document pairs are treated as positive instances. (ii) **Vital + Useful**. Both vital and useful entity-document pairs are treated as positive instances.

4.3 Comparison Methods

We conduct extensive comparisons with the following methods.

- Global Model (**GM**). The global discriminative model introduced in section 2.1.
- Source-based Latent Document Type Model (**src_LDTM**). A variant of LDTM that utilizes source-based features as document-type features.
- Topic-based Latent Document Type Model (**topic_LDTM**). A variant of LDTM that utilizes topic-based features as document-type features.
- Combination Latent Document Type Model (**combine_LDTM**). This approach utilizes source-based and topic-based features together as document-type features. In our experimental setting, we simply union the two feature vectors together into an integral feature vector.

For reference, we also include three top-ranked approaches in TREC-KBA-2013 track.

- **BIT-MSRA** (Wang et al., 2013). A global random forests classification method, the first place approach in TREC-KBA-2013 track.
- **UDEL** (Liu et al., 2013). An entity-centric query expansion approach, the second place approach in TREC-KBA-2013 track.
- **Official Baseline** (Frank et al., 2013). A strong baseline in which human annotators go through target entities and came up with a list of keywords for filtering vital documents.

4.4 Results and Discussion

Improving precision is harder than improving recall for CCR (Frank et al., 2013). Therefore, we care more about recommendation quality of CCR. Precision and overall accuracy are adopted as metrics to evaluate different approaches. All the metrics are computed in the test pool of all entity-document pairs. The results are reported in Table 2. In comparison to the baselines listed in the 2nd block of Table 2, our mixture models achieve higher or competitive precision and accuracy in both scenarios considerably. Compared with the official baseline, our best mixture model improves precision about 28%. In both scenarios, the variants of LDTM outperform GM on precision and accuracy, which validates our motivations that (i) introducing document latent types in mixture model can enhance the recommendation quality, and (ii) source-based and topic-based features can capture the hidden type information of documents.

Methods	Vital Only		Vital + Useful	
	P	Accu	P	Accu
Official Baseline	.171	.175	.540	.532
BIT-MSRA	.214	.445	.589	**.615**
UDEL	.169	.259	.573	.579
GM	.218	.587	.604	.565
src_LDTM	.273	**.763**	.626	.607
topic_LDTM	.293	.755	**.643**	.609
combine_LDTM	**.299**	.751	.633	**.611**

Table 2: Overall results of evaluated methods. Best scores are typeset boldface.

Moreover, topic_LDTM generally performs better than src_LDTM in both scenarios, which meets our expectation because topic-based features have far more dimensions than source-based features. However, even if source-based feature vector holds a few dimensions (10 in our experiments),

src_LDT improves the precision on the basis of GM. Thus, the precision can be enhanced further if we can develop more valuable features to represent the underlying document types. The combination variant of LDTM achieve the best precision in **Vital Only** scenario and the best accuracy in **Vital + Useful** scenario. The naïve combination strategy of two types of features can improve the performance but not stable, so we need find better combination strategies.

For all variant of the LDTM, the number of latent types determined by AIC are reported in Table 3. The optimal number of latent types in **Vital + Useful** is more than that in **Vital Only**. This reveals that the types of **Vital** documents for entities have more restrictions than **Useful** documents, either by topics or by sources. In addition, the optimal number of latent topics is more than that of latent sources, which also follows our intuition that topic-based features holding more dimensions than source-based features. Since we employ a naïve combination strategy for the two types of features, the number of latent types of combine_LDTM is more close to topic_LDTM, which possesses more features than src_LDTM.

Model	Vital	Vital + Useful
src_LDTM	6	7
topic_LDTM	9	15
combine_LDTM	14	15

Table 3: Number of latent types determined by AIC.

5 Related Work

There are three kinds of approaches developed for CCR in previous work: query expansion (Liu et al., 2013; Wang et al., 2013), classification such as SVM (Kjersten and McNamee, 2012) and Random Forest classifier (Bonnefoy et al., 2013; Balog et al., 2013), and learning to rank approaches (Wang et al., 2013; Balog and Ramampiaro, 2013). Transfer learning is utilized to transfer the keyword importance learned from training pairs to query pairs (Zhou and Chang, 2013).

However, some highly supervised methods require training instances for each entity to build a relevance model, limiting their scalabilities. A compromised solution is to build a global discriminative model with all features indifferently. We spotlight document-type features and study the impacts of them in discriminative mixture models. Mixture model has been applied and proved effective in multiple information retrieval tasks, such as expert search (Fang et al., 2010) and federated search (Hong and Si, 2012). By learning flexible combination weights for different types of training instances, mixture model can outperform global models with fixed weights for all instances.

6 Conclusion

Cumulative Citation Recommendation (CCR) is an important task to automatically detect citation-worthy documents from volume text streams for knowledge base entities. We study CCR as a classification problem and propose a latent document type model (LDTM) through introducing a latent layer in a discriminative model to capture the correlations between documents and their intrinsic types. Two variants of LDTM are implemented by modeling the latent types with document source-based and topic-based features respectively. Experimental results on TREC-KBA-2013 dataset demonstrate that our mixture model can improve CCR performance significantly, especially on precision and accuracy, revealing the advantage of LDTM in enhancing recommendation quality of citation-worthy documents.

For future work, we wish to explore more useful document-type features and apply more proper combination strategies to improve the latent document type model.

Online Sentence Novelty Scoring for Topical Document Streams

Sungjin Lee
Yahoo Labs
229 West 43rd Street, New York, NY 10036, USA
junion@yahoo-inc.com

Abstract

The enormous amount of information on the Internet has raised the challenge of highlighting new information in the context of already viewed content. This type of intelligent interface can save users time and prevent frustration. Our goal is to scale up novelty detection to large web properties like Google News and Yahoo News. We present a set of lightweight features for online novelty scoring and fast nonlinear feature transformation methods. Our experimental results on the TREC 2004 shared task datasets show that the proposed method is not only efficient but also very powerful, significantly surpassing the best system at TREC 2004.

1 Introduction

The Internet supplies a wealth of news content with a corresponding problem: finding the right content for different users. Search engines are helpful if a user is looking for something specific that can be cast as a keyword query. If a user does not know what to look for, recommendation engines can make personalized suggestions for stories that may interest the user. But both types of systems frequently represent content that the user has already consumed, leading to delay and frustration. Consequently, identifying novel information has been an essential aspect of studies on news information retrieval. Newsjunkie (Gabrilovich et al., 2004), for instance, describes a system that personalizes a newsfeed based on a measure of information novelty: the user can be presented custom tailored news feeds that are novel in the context of documents that have already been reviewed. This will spare the user from hunting through duplicate and redundant content for new nuggets of information. Identifying genuinely novel information is also an essential aspect of *update summarization* (Nenkova and McKeown, 2012; Gao et al., 2013; Guo et al., 2013; Wang and Li, 2010; Bentivogli et al., 2011). But the temporal dynamics of a document stream are not generally the focus. Novelty detection has also been studied in *Topic Detection and Tracking* field for the *First Story Detection* task (Allan, 2002; Karkali1 et al., 2013; Karkali et al., 2014; Tsai and Zhang, 2011) where the aim is to detect novel documents given previously seen documents. In this paper, we examine a slightly different problem; we perform novelty detection at the sentence level to highlight sentences that contain novel information.

The novelty track in TREC was designed to serve as a shared task for exactly this type of research: finding novel, on-topic sentences from a news stream (Harman, 2002). There were four tasks in the novelty track but we only focus on task 2 in this paper: "given relevant sentences in all documents, identify all novel sentences." The track changed slightly from year to year. The data of the first run in 2002 (Harman, 2002) used old topics and judgments which proved to be problematic due to the small percentage of relevant sentences. TREC 2003 (Soboroff and Harman, 2003) included 50 new topics with an improved balance of relevant and novel sentences and chronologically ordered documents. TREC 2004 (Soboroff and Harman, 2005) used the same task settings and the same number of topics, but made a major change through the inclusion of irrelevant documents.

Although the participants in the novelty track of TREC and many followup studies have investigated a wide ranging set of features and algorithms (Soboroff and Harman, 2005), almost none were specifically focused on scalability. However, modern news aggregators are usually visited by millions of unique users and consume millions of stories each day. Moreover, every few minutes item churn takes place and the stories of interest are likely to be the ones that appeared in the last couple of hours. As real-time processing on a large scale gains more attention (Osborne et al., 2014), we investigate features that are both effective and efficient, and so could be used in a scalable online novelty scoring engine for making personalized newsfeeds on large web properties like Google News and Yahoo News.

To achieve this goal, our contributions are two-fold. First, we present a set of effective, light-weight features: KL divergence with asymmetric smoothing, nonlinear transformation of unseen word count, relative sentence position and word embedding-based similarity. Note that we restrict ourselves to only surface-level text features and algorithms that have time complexity of $O(W)$ where W is the number of unique words seen so far (previous studies often employed quite expensive

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 567–572,
Lisbon, Portugal, 17-21 September 2015.

features and algorithms that have time complexity of at least $O(WT)$ where T is the number of sentences so far). To fully comply with the online setting, we also exclude very popular methods for measuring similarity such as tf-idf, since we are not allowed to see the entire corpus. Second, we propose efficient feature transformation methods: recursive feature averaging and *Deep Neural Network* (DNN)-based nonlinear transformation. We evaluate our system on task 2 of the 2004 TREC novelty track. Interestingly, our experiment results indicate that our light-weight features are actually very powerful when used in conjunction with the proposed feature transformation; we obtain a significant performance improvement over the best challenge system.

The rest of this paper is structured as follows: Section 2 presents a brief summary of related work. Section 3 describes our algorithm and features. Section 4 outlines the experimental setup and reports the results of comparative analysis with challenge systems. We finish with some conclusions and future directions in Section 5.

Algorithm 1: Novelty scoring for a topical document stream

```
Data: a document stream
Result: a document stream with novelty annotation
Initialize a context C_0;
while not at end of the document stream do
    read a document;
    split the document into sentences;
    while not at end of the document do
        read a sentence S_t;
        perform preprocessing on S_t;
        compute novelty score as the posterior probability of a binary novelty random variable N_t, p(N_t|S_t, C_{t-1});
        update the context C_t with C_{t-1} and S_t;
    end
    compute a document-level score (e.g. average out all sentence-level scores)
end
```

2 Related Work

There were 13 groups and 54 submitted entries for the 2004 TREC novelty track task 2. The participants used a wide range of methods which can be roughly categorized into statistical and linguistic methods. Statistical methods included traditional information retrieval models such as tf-idf and Okapi, and metrics such as importance value, new sentence value, conceptual fuzziness, scarcity measure, information weakness, unseen item count with a threshold optimized for detecting novel sentences (Blott et al., 2004; Zhang et al., 2004; Abdul-Jaleel et al., 2004; Eichmann et al., 2004; Erkan, 2004; Schiffman and McKeown, 2004). Thresholds are either learned on the 2003 data or determined in an ad hoc manner. Some groups also used machine learning algorithms such as SVMs by casting the problem as a binary classification (Tomiyama et al., 2004). Many groups adopted a variety of preprocessing steps including expansion of the sentences using dictionaries, ontologies or corpus-based methods and named entity recognition. Graph-based analysis has also been applied where directed edges are established by cosine similarity and chronological order. After this graph is constructed, the eigenvector centrality score for each sentence was computed by using a power method. The sentences with low centrality scores were considered as new (Erkan, 2004). Graph-based approaches were further pursued by Gamon (2006) that drew a richer set of features from graph topology and its changes, resulting in a system that ties with the best system at TREC 2004 (i.e. Blott et al. (2004)). On the other hand, deep linguistic methods included parsing, coreference resolution, matching discourse entities, searching for particular verbs and verb phrases, standardizing acronyms, building a named-entity lexicon, and matching concepts to manually-constructed ontology for topic-specific concepts (Amrani et al., 2004). The difficulty of the novelty detection task is evident from the relatively low score achieved by even the best systems at TREC 2004 (Soboroff and Harman, 2005). The top scoring systems were mostly based on statistical methods while deep linguistic approaches achieved the highest precision at the cost of poor recall.

3 Method

For the purpose of this paper, we formulate task 2 of the TREC novelty detection track as an online probabilistic inference task. More specifically, we compute the novelty score as the posterior probability of a binary novelty random variable N:

$$p(N_t|S_t, C_{t-1}) = \frac{1}{Z} \exp \sum_i w_i f_i(N_t, S_t, C_{t-1}) \quad (1)$$

in which the f_i are feature functions, w_i model parameters, S_t the sentence in focus and C_{t-1} a context containing information about previously seen sentences S_1 through S_{t-1} across documents.

The overall procedure is listed in Algorithm 1. The algorithm takes as input documents which have been clustered by topic and chronologically ordered. For each sentence S_t in each document, basic preprocessing is performed (e.g. simple tokenization, stopword filtering and stemming (Porter, 1980)), then the inference is made whether S_t is novel given the context C_{t-1}. Without the use of the context, the time complexity of our algorithm would depend on the number of sentences so far. Thus, the features and the model for the context are important for efficiency. Note that our method only takes time complexity of $O(W)$ for

both context update and feature generation.

3.1 Features

KL divergence with asymmetric smoothing. KL divergence has been successfully adopted to measure the distance between a document and a set of documents (Gabrilovich et al., 2004; Gamon, 2006). We use it to measure the distance between context C and sentence S:

$$\sum_w p_C(w) \log \frac{p_C(w)}{p_S(w)} \quad (2)$$

The intuition is that the more distant the distributions are, the more likely it is that the sentence is novel. Since KL divergence is asymmetric, both directions are used as features, with and without scale normalization. The computation of KL divergence requires both p_C and p_S to be non-zero; while simple add-one smoothing is employed in previous work, we adopt novel asymmetric smoothing. We add a larger smoothing factor s for already seen words than the factor u for unseen words. The rationale behind this is that we intensify the difference caused by unseen words and attenuate the difference caused by seen words (Figure 1.) Asymmetric smoothing with various smoothing factors consistently showed better performance than symmetric smoothing in our experiments.

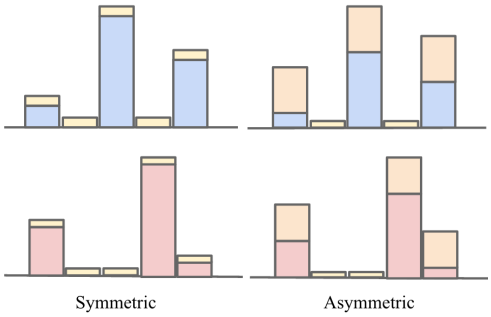

Figure 1: KL divergence with symmetric (left) and asymmetric (right) smoothing. Pink and blue correspond to two distributions while light yellow and orange to smoothing factors.

Nonlinear transformation of unseen word count. One of the simplest metrics to measure novelty is the plain count of unseen words. This measure, however, does not necessarily reflect human perception of novelty given the prevalence of nonlinearity in human perception (Kingdom and Prins, 2009). Thus, we explored the use of a simple nonlinear transformation of unseen word counts instead of the plain count (Figure 2):

$$T(n) = (\alpha n + \beta)^\gamma \quad (3)$$

where n is the number of new words and α, β and γ are parameters. In our experiments, the use of a nonlinear transformation helped yield better results.

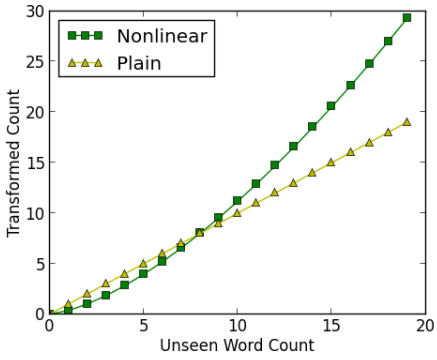

Figure 2: Nonlinear transformation of unseen word count with parameters set via cross-validation on the TREC training data: $\alpha = 0.5$, $\beta = 0$ and $\gamma = 1.5$.

Relative position in a document. Relative position of a sentence in a document is simple yet has been proven effective for summarization. Relative position is also closely related to novelty detection as follows: 1) There is in general a good chance that earlier sentences are more novel than the later ones. 2) We found a pattern that news articles coming in later are apt to present novel information first and then a summary of old information.

Word embedding-based similarity. Neural word embedding techniques can be effective in capturing syntactic and semantic relationships, and more computationally efficient than many other competitors (Socher et al., 2012; Mikolov et al., 2013). As reported in (Tai et al., 2015), a simple averaging scheme was found to be very competitive to more complex models for representing a sentence vector. These observations lead us to adopt the following additional features derived from word embeddings: 1) cosine similarity between the mean vectors of the context C and sentence S, 2) sigmoid function value for the dot product of the mean vectors of the context C and sentence S. The mean vectors of C and S are computed by taking the average of the word vectors of each unique word in C and S, respectively. We use word embedding with 100 dimensions trained on Wikipedia using the word2vec toolkit (https://code.google.com/p/word2vec).

3.2 Feature transformation

Recursive feature averaging. A large portion of the novel sentences in the TREC 2004 data appear in consecutive runs of two or more (Schiffman and McKeown, 2004). Sequential labeling would be a natural approach to take advantage of this characteristic of the problem, but the use of sequential labeling will make time complexity depend on the number of sentences T. Thus we came up with another way to exploit this characteristic, recursively averaging over previous feature vectors and augmenting the current feature vector with

the average:

$$R_t = \eta F_{t-1} + (1-\eta) R_{t-1} \quad (4)$$

$$F'_t = F_t :: R_t \quad (5)$$

where F is a feature vector, R the average vector of previous ones, F' the augmented feature vector, η the weight of the last feature vector in averaging and :: means concatenation.

DNN-based feature transformation. In order to better capture non-trivial interactions between the features described above, we adopt a DNN with a bottleneck. DNNs with a bottleneck have been successfully explored for nonlinear feature transformation (Grézl et al., 2007). The feature transformation is normally achieved from narrow hidden layers that retain only the information useful to classification. This leads us to introduce bottleneck hidden layers between the input layer and the *Logistic Regression* output layer (Figure 3.)

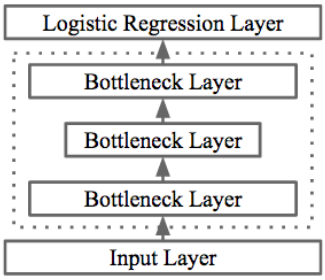

Figure 3: Flowchart for a bottleneck DNN. The dotted-box represents bottleneck generating hidden layers.

4 Experiments and Results

Following the guidelines of task 2 for the TREC 2004 novelty detection track, we used the TREC 2003 dataset as training data and the TREC 2004 dataset as test data. The training data includes 10,226 novel sentences out of 15,557 sentences. The test data includes 3,454 novel ones out of 8,343 sentences. We trained a DNN-based classifier and several logistic regression classifiers (which are the same model with the DNN model except without the hidden layers) using the Theano toolkit (Bergstra et al., 2010) to verify the effectiveness of each feature and feature transformation. We optimized all models by minimizing *logloss* with the stochastic gradient decent algorithm with momentum. We classified a sentence as novel if the posterior probability is greater than 0.5. We performed a search based on five-fold cross validation to identify optimal values for the parameters defined in Section 3, and obtained the following values: $s = 10$, $u = 0.1$, $\alpha = 0.5$, $\beta = 0$, $\gamma = 1.5$ and $\eta = 0.5$. For the DNN classifier, we used a set of five bottleneck hidden layers. The number of nodes for each hidden layer were set to 10, 5, 3, 5 and 10, respectively.

Comparative evaluation results in F-score (following the TREC protocol) are shown in Table 1. In Table 1, the first four entries refer to the best top systems from TREC 2004 and followup studies, *KLdiv* to a system using only KL divergence features, *TransCount* to a system using only nonlinear transformation of unseen word count features, *RelPos* to a system using only relative position features, *Word2Vec* to a system using only word embedding features, *All* to a system using all features, *All + Recursive* to *All* with recursive feature averaging applied, *All + DNN* to *All* with DNN-based feature transformation applied and *All + Recursive + DNN* to *All + Recursive* with DNN-based feature transformation applied. The best result (in bold) is significantly better than the best system results from TREC 2004, while still being very computationally efficient and therefore scalable. In terms of individual features, *KLdiv* (ties for 5th place at TREC 2004) and *TransCount* (outperforms the 6th entry) showed very strong results. Although *RelPos* and *Word2Vec* did not yield good results, we found them complementary to other features; performance was degraded to 0.621 and 0.624, respectively, when they were excluded from *All + Recursive + DNN*. The DNN-based feature transformation generally yielded better results. In particular, it becomes very effective in conjunction with recursive feature averaging. This result indicates that the DNN-based transformation allows the system to capture the non-trivial interactions between previous sentences and the current one.

Systems	F-score
Blott et al. (2004) / Gamon (2006)	0.622
Tomiyama et al. (2004)	0.619
Abdul-Jaleel et al. (2004)	0.618
Schiffman and McKeown (2004)	0.617
KLdiv	0.614
TransCount	0.611
RelPos	0.577
Word2Vec	0.577
All	0.615
All + Recursive	0.615
All + DNN	0.617
All + Recursive + DNN	**0.625**

Table 1: Performance breakdown. The best result is significantly better than the other configurations ($p < 0.01$) based on the McNemar test. Since the systems' output is not available, we are not able to calculate statistical significance against TREC systems.

5 Conclusions

We explored the space of light-weight features and their nonlinear transformation with the goal of supporting online web-scale sentence novelty detection. The experiment results show that these features are not only efficient but also very powerful; a combination of these

features with a simple, scalable classification approach significantly surpassed the best challenge system at TREC 2004. For future work, it would be interesting to see if more sophisticated DNN training techniques (e.g. unsupervised pre-training and different optimization algorithms) would yield a better performance.

Global Thread-Level Inference for Comment Classification in Community Question Answering

Abstract

Community question answering, a recent evolution of question answering in the Web context, allows a user to quickly consult the opinion of a number of people on a particular topic, thus taking advantage of the wisdom of the crowd. Here we try to help the user by deciding automatically which answers are good and which are bad for a given question. In particular, we focus on exploiting the output structure at the thread level in order to make more consistent global decisions. More specifically, we exploit the relations between pairs of comments at any distance in the thread, which we incorporate in a graph-cut and in an ILP frameworks. We evaluated our approach on the benchmark dataset of SemEval-2015 Task 3. Results improved over the state of the art, confirming the importance of using thread level information.

1 Introduction

Community question answering (CQA) is a recent evolution of question answering, in the Web context, where users pose questions and then receive answers from other users. This setup is very attractive, as the anonymity on the Web allows users to ask just about anything and then hope to get some honest answers from a number of people. On the negative side, there is no guarantee about the quality of the answers as people of very different background, knowledge, and with different motivation contribute answers to a given question.

Unlike traditional question answering (QA), in CQA answering takes the form of commenting in a forum. Thus, many comments are only loosely connected to the original question, and some are not answers at all, but are rather interactions between users.

As question-comment threads can get quite long, finding good answers in a thread can be time-consuming. This has triggered research in trying to automatically determine which answers might be good and which ones are likely to be bad or irrelevant. One early work going in this direction is that of Qu and Liu (2011), who tried to determine whether a question is "solved" or not, given its associated thread of comments. As a first step in the process, they performed a comment-level classification, considering four classes: *problem*, *solution*, *good feedback*, and *bad feedback*.

More recently, the shared task at SemEval 2015 on Answer Selection in CQA (Nakov et al., 2015), whose benchmark datasets we will use below, tackled the task of identifying *good*, *potentially* useful, and *bad* comments within a thread. In that task, the top participating systems used thread-level features, in addition to the usual local features that only look at the question–answer pair. For example, the second-best team, HITSZ-ICRC, used as a feature the position of the comment in the thread (Hou et al., 2015). Similarly, our participation, which achieved the third-best postition, used features that try to describe a comment in the context of the entire comment thread, focusing on user interaction (Nicosia et al., 2015). Finally, the fifth-best team, ICRC-HIT, treated the answer selection task as a sequence labeling problem and proposed recurrent convolution neural networks to recognize good comments (Zhou et al., 2015b).

In a follow-up work, Zhou et al. (2015a) included a long-short term memory in their convolution neural network to learn the classification sequence for the thread. In parallel, in our recent work (Barrón-Cedeño et al., 2015), we tried to exploit the dependencies between the thread comments to tackle the same task. We did it by designing features that look globally at the thread and by applying structured prediction models, such as Conditional Random Fields (Lafferty et al., 2001).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 573–578,
Lisbon, Portugal, 17-21 September 2015.

Our goal in this paper goes in the same direction: we are interested in exploiting the output structure at the thread level to make more consistent global assignments.

To the best of our knowledge, there is no work in QA that identifies good answers based on the selection of the other answers retrieved for a question. This is mainly due to the loose dependencies between the different answer passages in standard QA. In contrast, we postulate that in a CQA setting, the answers from different users in a common thread are strongly interconnected and, thus, a joint answer selection model should be adopted to achieve higher accuracy. In particular, we focus on the relations between two comments *at any distance in the thread*. This is more general than previous approaches, which were either limited to sequential interactions or considered conversational interactions only at the level of features.

We propose a model based on the idea that similar comments should have similar labels. Below, we apply graph-cut and we compare it to an integer linear programming (ILP) formulation for decoding under global constraints; we also provide results with a linear-chain CRF. We show that the CRF is ineffective due to long-distance relations, e.g., a conversation in a thread can branch and then come back later. On the contrary, the global inference models (either graph-cut or ILP) using the similarity between pairs of comments manage to significantly improve a strong baseline performing local comment-based classifications.

2 The Task

We use the CQA-QL corpus from Subtask A of SemEval-2015 Task 3 on Answer Selection in CQA. The corpus contains data from the *Qatar Living* forum,[1] and is publicly available on the task's website.[2] The dataset consists of questions and a list of answers for each question, i.e., *question-answer threads*. Each question, and each answer, consist of a short title and a more detailed description. There is also meta information associated with both, e.g., ID of the user asking/answering the question, timestamp, category. The task asks participants to determine for each answer in the thread whether it is *Good*, *Bad*, or *Potential*ly useful for the given question.

[2] http://alt.qcri.org/semeval2015/task3/

Q: Can I obtain Driving License my QID is written Employee

$\mathbf{A}_1$ the word employee is a general term that refers to all the staff in your company either the manager, secretary up to the lowest position or whatever positions they have. you are all considered employees of your company.

$\mathbf{A}_2$ your qid should specify what is the actual profession you have. i think for me, your chances to have a drivers license is low.

$\mathbf{A}_3$ dear richard, his asking if he can obtain. means he have the driver license

$\mathbf{A}_4$ Slim chance ...

Figure 1: **Example from SemEval-2015 Task 3.**

A simplified example is shown in Figure 1,[3] where answers 2 and 4 are good, answer 1 is potentially useful, and answer 3 is bad. In this paper, we focus on a *2-class* variant of the above Subtask A, which is closer to a real CQA application. We merge *Potential* and *Bad* labels into *Bad* and we focus on the 2-class problem: Good-vs-Bad. Table 1 shows some statistics about the resulting dataset used for development, training and testing.

Category	Train	Dev	Test
Questions	2,600	300	329
Comments	16,541	1,645	1,976
Good	8,069	875	997
Bad	8,472	770	979

Table 1: **Statistics about the CQA-QL dataset:** after merging *Bad* and *Potential* into *Bad*.

3 Our Proposed Solution

We model the pairwise relations between the comments in the answer thread ($\{c_i\}_{i=1}^{n}$) to produce a better global assignment: we combine the predictions of a Good-vs-Bad classifier at the comment level with the output of a pairwise classifier, Same-vs-Different, which takes two comments and predicts whether they should have the same label.

Each comment c_i has an individual score s_{iK}, provided by the Good-vs-Bad classifier, for being in class $K \in \{G, B\}$ (i.e., G for *Good* and B for *Bad*). Moreover, for each pair of comments (c_i, c_j), we have an association score s_{ij}, an estimate by the pairwise classifier about how likely it is that the comments c_i and c_j will have the same label. Next, we define two ways of doing global inference using these two sources of information.

[3] http://www.qatarliving.com/moving-qatar/posts/can-i-obtain-driving-license-my-qid-written-employee

3.1 Graph Partition Approach

Here our goal is to find a partition $P = (G, B)$ that *minimizes* the following cost:

$$C(P) = \lambda\Big[\sum_{c_i \in G} s_{iB} + \sum_{c_i \in B} s_{iG}\Big] + (1-\lambda) \sum_{c_i \in G, c_j \in B} s_{ij}$$

The first part of the cost function discourages misclassification of individual comments, while the second part encourages similar comments to be in the same class. The mixing parameter $\lambda \in [0, 1]$ determines the relative strength of the two components. Our approach is inspired by Pang and Lee (2004), where they model the proximity relation between sentences for finding subjective sentences in product reviews, whereas we are interested in global inference based on local classifiers.

The optimization problem can be efficiently solved by finding a *minimum cut* of a weighted undirected graph $G = (V, E)$. The set of nodes $V = \{v_1, v_2, \cdots, v_n, s, t\}$ represent the n comments in a thread, the *source* and the *sink*. We connect each comment node v_i to the source node s by adding an edge $w(v_i, s)$ with capacity s_{iG}, and to the sink node t by adding an edge $w(v_i, t)$ with capacity s_{iB}. Finally, we add edges $w(v_i, v_j)$ with capacity s_{ij} to connect all pairs of comments.

Minimizing $C(P)$ amounts to finding a partition (S, T), where $S = \{s\} \cup S'$ and $T = \{t\} \cup T'$ for $s \notin S', t \notin T'$, that minimizes the cut capacity, i.e., the net flow crossing from S to T. One crucial advantage of this approach is that we can use *max-flow* algorithms to find the exact solution in polynomial time — near-linear in practice (Cormen et al., 2001; Boykov and Kolmogorov, 2004).

3.2 Integer Linear Programming Approach

Here we follow the *inference with classifiers* approach by Roth and Yih (2004), solved with Integer Linear Programming (ILP). We have one ILP problem per question–answer thread. We define a set of binary variables, whose assignment will univocally define the classification of all comments in the thread. In particular, we define a pair of variables for each answer: x_{iG} and x_{iB}, $1 \leq i \leq n$. Assigning 1 to x_{iG} means that comment c_i in the thread is classified as *Good*; assigning it 0 means that c_i is not classified as *Good*. The same applies to the other classes (here, only *Bad*). Also, we have a pair of variables for each pair of comments (to capture the pairwise relations): x_{ijS} and x_{ijD}, $1 \leq i < j \leq n$. Assigning 1 to x_{ijS} means that c_i and c_j have the same label; assigning 0 to x_{ijS} means that c_i and c_j do not have the same label. The same interpretation holds for the other possible classes (in this case only *Different*).[4]

Let c_{iG} be the cost of classifying c_i as *Good*, c_{ijS} be the cost of assigning the same labels to c_i and c_j, etc. Following (Roth and Yih, 2004), these costs are obtained from local classifiers by taking log probabilities, i.e., $c_{iG} = -\log s_{iG}$, $c_{ijS} = -\log s_{ij}$, etc. The goal of the ILP problem is to find an assignment A to all variables x_{iG}, x_{iB}, x_{ijS}, x_{ijD} that *minimizes* the cost function:

$$C(A) = \lambda \cdot \sum_{i=1}^{N} (c_{iG} \cdot x_{iG} + c_{iB} \cdot x_{iB}) + (1-\lambda) \cdot \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} (c_{ijS} \cdot x_{ijS} + c_{ijD} \cdot x_{ijD})$$

subject to the following constraints: (*i*) All variables are binary; (*ii*) One and only one label is assigned to each comment or pair of comments; (*iii*) The assignments to the comment variables and to the comment-pair variables are consistent: $x_{ijD} = x_{iG} \oplus x_{jG}, \forall i, j \quad 1 \leq i < j \leq n$. $\lambda \in [0, 1]$ is a parameter used to balance the contribution of the two sources of information.

4 Local Classifiers

For classification, we use Maximum Entropy, or MaxEnt, (Murphy, 2012), as it yields a probability distribution over the class labels, which we then use directly for the graph arcs and the ILP costs.

4.1 Good-vs-Bad Classifier

Our most important features measure the similarity between the question (q) and the comment (c). We compare lemmata and POS [1-4]-grams using Jaccard (1901), containment (Lyon et al., 2001), and cosine, as well as using some similarities from DKPro (Bär et al., 2012) such as longest common substring (Allison and Dix, 1986) and greedy string tiling (Wise, 1996). We also compute similarity using partial tree kernels (Moschitti, 2006) on shallow syntactic trees.

Forty-three Boolean features express whether (*i*) c includes URLs or emails, the words "yes", "sure", "no", "neither", "okay", etc., as well as '?' and '@' or starts with "yes" (12 features); (*ii*) c includes a word longer than fifteen characters (1);

[4] Setting a binary variable for each class label is necessary to have an objective function that is linear on the labels.

(*iii*) q belongs to each of the forum categories (26); and (*iv*) c and q were posted by the same user (4). An extra feature captures the length of c.

Four features explore whether c is close to a comment by the user who asked the question, u_q: (*i-ii*) there is a comment by u_q following c and (not) containing an acknowledgment or (*iii*) containing a question, or (*iv*) among the comments preceding c there is one by u_q asking a question. We model dialogues by identifying conversation chains between two users with three features: whether c is at the beginning/middle/end of a chain. There are copies of these features for chains in which u_q participates. Another feature for c_{u_i} checks whether the user u_i wrote more than one comment in the current thread. Three more features fire for the first/middle/last comment by u_i. One extra feature counts the total number of comments written by u_i. Finally, there is a feature modeling the position of c in the thread.

4.2 Same-vs-Different Classifier

We use the following types of features for a pair of comments (c_i, c_j): (*i*) all the features from the Good-vs-Bad classifier (i.e., we subtracted the feature vectors representing the two comments, $|v_i - v_j|$)[5]; (*ii*) the similarity features between the two comments, $sim(c_i, c_j)$; and (*iii*) the prediction from the Good-vs-Bad classifiers on c_i and c_j (i.e., the scores for c_i and c_j, the product of the two scores, and five boolean features specifying whether any of c_i and c_j are predicted as *Good*, *Bad*, and whether their predictions are identical).

5 Experiments and Evaluation

We performed standard pre-processing, and we further filtered user's signatures. All parameters (e.g., Gaussian prior for MaxEnt and the mixing λ for the graph-cut and ILP) were tuned on the development set. We also trained a second-order linear-chain CRF to check the contribution of the sequential relations between comments. We report results on the official SemEval test set for all methods. For the Same-vs-Different problem, we explored a variant of training with three classes, by splitting the *Same* class into *Same-Good* and *Same-Bad*. At test time, the probabilities of these two subclasses are added to get the probability of *Same* and all the algorithms are run unchanged.

[5]Subtracting vectors is standard in preference learning (Shen and Joshi, 2003). The absolute value is necessary to emphasize comment differences instead of preferences.

Classifier	P	R	F_1	Acc
baseline: *Same*				69.26
MaxEnt-2C	73.95	90.99	81.59	71.56
MaxEnt-3C	77.15	80.42	78.75	69.94

Table 2: **Same-vs-Different classification.** P, R, and F_1 are calculated with respect to *Same*.

Table 2 shows the results for the Same-vs-Different classification. We can see that the two-class MaxEnt-2C classifier works better than the three-class MaxEnt-3C. MaxEnt-3C has more balanced P and R, but loses in both F_1 and accuracy. MaxEnt-2C is very skewed towards the majority class, but performs better due to the class imbalance. Overall, it seems very difficult to learn with the current features, and both methods only outperform the majority-class baseline by a small margin. Yet, while the overall accuracy is low, note that the graph-cut/ILP inference allows us to recover from some errors, because if nearby utterances are clustered correctly, the wrong decisions should be outvoted by correct ones.

The results for Good-vs-Bad are shown in Table 3. On the top are the best systems at SemEval-2015 Task 3. We can see that our MaxEnt classifier is competitive: it shows higher accuracy than two of them, and the highest F_1 overall.[6]

System	P	R	F_1	Acc
Top-3 at SemEval-2015 Task 3				
JAIST	80.23	77.73	78.96	79.10
HITSZ-ICRC	75.91	77.13	76.52	76.11
QCRI	74.33	83.05	78.45	76.97
Instance Classifiers				
MaxEnt	75.67	84.33	79.77	78.43
Linear Chain Classifiers				
CRF	74.89	83.45	78.94	77.53
Global Inference Classifiers				
ILP	77.04	83.53	80.15	79.14‡
Graph-cut	78.30	82.93	**80.55**	**79.80**‡
ILP-3C	78.07	80.42	79.23	78.73
Graph-cut-3C	78.26	81.32	79.76	79.19†

Table 3: **Good-vs-Bad classification.** ‡ and † mark statistically significant differences in accuracy compared to the baseline MaxEnt classifier with confidence levels of 99% and 95%, respectively (randomized test).

[6]This comparison is not strictly fair as the SemEval systems were trained to predict three classes, and here we remapped them to two. We just want to show that our baseline system is very strong.

The CRF model is worse than MaxEnt on all measures, which suggests that the sequential information does not help. This can be because many interactions between comments are long-distance and there are gaps in the threads due to the annotation procedure at SemEval (Nakov et al., 2015).

However, global inference with graph-cut and ILP improves both F_1 and accuracy, mostly due to better recall. Graph-cut works better than ILP as it has higher precision, which helps F_1 and accuracy.

Both yield statistically significant improvements over the MaxEnt classifier; they also improve over the state-of-the-art JAIST system. Note that the devtest-tuned values of λ for graph-cut and ILP put much lower weight to the Same-vs-Different component (values are 0.95 and 0.91, respectively). Finally, as expected, using the predictions of MaxEnt-2C in the global classifiers is better than using those from MaxEnt-3C.

Q: I have a female friend who is leaving for a teaching job in Qatar in January. What would be a useful portable gift to give her to take with her?

$\mathbf{A}_1$ A couple of good best-selling novels. It's hard to find much here in Doha in the way of books.
Local: Good, Global: Good, Human: Good

$\mathbf{A}_2$ ipod to entertain herself in case of boredom... a lot of patience for her students...
Local: Good, Global: Good, Human: Good

$\mathbf{A}_3$ Thanks, please keep suggestions coming, would like to send her off with a useful gift.
Local: Bad, Global: Bad, Human: Bad

$\mathbf{A}_6$ Bacon. Nice bread, bacon, bacon, errmmm bacon and a pork joint..
Local: Bad, Global: Good, Human: Good

$\mathbf{A}_9$ Couple of good novels, All time favorite movies, ..
Local: Bad, Global: Good, Human: Good

$\mathbf{A}_{11}$ Ditto on the books and dvd's. Excedrin.
Local: Bad, Global: Bad, Human: Good

$\mathbf{A}_{12}$ Ditto on the bacon, pork sausage, pork chops, ham,..can you tell we miss pork! I think getting a care package together: her favorite perfume; shampoo; conditioner; glycerin soaps; set of DVDs of her favorite TV series.. Oh, and did I mention she should pack PATIENCE?
Local: Bad, Global: Good, Human: Good

Figure 2: **An excerpt of a thread** with decisions by local and global classifiers, and humans.

6 Discussion

We manually examined a number of examples where our global classfier could successfully recover from the errors made by the local classifier, and where it failed to do so. In Figure 2, we show the classification decisions of our local and global (graph-cut) classifiers along with the human annotations for an excerpt of a thread.

For example, consider answers A_6, A_9, and A_{12}, which were initially misclassified as *Bad* by the local classifier, but later recovered by the global classifier exploiting the *pairwise* information. In this case, the votes received by these answers from other *Good* answers in the thread for being in the *same* class won against the votes received from other *Bad* answers.

Now consider A_{11}, which our method failed to classify correctly as *Good*. Our investigation revealed that in this case the votes from the *Bad* answers won against the votes from the *Good* ones. The accuracy of the pairwise classifier has proven to be crucial for the performance of our overall framework. We probably need more informative features (e.g., textual entailment and semantic similarity to capture the relation between books and novels, movies and DVDs, etc.) in order to improve the pairwise classification performance.

7 Conclusion and Future Work

We have investigated the use of thread-level information for answer selection in CQA. We have shown that using a pairwise classifier that predicts whether two comments should get the same label, followed by a graph-cut (or ILP) global inference improves significantly over a very strong baseline as well as over the state of the art. We have further shown that using a linear-chain CRF model does not help, probably because many interactions between comments are long distance.

In future work, we would like to improve the pairwise classifiers with richer features, as this is currently the bottleneck for improving the performance in the global model. We further plan to test our framework on other CQA datasets, including on other languages.[7] Last but not least, we are interested in extending this research with even more global information, e.g., by modeling global decision consistency across multiple threads.

Acknowledgments

This research was performed by the Arabic Language Technologies (ALT) group at the Qatar Computing Research Institute (QCRI), HBKU, part of Qatar Foundation. It is part of the Interactive sYstems for Answer Search (Iyas) project, which is developed in collaboration with MIT-CSAIL.

[7] SemEval-2015 Task 3 had an Arabic subtask, but there the answers were not coming from the same thread.

Abstract

The difficult language in Electronic Health Records (EHRs) presents a challenge to patients' understanding of their own conditions. One approach to lowering the barrier is to provide tailored patient education based on their own EHR notes. We are developing a system to retrieve EHR note-tailored online consumer oriented health education materials. We explored topic model and key concept identification methods to construct queries from the EHR notes. Our experiments show that queries using identified key concepts with pseudo-relevance feedback significantly outperform (over 10-fold improvement) the baseline system of using the full text note.

1 Introduction

Allowing patients access to their own electronic health records (EHRs) can enhance medical understanding and provide clinical relevant benefits (Wiljer et al., 2006), including increased medication adherence (Delbanco et al., 2012). However, EHR notes present unique challenges to the average patients. Since these notes are not usually targeted at the patients (Mossanen et al., 2014), languages that may be difficult for non-medical professionals to comprehend are prevalent, including medical terms, abbreviations, and medical domain-specific language patterns. The valuable and authoritative information contained in the EHR is thus less accessible to the patients, who ultimately stand to benefit the most from the information.

To address the challenges, we are developing a system to link medical notes to targeted education materials from trusted resources. The textual narratives in the EHR notes are not conducive to effective and efficient query. We therefore explored topic model and key concept identification methods to construct short queries from the EHR notes.

2 Related Work

Patent retrieval (Fujii et al., 2007) is similar to this work, as the queries are usually long and complex patent documents. Several methods have been proposed to construct shorter queries from the documents. For example, words in the summary section of a patent document can be ranked by TFIDF scores and extracted to form a query (Xue and Croft, 2009). Sentences that are similar to pseudo-relevant documents according to a language model are also used to reduce query length (Ganguly et al., 2011). Other similarity measures such as Kullback-Leibler divergence are used to extract terms, which are expanded to generate queries in the patent retrieval domain (Mahdabi et al., 2012). However, the patent retrieval domain is recall-driven, while in our scenario, patients are generally not expected to read relevant education documents exhaustively.

Various methods have also been proposed to retrieve documents relevant to passages of text or web documents. A model extended from CRF is proposed to identify noun phrases and named entities from a user-selected passage as queries (Lee and Croft, 2012). Similarly, noun phrases in a verbose query are also used as candidates for key concepts (Bendersky and Croft, 2008). Other related work that reduces long queries includes ranking all subsets of the original query (Kumaran and Carvalho, 2009). However, typical EHR notes are longer than the passages and verbose queries in these systems, which makes the graphical model and other learning based models less efficient. Moreover, parsers as required by Bendersky et al. (2009) and Named Entity Recognizers for the medical domain are less effective than the general domain.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 579–584,
Lisbon, Portugal, 17-21 September 2015.

TREC Clinical Decision Support Track[1] is an IR challenge to link medical cases to information relevant for patient care. Unlike our system, this task is designed to address the physicians' information needs of diagnosis, testing and treatment for the patients.

3 Materials and Methods

3.1 Data

MedlinePlus[2] provides current and reliable information about over 900 health topics pages and 1000 medication pages to users in consumer-oriented lay language. Additionally, the medical encyclopedia section includes over 7000 articles about diseases, tests, symptoms, injuries, and surgeries. We include in this study the textual narratives in the "health topics", "drugs, supplements, and herbal information", and "medical encyclopedia" sections of the MedlinePlus as the collection of educational materials. There are a total of approximately 9400 articles in this collection, which we designate as *MedlinePlus*. Table 3.1 summarizes the characteristics of the collection.

We index the *MedlinePlus* documents with Galago, an advanced open source search engine. Galago implements the inference network retrieval model (Turtle and Croft, 1991). This model calculates the probability of the user's information needs being satisfied given a document in a directed acyclic graph. This framework is applied in many information retrieval tasks, and shown to be successful (Metzler et al., 2004).

Twenty progress notes are randomly selected from a corpus of de-identified EHR notes as the EHR document collection. Each note contains on average 261 tokens, with a standard deviation of 133. A physician read each note, and manually identified relevant education materials from the *MedlinePlus* documents. Each EHR note is linked to 22 education material documents on average. For example, Table 3.1 shows the summary of one EHR note and some of its relevant *MedlinePlus* documents. There are approximately 30 sentences or 360 tokens in the actual document.

We adopted Mean Average Precision (MAP) and Precision at 10 to evaluate the IR systems.

Summary of EHR Note
Patient remains in ICU with the following problems: respiratory failure, hemodynamics, renal failure, status post liver transplant, atrial fib, infectious disease, nutrition.
Select Relevant Documents
Respiratory Failure
Deep Vein Thrombosis
Aspiration pneumonia
Pulmonary Hypertension
Kidney Failure
Atrial Fibrillation or Flutter
Liver Transplantation
Dialysis - Hemodialysis

Table 2: Example EHR Note and its relevant documents

3.2 IR Systems

We investigate several query generation approaches, whereby short queries are built from an EHR note. In our queries, sequential dependence model (Metzler and Croft, 2005) was used to capture the dependencies in a multi-word query term. In this model, given a query, documents are ranked based on features of documents containing a single query term, two query terms sequentially appearing in the query, and two query terms in any order. This model has been shown to be effective in many applications (Balasubramanian et al., 2007; Cartright et al., 2011; Bendersky et al., 2009).

3.2.1 Baseline Approach

Our baseline approach issues each of the 20 test EHR notes as the query to the *MedlinePlus* document index and retrieves top 500 relevant documents. Although queries are not generally as long as EHR notes, an average patient without adequate medical knowledge may have difficulties constructing effective queries. Thus, this baseline can be considered as a proxy to how a patient actually conducts his own search in the real word.

3.2.2 LDA Models

We trained LDA topic models from over 6000 de-identified EHR notes to identify prominent topics from the test notes. The number of topics are selected based on retrieval performance. LDA models extract distributions over individual word tokens for each topic. However, medical con-

Document Type	Documents (Tokens)	Average Tokens (StdDev)
Health Topics	956 (141,185)	147.7 (37.6)
Medical Encyclopedia	7078 (5,126,101)	724.2 (363.7)
Drugs, Supplements, and Herbal Information	1332 (1,726,570)	1296.2 (992.8)
Total	9366 (6,993,856)	749.1 (565.9)

Table 1: MedlinePlus Collection

cepts often contain more than one token. We employ turbo topics (Blei and Lafferty, 2009) to find phrases from these topics. This method builds significant n-grams based on a language model of arbitrary length expressions. Queries are then generated from the n-grams. We take the top 5 phrases as queries from the topics that has a combined probability of over 80%.

3.2.3 Learning-Based Key Concept Identification

We also developed learning-based key concept identification to build queries from EHR notes. We employed Conditional Random Fields (CRF) model (Lafferty et al., 2001) to identify key concepts, which are most in need of explanation by external education materials. These key concepts can be considered in a broad sense topics, as they also capture various aspects of the EHR note content. We explored lexical, morphological, UMLS (Bodenreider, 2004) semantic type, and word embeddings as features. The word embeddings were induced from a combination of Wikipedia articles in the Medicine category and de-identified EHR progress notes.

Three CRF models are learned using different training data. One uses Wikipedia articles. Wikipedia, especially the Medicine category, is an appealing resource for such information as the human curated links in them are naturally concepts that are important. However, the number of articles in the Medicine category outnumbers our EHR notes substantially, we therefore restricted the Wikipedia articles to the Diabetes category. The paragraphs before the table of contents box are used. Anchor texts in these paragraphs are treated as key concepts. The second model uses EHR notes. Training data for the model was generated from the retrieval gold standard. A phrase in an EHR note would be annotated as a key concept if it matches the title of one of the note's relevant *MedlinePlus* documents. Lastly, we augmented the EHR corpus with Wikipedia articles, and compared its performance to the other CRF-based models. Leave-one-out cross validation is used in the last two models.

	System	P@10	MAP	Increase
1	Baseline	0%	0.0091	-
2	CHV	5%	0.0240	2.6
3	LDA	10%	0.0489	5.4
4	Key (Wiki)	16%	0.0851	9.4
5	Key (EHR)	16.5%	0.0879	9.7
6	Key (Wiki+EHR)	18%	0.1030	11.3

Table 3: System Performance

3.2.4 Query Expansion

We explored query expansion by incorporating relevance feedback from pseudo-relevant documents. The initial queries are generated using methods described previously. Among the top 20 retrieval results, those with a title that matches one of the identified key concepts are considered pseudo-relevant documents. This additional requirement is to ensure that the expanded concepts do not drift from the main topic of the medical notes. From these documents, medical concepts are extracted using MetaMap (Aronson and Lang, 2010). These concepts, with their synonyms provided by UMLS, are used as expansions.

4 Experiment Results

4.1 LDA Models

100 topics are learned from the de-identified EHR note collection. This level of topic granularity shows the best performance in our experiments. The retrieval result is shown in Table 4, row 3. The improvement over the baseline is 5.4 folds, and is statistically significant using a paired Student's t-test ($p < 0.05$).

4.2 Key Concept Identification

The key concept identification performance of the three CRF models is shown in Table 4.2. Retrieval

	Training Data		
	Wiki	EHR	Wiki+EHR
Precision	16.27%	35.92%	33.79%
Recall	26.88%	34.09%	33.18%
F1	18.74%	33.70%	32.54%

Table 4: Key concept identification performance

Training Data	P@10	MAP
Wiki	20% (16%)	0.1067 (0.0851)
EHR	16% (16.5%)	0.0951 (0.0879)
Wiki+EHR	21% (18%)	0.1169 (0.1030)

Table 5: System performance with pseudo-relevance feedback. Numbers in parentheses are without pseudo-relevance feedback.

performance of these models are shown in Table 4, rows 4 to 6. All systems showed a statistical significant improvement over the baseline. The last model's improvement is also statistically significant over the LDA approach. Query expansion methods further improved system performance, as shown in Table 4.2.

5 Discussions

From the LDA model, Table 5 shows the top 10 n-grams from 7 topics trained on the medical text. It is clear that while topics like the first one capture medical concepts, others like the second one do not. The LDA results also highlight the noisy nature of the EHR notes. Queries formed by including the generic or noisy terms such as "continue on" will not benefit retrieval results. Examining the retrieval results, we found that when the prominent topics include medical concepts, the top 10 results usually contain at least one relevant document. When only generic topics are identified, relevant documents are absent in the top 10 results.

The CRF models, on the other hand, are better at capturing the concepts in the EHR notes. All three models outperformed the LDA model. One drawback of using models trained from title-matching phrases is that the identified key concepts fail to cover the scope of the medical concepts contained in an EHR note. On average only 23.6% of the concepts are annotated as key phrases in each note. In the evaluation of the CRF models for their key concept identification performance, inclusion of Wikipedia data slightly decreased the F1 score when they were tested on EHR notes. This can be attributed to the fact that the Wikipedia articles outnumbered the EHR data by 7 times. However, this data helped improve the coverage of the key concepts. In one document, the augmented model identified two more out of the total eight key concepts.

	Phrases with the highest probability
1	dialysis, hemodialysis, catheter, renal failure, renal, coumadin, line, picc line, dialysis catheter, failure
2	job id, today, point, continue on, reasonable, try to, continue, yesterday, left, right
3	continue, patient, job id, pain, patient has, normal, patient s, white count, secondary to, culture
4	liver, ascites, normal, tenderness, fluid, stable, elevated, today, edema, chest
5	preliminary, patient, patient s, time, blood, mmoll, patient has, routine, high, vial
6	diarrhea, abdominal, flagyl, stool, abdominal pain, colitis, abdomen, difficile, fluid, distended
7	bipap, pneumonia, year old, respiratory failure, failure, minutes, requiring, encephalopathy, ards, patient

Table 6: Top 10 n-grams from 7 topics using the LDA model

Finally, to investigate the gap between medical language and lay language, we substituted the medical concepts recognized by MetaMap with their consumer-oriented counterparts created by the Consumer Health Vocabulary (CHV) Initiative (Zeng and Tse, 2006). Performance using the substituted EHR notes as shown in Table 4, row 2 more than doubled. The gap highlights the issue that patients may have difficulty finding relevant health information without assistance due to vocabulary mismatch.

6 Conclusions, Limitations and Future Plan

We have shown that using full EHR notes is ineffective at retrieving relevant education materials. Identifying key concepts of an EHR note and then using the key concepts as query terms re-

sult in significantly improved performance (over 10-fold). Furthermore, a query expansion approach in which key concepts are complemented by other medical concepts from pseudo-relevant documents further improves the performance.

One limitation of our design is that only one physician provided relevancy judgments. Additional annotators would provide a more rigorous set of gold standard, allowing us to measure inter-annotator agreement.

There are several directions we can explore in our future research. Firstly, our key concept identification methods are not optimized for the retrieval results, but for the identification subtask only. We hypothesize that directly optimizing the key concept identifier for retrieval would lead to better performance. We would also investigate domain adaptation techniques to learn key concept identification models from other data sources.

Image-Mediated Learning for Zero-Shot Cross-Lingual Document Retrieval

Ruka Funaki, Hideki Nakayama
Machine Perception Group
Graduate School of Information Science and Technology
The University of Tokyo
{funaki,nakayama}@nlab.ci.i.u-tokyo.ac.jp

Abstract

We propose an image-mediated learning approach for cross-lingual document retrieval where no or only a few parallel corpora are available. Using the images in image-text documents of each language as the hub, we derive a common semantic subspace bridging two languages by means of generalized canonical correlation analysis. For the purpose of evaluation, we create and release a new document dataset consisting of three types of data (English text, Japanese text, and images). Our approach substantially enhances retrieval accuracy in zero-shot and few-shot scenarios where text-to-text examples are scarce.

1 Introduction

Cross-lingual document retrieval (CLDR) is the task of finding relevant documents in one language given a query document in another language. While sufficiently large-scale corpora are critical for parallel corpus-based learning methods, manually creating corpora requires huge human effort and is unrealistic in many cases.

A straightforward approach is to crawl bilingual documents from the Web for use as training data. However, because most documents on the Web are written in one language, it is not always easy to collect a sufficient number of multilingual documents, especially those involving minor languages. Let us consider the multimedia information in documents. We can, for example, find abundant pairings of text and images, e.g., text with the ALT property of <IMG> tags in HTML, text with photos posted to social networking sites, and articles on Web news posted with images. Unlike text, an image is a universal representation; we can easily understand the semantic content of images regardless of our mother tongue. Motivated by this observation, we expect that we can learn the relation of two languages indirectly through images, even if we do not have sufficient bilingual text pairs (Figure 1).

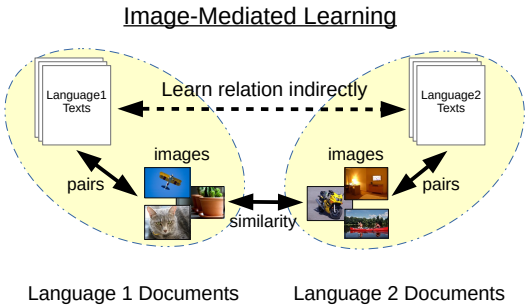

Figure 1: Concept of image-mediated learning. Our idea is to learn the relation between two languages indirectly by using images attached to text. If two documents written in different languages include images with similar image features, it is likely that the texts contained in the two documents are similar. Based on this idea, we seek the relation of texts written in different languages mediated by the similarity between images.

Generally, traditional image recognition techniques (or image features) are very poor compared with those in the natural language processing field. In recent years, however, deep learning has resulted in a breakthrough in visual recognition and dramatically improved image recognition accuracy in generic domains, which is rapidly approaching human recognition levels (Fang et al., 2015). We expect that these state-of-the-art image recognition technologies can effectively assist CLDR tasks.

We show that hub images enable zero-shot training of CLDR systems and improve retrieval accuracy given only a few parallel text samples.

2 Related Work

2.1 Multimodal Learning for CLDR

Multimodal learning, defined as a framework for machine learning using inputs from multiple media or sensors, has played a key role in various cross-modal applications. The most widely used standard method for multimodal learning is canonical correlation analysis (CCA) (Hotelling, 1936), which projects multimodal data into a shared representation. For example, CCA has been successfully used in image retrieval (tag to images) and image annotation (image to tags) (Hardoon et al., 2004; Rasiwasia et al., 2010; Gong et al., 2014). In the context of CLDR, each language's texts constitute one modality. CCA has also commonly been used for cross-lingual information retrieval (Vinokourov et al., 2002; Li and Shawe-Taylor, 2004; Udupa and Khapra, 2010). Whereas CCA can handle only two modalities, we need to consider relations between three modalities because we use images in addition to the two languages. Therefore, we focus on an extension of CCA, generalized canonical correlation analysis (GCCA), to handle more than two inputs (Kettenring, 1971).

2.2 Zero-Shot Learning for CLDR

Our core idea is to use another modality (image) as a hub to indirectly learn the relevance between two different languages. The work by Rupnik et al. is probably the closest to ours (Rupnik et al., 2012). In their study, they used a popular language (e.g., English) with enough bilingual documents shared with other languages as a hub to enhance CLDR for minor languages with few direct bilingual texts available. Nevertheless, this method assumes that parallel corpora of the hub and target languages exist and therefore, its application is limited to specific domains where manual translations are readily available, such as Wikipedia and news sites. Contrarily, because we use images as the hub, we can use documents closed with respect to each language for training. Considering that current generic Web documents are mostly closed with respect to one language, yet equipped with rich multimedia data, our setup is assumed to be more reasonable.

	Division	English	Images	Japanese
1	[train-E/I]	E_1	I_1	-
2	[train-I/J]	-	I_2	J_2
3	[train-E/J]	E_3	-	J_3
4	[test-E/J]	E_4	-	J_4

Table 1: Division of training and test data. Each division of training dataset is missing one of the three modalities.

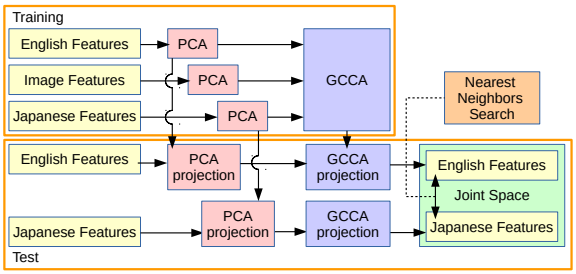

Figure 2: System overview

3 Our Approach

3.1 Overview of Image-Mediated Learning

We use the following notations for specifying each non-overlapping data division.

1. [train-E/I]: Training documents consisting of English text and images.
2. [train-I/J]: Training documents consisting of images and Japanese text.
3. [train-E/J]: Training documents consisting of English and Japanese text.
4. [test-E/J]: Test documents consisting of English and Japanese text.

We define IDs for each modality in each division as given in Table 1. For example, E_1 represents features of English text in the [train-E/I] division. Typical CLDR based on parallel corpora uses only [train-E/J] for training and [test-E/J] for evaluation. In the zero-shot learning scenario without any [train-E/J] data, we use only [train-E/I] and [train-I/J] for training. In the few-shot learning scenario, we also use a small number of [train-E/J] samples. We call this approach image-mediated learning.

An overview of our system is depicted in Figure 2. We compress features by principal component analysis (PCA) and train them by GCCA. For testing, we compress features by PCA, project features by GCCA, then, search the nearest neighbors from Japanese to English in the joint space.

3.2 Feature Extraction

A convolutional neural network (CNN) is one of the most successful deep learning methods for visual recognition. It is known that we can obtain very good image features by taking activation of hidden neurons in a network pre-trained by a sufficiently large dataset (Donahue et al., 2013). We apply the CNN model pre-trained using the ILSVRC2012 dataset (Russakovsky et al., 2015) provided by Caffe (Jia et al., 2014), a standard deep learning software package in the field of visual recognition.

As the text feature for both English and Japanese, we use the bag-of-words (BoW) representation and term frequency-inverse document frequency (TF-IDF) weighting. The MeCab (Kudo et al., 2004) library is used to divide Japanese text into words by morphological analysis. No preprocessing approaches like eliminating stop words and stemming, are used.

3.3 GCCA

GCCA is a generalization of CCA for any m modalities ($m = 3$ in our case). Although several slightly different versions of GCCA have been proposed (Carroll, 1968; Rupnik et al., 2012; Velden and Takane, 2012), we implement the simplest one (Kettenring, 1971) because GCCA itself is not the main focus of this study.

Let E, I, and J denote English, images, and Japanese, respectively. For feature vector $\mathbf{x}_k, \forall k \in \{E, I, J\}$, let $\mathbf{z}_k = (\mathbf{x}_k - \overline{\mathbf{x}}_k)\mathbf{h}_k$ denote its canonical variables. Σ_{ij} denotes a covariance matrix of modalities i and j where $i, j \in \{E, I, J\}$. Projection vectors $\mathbf{h}_k$ are computed such that they maximize the sum of correlations between each pair of modalities obtained by solving the following generalized eigenvalue problem:

$$\frac{1}{2}\begin{pmatrix} \mathbf{0} & \Sigma_{EI} & \Sigma_{EJ} \\ \Sigma_{IE} & \mathbf{0} & \Sigma_{IJ} \\ \Sigma_{JE} & \Sigma_{JI} & \mathbf{0} \end{pmatrix}\mathbf{h} = \rho\begin{pmatrix} \Sigma_{EE} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \Sigma_{II} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \Sigma_{JJ} \end{pmatrix}\mathbf{h} \quad (1)$$

where $\mathbf{h} = (\mathbf{h}_E^T, \mathbf{h}_I^T, \mathbf{h}_J^T)^T$. The canonical axises $\mathbf{h}$ are normalized such that $\frac{1}{3}\sum_{k\in\{E,I,J\}}^{3} \mathbf{h}_k^T \Sigma_{kk} \mathbf{h}_k = 1$. Additionally, we add a regularization term to the self covariance matrices to prevent over-fitting; that is, we set $\Sigma_{kk} \rightarrow \Sigma_{kk} + \alpha I$, where α is a parameter to avoid the singularity issue.

Despite our training datasets having only two of the three modalities as given in Table 1, we can handle this situation naturally by computing covariance matrices from the available data only. For example, in the few-shot learning scenario, we compute Σ_{EI} using E_1 and I_1, and Σ_{EE} using E_1 and E_3. In the zero-shot learning scenario, because [train-E/J] is not available, we compute Σ_{EE} using E_1 only and use a zero matrix for Σ_{EJ}.

3.4 Nearest Neighbor Search in Joint Space

We can find relevant documents in another language by computing the distances from the query documents using the coupled canonical subspaces. Having set Japanese as the query language, we retrieve documents written in English. Nearest neighbors are obtained as follows:

$$\hat{j} := \arg\min_j d(\mathbf{z}_J^i, \mathbf{z}_E^j), \quad (2)$$

where $\mathbf{z}_J^i$, $\mathbf{z}_E^j$ are projected feature vectors of the query and target documents, respectively, and $d(\cdot)$ is a distance function, which in our case, is the Euclidean distance.

4 Experiment

4.1 Pascal Sentence Dataset with Japanese Translation

The UIUC Pascal Sentence Dataset (Rashtchian et al., 2010) contains 1000 images, each of which is annotated with five English sentences describing its content. This dataset was originally created for the study of sentence generation from images, which is one of the current hot topics in computer vision. To establish a new benchmark dataset for image-mediated CLDR, we included a Japanese translation for each English sentence provided by professional translators[1], as shown in Figure 3. In this experiment, we bundled the five sentences attached to each image for use as one text document. Therefore, in our setup, each of the 1000 documents in the dataset consists of three items: an image, and the corresponding English and Japanese text.

[1]Dataset is available at:
http://www.nlab.ci.i.u-tokyo.ac.jp/dataset/pascal_sentence_jp/

English Texts	Images	Japanese Texts
- A family on a boat with a cross on a river - A happy couple with a young child wearing a life preserver sitting on a boat. - A man, a woman, and a child sit on boat with a large cross on it. - A man, women and small child sitting on top of a boat moving along the river. - Family of three sitting on deck, child wearing red vest, brush and shoes are seen in the foreground.		- 川で十字架のあるボートに乗っている家族。 - ボートに座っている、救命具を着た幼い子どもと幸せなカップル。 - 男性、女性と子どもが大きな十字架のあるボートに座っています。 - 川に沿って動いているボートの上部に座っている男性、女性と小さな子ども。 - ブラシと靴が前景に写されている、子どもが赤いベストを着て、デッキに座っている三人の家族。
- A black and white cow in a grassy field stares at the camera. - A black and white cow standing in a grassy field. - A black and white cow stands on grass against a partly cloudy blue sky. - a cow is gazing over the grass he is about to graze - Black and white cow standing in grassy field.		- 草地の黒と白の雌牛がカメラをじっと見ています。 - 草地に立っている黒と白の雌牛。 - 一部曇った青空を背に黒と白の雌牛が草地に立っています。 - 雌牛が食べようとしている草をじっと眺めています。 - 草地に立っている黒と白の雌牛。
⋮	⋮	⋮

Figure 3: Examples from the Pascal Sentence Dataset with Japanese translations: each image has about five sentences describing it from different perspectives.

4.2 Evaluation

We randomly sampled data from the dataset for each division in Table 1 without any overlap; we ignored the modality of each document that was not available in each data division (e.g., Japanese text in [train-E/I]). We ran experiments with varying sample sizes for [train-E/I] and [train-I/J], that is, 100, 200, 300, and 400. Furthermore, we gradually increased the number of [train-E/J] samples from 0 to 100 to emulate the few-shot learning scenario. The size of the test data [test-E/J] was fixed at 100. Following this setup, we performed image-mediated CLDR based on GCCA, and compared the results with those obtained by standard CLDR using only [train-E/J] data with CCA. We evaluated the performance with respect to the top-1 Japanese to English retrieval accuracy in the test data. Given that we used 100 test samples, the chance rate was 1%. For each run, we conducted 50 trials randomly replacing data and used the average score. All features were compressed into 100 dimensions via PCA and α was set to 0.01.

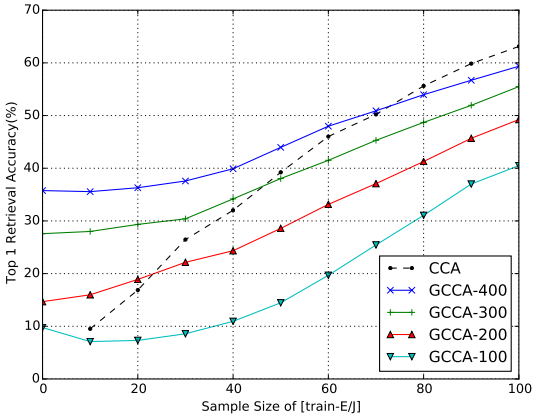

Figure 4: Retrieval accuracy varying the number of [train-E/J] data. Each colored line shows the performance of our method with a different sample size of [train-E/I] and [train-I/J] data (e.g., GCCA-400 denotes respective 400 samples of [train-E/I] and [train-I/J] for GCCA). We used image features extracted from GoogLeNet and text features represented as bags-of-words.

The experimental results, illustrated in Figure 4, clearly show that better accuracy is obtained with a greater number of text-image data in both zero-shot and few-shot scenarios. We can expect even better zero-shot accuracy with more text-image data, although, we cannot increase [train-E/I] and [train-I/J] more than 400 each in the current setup because of the restricted dataset size. We summarized results in zero-shot scenario in Table 2 in several cases. Although both GCCA and CCA show improved performance as the sample size of [train-E/J] increases, not surprisingly, GCCA is gradually overtaken by CCA when we have enough samples to learn the relevance between English and Japanese texts directly. However, accuracies of image-mediated learning in the cases when [train-E/J] is scarce are higher than CCA baseline. Hence, we confirmed that the image-mediated model is also effective in the few-shot learning scenario.

Model	Accuracy(%)
GCCA-400(BoW)	37.4 ± 3.8
GCCA-300(BoW)	27.6 ± 3.4
GCCA-200(BoW)	14.7 ± 3.2
GCCA-100(BoW)	9.8 ± 2.3
GCCA-400(TF-IDF)	42.0 ± 4.6
GCCA-300(TF-IDF)	31.6 ± 4.3
GCCA-200(TF-IDF)	17.2 ± 2.6
GCCA-100(TF-IDF)	11.8 ± 2.7

Table 2: Accuracy of zero-shot learning. Image features are extracted from GoogLeNet and both the bag-of-words (BoW) and the TF-IDF model are used as text features.

Feature	Accuracy(%)
CNN(GoogLeNet), BoW	37.4 ± 3.8
CNN(VGG), BoW	31.3 ± 3.5
CNN(CaffeNet), BoW	25.1 ± 3.4
FisherVector, BoW	10.8 ± 2.7
CNN(GoogLeNet), TF-IDF	42.0 ± 4.6
CNN(VGG), TF-IDF	37.8 ± 2.9
CNN(CaffeNet), TF-IDF	29.7 ± 4.4
FisherVector, TF-IDF	12.6 ± 2.7

Table 3: Accuracy of zero-shot learning in multiple image features. The sample size of both [train-E/I] and [train-I/J] is 400. Both the bag-of-words (BoW) and the TF-IDF model are used as text features.

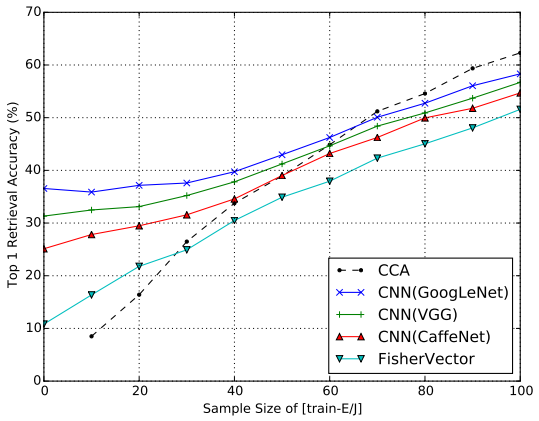

Figure 5: Retrieval accuracy using different image features in image-mediated CLDR. The sample size of both [train-E/I] and [train-I/J] is 400. Text features are based on the bag-of-words model.

4.3 Effect of Image Features

We also verified the effect of the performance of image features in our framework (see Figure 5 and Table 3). CNN has improved dramatically over the last few years, and many new powerful pre-trained networks are currently available. We compared three different features extracted from GoogLeNet (Szegedy et al., 2014), VGG 16 layers (Chatfield et al., 2014), and CaffeNet (Jia et al., 2014; Krizhevsky et al., 2012). Additionally, we tested the Fisher Vector (Perronnin et al., 2010), which was the standard hand-crafted image feature before deep learning. We extracted features from the pool5/7x7_s1 layer in GoogLeNet, fc6 layer in VGG, and fc6 layer in CaffeNet. For the Fisher Vector, following the standard implementation, we compressed SIFT descriptors (Lowe, 1999) into 64 dimensions by PCA, and used a Gaussian mixture model with 64 components. We used four spatial grids for the final feature extraction. Overall, the order of performance of features corresponds to that known in the image classification domain (Russakovsky et al., 2015). This result indicates that when more powerful image features are used, better performance can be achieved in image-mediated CLDR.

5 Conclusion

We proposed an image-mediated learning approach to realize zero-shot or few-shot CLDR. For evaluation, we created and released a new dataset consisting of Japanese, English, and image triplets, based on the widely used Pascal Sentence Dataset. We showed that state-of-the-art CNN-based image features can substantially improve zero-shot CLDR performance. Considering that image features have continued to improve rapidly since the deep learning breakthrough and the universality of images in Web documents, this approach could become even more important in the future.

Detecting Risks in the Banking System by Sentiment Analysis

Abstract

In November 2014, the European Central Bank (ECB) started to directly supervise the largest banks in the Eurozone via the Single Supervisory Mechanism (SSM). While supervisory risk assessments are usually based on quantitative data and surveys, this work explores whether *sentiment analysis* is capable of measuring a bank's attitude and opinions towards risk by analyzing text data. For realizing this study, a collection consisting of more than 500 CEO letters and outlook sections extracted from bank annual reports is built up. Based on these data, two distinct experiments are conducted. The evaluations find promising opportunities, but also limitations for risk sentiment analysis in banking supervision. At the level of individual banks, predictions are relatively inaccurate. In contrast, the analysis of aggregated figures revealed strong and significant correlations between uncertainty or negativity in textual disclosures and the quantitative risk indicator's future evolution. Risk sentiment analysis should therefore rather be used for macroprudential analyses than for assessments of individual banks.

1 Introduction

From 2007 on, a global crisis struck the financial markets and led to a severe slow-down of the real economy. It was triggered by the collapsing US subprime mortgage sector, where loans had been issued to borrowers with poor credit ratings. Due to the tight interconnectedness of the financial system, problems quickly propagated in the global banking system. Governments had to bail out important institutions like *Northern Rock*, but such solutions could not be provided for every troubled bank. In September 2008, the large investment bank *Lehman Brothers* had to file bankruptcy. In the aftermath of this event, further banks had to be rescued in order to stabilize the financial system. This deep financial crisis highlighted the necessity of better financial regulation as well as more effective financial supervision in the future (Hodson and Quaglia, 2009).

As a reaction to the crisis and its severe economic consequences, EU institutions decided to build up an *European Banking Union* (EBU). The EBU consists of three pillars, one of them being a new system of financial supervision, the *Single Supervisory Mechanism* (SSM). Its goal is to "promote long-term safety and soundness of credit institutions and the stability of the financial system within the Union and each Member State [...]" (Council of the EU, 2013, p. 72).

For supervising over 120 of the largest banks in the Eurozone, the SSM utilizes a range of information sources in order to detect vulnerabilities and risks. The sources include mainly backward-looking quantitative *Key Risk Indicators* (KRIs), which are complemented with surveys in order to include forward-looking information as well (European Banking Authority, 2014). However, another source of information seems to be largely untapped, namely textual data published by the banks. Publications like periodic reports, press releases, and news published for investors also contain forward-looking information. Analyzing this readily available data would be more cost-efficient in comparison to traditional approaches like surveys. It could provide answers to questions like: what does official communication by banks reveal about their expectations and attitudes towards risk?

In this paper, we present a novel application of *sentiment analysis* for exploring attitudes and opinions about risk in textual disclosures by

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 591–600,
Lisbon, Portugal, 17-21 September 2015.

banks. In particular, this work (1) finds suitable data sources, (2) identifies appropriate techniques for risk sentiment analysis, and (3) analyzes risk sentiment within the last decade in order to cover the financial crisis of 2007-08 adequately. The derived sentiment scores quantify uncertainty, negativity, and positivity in the analyzed documents. All of them are interesting with regards to risk sentiment analysis: uncertainty relates to risk in a direct way since the latter are "uncertainties resulting in adverse variations of profitability or in losses" (Bessis, 2002, p. 11). Highly negative sentiment refers to current or future problems, and too positive sentiment could represent overconfidence. We find that sentiment scores reflect not only the financial crisis, but also other major economic events within the last decade.

In addition, we test for correlations between the sentiment scores and a popular quantitative risk indicator. It turns out that aggregated risk sentiment in forward-looking documents is a leading indicator for the actual risk figures, so it can be used within predictive models.

The remainder of this paper, which is based on the Master's thesis of one of the authors (Nopp, 2015), is organized as follows: first, we give an overview on related work in the field of risk sentiment analysis. The following section introduces the chosen sources for text data and quantitative figures. Afterwards, we give an overview on the chosen methodologies and evaluate the experimental results. The last section concludes.

2 Related Work

Sentiment analysis in general and its application in the financial domain in particular gained a lot of interest within the last decade. There is a number of studies which aim to identify risks by means of text mining. A common question tackled by researchers is whether corporate disclosures drive stock price volatilities or future earnings of the respective firm (Groth and Muntermann, 2011; Kogan et al., 2009; Tsai and Wang, 2013). Hence, they focus on the risk an *investor* takes if he or she buys stocks of a company. Generally spoken, these studies find significant correlations between sentiment extracted from corporate disclosures and future volatilities. Other papers deal with *financial distress prediction*, for example Hajek and Olej (2013). As a baseline, they classify companies based on financial indicators. It turned out that the inclusion of sentiment indicators improved financial distress prediction.

Among the text data sources for these studies are mainly annual reports, but also news stories or earning calls transcripts[1]. Kogan et al. (2009) exclude irrelevant information from the annual reports by focusing on a section which contains important forward-looking content.

In the related studies, authors work with similar approaches for extracting sentiment from texts. Linguistic preprocessing generally involves tokenization, lemmatization, and removing non-essential items like tables, exhibits, or digit sequences. In almost every study, the authors also make use of term weighting schemes. With the selected features and additional quantitative data, the studies either employ machine learning algorithms, or use the data for regression analyses.

Although none of the mentioned papers focuses on risk sentiment analysis in the banking industry, parts of their processing pipelines and approaches can be reused for this work. With regards to the selection of appropriate data sources, it can be concluded that analyzing annual reports is very popular in this field of research. Hence, these data should also be considered for the experiments of this study. In contrast to the majority of the related papers, we only use specific sections of the annual reports, namely CEO letters and outlook sections (see Section 3).

Regarding the machine learning algorithms and the incorporation of quantitative indicators, the approaches of Groth and Muntermann (2011), Kogan et al. (2009), and Hajek and Olej (2013) are a good basis for the experiments of this study. All of them define the document labels based on suitable quantitative indicators. For labeling, the related studies consider the fact that text data are forward-looking, but quantitative indicators reflect the past. Hence, the indicators are taken from one period after publication of the text data. The labeled data are then used for training machine learning algorithms. Since the focus of our work lies on banks, we make use of a specific quantitative risk indicator which is not employed by related studies. In the following section, we introduce this indicator and the selected text data sources.

[1] Earning calls are regular events where managers report about the company's current situation and answer questions from business analysts.

3 Data Sources

Among this work's aims is to test for relations between textual risk sentiment and quantitative risk indicators. A careful selection of sources for both types of data is crucial since irrelevant ones would lead to biased conclusions.

Quantitative Risk Indicator. The selected quantitative risk indicator has to represent financial health and the general risk exposure of a bank within a specific period or at a specific point in time. Furthermore, the data have to be (1) publicly accessible, (2) available for each analyzed bank, (3) published at least annually, and (4) comparable among the different banks.

A comparison of several quantitative risk indicators based on expert interviews revealed that only the *Tier 1 Capital Ratio* (T1) fulfills all criteria. The T1 is one of the most important ratios based on risk-weighted amount of the bank's assets. In particular, it refers to the bank's Tier 1 capital as a percentage of its risk-weighted assets:

$$\text{Tier 1 Capital Ratio} = \frac{\text{Tier 1 Capital}}{\text{Risk-Weighted Assets}} \quad (1)$$

Tier 1 capital is considered as the best form of bank capital and has to fulfill several criteria making it relatively secure. As Cannata et al. (2012, p. 12) put it, this ratio "measures the ability of the bank to absorb losses". If the T1 is high, the bank acts conservatively and with a high risk buffer. A high ratio can be achieved by either increasing the Tier 1 capital or by reducing the amount of risk-weighted assets, i.e. reducing the amount of total assets or replacing them with safer ones.

The T1 also played a major role during the 2014 EU-wide banking stress test, which was an important part of the preparation phase for the Single Supervisory Mechanism. The stress test had the purpose to assess the resilience of large EU banks in different macroeconomic scenarios, measured by the impact on the T1.

Text Data Sources. In order to minimize noise and to enhance the sentiment analysis validity, it is crucial to work with the documents well adapted to the task of risk sentiment analysis. Like the quantitative risk indicators, they need to be (1) publicly accessible, (2) available for every analyzed bank, and (3) published at least annually. In addition, for this study, the documents need to be (4) written in the English language, (5) directly published by the bank, and (6) contain forward-looking and subjective information about the bank's attitude and expectations towards risk.

These criteria are best fulfilled by two types of document published in the banks' annual reports, namely *CEO letters* and *outlook sections*. The former are carefully crafted documents which contain valuable information about the management's opinions about risk. Amernic et al. (2010) recognize in their study from 2010 that the word choice of managers strongly influences companies, and CEO letters are a way for communicating their attitudes and values.

Outlook sections are usually a part of the *management report*, which is a textual summary of the bank's results, its business environment, and regulatory as well as internal developments. In their outlook on the next year, banks write about the expected macroeconomic environment, management guidelines, and priorities for the next period. These documents might be less subjective compared to CEO letters, but they are usually more comprehensive and contain interesting forward-looking information.

Collection of Data. The annual reports for this work were collected via a *Bloomberg Terminal*, supplemented by direct downloads from bank websites. In total, over 500 documents from 27 banks which published them between 2001 and 2013 were collected. The sample contains banks from all 12 countries which have belonged to the Eurozone at least since 2002. This promotes comparability of the data because the banks operated in similar economic circumstances and with the same currency.

Further data were retrieved from the online database *Bankscope*: the bank's country of residence, its full name, its size measured by total assets, and its Tier 1 capital ratio at the end of each year between 2001 and 2013. 31 % of the Tier 1 capital ratios could not be directly retrieved from the database, so they had to be manually extracted from the respective annual reports.

4 Methodologies

Two independent approaches are employed for the risk sentiment analysis. First, a lexicon-based approach derives and analyzes negativity, positivity, and uncertainty in publications by banks. The second approach aims to predict the evolution of

quantitative risk indicators by means of supervised classification. The aim of both approaches is to assess the potential of risk sentiment analysis in banking supervision.

Creation of the Document Collection. The original documents are provided as PDF files. For building up the collection, they have to be parsed in order to acquire plain text files containing the required sections. One method for extracting the relevant sections is to split the original PDF files according to their bookmarks and to convert them into plain text files afterwards. Another way is to convert the PDF files already in the first step and to extract the relevant sections by making use of specific *tokens*. For example, a typical CEO letter is delimited by the tokens *Dear Shareholders* and *Sincerely*. If neither of these semi-automated approaches is applicable, the extraction has to be done manually[2].

Table 4 gives an overview of the number of documents in the created collection. It shows that the number of published outlook sections constantly increased between 2002 and 2008. From 2009 on, the number was quite stable. The number of CEO letters also increased over time, but only until 2008, when some CEOs stopped writing letters in the course of the financial crisis.

Year	# of CEO letters	# of outlooks
2002	15	14
2003	19	19
2004	17	20
2005	19	20
2006	19	21
2007	23	22
2008	25	23
2009	21	23
2010	20	23
2011	21	23
2012	20	23
2013	22	24
2014	22	23
Total	**263**	**278**

Table 1: An overview of the document collection.

4.1 Lexicon-based Approach

The first experiment is about analyzing sentiment scores derived from the documents by incorporating finance-specific word lists. The objective of this experiment is to show how the language of forward-looking disclosures by European banks evolved within the last decade. The workflow consists of the following steps: (1) pre-processing the collected data, (2) the actual sentiment analysis which derives the scores, (3) data consolidation, and (4) data evaluation.

Sentiment Tagging. In the first step of the analysis, sentiment words in the textual data are tagged. In particular, this study works with negative words (*Fin-Neg*), positive words (*Fin-Pos*), and words related to uncertainty (*Fin-Unc*). All of these word lists are provided by Loughran and McDonald (2011). Such topic-specific word lists are necessary because many words bear a different sentiment if used in a financial context: according to Loughran and McDonald (2011), almost three quarters (73.8 %) of typically negative words cannot be considered as negative when they appear in financial texts. Kearney and Liu (2014) give the examples *tax* and *liability*. These words appear in the *Harvard IV Negative Word List* (H4N), but are neutral when used in a financial context, e.g. in an annual report. Table 2 lists some examples for sentiment words in the financial context.

Positive	efficient, stabilized, vibrant
Negative	closure, postpone, threat
Uncertainty	approximately, might, volatility

Table 2: Examples for opinion words in the financial context (Loughran and McDonald, 2011).

Term Weighting. All terms in a document are normalized by

$$N_j = \frac{1}{\sqrt{\sum_{i=0}^{m}(G_i L_{i,j})^2}}. \qquad (2)$$

This equation is based on Salton and Buckley (1988) and accounts for documents of different lengths. G_i is the *global weight* of term i and $L_{i,j}$ the *local weight* of term i in document j. An established method for the latter is given by the following formula (Manning and Schütze, 1999, p. 543):

$$L_{i,j} = \begin{cases} 1 + \log(tf_{i,j}) & \text{if } tf_{i,j} \geq 1 \\ 0 & \text{otherwise} \end{cases} \qquad (3)$$

[2]This was the case for around 20 % of the documents.

The term frequency is denoted as $tf_{i,j}$. The most popular global weight is the *inverse document frequency* (IDF). In

$$G_i = \log\left(\frac{N}{df_i}\right), \tag{4}$$

the total number of documents is denoted by N, and df_i is the number of documents where term i occurs at least once (Salton and Buckley, 1988).

Valence Shifting. In order to account for negated sentiment words, the simple negation handling algorithm proposed by Polanyi and Zaenen (2006) is implemented. If one of the three direct predecessors of a sentiment word is a negation word[3], its sentiment score will be negated. This is done by assigning -1 to the valence shifter variable v_i of term i. If there is no negation word among the predecessors, v_i is set to 1.

Calculating Sentiment Scores. The document-level sentiment scores are calculated for three sentiment classes, namely uncertainty, positivity, and negativity. In

$$s_{c,j} = \sum_{i \in c} L_{i,j} G_i N_j v_i, \tag{5}$$

the term-level sentiment score is represented by the product of the term weights $L_{i,j}$ and G_i, the normalization factor N_j, and the valence shifter v_i. The document sentiment score $s_{c,j}$ is the sum of the term sentiment scores which belong to the document j and the sentiment class c.

Data Consolidation and Evaluation. After calculating the sentiment scores, the data are filtered and grouped in order to prepare them for the evaluations. In particular, the data are filtered according to specific countries and grouped by year respectively by bank.

4.2 Supervised Classification

For the second experiment, the documents are labeled based on a quantitative risk measure, namely the T1 dating to the end of the period referred to in the CEO letters and outlook sections. These data are then used for training supervised classification algorithms which aim to predict the indicator's evolution.

[3]The considered negation words are *no*, *not*, *don't*, *never*, *none*, and *neither*.

The experiment consists of three steps: (1) reading and parsing the collected data as well as assigning the class labels, (2) linguistic preprocessing and feature selection, and (3) classifying the data with *Naïve Bayes* (NB) and *Support Vector Machine* (SVM).

Assigning the Class Labels. The Tier 1 capital ratio is published by banks at least once a year. Since it is actually a continuous measure, it always strongly depends on the previous year's ratio. Banking supervisors like the ECB are interested in the future evolution of the ratio: if it increases, the bank acts in a less risky way, and vice versa. Hence, appropriate labels for the supervised classification task are *UP* for an increasing T1, and *DOWN* for a decreasing one. We assume that the T1 did not change notably if the difference to the previous year is less than 0.2 percent points[4]. In this case, no class label is assigned.

Preprocessing and Feature Selection. Linguistic preprocessing comprises the removal of punctuation, numbers, single characters, and stop words. The remaining words are converted to lower case. Furthermore, the terms are weighted according to the term weighting strategy presented in Section 4.1.

For feature selection, two approaches are followed. The first one assumes that the sentiment words used in the lexicon-based analysis are the relevant features for this experiment. Hence, all words which do not appear in the first experiment's dictionaries are removed. The second approach utilizes a *Snowball Stemmer* to ensure that different versions of the same word are treated as equal. Its feature selection strategy is based on the concepts of *document frequency* (DF) and *information gain* (IG). For DF, tests showed that a lower bound of 20 documents yields the best results. The objective of the IG measure is to identify those features which have the highest discriminatory power in a classification problem. It measures the impurity of a dataset, i.e. its *entropy*. If a feature is able to reduce the entropy in a data set by a large amount, its *information gain* is high. Such features have a relatively high ability to predict the corresponding class. For calculating the information gain, one has to compute the entropies given the presence or absence of a feature in a data set and subtract the results from the entropy

[4]This affected 17 % of the data points in the sample.

of the original data set (Aggarwal and Zhai, 2012, p. 169).

Classification. The outcome of the previous steps is a set of document vectors with associated class labels. With these data, the classification algorithms *Naïve Bayes* (NB) and *Support Vector Machine* (SVM) are trained. The latter is used in its basic version, i.e. with a linear kernel. The performance measures are determined by employing *10-fold cross validation*, which helps to avoid problems like overfitting.

While Naïve Bayes works without parameters, the linear SVM depends on the parameter C. Its optimal value of 111 was determined by conducting an automated *grid search*.

5 Evaluation of the Experiments

Both experiments aim to capture attitudes and opinions about risk by analyzing CEO letters and outlook sections of Eurozone banks. In this section, conclusions are drawn from the results of the experiments.

5.1 Evaluation of the Lexicon-based Approach

The outcome of the lexicon-based approach consists of sentiment scores for each document representing the degrees of uncertainty, negativity, and positivity.

Evolution of Sentiment Over Time. Figure 1 shows how sentiment in CEO letters has been evolving since 2002. The evolution of sentiment in outlook sections is not depicted, but is very similar to that of CEO letters. The individual data points represent the arithmetic mean of the document-level sentiment scores for each year. In 2002 and 2003, CEO letters contained more negative sentiment than in the following years. Banks might have emphasized that the recession following the burst of the *dot-com bubble* was still not over and that recovery had not yet arrived. Between 2003 and 2006, the letters became more positive and less negative from year to year. The turning point was in 2006—from that time on, negativity in CEO letters rose and quadrupled within three years. During the same period, positive sentiment scores decreased continuously. The summit of these evolutions was in 2009, in the midst of the financial crisis. The letters in 2010 had been already much more optimistic, but negativity increased in 2011 and 2012 again when CEOs recognized that the crisis was still not over.

The evolution of the uncertainty scores is similar to the negative sentiment scores. This observation is supported by a high correlation coefficient of 0.93 between uncertainty and negativity scores. Since 2012, uncertainty has been decreasing quite sharply. This can potentially be attributed to an important and often-cited speech by ECB president Mario Draghi, who calmed the financial markets with the announcement to do "whatever it takes to preserve the Euro. And believe me, it will be enough"[5].

Another observation is that the average uncertainty scores are much lower than the average positivity and negativity scores. A plausible interpretation thereof is that CEOs rather use clear statements than uncertain language.

Do Sentiment Scores Predict Quantitative Risk Measures? A comparison of the T1 average evolution and the corresponding sentiment scores reveals interesting relations, see Figure 2. The correlation coefficients in Table 3 indicate that a higher degree of uncertainty or negativity in the documents is commonly followed by a higher increase of the T1, and vice versa.

It is interesting to analyze the data by a regression model for predicting the T1 evolution. Table 4 shows such a model with *negativity* as the only explaining variable. The coefficients can be interpreted as follows: if the average negativity score rises by one unit, the T1 evolution increases by 0.9963 pp. If negativity is zero, the Tier 1 capital ratio would decrease by the computed intercept, which is -0.502 pp. Both coefficients are statistically significant if a 95 % confidence level is assumed.

About 76 % of the average T1 evolution's *variation* can be explained by the negativity score. A model of similar quality could be constructed by analyzing uncertainty in outlook sections. Hence, sentiment scores can be considered as an additional leading indicator for the future evolution of the Tier 1 capital ratio.

Limitations. A drawback of this regression model is that it cannot model *external shocks* which influence the T1 evolution, but are not ad-

[5] A transcript of this speech is available at `https://www.ecb.europa.eu/press/key/date/2012/html/sp120726.en.html`, accessed April 20th, 2015.

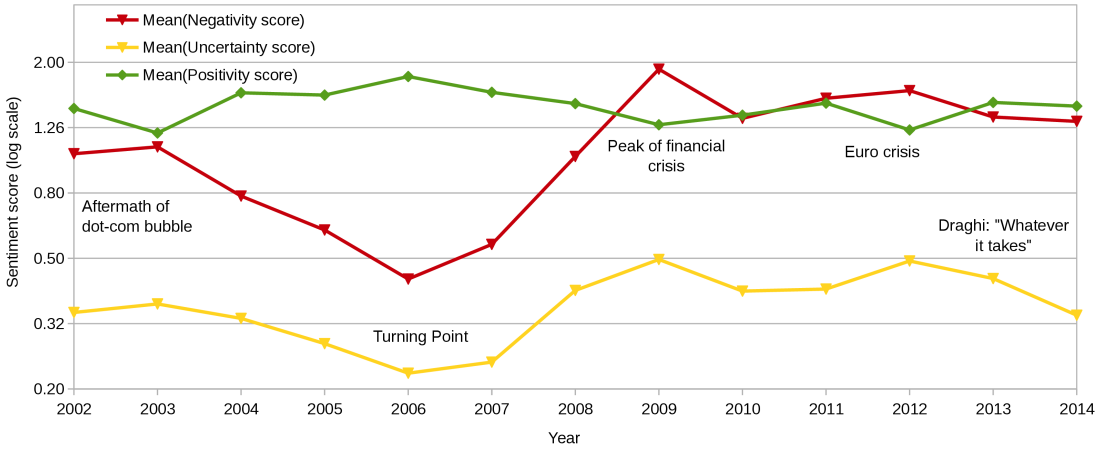

Figure 1: Evolution of positivity, negativity, and uncertainty in CEO letters over time.

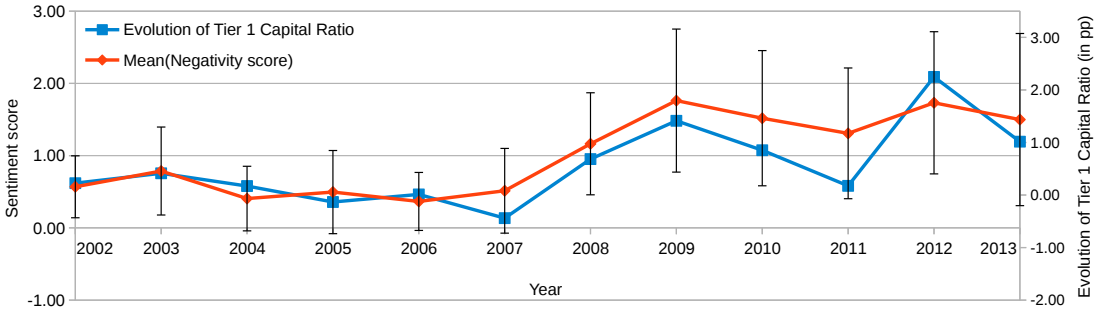

Figure 2: Evolution of the Tier 1 capital ratio compared to negativity in outlook sections. The error bars represent the standard deviation of the negativity scores.

Correlation coefficient	Uncertainty	Negativity	Positivity
T1 evolution (CEO letters)	0.86	0.79	-0.69
T1 evolution (Outlooks)	0.85	0.89	0.12

Table 3: Correlation coefficients between T1 evolution and sentiment scores.

Variable	Coeff.	Std. Err.	t-value	P>t
Mean(Negativity score)	0.9963	0.1647	6.0478	0.0001
Intercept	-0.5020	0.1883	-2.6651	0.0237

Table 4: Regression model based on negativity in outlook sections.

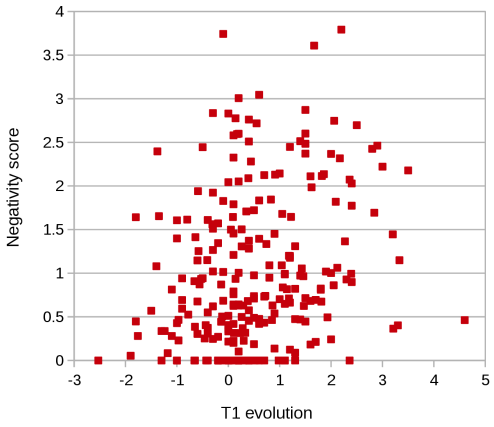

Figure 3: Individual negativity scores in outlook sections compared to the T1 evolution.

equately covered in the text data. Examples for such shocks would be new regulations concerning the minimum capital ratio or monetary policy actions by the ECB. A further limitation is induced by the fact that our methodology makes use of the *bag of words* (BoW) model, which ignores the documents internal structure. Hence, it is not possible to utilize information like word order and grammar, although this definitely plays a role in carefully crafted documents like CEO letters.

It should also be emphasized that the model is based on figures aggregated by year. Applying it on the data of *individual* banks could lead to incorrect conclusions. This assumption is supported by Figure 3, which compares negativity scores of individual outlook sections with the associated T1 evolutions. Although it is still possible to identify a positive relationship between the variables, the variance is too big for satisfactory representation by a regression model[6]. This observation is in line with the relatively high standard deviations if the figures are aggregated by year, see Figure 2.

5.2 Evaluation of the Supervised Classification Approach

The supervised classification experiment aims to assess whether this approach works better than the lexicon-based approach in terms of predicting the T1 evolution for *individual* banks based on their CEO letters or outlook sections. The class labels *UP* and *DOWN* have been assigned according to the direction of the T1 evolution. Table 5 gives an overview of the experiments and lists the respective performance measures. An analysis of the data in the table reveals interesting results. First, feature selection based on document frequency and information gain works better than the approach based on word lists. Second, the classifiers trained with CEO letters yield better results than the ones trained with outlook sections. Finally, three out of the four SVM results are not meaningful due to the following reason: the parameter optimization of C suggests to choose a very low value, which indeed maximizes the classifier accuracy—but these SVMs simply assign the class *UP* to every instance. These classifiers can be seen as a baseline for comparisons. However, the remaining SVM clearly yields the best results among the employed algorithms.

None of the classifiers based on the feature selection method (1) is able to outperform the baseline (assigning every instance to the UP class). Both SVMs simply classify every instance as *UP*, and the Naïve Bayes classifiers also deliver unsatisfactory results. Feature selection based on document frequency and information gain achieves better results than the first one, but only when the classifiers are trained with the CEO letter collection. Most likely, this can be explained with the fact that outlook sections provide less terms with discriminatory power than CEO letters. Naïve Bayes correctly classifies 75 % of the instances, and the optimized SVM yields 79.2 %. The other SVM performance measures can be interpreted as follows: 81 % of the instances classified as *UP* were indeed instances where the Tier 1 capital ratio increased (= precision U). Furthermore, the SVM correctly identified almost 92 % of the instances which belong to the class *UP* (= recall U).

These results are better than the baseline and demonstrate a noticeable potential for supervised classification even at the level of individual bank disclosures. Nevertheless, they are not good enough for reliable predictions. However, the aggregated classification data accurately predict whether the majority of banks will increase or decrease their Tier 1 capital ratio in the following year: for 12 out of 13 years, the algorithm correctly predicts the direction of the T1 evolution. This finding is in line with the lexicon-based approach, where the aggregated data yielded much better results than the individual ones.

[6] If the regression model is built with non-aggregated data, it explains only 6.6 % of the variation.

Feature selection	Document type	Classifier	Accuracy	Precision U	Recall U	Precision D	Recall D
(1) based on topic-specific sentiment words	CEO letters	NB	0.703	0.741	0.889	0.500	0.263
		SVM	0.703	0.703	**1.000**	n.a.	0.000
	Outlook sections	NB	0.563	0.685	0.703	0.246	0.230
		SVM	0.703	0.703	**1.000**	n.a.	0.000
(2) based on document frequency and information gain	CEO letters	NB	0.750	0.774	0.911	0.636	0.368
		SVM	**0.792**	**0.810**	0.919	**0.718**	**0.491**
	Outlook sections	NB	0.704	0.704	**1.000**	n.a.	0.000
		SVM	0.704	0.704	**1.000**	n.a.	0.000

Table 5: Overview of the results of the supervised classification experiment. Bold numbers indicate the best results, U class *UP*, and D class *DOWN*.

6 Conclusion

This study explored how banking supervisors could utilize *sentiment analysis* for risk assessments. The analysis of potential document types revealed that two sections in a bank's annual report are particularly well suited for this work, namely *CEO letters* and *outlook sections*. The former represent the *tone from the top* and provide subjective information about the bank's current and future situation. Outlook sections are exclusively forward-looking and reveal opinions about the near future. Furthermore, the *Tier 1 capital ratio* (T1) is the best suited quantitative risk indicator. The T1 sets the most secure forms of bank capital in relation to its risk-weighted assets and is widely used in banking supervision, e.g. as a key ratio for the ECB's stress test in fall 2014.

The lexicon-based analysis showed that sentiment scores reflect major economic events between 2002 and 2014 very well. In addition, there is a strong correlation between uncertainty, negativity, and the Tier 1 capital ratio evolution over time. Hence, the sentiment scores could be used in regression models for predicting the T1 evolution. However, the results are only meaningful if the figures are aggregated by year. Applying the model on data of individual banks leads to inaccurate results. It should also be noted that this method is not meant to be used as a stand-alone estimator for the T1 evolution. Instead, it should be combined with other estimation methods.

The supervised risk classification approach correctly classifies 79.2 % of the CEO letters. This is not good if one considers that it is possible to yield an accuracy of 70 % simply by assigning the class *UP* to every instance. However, if the results of the best SVM classifier are aggregated by year, the data correctly predict for 12 out of 13 years whether the majority of banks will increase or decrease their Tier 1 capital ratio.

The described systems have the potential to provide valuable insights for banking supervisors, in particular because of the strong correlation between sentiment scores derived from textual data and the T1. Because of the mentioned limitations, these techniques should only be used for macroprudential analyses, i.e. the promotion of stability in the whole financial system. Examples are predictions for the average Tier 1 capital ratio's evolution in the whole Eurozone or in groups of countries. Another option is to improve existing risk prediction frameworks.

For future research, it would be interesting to validate the results by conducting the study on a larger scale. One could incorporate data from all European banks, or from other regions. The approach could also be used for other document types, for example analyst reports or internal memos, or in other industries. Regarding the methodology, it would be interesting to see how alternative algorithms or word lists would affect the results.

Sentiment Flow – A General Model of Web Review Argumentation

Henning Wachsmuth and **Johannes Kiesel** and **Benno Stein**
Faculty of Media, Bauhaus-Universität Weimar, Germany
{henning.wachsmuth,johannes.kiesel,benno.stein}@uni-weimar.de

Abstract

Web reviews have been intensively studied in argumentation-related tasks such as sentiment analysis. However, due to their focus on content-based features, many sentiment analysis approaches are effective only for reviews from those domains they have been specifically modeled for. This paper puts its focus on domain independence and asks whether a general model can be found for how people argue in web reviews. Our hypothesis is that people express their global sentiment on a topic with similar sequences of local sentiment independent of the domain. We model such *sentiment flow* robustly under uncertainty through abstraction. To test our hypothesis, we predict global sentiment based on sentiment flow. In systematic experiments, we improve over the domain independence of strong baselines. Our findings suggest that sentiment flow qualifies as a general model of web review argumentation.

1 Introduction

The web is full of user-generated reviews on products, services, and works of art, like those from Amazon, TripAdvisor, and Rotten Tomatoes. Such web reviews provide facts, positive opinions, and negative opinions on different aspects. By that, the reviews express, implicitly or explicitly, an overall opinion on the topic in question. From an abstract viewpoint, the argumentation of a web review can thus be seen as a composition of local sentiments used to justify some global sentiment.

Both local and global sentiment of reviews are in the focus of numerous sentiment analysis approaches (cf. Section 2 for details). Many of these approaches model reviews primarily with content-based features, derived from the words in the reviews. The use of words, however, varies strongly across domains, as illustrated in Figure 1 for a product, a hotel, and a movie review. As a consequence, sentiment analysis suffers from domain dependence (Wu et al., 2010), i.e., high effectiveness is often achieved only in the domain an approach has been specifically modeled for. To adapt to other domains, prior knowledge about these domains or about domain-independent features is needed (Prettenhofer and Stein, 2010).

This paper considers the question as to whether the overall argumentation of web reviews can be modeled in a general way in order to increase domain independence in sentiment analysis. We observe that people structure web reviews largely sequentially—in contrast to the complex structures of many other argumentative texts. While the reviewed aspects differ between domains, our assumption is that the overall argumentation of a web review is generally represented by a sequence of local sentiments, called the review's *sentiment flow* (Mao and Lebanon, 2007). In particular, we hypothesize that, under an adequate model, similar sentiment flows express similar global sentiments, also across domains. All reviews in Figure 1, for instance, express neutral global sentiment starting with positive, continuing with negative, and ending with positive local sentiment.

Unlike in our previous approach (Wachsmuth et al., 2014a), we analyze the major abstraction steps when modeling sentiment flow to represent global sentiment. A general model should abstract from both content and other domain differences, such as a review's length or the density of local sentiment in it. Based on web review corpora with known sentiment flows, we empirically analyze several model variants across three domains. Our results offer clear evidence for the truth of our hypothesis, indicating the generality of sentiment flow as a model of web review argumentation.

The abstract nature of sentiment flow, however, does not directly achieve domain independence, as

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 601–611,
Lisbon, Portugal, 17-21 September 2015.

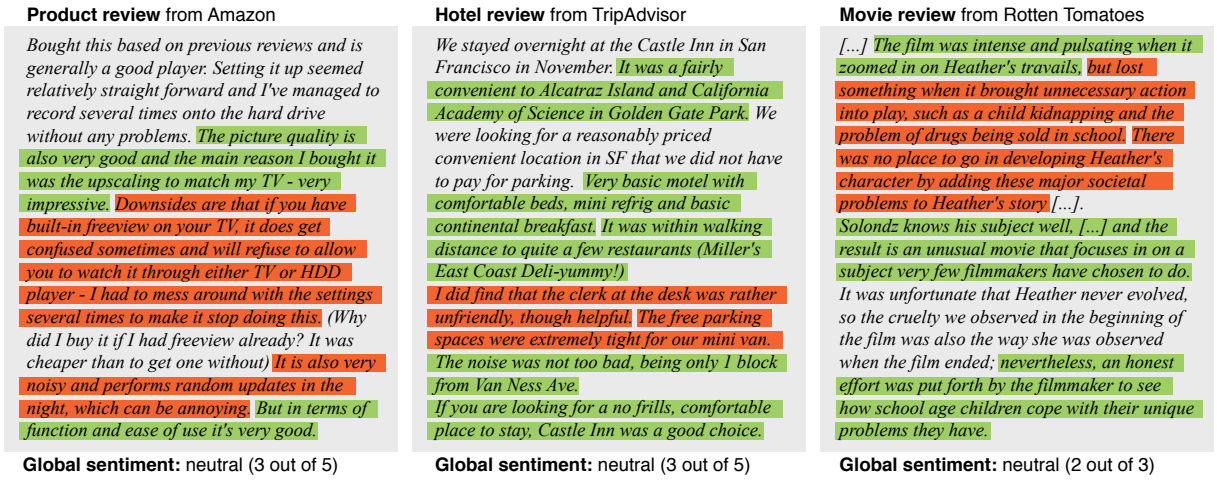

Figure 1. Example web reviews with neutral global sentiment from three domains, taken from the corpora described in Section 5. Corpus annotations of positive and negative local sentiment are marked in light green and medium red, respectively.

the recognition of local sentiment in unknown reviews may still be domain-dependent. We therefore also present a novel edit distance approach to robustly compare flows, when local sentiment is obtained using state-of-the-art techniques (Socher et al., 2013). In systematic cross-domain experiments with the given corpora, we classify global sentiment based on sentiment flow without any domain adaptation. While not being perfectly effective, our approach improves over the domain robustness of strong baselines.

Altogether, the paper's main contributions are:

1. Evidence that sentiment flow qualifies as a general model of the overall argumentation of web reviews across domains.
2. A domain-robust approach for the classification of the global sentiment of web reviews.

2 Related Work

As surveyed by Pang and Lee (2008) and by Liu (2012), numerous sentiment analysis approaches have been proposed for different text types, levels of granularity, sentiment scales, and domains. We target at global text-level sentiment of web reviews. While we distinguish three sentiment classes here, our approach can be adapted to other scales. Our goal is not to optimize sentiment analysis in a specific domain, but to find a model that supports sentiment analysis across domains.

As common in text classification (Manning et al., 2008), sentiment analysis often relies on words and other content features, which tends to be prone to domain dependence (Wu et al., 2010). Existing domain adaptation techniques for sentiment analysis require a few training texts from each target domain or a few domain-independent pivot features to align domain-specific features (Prettenhofer and Stein, 2010). Our model complements these techniques and could be leveraged for pivot features. In tasks like authorship attribution and argumentative zoning, non-topical words benefit domain independence (Menon and Choi, 2011; Ó Séaghdha and Teufel, 2014). Instead, we focus on the local sentiment on different aspects in a review here.

Aspect-based sentiment analysis extracts fine-grained opinions from a review (Popescu and Etzioni, 2005). These aspects in turn impact the review's global sentiment (Wang et al., 2010). However, relevant aspects naturally tend to be domain-specific, like the picture quality of HDD players or the beds of hotels (cf. Figure 1). While weakly-supervised approaches to extract aspects and local sentiment exist (Brody and Elhadad, 2010; Lazaridou et al., 2013), it is not clear how to align aspects from different domains. We ignore aspects here, only preserving the local sentiment itself.

State-of-the-art approaches for classifying local sentiment within a domain model the composition of words, e.g., relying on deep learning (Socher et al., 2013). We do not compete with such an approach, but we use it to then predict global sentiment. Täckström and McDonald (2011) observe that local and global sentiment correlate, aiming for the opposite direction, though. In (Wachsmuth et al., 2014b), we already compute frequent flows of local sentiment, but we neither analyze their generality, nor do we use them for prediction.

The idea of modeling sentiment flow was introduced by Mao and Lebanon (2007) who classify local sentiment based on neighboring local sentiment in a review. When inferring global sentiment from a flow, however, the authors model only

single flow positions, not their ordering. In contrast, we capture the overall structure of reviews in (Wachsmuth et al., 2014a) by measuring the similarity of a given flow to known sentiment flow patterns. We point out the domain robustness of sentiment flow there, but we still use domain-specific local sentiment classifiers and we do not handle some major domain differences of web reviews. Both limitations are addressed in this paper, where we align flows similar to how Persing et al. (2010) align essay organizations.

We claim that sentiment flow models a review's argumentation, such that local sentiments ressemble rhetorical moves. Comparable simplifications are common for scientific argumentation (Teufel, 2014). Usually, argumentative texts are studied more deeply, considering different types of argument components and their relations (Mochales and Moens, 2011). Mining such structure is getting increasing attention recently (Habernal et al., 2014), also in the analysis of reviews (Villalba and Saint-Dizier, 2012). To express global sentiment, however, web reviews argue in simpler ways.

3 Web Review Argumentation

Argumentation refers to the exchange of opinions, to defending positions, and to convincing others of certain stances (van Eemeren et al., 2014). A review is a written form of monological argumentation, where an author structures a selection of arguments in order to justify his or her conclusion on a topic of discussion (Besnard and Hunter, 2008). Reviews, in particular, discuss products, services, works of art, or similar. The arguments in a review correspond to objective facts, positive and negative opinions, and mixtures of these on the topic as a whole or on specific aspects of the topic.

In this paper, we are interested in the *overall argumentation* of reviews. Our assumption is that the conclusion of a review's overall argumentation consists in its global sentiment. Global sentiment is often explicitly reflected by an assigned overall rating, at least for *web reviews*.

Many web reviews are written by people in an ad-hoc fashion to quickly share opinions. As a result, unlike other argumentative texts, web reviews often remain with a sequential structure (Villalba and Saint-Dizier, 2012) and miss explicit relations between the shared opinions. E.g., while the product review and the hotel review in Figure 1 cover opinions on several aspects, no deliberate structure is found in their argumentation. However, the excerpt of the more professional movie review shows that this is not always the case.

3.1 Domain Differences

In Figure 1, we categorize domains by source and topical theme (e.g., Amazon products). Other granularities would be possible (e.g., consumer electronics) or other categorization schemes (e.g., user vs. pro reviews). That being said, we speak of *domains* only to roughly distinguish web reviews that vary in how they argue for a conclusion.[1] We observe major differences in three broad respects:

Content Especially topical web review domains differ widely regarding the terms and phrases that play a role in their argumentation. This includes the aspects being discussed (e.g., "beds" of hotels vs. the "subject" of movies) as well as the words used to express sentiment and their explicitness (e.g., "yummy" vs. "an unusual movie").

Form As sketched above, further differences refer to the structure and style of web reviews. Some are rather subtle, like a careful use of paragraph breaks, whereas others are obvious, like a review's length. The movie review in Figure 1, for instance, is actually over twice as long as the shown excerpt, starting with an objective synopsis of the plot and including "sub-reviews" of different aspects.[2]

Subjectivity Finally, the use of subjectivity varies across web review domains: First, the density of sentiment tends to be high in some cases, like hotel reviews (cf. Figure 1), but low in others, like movie reviews, where objective plot descriptions and subjective opinions often alternate (the shortened excerpt in Figure 1 hides this to some extent). Second, sentiment is sometimes very intense (as in the product review in Figure 1), sometimes subtle. And third, in some domains even single sentences often contain mixed sentiment, whereas in others opinions tend to be laid out across sentences.

We will empirically underpin most observations in Section 5, where we analyze the domain independence of the model described next.

4 Sentiment Flow as a General Model

In the following, we introduce our model of web review argumentation. We discuss how to abstract for generality and how to deal with uncertainty.

[1] In the end, this paper seeks for findings that generalize from domains, making an exact distinction unnecessary.

[2] Also, many web reviews have explicit structure elements like a title. To obtain a common ground, however, we consider only the plain text of a web review's body in this paper.

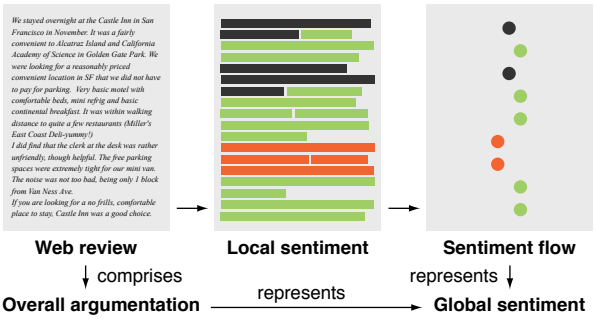

Figure 2. Modeling the overall argumentation of a web review as a flow of positive (light green), neutral (dark gray), and negative (medium red) local sentiments.

Figure 3. The original sentiment flow from Figure 2 and the resulting flow for each of the three proposed transformations.

4.1 Modeling a Review by its Sentiment Flow

We propose a fairly simple argumentation model based on the observation that many web reviews are organized sequentially (cf. Section 3). As we assume that the overall argumentation of a web review represents global sentiment in the first place, we fully abstract from the content of the facts and opinions that serve as arguments. In particular, we model the argumentation of a web review solely by its *sentiment flow*, i.e., the sequence of local sentiments comprised in the review's text. We do not presume the granularity of local sentiment, but we propose to distinguish positive, neutral, and negative local sentiment, which is the common ground of related works (cf. Section 2).

Figure 2 illustrates how we model web review argumentation. Our hypothesis is that similar sentiment flows are used across domains of web reviews to express the same global sentiment. However, because of the domain differences described in Section 3, we do not expect that the *original* sentiment flows of web reviews generalize well.

4.2 Abstracting Flows for Generality

By concept, sentiment flow avoids to capture content and some facets of form like paragraph usage. To abstract from the length of reviews, Mao and Lebanon (2007) and our approach in (Wachsmuth et al., 2014a) length-normalize sentiment flow via interpolation. While this may preserve all information, it does not account for sub-reviews and the density of subjectivity. Here, we investigate more informed ways of abstracting flows. In particular, we consider three transformations of flows:

Change Deletion of repeating local sentiments. The rationale is to reduce subjectivity differences by focusing on changes of local sentiment.

NoLoops Deletion of repeating sequences of two or more local sentiments. The rationale is to reduce length differences by merging similar sub-reviews.

2Class Deletion of neutral local sentiments. The rationale is to reduce length and subjectivity differences emanating from objective descriptions.

Figure 3 exemplifies the three transformations. They are not commutative, as can partly be seen for the example. In Section 5, we test what combinations of transformations lead to an adequate sentiment flow model. While more transformations will benefit generality, the lost specificity may decrease the correlation with global sentiment.

4.3 Analyzing Flows under Uncertainty

Given an adequate sentiment flow model, we seek to find out to what extent it enables domain-robust sentiment analysis. This brings up two challenges related to uncertainty: (1) The classification of local sentiment in unknown reviews will not be free of errors, and, (2) reviews may comprise flows for which the global sentiment is unknown.

Classification errors are naturally problematic for modeling sentiment flow. At least, some errors are bypassed by the three transformations. E.g., if one negative local sentiment in the original flow in Figure 3 is misclassified as positive, the *Change* transformation fixes this. If it is classified as neutral, *Change* and *2Class* together eliminate the effect. Moreover, errors can be countered by limiting the impact of single positions in a flow.

In (Wachsmuth et al., 2014a), we learn to infer global sentiment from the Manhattan distances between a sentiment flow and a set of common flows, thereby analyzing the flow as a whole. The common flows are found in a preceding clustering step. While we adopt the learning approach here, the Manhattan distances imply that flows are similar only if their changes are at similar positions.

Instead, we compare sentiment flows (modified with zero to three transformations) based on their normalized minimum *edit distance* (Cormen et al., 2009). Analog to Persing et al. (2010), we incrementally compute the edit distance using sequence alignment. To this end, we specify costs for pos-

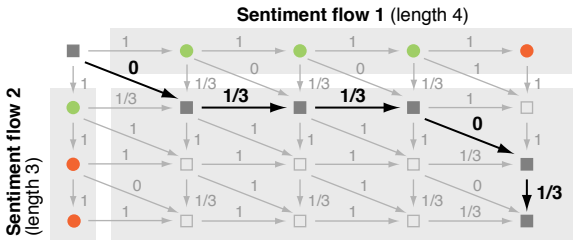

Figure 4. Computation of the normalized edit distance of two sentiment flows, resulting in $(2 \cdot 0 + 3 \cdot 1/3) \,/\, 4 = 1/4$.

sible edit operations, i.e., substitutions, insertions, and deletions of single local sentiments. We map positive local sentiment to the value 1.0, neutral to 0.5, and negative to 0.0. The cost is then provided by a function d for any two values s and s':

$$d(s, s') = \begin{cases} |s - s'| & \text{If } s' \text{ substitutes } s. \\ \alpha + (1-\alpha) \cdot |s - s'| & \text{If } s' \text{ is inserted or deleted after } s. \end{cases}$$

Here, $\alpha \in [0, 1]$ specifies some fixed cost (we set α to $1/3$ in Section 6). The intuition behind d is to have a higher cost the more s and s' differ. Still, insertions and deletions are never free, as they affect differences that remain after applying transformations to abstract from irrelevant differences.

Figure 4 illustrates the alignment of two flows as a shortest-path search. We normalize the flows' minimum edit distance by their maximum length. Before we evaluate if the edit distance captures flow similarity more robustly than the Manhattan distance, we analyze what representation of sentiment flows proves most general. This will also reveal that the proposed abstractions reduce the need to perform clustering for finding common flows.

5 Analysis of the Generality of the Model

We now report on experiments on corpora from three domains that empirically analyze to what extent different sentiment flow variants qualify as general models of web review argumentation.[3]

5.1 Ground-Truth Data with Sentiment Flow

We process three existing corpora with local sentiment annotations of complete texts. While the first two are available online, we obtained the last from the authors. Each corpus comprises English web reviews from one broad topical domain. Table 1 lists some statistics of the three corpora, which indicate clear domain differences.

Product Domain The *Finegrained Sentiment Data Set, Release 1* (Täckström and McDonald, 2011) contains 294 Amazon reviews, nearly balanced among five categories: books (59 reviews), DVD (59), electronics (57), music (59), and videogames (60). We use the first three for training and the others for testing. Under the authors' mapping from Amazon star ratings to global sentiment, all categories subsume 19 to 20 positive, neutral, and negative reviews each. In each review, every sentence is classified as positive, negative, neutral, mixed, or irrelevant. To match the other corpora, we merge the three latter into one neutral class.

Corpus domain	Sentences per text	Tokens per sent.	Local sentiment positive	neutral	negative
Product	14.0	22.7	24.1%	41.5%	34.4%
Hotel	11.5	18.3	38.0%	20.3%	41.7%
Movie	28.8	30.3	17.6%	61.2%	21.2%

Table 1. Sentences, tokens, and annotated local sentiments for the domains represented by the given web review corpora.

Hotel Domain Our *ArguAna TripAdvisor corpus* (Wachsmuth et al., 2014b) consists of 2 100 TripAdvisor reviews, 300 for seven hotel locations each. Three locations belong to a predefined training set and two to a validation and a test set each. For all locations, the reviews are evenly distributed over the five TripAdvisor overall scores. In accordance with the product corpus, we see score 4–5 as positive global sentiment, 3 as neutral, and 1–2 as negative. In each review, all main clauses together with their subordinate clauses have been classified as being positive, negative, or neutral.

Movie Domain Finally, the third corpus (Mao and Lebanon, 2007) compiles 450 Rotten Tomatoes reviews from the *Cornell Movie Review Data scale dataset v1.0* (Pang and Lee, 2005) that refer to two authors. We use the 201 reviews of Scott Renshaw for training and the 249 of Dennis Schwartz for testing. The reviews lack punctuation, capitalization, and their overall ratings. We recovered the overall ratings from the original dataset based on the rating scale 0–2, resulting in 178 positive, 139 neutral, and 133 negative reviews. In each review, Mao and Lebanon (2007) classified all sentences to be very positive, positive, neutral, negative, or very negative, which we reduce to three classes.

5.2 Experimental Set-up

To find the most general model of web review argumentation across domains, we compare 16 sentiment flow variants using three measures:

Model Variants The original sentiment flow of all corpus reviews can be directly derived from the ground-truth data. In each model variant, the flow is modified by a combination of zero to three of the

[3] The source code that can be used to reproduce the experiments is provided at http://www.arguana.com/software.

Training domain	Model variant of sentiment flows	# Flows		Aggregate recall			Weighted precision			W'd Hellinger distance

Table 2. Results on the generality of sentiment flow for all evaluated model variants on ground-truth data for each combination of training and test domain. The most general variants in terms of both aggregated recall and weighted precision are marked in bold. For illustration, *# Flows* lists the numbers of *all* flows in the training reviews and of those with a recall of at least *1%*.

transformations from Section 4. All variants are named according to the applied transformations.

Measures In (Wachsmuth et al., 2014b), we propose specific notions of the recall and precision of a sentiment flow f in a given collection of reviews: The recall R_f denotes the relative frequency of reviews with flow f, while the precision $P_f(\mathrm{s})$ with respect to some global sentiment s denotes the relative co-occurrence of f with s. Here, we extend these measures for complete models as follows.

We define the *aggregate recall* of a model on a collection of reviews as the sum of the recall of the set F of all its known sentiment flows:

$$\textit{Aggregate Recall}(F) = \sum_{f \in F} R_f$$

With *weighted precision*, we denote the sum of the maximum precision of each such flow in F, weighted with the recall of the flow:

$$\textit{Weighted Precision}(F) = \sum_{f \in F} \max_{\mathrm{s}} \{P_f(\mathrm{s})\} \cdot R_f$$

In addition, we assess how much two domains differ under a given model variant. To this end, we measure the *Hellinger distance* H_f (in the range $[0, 1]$) between the global sentiment distributions of each flow f known for both domains:

Model variant	Domain	Most common flow	Rank	Recall	Positive	Neutral	Negative
change-2class-noloops	**Product**	(negative, negative)	**1.**	13.6	0.0 %	25.0 %	75.0 %
	Hotel		9.	4.2	0.0 %	8.9 %	91.1 %
	Movie		4.	6.7	0.0 %	0.0 %	100.0 %
	Product	(positive, negative, positive)	8.	3.4	34.1 %	65.9 %	0.0 %
	Hotel		**1.**	10.5	45.1 %	49.6 %	5.3 %
	Movie		14.	2.3	0.0 %	73.3 %	26.7 %
	Product	(negative, negative, positive, negative)	10.	3.4	0.0 %	33.3 %	66.7 %

Table 3. The most common flow in the training set of each evaluated domain for three of the 16 evaluated model variants. For each flow, the recall rank, the recall, and the distribution over the three global sentiments within each domain are given.

$$H_f(\mathbf{p}_1, \mathbf{p}_2) = \frac{1}{\sqrt{2}} \cdot \sqrt{\sum_{\mathrm{s}} (\sqrt{\mathbf{p}_1(\mathrm{s})} - \sqrt{\mathbf{p}_2(\mathrm{s})})^2}$$

Here, $\mathbf{p}_1$ and $\mathbf{p}_2$ denote the global sentiment distributions of f. For *weighted Hellinger distances*, we multiply the distance of each flow in F with the sum of its recall in both domains.[4]

Experiments Given all 16 possible model variants for all reviews, we analyze the generality of each variant for every combination of domains. I.e., we first determine the known sentiment flows on the training set of one domain. Then, we compute the aggregate recall, weighted precision, and weighted Hellinger distance once for the in-domain test set and once for both full out-of-domain corpora.[5]

5.3 Results on the Generality across Domains

Table 2 contains the number of known flows and the experiment results for each domain combination. Model variants whose benefit seems limited are not marked in bold: The bottom six have a low aggregate recall in all domains, suggesting that they do not generalize well. Most significantly, the *original* flows from the movie training set are not found in any test domain. The top five achieve almost total recall, but much less precision than the others, indicating that they abstract too much.

Among the five robust model variants (marked in bold), *change-2class-noloops* has the highest aggregate recall throughout, ranging from 73.0 to 92.9. Consistently, global sentiment is represented best by *change-noloops* in the product domain and by *2class-noloops* in the other domains (with up to 85.1 weighted precision). Also, *2class-noloops* is third-best in terms of recall. While no clear "winner" exists, this variant seems most promising for modeling web review argumentation.

The weighted Hellinger distances show that the domain differences of many variants are small. On average, *change-2class* has the most stable global sentiment distribution. Most distances are only slightly higher out-of-domain than in-domain or even lower. Hence, sentiment flows hardly vary stronger across domains than within a domain.

5.4 The Most Common Sentiment Flows

To investigate what sentiment flows actually occur in web reviews, we determined the flow with highest recall for the training set of each corpus. For comparability, we balanced the flows in the training set before by weighting their occurrences according to the distribution of global sentiment.[6]

[4] We chose the Hellinger distance, as it applies to distributions with zero-probabilities (unlike alternatives like the KL-divergence). Also, it is a true metric (Lebret and Collobert, 2014), allowing for relative comparisons. On the flipside, the meaning of concrete distances is not clear by itself.

[5] Here, we use *all* occurring sentiment flows to evaluate a model variant in its overall manifestation. In Section 6, we consider only frequent flows in order to refrain from outliers.

[6] E.g., if 40% of all reviews are positive, 30% neutral, and 30% negative, then the occurrences of flows with positive global sentiment are weighted by 0.75 and the others by 1.0.

Table 3 shows the recall and the sentiment distribution of each such flow in all evaluated domains exemplarily for three of the model variants discussed above. While high-recall flows naturally tend to be simple, we also observe more complex flows, such as *(negative, negative, positive, negative)* in case of *change-2class-noloops*. Except for the *change-noloops* flow *(positive)*, which does not occur at all in the movie training set, all shown flows are common across domains, achieving a recall of over 2% in most cases. For *2class-noloops*, only two flows are listed, because *(negative, negative)* is the most common flow in both the product and the movie domain. Regarding the distribution of global sentiments, nearly all flows behave similar across domains. The only exception is *(positive, negative, positive)* in *change-2class-noloops*, which never turns out negative in product reviews but never positive in movie reviews.

Altogether, we conclude that sentiment flow is not a fully precise model of web review argumentation, but it proves general with respect to global sentiment. What remains to be checked is the benefit of modeling sentiment flow under uncertainty.

6 Analysis of the Robustness of the Model

Finally, we evaluate how effectively and domain-robustly sentiment flow predicts global sentiment, when local sentiment is not given but classified. To analyze the domain independence of our model, no knowledge about target domains is used.

6.1 Sentiment Analysis Approaches

To classify sentiment flows, we build on the edit distance approach presented in Section 4:

Model Variants As in Section 5, we look at all 16 possible variants of the proposed model. For each variant, we determine all sentiment flows that represent at least 1% of all reviews in a given training set. We learn a mapping from the edit distance between a review's sentiment flow and each of these flows to global sentiment. For robustness, we also combine different model variants.

We compare the accuracy of the model variants to previous approaches evaluated on the given corpora. In addition, we analyze domain robustness based on three baselines, which relate to the three abstraction levels in Figure 2 (cf. Section 4):

Bag-of-Words (b1) The frequencies of all tokens that occur in at least 5% of all training reviews.

Local Sentiment (b2) The frequencies of positive, neutral, and negative local sentiment in a review as well as the first and last local sentiment (analog to Section 4, local sentiment is mapped to $[0, 1]$).

Sentiment Flow Patterns (b3) The Manhattan distances to those sentiment flows obtained by our clustering approach (Wachsmuth et al., 2014a).

All approaches are used as feature types in machine learning (with values normalized to $[0, 1]$).

6.2 Experimental Set-up

We tackle three-class sentiment analysis, which is supposed to be particularly hard due to the fuzzy nature of neutral sentiment (Täckström and McDonald, 2011). Given the three review corpora described in Section 5, we proceed as follows:[7]

Local Sentiment For feature computations, we split all reviews into tokens and sentences. Then, we classify local sentiment with the algorithm of Socher et al. (2013) from Stanford CoreNLP.[8] The algorithm was trained on subjective movie review sentences. We found that its accuracy is limited to around 50% on the given corpora, partly as it tends to misclassify objective sentences. Still, we use it to avoid any adaptation to the domains at hand.

Global Sentiment To determine global sentiment, we perform supervised learning based on the feature types outlined above. In particular, we use the default configuration of the random forest classifier from Weka (Breiman, 2001; Hall et al., 2009) without any parameter optimization.

Experiments Having classified local sentiment in all reviews, we learn a random forest classifier on each feature type and different feature sets for all combinations of training and test domain. To prevent class bias, the training sets are balanced with duplicate oversampling. Since the size of the corpora is limited, we evaluate in-domain accuracy on the whole corpora using 10-fold cross-validation, averaged over five runs. Afterwards, we test the out-of-domain accuracy by applying the learned classifier to the other complete corpora.

6.3 Results on the Domain Robustness

Table 4 lists accuracy results for all domain combinations. In the movie domain, we obtain an overall accuracy of 71.8. On average, we thus succeed over Pang and Lee (2005) who report about 75 on the reviews of Scott Renshaw and 63 on those of Dennis Schwartz. Similarly, we beat all our three-class sentiment analysis results from (Wachsmuth,

Table 4. Accuracy of predicting 3-class global sentiment for each combination of training and test domain using the baselines and/or a selection of the 16 evaluated model variants.

2015) in the hotel domain. In the product domain, our approach fails to compete with Täckström and McDonald (2011) who classify the global sentiment of 66.6% of all reviews correctly after training on large-scale product corpora. The small size of the given corpus explains the limited in-domain accuracy in Table 4; even some out-of-domain classifiers perform better on the product reviews. Still, the value 54.2 significantly improves over all baselines under a paired t-test ($p < 5\%$).

As expected, bag-of-words (b1) proves strong in some in-domain tasks—achieving even the best overall accuracy in the hotel domain (79.6)—but it consistently fails out-of-domain. Although less clear, similar observations can be made for b2. This shows that a restriction to the distribution of local sentiment is insufficient to tackle domain dependence. The sentiment flow patterns are comparably effective out-of-domain, but still suffer from the domain change on the evaluated corpora.

For space reasons, we compare the baselines b1 to b3 only to a selection of five of the most effective model variants, v1 to v5. Alone, these variants only occasionally do better than the sentiment flow patterns (b3). However, their combination (v1–5) clearly outperforms b3 in 4 out of 6 out-of-domain experiments. A strong variant is *2class-noloops*, which already proved general in the results from Section 5. In contrast, *2class* (v4) appears controversial. While it turns out being both effective and domain-robust when training in the product and hotel domain, no *2class* sentiment flow represents at least 1% of the movie corpus, emphasizing that more abstraction is required for robustness.

Altogether, the bottom lines of each domain in Table 4 provide clear evidence that our approach improves domain robustness in sentiment analysis: In all cases, the out-of-domain accuracy is best when using our sentiment flow features v1–5. At the same time, our results suggest that very high effectiveness might require more adaptation to the target domain. In this regard, modeling sentiment flow serves as a promising basis to align more effective but domain-dependent features.

7 Conclusion

This paper puts the goal of domain independence in the sentiment analysis of web reviews into the focus. In particular, we hypothesize that an abstract model of the local sentiment flow in a review generally captures the review's overall argumentation regarding global sentiment. In ground-truth data from three domains, we have found clear evidence for our hypothesis, indicating that people write reviews in similar ways across domains.

On this basis, we have presented a novel learning approach, which predicts the global sentiment of a review from the edit distance between the review's sentiment flow and a set of common flows. While we determined common flows with clustering in previous work (Wachsmuth et al., 2014a), instead here we rely on different flow abstractions at the same time. Systematic experiments emphasize that, in this manner, our approach achieves domain robustness without any domain adaptation even when the accuracy of the local sentiment in the flows is limited.

However, our experiments also show that sentiment flow alone does not always suffice to predict global sentiment. In future sentiment analysis approaches, sentiment flows may therefore rather serve as pivot features for domain adaptation.

Neural Networks for Open Domain Targeted Sentiment

Meishan Zhang and **Yue Zhang** and **Duy-Tin Vo**

Abstract

Open domain targeted sentiment is the joint information extraction task that finds target mentions together with the sentiment towards each mention from a text corpus. The task is typically modeled as a sequence labeling problem, and solved using state-of-the-art labelers such as CRF. We empirically study the effect of word embeddings and automatic feature combinations on the task by extending a CRF baseline using neural networks, which have demonstrated large potentials for sentiment analysis. Results show that the neural model can give better results by significantly increasing the recall. In addition, we propose a novel integration of neural and discrete features, which combines their relative advantages, leading to significantly higher results compared to both baselines.

1 Introduction

Targeted sentiment analysis has drawn growing research interests over the past few years. Compared with traditional sentiment analysis tasks, which extract the overall sentiment of a document, a sentence or a tweet, targeted sentiment analysis extracts the sentiment over given targeted entities from a text, and therefore is practically more informative. An example is shown in Figure 1. There are at least two practical scenarios:

(1) Certain entities of concern are specified, and the requirement is to extract the sentiment towards their mentions in a text. For example, one can be interested in the sentiment towards *Google Inc.*, *Microsoft* and *Facebook* in financial news texts, or the sentiment towards *Manchester United*, *Liverpool* and *Chelsea* in tweets.

So excited to meet my [**baby Farah**]$_+$!!!
[**Baseball Warehouse**]$_+$: easy to understand information.
The [**#Afghan #Parlaiment Speaker**]$_-$ should Resign .
Saw [**Erykah Badu**]$_-$ last night , vile venue unfortunately .
[**AW service**]$_0$ will be back at work .

Figure 1: *Targeted sentiment analysis*.

(2) No specified target is given, and the requirement is to find sentiments towards entities in the open domain. For example, one might be interested extracting the mentions to all persons and organizations, together with the sentiments towards each mention, from a news archive or a collection of novels.

There are two sub tasks in targeted sentiment analysis, namely entity recognition and sentiment classification for each entity mention which apply to both scenarios above. In scenario (1), *entity recognition* is relatively trivial, and can typically be achieved by pattern matching. Partly due to this reason, most previous work has addressed targeted sentiment analysis as a pure classification task, assuming that target mentions have been given (Jiang et al., 2011; Chen et al., 2012; Dong et al., 2014; Vo and Zhang, 2015). For scenario (2), a named entity recognition (NER) system can be used to extract targets, before the same targeted sentiment classification algorithms are applied. There has also been work that concentrates on extracting opinion targets (Jin et al., 2009; Jakob and Gurevych, 2010). In both cases, the data in Figure 1 can be used for training sentiment classifiers.

Mitchell et al. (2013) took a different approach, extracting named entities and their sentiment classes jointly. They model the joint task

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 612–621,
Lisbon, Portugal, 17-21 September 2015.

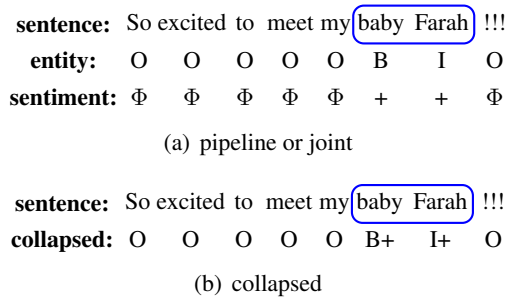

Figure 2: Pipeline, joint and collapsed models for *open targeted sentiment analysis*.

as an extension to the NER task, where an extra sentiment label is assigned to each named entity, in addition to the entity label. As a result, the task can be solved using sequence labeling methods. As claimed by Mitchell et al. (2013), the joint task is particularly suitable when no extra resources are available for training separate syntactic analyzers or name entity recognizers. Such situations can include tweets and low-resource languages/domains. Interestingly, because of containing entity information, the annotation in Figure 1 suffices for training joint entity and sentiment labels even if it is the only resource available.

The annotations in Figure 1 can be transformed into label sequences, as shown in Figure 2. Figure 2 consists of two types of labels, where the B/I/O labels indicate span boundaries, and the +/-/0 labels indicate sentiment classes. The two types of labels can be assigned in a span→sentiment pipeline, or jointly as a multi-label task. Alternatively, as shown in Figure 2(b), the two types of labels can be collapsed into a joint label, such as B+ and I-, indicating the beginning of a positive entity and the middle of a negative entity, respectively. The collapsed labels allow joint entity recognition and sentiment classification to be achieved using a standard sequence labeler.

Mitchell et al. (2013) compare a pipeline model, a joint model and a collapsed model under the same conditional random field (CRF) framework, finding that the pipeline method outperforms the joint model on a tweet dataset. Intuitively, the interaction between entity boundaries and sentiment classes might not be as strong as that between more closely-coupled sources of information, such as word boundaries and POS (Zhang and Clark, 2008), or named entities and constituents (Finkel and Manning, 2009), for which joint models significantly outperform pipeline models. On the other hand, there do exist cases where entity boundaries and sentiment classes reinforce each other. For example, in a tweet such as 'I like *X*.', the contextual pattern indicate both a positive sentiment and an entity in the place of *X*.

Recently, neural network models have been increasingly used for sentiment analysis (Socher et al., 2013; Kalchbrenner et al., 2014; dos Santos and Gatti, 2014), achieving highly competitive results, which show large potentials of neural network models for this task. The main advantages of neural networks are two-fold. First, neural models use real-valued hidden layers to automatically learn feature combinations, which can capture complex semantic information that are difficult to express using traditional discrete manual features. Second, neural networks take distributed word embeddings as inputs, which can be trained from large-scale raw text, thus alleviating the scarcity of annotated data to some extent. In this paper, we exploit structured neural models for open targeted sentiment.

We take the CRF model of Mitchell et al. (2013) as the baseline, and explore two research questions. First, we make an empirical comparison between discrete and neural CRF models, and further combine the strengths of each model via feature integration. Second, we compare the effects of the pipeline, joint and collapsed models for open targeted sentiment analysis under the neural model settings. Our experiments show that the neural model gives competitive results compared with the discrete baseline, with relatively higher recalls. In addition, the integrated model significantly improves over both the discrete and the neural models.

2 Related Work

Targeted sentiment analysis is closely related prior work on aspect-oriented (Hu and Liu, 2004), feature-oriented (Popescu and Etzioni, 2007) and topic-oriented (Yi et al., 2003) sentiment analysis. These related tasks are typically concentrated on product review settings. In contrast, targeted sentiment analysis has a more general setting.

Recently, Wang et al. (2011) proposed a topic-oriented model, which extracts sentiments towards certain topics from tweets. Topics in their model resemble targets in our work, although topics are represented by hashtags, which exists in 14.6% tweets and 27.5% subjective tweets (Wang et al.,

2011). In contrast, targeted sentiment analysis can identify all the mentions to target entities in tweets, thereby having a larger coverage. The drawback is that the identification of mentions is subject to errors, and thus suffers a lower precision compared to hashtag matching.

Sequence labeling models have been used for extracting opinions and target entities as a joint task. Jin et al. (2009) use HMM to extract opinion-baring expressions and opinion targets. Li et al. (2010) improve the results by using CRF to identify the opinion expressions and targets jointly. The task is sometimes referred to as fine-grained sentiment analysis (Wiebe et al., 2005). It is different from our setting in that the predicate-argument relation between opinion-baring expressions and target entities are not explicitly modeled.

Recently, Yang and Cardie (2013) use CRF to extract opinion-baring expressions, opinion holders and opinion targets simultaneously. Their method is also centralized on opinion-baring expressions and therefore in line with Jin et al. (2009) and Li et al. (2010). In contrast, targeted sentiment analysis directly studies entity mentions and the sentiment on each mention, without explicitly modeling the way in which the opinion is expressed. As a result, our task is more useful for applications such as broad-stroke reputation management, but offer less fine-grained operational insight. It requires less fine-grained manual annotation.

As discussed in the introduction, targeted sentiment analysis falls into two main settings. The first is targeted sentiment classification, assuming that entity mentions are given. Most previous work fall under this category (Jiang et al., 2011; Chen et al., 2012; Dong et al., 2014). The second is open domain targeted sentiment, which has been discussed by Mitchell et al. (2013). The task jointly extracts entities and sentiment classes, and is analogous to joint entity and relation extraction (Li and Ji, 2014) in that both are information extraction tasks with multi-label outputs.

Our work is related to the line of work on using neural networks for sentiment analysis. Socher et al. (2011) use recursive auto-encoders for sentiment analysis on the sentence level. They further extend the method to a syntactic treebank annotated with sentiment labels (Socher et al., 2013). More recently, Kalchbrenner et al. (2014) use a dynamic pooling network to include the structure

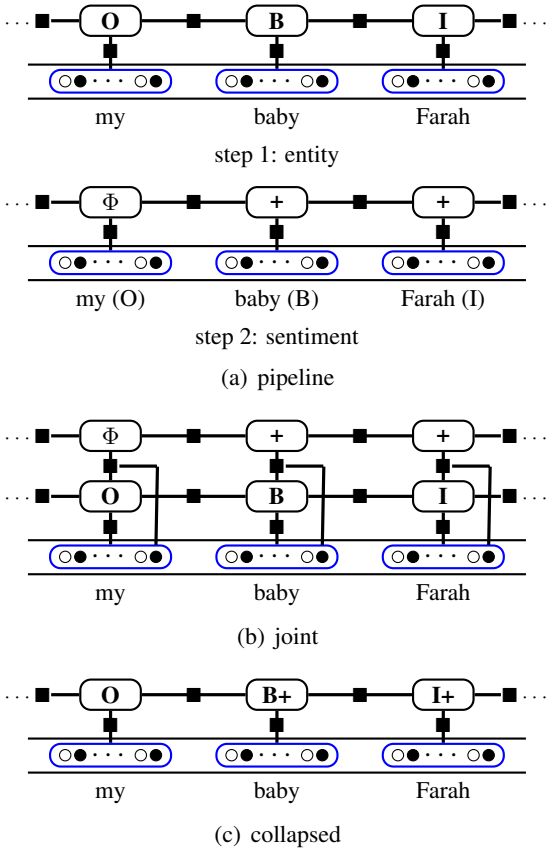

Figure 3: Discrete CRF models for pipeline, joint and collapsed targeted sentiment labeling.

of a sentence automatically, before classifying its sentiment. Zhou et al. (2014) apply deep belief networks for semi-supervised sentiment classification. dos Santos and Gatti (2014) use deep convolution neural networks with rich features to classify sentiments over tweets and movie reviews. These methods use different models to represent sentence structures, performing sentiment analysis on the sentence level, without modeling targets.

Dong et al. (2014) perform targeted sentiment classification by using a recursive neural network to model the transmission of sentiment signal from opinion baring expressions to a target. They assume that the target mention is given, and perform three-way sentiment classification. In contrast, we apply a structural neural model for open domain targeted sentiment analysis, identifying and classifying all targets in a sentence simultaneously.

3 Discrete CRF Baselines

As shown in Figure 2, the input $\vec{x}$ to our tasks is a word sequence. Assuming no external resources, there is no POS given to each input word x_i. For

the pipeline and collapsed tasks, there is a single output label sequence $\vec{y}$. For the joint task, there are two label sequences $\vec{y}$ and $\vec{z}$, for entity and sentiment labels, respectively. We take the models of Mitchell et al. (2013) as our baseline, which are standard CRFs with discrete manual features. To facilitate comparison between the discrete baseline and our neural models, we give a unified formulation to all the models in this paper, introducing the neural and integrated models as extensions to the discrete models.

The baseline CRF structures for pipeline, joint and collapsed targeted sentiment analysis are shown in Figure 3(a), 3(b) and 3(c), respectively. In the figures, the input features are represented as black and white circles, indicating that they take $0/1$ binary values. The labels O, B and I indicate a non-target, the beginning of a target, and part of a target, respectively. The labels $+$, $-$, 0 and Φ indicate positive, negative, neutral and *NULL* sentiments, respectively. The *NULL* sentiment is assigned to O entities automatically, and modeled as a hidden variable in the pipeline and joint CRFs.[1] The collapsed labels take combined meanings from their components.

The links between labels and inputs represent output clique potentials:

$$\Psi(\vec{x}, y_i) = exp\Big\{\vec{\theta} \cdot \vec{f}(\vec{x}, y_i)\Big\},$$

where $\vec{f}(\vec{x}, y_i)$, is a discrete manual feature vector, and $\vec{\theta}$ is the model parameter vector.

The links between labels represent edge clique potentials:

$$\Phi(\vec{x}, y_i, y_{i-1}) = exp\Big\{\tau(y_i, y_{i-1})\Big\},$$

where $\tau(y_i, y_{i-1})$ is the transition weight, which is also a model parameter.

For both the pipeline and collapsed models, the conditional probability of a label sequence given an input sequence is:

$$P(\vec{y}|\vec{x}) = \frac{\prod_{i=1}^{|x|} \Psi(\vec{x}, y_i) \prod_{j=1}^{|x|} \Phi(\vec{x}, y_i, y_{i-1})}{Z(\vec{x})},$$

[1]Note the difference between neural and *NULL* sentiments. The former indicates that a target does not bare any sentiment, and the latter simply means that the term is not a part of a target.

where $Z(\vec{x})$ is the partition function:

$$Z(\vec{x}) = \sum_{\vec{y}'} \Big(\prod_{i=1}^{|x|} \Psi(\vec{x}, y'_i) \prod_{j=1}^{|x|} \Phi(\vec{x}, y'_i, y'_{i-1}) \Big),$$

For the joint model, we apply a multi-label CRF structure, where there are two separate sets of output clique potentials $\Psi_1(\vec{x}, y_i)$ and $\Psi_2(\vec{x}, z_i)$ and two separate sets of edge clique potentials $\Phi_1(\vec{x}, y_i, y_{i-1})$ and $\Phi_2(\vec{x}, z_i, z_{i-1})$ for the label sets $\{B, I, O\}$ and $\{+, -, 0\}$, respectively. In the Figure 3(b), there are also links between the span label y_i and the sentiment label z_i for each word x_i. These links indicate label dependencies, which are constraints for decoding. For example, if $y_i = O$, then z_i must be ϕ.

We apply Viterbi decoding for all tasks, and training is performed using a max-margin objective, which is discussed in Section 6. Our training algorithm is different from that of Mitchell et al. (2013), but gives similar discrete CRF accuracies in our experiments. Wang and Mori (2009) also applied a max-margin trainig strategy to train CRF models. The set of features is taken from Mitchell et al. (2013) without changes, as shown in Table 1. Here the cluster features refer to Brown word clusters (Brown et al., 1992).

4 Neural Models

We extend the discrete baseline system with two salient changes, which are illustrated in Figure 4. First, the input discrete features are replaced with continuous word embeddings. Each node in the input takes a real value between 0 and 1, as represented by grey nodes in Figure 4. Second, a hidden

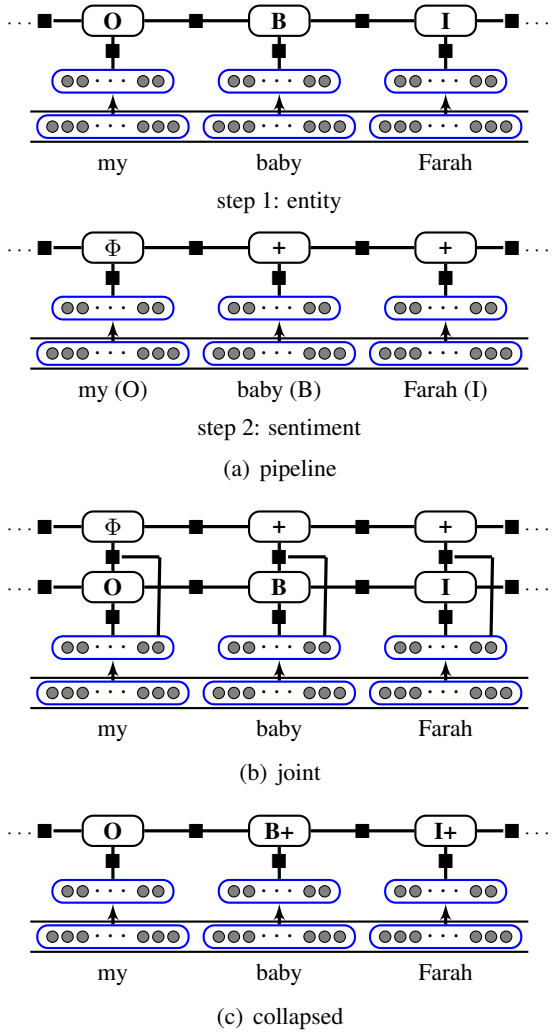

Figure 4: Neural networks for pipeline, joint and collapsed targeted sentiment labeling.

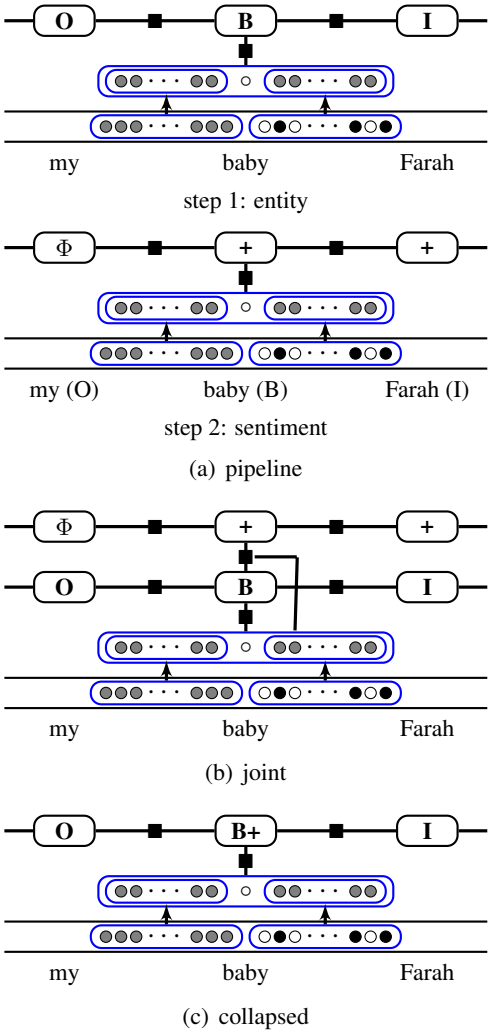

Figure 5: Integrated models for pipeline, joint and collapsed targeted sentiment labeling.

neural layer $\vec{h}$ is added between the input nodes $\vec{x}$ and the label nodes y_i.

Formally, the links between the input nodes $\vec{x}$ and the hidden nodes $\vec{h}_i$ for the node y_i in Figure 4 represent a feature combination function:

$$\vec{h}_i = tanh\Big(\mathbf{W}.(e(\vec{x}_{i-2}) \oplus e(\vec{x}_{i-1}) \oplus e(\vec{x}_i) \oplus e(\vec{x}_{i+1}) \oplus e(\vec{x}_{i+2})) + \vec{b}\Big)$$

where e is the embedding lookup function, $\oplus$ is the vector concatenation function, the matrix $\mathbf{W}$ and vector $\vec{b}$ are model parameters and *tanh* is the activation function.

The output clique potential of y_i becomes:

$$\Psi(\vec{x}, y_i) = exp\Big\{\vec{\sigma} \cdot \vec{h}_i\Big\}$$

where $\vec{\sigma}$ is a model parameter, and the edge clique potentials remain the same as the baseline. By using a hidden layer for automatic feature combinations, the neural model is free of manual features, and can benefit from unsupervised embeddings. Decoding and training are performed using the same algorithms as the baseline.

The major neural architectures in Figure 4 have been explored as *conditional neural fields* by Peng et al. (2009) and *neural conditional random fields* by Do et al. (2010), and is connected to the sentence-level likelihood neural networks of Collobert et al. (2011), as pointed out by Wang and Manning (2013b). The main differences between our model and the prior work are in the multi-label settings and training details.

5 Integrated Models

Gleaning different sources of information, neural features and discrete linear features comple-

ments each other. As a result, a model that integrates both features can potentially achieve performance improvements. Most work attempts to add neural word embeddings into a discrete linear model (Turian et al., 2010; Yu et al., 2013; Guo et al., 2014), or add discreted features into a neural model (Ma et al., 2014). We make a novel combination of the discrete models and the neural models by integrating both types of inputs into a same CRF framework.[2]

The architectures of the integrated models are shown in Figure 5. The main difference between Figure 5 and Figure 3 is the input layer. The integrated model takes both continuous word embeddings, which are shown in grey nodes, and discrete manual features, which are shown in black or white nodes, as the input.

A separate hidden layer is given to each type of input nodes, with the hidden layer for the embeddings being the same as the neural baseline:

$$\vec{h}_i = tanh\Big(\mathbf{W} \cdot (e(\vec{x}_{i-2}) \oplus e(\vec{x}_{i-1}) \oplus e(\vec{x}_i) \oplus e(\vec{x}_{i+1}) \oplus e(\vec{x}_{i+2})) + \vec{b}\Big)$$

The hidden nodes $\vec{g}_i$ between the discrete features and the node y_i are:

$$\vec{g}_i = tanh\Big(\vec{\theta} \cdot \vec{f}(\vec{x}, y_i)\Big)$$

Finally, the output clique potential of y_i becomes:

$$\vec{\Psi}(\vec{x}, y_i) = exp\Big\{\vec{\sigma} \cdot (\vec{h}_i \oplus \vec{g}_i)\Big\}$$

The edge clique potentials remain the same as the baseline models; the same training and decoding algorithms are used.

6 Training

We use a max-margin objective to train our model parameters Θ, which consist of $\vec{\theta}$, τ, $\mathbf{W}$, $\vec{b}$ and $\vec{\sigma}$ for each model. The objective function is defined as:

$$L(\Theta) = \frac{1}{N}\sum_{n=1}^{N} l(\vec{x}_n, \vec{y}_n, \Theta) + \frac{\lambda}{2} \parallel \Theta \parallel^2,$$

where $(\vec{x}_n, \vec{y}_n)|_{n=1}^{N}$ are the set of training examples, λ is a regularization parameter, and $l(\vec{x}_n, \vec{y}_n, \Theta)$ is the loss function towards one example $(\vec{x}_n, \vec{y}_n)$.

The loss function is defined as:

$$l(\vec{x}_n, \vec{y}_n, \Theta) = \max_{\vec{y}}(s(\vec{x}_n, \vec{y}, \Theta) + \delta(\vec{y}, \vec{y}_n)) - s(\vec{x}_n, \vec{y}_n, \Theta),$$

where $s(\vec{x}, \vec{y}, \Theta) = logP(\vec{y}|\vec{x})$ is the log probability of $\vec{y}$, and $\delta(\vec{y}, \vec{y}_n)$ is the Hamming distance between $\vec{y}$ and $\vec{y}_n$.

We use online learning to train model parameters, updating the parameters using the AdaGrad algorithm (Duchi et al., 2011). One thing to note is that, our objective function is not differentiable because of the loss function $l(\vec{x}_n, \vec{y}_n, \Theta)$. Thus we use sub-gradients for $l(\vec{x}_n, \vec{y}_n, \Theta)$ instead, which can be computed by the formula:

$$\frac{\partial l(\vec{x}_n, \vec{y}_n, \Theta)}{\partial \Theta} = \frac{\partial s(\vec{x}_n, \hat{\vec{y}}, \Theta)}{\partial \Theta} - \frac{\partial s(\vec{x}_n, \vec{y}_n, \Theta)}{\partial \Theta},$$

where $\hat{\vec{y}}$ is the predicted label sequence which corresponds to $l(\vec{x}_n, \vec{y}_n, \Theta)$.

Maximum-likelihood training is a commonly used alternative to max-margin training for neural networks. It has been applied to the models of Do et al. (2010) and Collobert et al. (2011), for example. However, our experiments show that maximum-likelihood training cannot be applied to open-domain targeted sentiment tasks. Although giving comparable overall accuracies in both entity and sentiment labels, it suffers from unbalanced sentiment labels, assigning the neutral sentiment to most entities. This problem can be addressed by imposing a polarity-sensitive cost to the training, such as the sentence-level averaged F1-score between positive, negative and neutral labels. We skip these results due to space limitations. In contrast, max-margin training does not suffer from the label skew issue, thanks to the use of Hamming loss in the objective function.

7 Experiments

7.1 Experimental Settings

Data: We use the data of Mitchell et al. (2013)[3] to conduct all the experiments, which consist of entity and sentiment annotations on both English and Spanish tweets. Simple normalizations are

[2] Wang and Manning (2013a) also investigated the integration of discrete and neural features in CRF models. They compared the effect of integration without hidden layers (i.e. Turian et al. (2010)) and with hidden layers (i.e. our methods) for NER and chunking, finding that the formal outperforms the latter. Our results are different from theirs, and a hidden layer gives significant improvements to the targeted sentiment analysis task.

[3] http://www.m-mitchell.com/code/index.html

Domain	#Sent	#Entities	#+	#-	#0
English	2,350	3,288	707	275	2,306
Spanish	5,145	6,658	1,555	1,007	4,096

Table 2: Experimental corpus statistics.

conducted to replace all usernames and URLs into the special tokens $\langle username \rangle$ and $\langle url \rangle$, respectively. Following Mitchell et al. (2013), we report ten-fold cross-validation results. During training, we split 10% of the training corpus as the development corpus to tune hyper-parameters. Table 2 shows the corpus statistics.

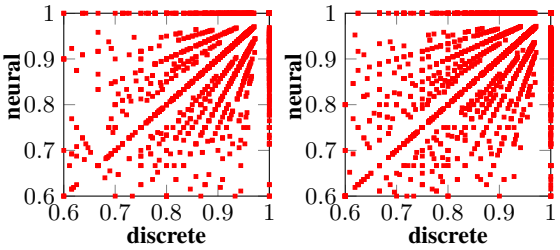
Parameters: For all the neural models, we set the hidden layer size $|\vec{h}|$ for neural features to 200, the hidden layer size $|\vec{g}|$ for discrete features to 30, the initial learning rate for adagrad to 0.01 and the regularization parameter λ to 10^{-8}. English and Spanish word embeddings are trained using the *word2vec* tool[4], with respective corpora of 20 minion random tweets crawled by tweet API[5]. The size of word embeddings is 100. For English, there are 8,061 unique words, for which 25% are out of *word embedding* vocabulary (OOE) words, while for Spanish, there are 14,648 unique words, for which 15% are OOE words.

Metrics: We take full-span metrics for evaluation, which is different from Mitchell et al. (2013), who evaluate mainly the beginning of spans. We measure the precision, recall and F-score of entity recognition (**Entity**), targeted sentiment analysis (**SA**) (both entity and sentiment), and targeted subjectivity detection (**Subjectivity**) (both entity and subjectivity, namely merging the + and - labels as "1" label, and performing two-way 0/1 subjectivity classification on entities). For **SA**, an entity is taken as correct only when the span and the sentiment are both correctly recognized. Similarly, for **Subjectivity**, an entity is taken as correct only when both the span and the subjectivity are correctly recognized.

Code: We make the C++ implementations of the discrete, neural and combined models available and GPL, at `https://github.com/SUTDNLP/OpenTargetedSentiment`.

7.2 Comparing Neural and Discrete Models

The main results on both the English and Spanish dataset are shown in Table 3, which are measured on the pipeline, the joint and the collapsed tasks, respectively. As can be seen from the table, the neural models give higher F-scores than the discrete CRF models on the English dataset, while comparable overall F-scores on the Spanish dataset. The gains on English are mostly attributed to improved recalls, while the precision of the neural CRF models are relatively lower. A likely reason for this observation is that the neural model takes embedding inputs, which allow semantically similar words to be represented with similar vectors. As a result, the neural model can better capture patterns that do not occur in the training data. In contrast, the discrete model is based on manually defined binary features, which do not fire if not contained in the training data. Because discrete feature instantiation is based on exact matching, the discrete model gives a relatively higher precision.



(a) English (b) Spanish

Figure 6: Labeling accuracy comparisons.

To further contrast the discrete and neural models, we draw the per-word accuracies of sentiment labels according to both models in Figure 6. In the figure, each dot represents the accuracy of a sentence, measured in the pipeline task. The dots for both English and Spanish are scattered from the reverse diagonal, showing that the two models make very different errors, which suggests that model integration can lead to better accuracies.

7.3 The Integrated Model

As shown in Table 3, the integrated model combines the relative advantages of both pure models, improving the recall over the discrete model and the precision over the neural model. In most cases, it gives the best results in terms of both precision and recall. For the English pipeline model, the integrated model improves the entity recognition F-score from 43.84% to 55.67% (significant with $p < 10^{-5}$ by pair-wise t-test) as compared to the discrete baseline, namely Mitchell et al. (2013).

(a) Neural (b) Integrated

Figure 7: Effect of fine-tuning (+T — with fine-tuning; -T — without fine-tuning).

The overall SA score is improved from 31.73% to 40.06% ($p < 10^{-5}$). Similar improvements are achieved to the other test datasets.

7.4 Fine-tuning Word Embeddings

In the experiments above, word embeddings are fine-tuned for the neural models, but not for the integrated models. By fine-tuning, embeddings of in-vocabulary words are treated as model parameters, and updated with other parameters in supervised training. This can improve the accuracy of the model by significantly enlarging the parameter space. However, it can make the embeddings of OOV words less useful to the model, because the hidden layers are tuned with adjusted embeddings.

Figure 7 shows the effectiveness of fine-tuning on the neural and integrated models using the Spanish data. Similar findings apply to the English data. The neural model heavily relies on fine-tuning of embeddings, and a likely reason is that manual discrete features offer sufficient parameters for capturing in-vocabulary patterns. On the other hand, thanks to the rich discrete features in parameter space, the integrated model does not rely on fine-tuning of word embeddings, which even caused slight overfitting and reduced the performances. This makes the non-fine-tuned integrated model potentially advantageous in handling test data with many OOV words.

7.5 Comparing pipeline, joint and collapsed models

Mitchell et al. (2013) find that for discrete CRF, the pipeline task gives competitive overall performances compared with the joint task. This suggests a relatively weak connection between entity boundary information and sentiment classes. We re-examine the comparisons under the neural network setting, where automatic feature combinations can be useful in capturing more subtle correlations between two sources of information.

As shown in Table 3, the overall results are similar to those of Mitchell et al. (2013), with both the neural and the integrated models demonstrating the same trends as the discrete baselines. A more detail analysis, however, shows some relative strengths of the joint task. Table 4 give the precision, recall and F-scores of subjectivity, and those of SA excluding neutral sentiment labels on the Spanish data. Findings on the English dataset are consistent.

The latter metrics highlight sentiment polarities, which can be relatively more useful. The joint task gives better F-scores on both metrics, which suggest that is a considerable choice for open targeted sentiment. When there is external resource for en-

Model	Subjectivity			SA/0

pipeline	47.92	**42.26**	44.84	**42.93**	18.02	25.14
joint	49.17	42.13	**45.32**	40.93	**21.62**	**27.93**
collapsed	**49.63**	35.94	41.63	42.10	15.62	22.49

Table 4: Results on subjectivity and polarity.

tity recognition, the pipeline can be a favorable choice. On the other hand, although useful for some joint sequence labeling task (Ng and Low, 2004), the collapsed task does not seem to address the joint sentiment task as effectively. We find this result empirical, but consistent across our datasets.

8 Conclusion

We explored open domain targeted sentiment analysis using neural network models, which gave competitive results when evaluated against a strong discrete CRF baseline, with relatively higher recalls. Given complementary error distributions by the discrete and neural CRFs, we proposed a novel combination which significantly outperformed both models. Under the neural setting, we find that it is preferable to solve open targeted sentiment as a pipeline or joint multi-label task, but not as a joint task with collapsed labels.

Extracting Condition-Opinion Relations Toward Fine-grained Opinion Mining

Yuki Nakayama **Atsushi Fujii**

{nakayama.y.aj@m,fujii@cs}.titech.ac.jp

Abstract

A fundamental issue in opinion mining is to search a corpus for opinion units, each of which typically comprises the evaluation by an author for a target object from an aspect, such as "This hotel is in a good location". However, few attempts have been made to address cases where the validity of an evaluation is restricted on a condition in the source text, such as "for traveling with small kids". In this paper, we propose a method to extract condition-opinion relations from online reviews, which enables fine-grained analysis for the utility of target objects depending the user attribute, purpose, and situation. Our method uses supervised machine learning to identify sequences of words or phrases that comprise conditions for opinions. We propose several features associated with lexical and syntactic information, and show their effectiveness experimentally.

1 Introduction

Reflecting the rapid growth in the use of opinionated texts on the Web, such as comments on news articles and customer reviews, opinion mining has been explored to facilitate utilizing opinions mainly for improving products and decision-making purposes. While in a broad sense opinion mining refers to a process to discover useful knowledge latent in a corpus of opinionated texts, fundamental issues involve modeling an unit of opinions and searching the corpus for those units, each of which typically comprises the evaluation by an author for a target object from an aspect. Other elements, such as when the opinion was submitted, can optionally be included in an opinion unit. We take the following review sentence as an example opinionated description.

(1) I think hotel A offers a reasonable price if you take a family trip with small kids.

From the above example, existing methods (Pang and Lee, 2008; Seki et al., 2009; Jin et al., 2009; Zhao et al., 2010; He et al., 2011; Liu and Zhang, 2012; Liu et al., 2013; Yang and Cardie, 2013; Liu et al., 2014) are intended to extract the following quintuple as an opinion unit.

> Target = "hotel A", Aspect = "price", Evaluation (Polarity) = "reasonable" (positive), Holder = "I (author)", Time = N/A

Depending on the application, "Evaluation" can be any of a literal opinion word (e.g., "reasonable"), a polarity (positive/negative), or a value for multi-point scale rating.

Given those standardized units extracted from a corpus, it is feasible to overview the distribution of values for each element or a combination of elements. For example, those who intend to improve the quality of hotel A may investigate representative values for "Aspect" in the units satisfying "Target=hotel A & Polarity=negative", while those who look for accommodation may collect the opinion units for one or more candidate hotels and investigate the distribution of values for "Polarity" on an aspect-by-aspect basis.

However, in the above example (1), the evaluation for hotel A ("a reasonable price") is valid for "if you take a family trip with small kids", and thus it is not clear whether this evaluation is valid irrespective of the condition. For example, the price may not be reasonable for a single customer intending for business purposes. In this paper, we shall call such a condition "condition for opinion (CFO)". We define CFO as a condition for which an opinion unit has a polarity.

The existing methods for opinion mining, which do not consider whether a target opinion is conditional, potentially overestimate or underestimate

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 622–631,
Lisbon, Portugal, 17-21 September 2015.

the utility of hotel A and consequently decrease the quality of opinion mining. We manually analyzed the first 7 000 sentences in the Rakuten Travel data, which consists of 348 564 Japanese reviews for hotels in Japan (see Section 4 for details of this data) and found that 2 272 sentences are opinions, of which 630 opinions are conditional and thus the result for an existing method includes up to 28% (630/2272) errors.

Motivated by the above discussion, in this paper we propose a method to extract pairs of a CFO and its corresponding opinion unit from online reviews. This method provides two solutions to the above problem. First, a passive solution is detecting whether an opinion includes a CFO and, if any, isolating that opinion from the target of opinion mining. As a result, we can avoid potential errors as much as possible but the coverage is decreased.

Second, an active solution is identifying the span of each CFO in conditional opinions and classify them according to semantic categories, such as purpose, situation, and user attribute so that finer-grained opinion mining can be realized. For example, the distribution of positive and negative opinions can be available on a category-by-category basis. However, in this paper we focus only on the identification for CFOs and leave the semantic classification future work.

To produce a practical model for CFOs, it is important to investigate them from a grammar point of view. It can easily be predicted that a typical grammatical unit for CFOs is a conditional clause as in example (1). Additionally, restrictive modifiers in general can potentially be CFOs because they restrict the validity of an opinion unit from a specific perspective. A restrictive modifier comprises a word, phrase, or clause. The CFO in example (1), which is a dependent clause functioning as a condition, is also a restrictive modifier.

Example (2), which has the same meaning as example (1), includes a CFO as a prepositional phrase.

(2) Hotel A offers a *reasonable* price **for taking a family trip with small kids**.

We denote CFOs and opinion words in bold and italic faces, respectively. Examples (3) and (4) also include a CFO as a prepositional phrase. Unlike example (2), the validity of "reasonable" is restricted from time and comparison points of view, respectively.

(3) Hotel A offers a *reasonable* price **during this holiday season**.

(4) Hotel A offers a *reasonable* price **for a four star hotel**.

In example (5), which has a similar meaning to example (1), the CFO is a dependent clause functioning as a reason.

(5) Hotel A offers a *reasonable* price **because we take a family trip with small kids**.

Finally, as in example (6), an opinion holder can also be a CFO because the evaluation is restricted from a perspective of that specific person.

(6) **My mother** regarded hotel A as a *reasonable* choice.

If the restriction by a CFO is associated with a user-related perspective, we call such CFOs "user-restrictive CFOs (U-CFOs)". In other words, target users to whom an opinion unit is relevant are restricted by its corresponding U-CFO, although those users may agree or disagree with the opinion. The CFOs in examples (1), (2), and (5) are U-CFOs because the target users are mainly those who intend to travel with their children.

The CFO in example (3) is also U-CFO because the target users are those who intend to travel during a specific holiday season. The CFO in example (6) is also U-CFO because the opinion holder ("my mother") implies the opinion is relevant mainly to adult females. However, opinion holders who do not represent user-related perspectives, such as "I" without any profile, are not U-CFOs.

The CFO in example (4) is not a U-CFO because the relevance of the opinion is not restricted to specific customers. It may be argued that in example (4) the target users are restricted to those who are interested in the price. However, in example (4) the price restricts the aspect of the opinion unit, and should not be confused with U-CFOs and even CFOs, which restrict the validity of the opinion unit.

If we fully utilize U-CFOs, as discussed for the active solution above, we need to classify U-CFOs into semantic categories so that users can selectively read relevant opinions. In other words, the identification for U-CFOs facilitates predicting the review helpfulness (O'Mahony and Smyth, 2010; Moghaddam et al., 2012). Candidate categories

include demographic and psychographic attributes for target users (e.g., age and hobby) and situations of target users (e.g., purpose, time, and place). However, we leave the classification for U-CFOs future work.

2 Related work

As described in Section 1, the fundamental methods for opinion mining include opinion extraction, which identifies elements for opinion units (i.e., target, aspect, evaluation, holder, and time) (He et al., 2011; Jin et al., 2009; Liu et al., 2013; Seki et al., 2009; Yang and Cardie, 2013; Zhao et al., 2010), and opinion classification, which determines the non-literal evaluation of each opinion unit based on bipolar categories (i.e., positive and negative) (He et al., 2011; Meng et al., 2012) or multipoint scale categories (Fu and Wang, 2010; Moghaddam and Ester, 2013). However, none of these methods intends to determine whether or not an opinion is conditional and to extract their condition.

Narayanan et al. (2009) proposed a method for sentiment classification targeting conditional sentences. Although a conditional opinion is a kind of conditional sentence, their research is fundamentally different from our research. Narayanan et al. (2009) targeted such a conditional sentence that comprises a single opinion as a whole, and intended to categorize its polarity into any of positive, negative, or neutral. Examples (7) and (8) are such conditional sentences associated with neutral and positive categories, respectively.

(7) Hotel A would not have survived if the price was not reasonable.

(8) If you are looking for a hotel with a reasonable price, stay at hotel A.

In example (7), although the subordinate clause includes the opinion word "reasonable", none of the subordinate clause, main clause, or entire sentence is an opinion. In example (8), the entire sentence is an unconditional opinion about the price for hotel A, but the main and subordinate clauses are not opinions independently. In contrast, the purpose of our research is to identify conditional opinions, in which the main and subordinate clauses are an opinion and its condition, respectively.

Kim and Hovy (2006) proposed a method to identify a reason for the evaluation in an opinion, such as "the service was terrible because the staff was rude". Although as discussed in Section 1 reasons can be CFOs, their purpose is to identify grounds that justify the evaluation and thus is different from our purpose.

As discussed in Section 1, our research is related to predicting the review helpfulness (O'Mahony and Smyth, 2010; Moghaddam et al., 2012). The method proposed by O'Mahony and Smyth (2010) determines the helpfulness of a product review independent of the user profile and thus cannot recommend reviews based on user-related attributes.

Moghaddam et al. (2012) used collaborative filtering to predict the review helpfulness. The evaluation by a target user for past reviews is used to model the user and predict the helpfulness for unread reviews, which results in different predictions depending on the user. An advantage of collaborative filtering is its applicability to items whose content is usually difficult to analyze, such as videos. However, this advantage is diluted in recommending review text, from which effective features for user modeling, such as U-CFOs, can be obtained by opinion mining.

3 Proposed method

The task in this paper is to extract condition-opinion relations from reviews in Japanese. Currently, we assume that an opinion unit and its corresponding CFO are in the same sentence, and thus perform the extraction on a sentence-by-sentence basis. Given a sentence in reviews, we first search for an opinion unit, and if found, we also search for its corresponding CFO. Because in the first process we rely on an existing method for the opinion extraction, in this paper we focus only on the extraction for CFOs.

As discussed in Section 1, because CFOs can be different grammatical units, their length and structure are not standardized. We model the extraction for CFOs as the BIO chunking, which labels each token in a sentence as being the beginning (B), inside (I), or outside (O) of a span of interest. We use "Other" to refer to "O" to avoid confusion between "O" and "0" (zero). To subdivide "B" and "I" into U-CFOs and other CFOs, we use suffixes "U" and "C", respectively, such as "BU" denoting the beginning of a U-CFO. We use "Cond" to refer to any of BU, IU, BC, or IC.

Because we use the same method for both U-

CFOs and other CFOs, the above distinction only increases the number of categories to which each token is classified. If the distinction of U-CFOs is not important, the above suffixes can be omitted.

We regard Japanese *bunsetsu* phrases, which consist of a content word and one or more postpositional particles, as tokens, and extract a sequence of a BU-phrase and one or more IU-phrases, or an independent BU-phrase as a condition. The same method is used for BC/IC-phrases. However, words and phrases in an opinion unit are classified into its corresponding element. For example, an aspect phrase is classified into the aspect category.

Given an input sequence of *bunsetsu* phrases, $\boldsymbol{x} = x_1 \dots x_n$, our task is to predict a sequence of labels, $\boldsymbol{y} = y_1 \dots y_n$, where $y_i \in \{BU, IU, BC, IC, Other, Target, Aspect, OpinionWord\}$. However, because an opinion unit in an input sentence has been identified in advance, the task is a quinary classification with respect to $y_i \in \{BU, IU, BC, IC, Other\}$. We use Conditional Random Fields (CRF) (Lafferty et al., 2001) to train a classifier for categorizing each *bunsetsu* phrase into any of the aforementioned five categories. We use a combination of unigram and bigram models and calculate the conditional probability, $p(\boldsymbol{y}|\boldsymbol{x})$, for linear-chain CRF by Equation (1).

$$p(\boldsymbol{y}|\boldsymbol{x}) = \frac{1}{Z_{\boldsymbol{x}}} \exp\Big(\sum_{i,k} \lambda_k \cdot f_k(y_i, \boldsymbol{x}) + \sum_{i,k} \mu_k \cdot g_k(y_{i-1}, y_i, \boldsymbol{x})\Big) \quad (1)$$

Here, $Z_{\boldsymbol{x}}$ denotes a normalization factor, and f_k and g_k denote feature functions for unigram and bigram models, respectively. Let $x_{i,v}$ denote a feature value for x_i. While in the unigram model y_i depends on either $x_{i-1,v}$ or $x_{i,v}$, in the bigram model y_i depends on either a combination of $x_{i,v}$ and y_{i-1} or that of $x_{i-1,v}$ and y_{i-1}. Feature functions are produced for any possible combinations of the values for the variables used ($x_{i,v}$, y_{i-1}, and y_i in f_k), and take 1 if the corresponding combination appears and 0 otherwise. We use the four combinations "unigram $x_{i,v}$", "unigram $x_{i-1,v}$", "bigram y_{i-1} $x_{i,v}$", and "bigram y_{i-1} $x_{i-1,v}$" for feature functions.

The question here is how CFOs and U-CFOs can be modeled and what kind of features are needed. We assume characteristics of CFOs, and U-CFOs and partially exemplify their validity using Figure 1, which depicts an example input sentence and information related to its constituent *bunsetsu* phrases. In the upper part of Figure 1, a rectangle and an arrow denote a bunsetstu phrase and a syntactic dependency between two phrases, respectively, and in each phrase we show Japanese words based on the Hepburn system and their English translations in parentheses.

CFOs are associated with the following characteristics.

(a) By definition, CFOs determine the validity of the evaluation in an opinion unit, and thus syntactically modify an opinion word. Consequently, CFOs usually do not modify other elements in an opinion unit, such as an aspect.

(b) Like a conjunction in a conditional clause in English, such as "if", a CFO in Japanese also includes a clue expression, which is usually a functional expression (Matsuyoshi et al., 2006) in the tail phrase, such as "ni wa ("for" in English)".

(c) The distribution for parts of speech as the head of CFOs is skewed and heads of CFOs are usually a noun or verb.

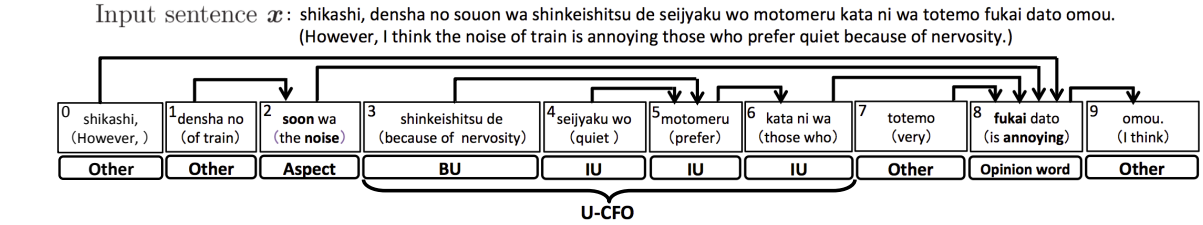
Additionally, U-CFOs are associated with the following characteristics.

(d) If a CFO is an opinion holder as in example (6) in Section 1, it is usually a U-CFO, which is the subject appearing at the beginning of a target sentence.

(e) By definition, U-CFOs include expressions related to user attributes, such as "nervosity" in Figure 1.

In this paper, we propose thirteen features to model CFOs and U-CFOs. In the bottom part of Figure 1, for each phrase we show the values of the thirteen features F1–F13 described below. These features were developed for the above five characteristics. F1–F5, F7–F10 and F13 are associated with (a), (b) and (c), respectively, while F6 and F11–F12 are associated with (d) and (e).

F1: Dependency distance to opinion word CFOs, which affect the evaluation in that opinion, usually syntactically modifies the opinion word. Thus, there should be a pass of dependencies between a Cond-phrase and the opinion word, and a



F1	1	2	aspect	3	3	2	1	1	opinion word	-1
F2	8	7	aspect	5	4	1	2	1	opinion word	-1
F3	1	0	aspect	1	1	1	1	1	opinion word	1
F4	2	1	aspect	-1	-1	-1	-1	-1	opinion word	-1
F5	7	5	aspect	2	1	1	1	0	opinion word	0
F6	0	0	aspect	0	0	0	0	0	opinion word	0
F7	nothing	nothing	aspect	nothing	nothing	nothing	ni wa	nothing	opinion word	nothing
F8	nothing	nothing	aspect	nothing	nothing	nothing	topic	nothing	opinion word	nothing
F9	nothing	nothing	aspect	ni wa	ni wa	ni wa	ni wa	nothing	opinion word	nothing
F10	nothing	nothing	aspect	topic	topic	topic	topic	nothing	opinion word	nothing
F11	nothing	densha	aspect	shinkeishitsu	nothing	nothing	kata	nothing	opinion word	nothing
F12	0	1	aspect	1	0	0	1	0	opinion word	0
F13	conjunction	noun	aspect	noun	noun	verb	noun	adverb	opinion word	verb

Figure 1: Example of Japanese sentence and the feature value for each constituent *bunsetsu* phrase

phrase that leads to the opinion word via a smaller number of dependency arrows is more likely to be a Cond-phrase. We use the dependency distance (i.e., the number of dependencies) between a phrase in question and the opinion word as the value for feature F1. The value for a phrase is -1 if there is no pass between that phrase and the opinion word. We use "CaboCha" (Kudo and Matsumoto, 2002) for dependency analysis purposes.

F2: Phrase distance to opinion word F1 is not robust against errors of the dependency analysis. To alleviate this problem, we approximate the dependency distance by a phrase distance. In practice, we subtract the ID for a phrase in question from that for the opinion word as the value for feature F2. If the opinion word consists of more than one phrase, we take the minimum difference. Because in Japanese a modifier is usually followed by its modifying object, a phrase with a negative value for feature F2 is usually an Other-phrase. For example, in the last phrase in Figure 1, which cannot be a modifier for the opinion word, is an Other-phrase.

F3: Dependency pass to aspect Because a CFO rarely modifies an aspect, for the value of feature F3 we take 0 if there is a pass of dependencies between a phrase in question and an aspect and 1 otherwise.

F4: Phrase distance to aspect Similar to F1, F3 is not robust against errors of the dependency analysis. As in F2, we approximate the value of F4 by a phrase distance between a phrase including an aspect and a phrase in question.

F5: Difference between values for F2 and F1 A CFO usually consists of a sequence of Cond-phrases where each phrase modifies the next phrase, as in Figure 1. There is a tendency that as the difference of values of F1 and F2 for a phrase becomes smaller, that phrase is more likely to be a Cond-phrase. In Figure 1, the values for Cond-phrases #3–#6 are smaller than those for Other-phrases #0–#1.

F6: Beginning of sentence The subject of an opinion sentence is often its U-CFO because the evaluation is valid only from the perspective of that specific subject. For example, in "my daughter was pleased with toys in the room" the positive evaluation is restricted by the daughter's perspective. Thus, the value of feature F6 takes 1 for the first phrase in a sentence excluding a conjunction, and 0 otherwise.

F7: Clue expression Because a CFO often ends with one or more specific particles or auxiliary verbs, we use the existence of those clue expressions in a phrase as the value for feature F7. We use words in a dictionary of Japanese functional expressions "Tsutsuji" (Matsuyoshi et al., 2006)

as the clue expressions. Table 1 shows examples of entries for Tsutsuji. Each entry is represented in a hierarchy structure with nine abstraction levels. We firstly collected "Head words" in the nineteen categories (e.g., resultative condition and purpose in L2) associated with our purpose, consulting "Meaning categories". Then we collected "Surface forms" corresponding to the collected head words and identified their corresponding surface forms to standardize different forms. For example, for ID 1 and ID 3 in Table 1, "to sure ba" and "nde" are regarded as identical to "to suru to" and "node", respectively. As a result, we collected 388 words, such as "ba (if)" and "ni (for)" and used their existence in a phrase in question as value for F7.

F8: Semantic categories for clue expression Because the data sparseness is a crucial problem for F7, we use the existence of semantic categories in Tsutsuji as the values of F8 for smoothing purposes. For example, in Table 1, "to suru to" and "ba" have the same feature values "resultative condition". If a clue expression belongs to more than one semantic category as in "ni" of Table 1, the feature value is a set of these categories.

F9: Dependency pass to phrase including clue expression (Surface form) As described in F7 above, the last phrase in a CFO often includes one or more clue expressions. In addition, a CFO often consists of more than one phrase. Given those conditions, a phrase that modifies a phrase containing a clue expression is also likely to be a Cond-phrase. We use the existence of a dependency pass between a phrase in question and a phrase containing a clue expression as the values of feature F9.

F10: Dependency pass to phrase including clue expression (Category) As with F8, we use the existence of semantic categories of Tsutsuji as the values of feature F10.

F11: Restrictive words We use the existence of words that are strongly associated with U-CFO as the value for F11. We call such words restrictive words. We automatically produced a dictionary of restrictive words from advertising slogans for hotels, which often include descriptions for target users, such as "★joshikai ya kappuru ni osusume!!★ (Recommended to girls get-together and couples)". First, we extracted words in the advertising slogan based on the following steps.

Entry ID	Abstraction levels			
	L1: Head word	L2: Meaning categories	...	L9: Surface forms
1	to suru to	resultative condition	...	to sure ba
2	ba		...	ba
3	node	reason	...	nde
4	ni	purpose	...	ni
5		target	...	

Table 1: Example entries for Tsutsuji

Step 1: Extracting sentences that match to a regular expression "(| hito | mono | kata) ni (| wa | mo) osusume" (i.e., "recommended to" or "recommend to those who").

Step 2: Collecting a sequence of content words for each bunsetsu-phrase in the extracted sentences.

For the above advertising slogan, we can collect two restrictive words "joshikai (girls get-together)" and "kappuru (couple)" by performing those 2 steps.

Second, we collected a sequence of independent words for bunsetsu phrases which comprises U-CFO in an annotated corpus. We combined the extracted words from the advertising slogans an annotated corpora, discarded redundancy, and standardized similar words, such as "kanko suru (do sightseeing) and "kanko (sightseeing)". As a result, we collected 934 words.

Finally, we calculated a mutual information like score, $Score(r, u)$, between a restrictive word r and labels u, Cond-phrases for U-CFOs (i.e., phrases labeled with either of BU or IU), by Equation 2.

$$Score(r, u) = P(r, u) \log \frac{P(r, u)}{P(r)P(u)} \quad (2)$$

$P(r, u)$ denotes the probability that a phrase including r is labeled with BU or IU in the annotated corpus. $P(r)$ denotes the probability that a phrase including r appears in the annotated corpus while $P(u)$ denotes the probability that a phrase labeled with BU or IU in the annotated corpus. If a phrase includes a restrictive word r and $Score(r, u)$ is greater than threshold θ, the feature value is r, and "nothing" otherwise.

F12: Existence of restrictive word Because the data sparseness is a crucial problem for F11, we integrate all the restrictive words for F11 into a single category for smoothing purposes. The value for F12 is the existence (1/0) of restrictive words.

F13: Part of speech for head The likelihood that a phrase in question is a Cond-phrases partially depends on the part of speech for the head in that phrase. For example, in Figure 1, a phrase whose head is a noun or verb tends to be a Cond-phrase

4 Experiments

To evaluate the effectiveness of our method, we used the Rakuten Travel data[1], which consists of 348 564 Japanese reviews for hotels in Japan. From this dataset, we selected 580 reviews and manually identified elements for opinion units. We removed sentences consisting only of opinion unit such as "The location is good" from the evaluation. As a result, 3 155 sentences remained, which comprise our corpus. To evaluate the effectiveness for identifying CFOs, we used the manually annotated opinion elements as output of a pseudo automatic method.

Given the above corpus, two annotators independently identified U-CFOs or CFOs, if any, for each opinion unit. For both annotations of CFOs and U-CFOs, the Kappa value for the inter-annotator agreement was 0.87, indicating strong agreement. We show the details of our corpus in Table 2. Using this corpus, we performed 10-fold cross-validation and compared different methods from different perspectives. Also, we determined the threshold for Score (see Eq 2) by a development set for each fold.

To evaluate the effectiveness of extracting U-CFOs and CFOs independently, we first classified bunsetsu phrases into any of BU, IU, BC, IC, or Other. Then, for the U-CFO extraction we regarded phrases for BU and IU as the Cond-phrases while for the CFO extraction we regarded phrases for BU, IU, BC, and IC as the Cond-phrases.

We used "Partial match" and "Exact match", which denote different criteria for the correctness of methods under evaluation. While in the partial match each method was requested to only detect whether or not a test sentence includes CFO, in the exact match each method was also requested to identify the span of each CFO. Also, we used different evaluation measures, namely precision (P), recall (R), F-measure (F), and accuracy (A).

Rule-based method and SVM-based method are used for comparison purposes. Rule-based method first identifies a *bunsetsu* phrase whose dependency distance to the opinion word is 1 and including a clue expression (see Section 3), and also identifies a sequence of the phrases from which there is a dependency path to the above phrase as a CFO. For example, in Figure 1 because phrase #6 includes a clue expression, a sequence of phrases #3–#6 is extracted as a CFO. These rules are based on features F1, F7 and F9. For the U-CFO extraction task, we regarded a sequence of Cond-phrases extracted by the above method as U-CFO if that sequence includes a restrictive word. For SVM, the thirteen features F1–F13 proposed in Section 3 was used. We used LIBSVM (Chang and Lin, 2011) to train a classifier. Our method used CRF to train a classifier with the thirteen features and four patterns for feature functions. We used CRF++[2] to train a classifier for each phrase and regularized the parameters using L2-norm.

Figure 2 shows the relationship between values of regularization parameter and F-measure for exact match. In Figure 2, "Rule", "SVM", and "CRF" denote a rule-based method, SVM-based method, and our method, respectively. The F-measure for Rule, independent of the regularization parameter, is a constant. While the F-measure for SVM substantially varied depending on the parameter value, that for CRF did not vary that much. Additionally, the F-measure for CRF was larger than that for SVM irrespective of the parameter value and matching criterion.

Table 3 shows results obtained with the optimal value for the regularization parameter. Looking at Table 3, one can see that CRF outperformed the other methods in terms of F-measure and accuracy for both partial and exact matches. We used the two-tailed paired t-test for statistical testing and found that the differences of CRF and each of the other methods in F-measure and accuracy were statistically significant at the 1% level irrespective of the configuration.

Figure 3 shows the effectiveness of the proposed features for exact match. The horizontal axis "w/o X" denotes a method without feature X. The vertical axis denotes a ratio of each method to our method. If a method without feature X takes less than 1 for value of vertical axis, the feature X is effective for extracting CFOs. Looking at Figure 3, one can see that our complete method outperformed any variation of our method in terms of

Figure 3: Effectiveness of proposed features for exact match

F-measure. Thus, we conclude that each of our thirteen features was independently effective for extracting CFO and U-CFO in review sentences and that when used together the improvement was even greater.

For the U-CFO extraction, we analyzed the errors by our method. The total number of errors was 363 by condition unit. We describe causes of the errors with example sentences, translated into English by the authors. In those examples, double and single underlines denote false positive and false negative, respectively. For each cause, we show the number of errors in parentheses.

E1 (124) Errors were due to F11 and F12 with insufficient dictionary for restrictive words. Typically, low frequency words (e.g., pilgrimage) and words related to miscellaneous activities during a travel (e.g., charging a battery of a mobile phone) were not included in our dictionary. While it is important to increase the vocabulary size of our dictionary, identifying synonymous expressions with partial matching (e.g., go to sleep / go to bed) is also important.

E2 (53) Errors were due to dependency analysis, which often mistakenly recognizes sentence boundaries in an informal writing style and dependency relations in a sentence comprising a phrase, such as "the best location for fully enjoying Asakusa". In this example, CaboCha mistakenly associated the adnominal modifier "for fully enjoying Asakusa" with "location (aspect)" instead of "best (opinion word)". As a result, F1 and F3 did not regard this modifier as a U-CFO.

E3 (40) Restrictive modifiers that modify a non-opinion segment were mistakenly extracted as U-CFOs. For example, in "I used this hotel for business and the meal was good", "for business" includes the clue expression "for" but does not modifies the opinion unit.

E4 (39) Similar to E3 but errors were due to restrictive words instead of clue expressions. In the example for E3, the restrict word "business" caused the error.

E5 (26) U-CFOs that consist of a large number of phrases were often not extracted due to F5, such as "This hotel is acceptable for one night to take the train at the Chuo station next morning".

E6 (25) Errors were due to irrelevant entries in our restrictive word dictionary.

E7 (11) Due to the sparseness problem for restrictive words in the training data, U-CFOs and CFOs were not correctly distinguished.

E8 (9) Errors were due to part-of-speech tagging.

E9 (6) Errors were due to extracting modifiers consisting of a personal pronoun without additional user-related attributes, such as "enough for me" , as U-CFOs. We need to identify whether an expression for a person is associated with user-related attributes, such as "the bed is small for a person who is tall", which indicates a physical attribute of a user.

Additionally, there are 65 errors for which we have not found a reason.

5 Conclusion

Although a number of methods have been proposed to search an opinionated corpus for opinion units, few attempts have so far been made at addressing cases where the validity of an evaluation is restricted on a condition in the source text. We proposed a method to identify such conditions from sentences including opinion units. Our method performs sequence labeling to determine whether each phrase is a constituent of an condition for opinion. We proposed thirteen features associated with lexical and syntactic information of Japanese, and showed their effectiveness using reviews for hotels. The contributions of this paper are introducing the notion of conditions for opinions, which is language-independent, proposing a method to extract condition-opinion relations from opinionated corpora, and giving an insight into its potential applications in opinion mining.

Acknowledgments

We would like to thank Professor Takenobu Tokunaga (Tokyo Institute of Technology) for his valuable comments. This research was supported in part by Grant-in-Aid for Scientific Research (Grant No. 15H02747).

Abstract

Understanding entailment and contradiction is fundamental to understanding natural language, and inference about entailment and contradiction is a valuable testing ground for the development of semantic representations. However, machine learning research in this area has been dramatically limited by the lack of large-scale resources. To address this, we introduce the Stanford Natural Language Inference corpus, a new, freely available collection of labeled sentence pairs, written by humans doing a novel grounded task based on image captioning. At 570K pairs, it is two orders of magnitude larger than all other resources of its type. This increase in scale allows lexicalized classifiers to outperform some sophisticated existing entailment models, and it allows a neural network-based model to perform competitively on natural language inference benchmarks for the first time.

1 Introduction

The semantic concepts of entailment and contradiction are central to all aspects of natural language meaning (Katz, 1972; van Benthem, 2008), from the lexicon to the content of entire texts. Thus, *natural language inference* (NLI) — characterizing and using these relations in computational systems (Fyodorov et al., 2000; Condoravdi et al., 2003; Bos and Markert, 2005; Dagan et al., 2006; MacCartney and Manning, 2009) — is essential in tasks ranging from information retrieval to semantic parsing to commonsense reasoning.

NLI has been addressed using a variety of techniques, including those based on symbolic logic, knowledge bases, and neural networks. In recent years, it has become an important testing ground for approaches employing *distributed* word and phrase representations. Distributed representations excel at capturing relations based in similarity, and have proven effective at modeling simple dimensions of meaning like evaluative sentiment (e.g., Socher et al. 2013), but it is less clear that they can be trained to support the full range of logical and commonsense inferences required for NLI (Bowman et al., 2015; Weston et al., 2015b; Weston et al., 2015a). In a SemEval 2014 task aimed at evaluating distributed representations for NLI, the best-performing systems relied heavily on additional features and reasoning capabilities (Marelli et al., 2014a).

Our ultimate objective is to provide an empirical evaluation of learning-centered approaches to NLI, advancing the case for NLI as a tool for the evaluation of domain-general approaches to semantic representation. However, in our view, existing NLI corpora do not permit such an assessment. They are generally too small for training modern data-intensive, wide-coverage models, many contain sentences that were algorithmically generated, and they are often beset with indeterminacies of event and entity coreference that significantly impact annotation quality.

To address this, this paper introduces the Stanford Natural Language Inference (SNLI) corpus, a collection of sentence pairs labeled for entailment, contradiction, and semantic independence. At 570,152 sentence pairs, SNLI is two orders of magnitude larger than all other resources of its type. And, in contrast to many such resources, all of its sentences and labels were written by humans in a grounded, naturalistic context. In a separate validation phase, we collected four additional judgments for each label for 56,941 of the examples. Of these, 98% of cases emerge with a three-annotator consensus, and 58% see a unanimous consensus from all five annotators.

In this paper, we use this corpus to evaluate

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 632–642,
Lisbon, Portugal, 17-21 September 2015.

A man inspects the uniform of a figure in some East Asian country.	**contradiction** C C C C C	The man is sleeping
An older and younger man smiling.	**neutral** N N E N N	Two men are smiling and laughing at the cats playing on the floor.
A black race car starts up in front of a crowd of people.	**contradiction** C C C C C	A man is driving down a lonely road.
A soccer game with multiple males playing.	**entailment** E E E E E	Some men are playing a sport.
A smiling costumed woman is holding an umbrella.	**neutral** N N E C N	A happy woman in a fairy costume holds an umbrella.

a variety of models for natural language inference, including rule-based systems, simple linear classifiers, and neural network-based models. We find that two models achieve comparable performance: a feature-rich classifier model and a neural network model centered around a Long Short-Term Memory network (LSTM; Hochreiter and Schmidhuber 1997). We further evaluate the LSTM model by taking advantage of its ready support for transfer learning, and show that it can be adapted to an existing NLI challenge task, yielding the best reported performance by a neural network model and approaching the overall state of the art.

2 A new corpus for NLI

To date, the primary sources of annotated NLI corpora have been the Recognizing Textual Entailment (RTE) challenge tasks.[1] These are generally high-quality, hand-labeled data sets, and they have stimulated innovative logical and statistical models of natural language reasoning, but their small size (fewer than a thousand examples each) limits their utility as a testbed for learned distributed representations. The data for the SemEval 2014 task called Sentences Involving Compositional Knowledge (SICK) is a step up in terms of size, but only to 4,500 training examples, and its partly automatic construction introduced some spurious patterns into the data (Marelli et al. 2014a, §6). The Denotation Graph entailment set (Young et al., 2014) contains millions of examples of entailments between sentences and artificially constructed short phrases, but it was labeled using fully automatic methods, and is noisy enough that it is probably suitable only as a source of supplementary training data. Outside the domain of sentence-level entailment, Levy et al. (2014) introduce a large corpus of semi-automatically annotated entailment examples between subject–verb–object relation triples, and the second release of the Paraphrase Database (Pavlick et al., 2015) includes automatically generated entailment annotations over a large corpus of pairs of words and short phrases.

Existing resources suffer from a subtler issue that impacts even projects using only human-provided annotations: indeterminacies of event and entity coreference lead to insurmountable indeterminacy concerning the correct semantic label (de Marneffe et al. 2008 §4.3; Marelli et al. 2014b). For an example of the pitfalls surrounding entity coreference, consider the sentence pair *A boat sank in the Pacific Ocean* and *A boat sank in the Atlantic Ocean*. The pair could be labeled as a contradiction if one assumes that the two sentences refer to the same single event, but could also be reasonably labeled as neutral if that assumption is not made. In order to ensure that our labeling scheme assigns a single correct label to every pair, we must select one of these approaches across the board, but both choices present problems. If we opt not to assume that events are coreferent, then we will only ever find contradictions between sentences that make broad universal assertions, but if we opt to assume coreference, new counterintuitive predictions emerge. For example, *Ruth Bader Ginsburg was appointed to the US Supreme Court* and *I had a sandwich for lunch today* would unintuitively be labeled as a contradiction, rather than neutral, under this assumption.

Entity coreference presents a similar kind of indeterminacy, as in the pair *A tourist visited New*

[1] http://aclweb.org/aclwiki/index.php?title=Textual_Entailment_Resource_Pool

York and *A tourist visited the city*. Assuming coreference between *New York* and *the city* justifies labeling the pair as an entailment, but without that assumption *the city* could be taken to refer to a specific unknown city, leaving the pair neutral. This kind of indeterminacy of label can be resolved only once the questions of coreference are resolved.

With SNLI, we sought to address the issues of size, quality, and indeterminacy. To do this, we employed a crowdsourcing framework with the following crucial innovations. First, the examples were grounded in specific scenarios, and the premise and hypothesis sentences in each example were constrained to describe that scenario from the same perspective, which helps greatly in controlling event and entity coreference.[2] Second, the prompt gave participants the freedom to produce entirely novel sentences within the task setting, which led to richer examples than we see with the more proscribed string-editing techniques of earlier approaches, without sacrificing consistency. Third, a subset of the resulting sentences were sent to a validation task aimed at providing a highly reliable set of annotations over the same data, and at identifying areas of inferential uncertainty.

2.1 Data collection

We used Amazon Mechanical Turk for data collection. In each individual task (each HIT), a worker was presented with premise scene descriptions from a pre-existing corpus, and asked to supply hypotheses for each of our three labels—*entailment*, *neutral*, and *contradiction*—forcing the data to be balanced among these classes.

The instructions that we provided to the workers are shown in Figure 1. Below the instructions were three fields for each of three requested sentences, corresponding to our *entailment*, *neutral*, and *contradiction* labels, a fourth field (marked optional) for reporting problems, and a link to an FAQ page. That FAQ grew over the course of data collection. It warned about disallowed techniques (e.g., reusing the same sentence for many different prompts, which we saw in a few cases), provided guidance concerning sentence length and

> We will show you the caption for a photo. We will not show you the photo. Using only the caption and what you know about the world:
>
> - Write one alternate caption that is **definitely** a **true** description of the photo. *Example: For the caption "Two dogs are running through a field." you could write "There are animals outdoors."*
> - Write one alternate caption that **might be** a **true** description of the photo. *Example: For the caption "Two dogs are running through a field." you could write "Some puppies are running to catch a stick."*
> - Write one alternate caption that is **definitely** a **false** description of the photo. *Example: For the caption "Two dogs are running through a field." you could write "The pets are sitting on a couch." This is different from the* maybe correct *category because it's impossible for the dogs to be both running and sitting.*

Figure 1: The instructions used on Mechanical Turk for data collection.

complexity (we did not enforce a minimum length, and we allowed bare NPs as well as full sentences), and reviewed logistical issues around payment timing. About 2,500 workers contributed.

For the premises, we used captions from the Flickr30k corpus (Young et al., 2014), a collection of approximately 160k captions (corresponding to about 30k images) collected in an earlier crowdsourced effort.[3] The captions were not authored by the photographers who took the source images, and they tend to contain relatively literal scene descriptions that are suited to our approach, rather than those typically associated with personal photographs (as in their example: *Our trip to the Olympic Peninsula*). In order to ensure that the label for each sentence pair can be recovered solely based on the available text, we did not use the images at all during corpus collection.

Table 2 reports some key statistics about the collected corpus, and Figure 2 shows the distributions of sentence lengths for both our source hypotheses and our newly collected premises. We observed that while premise sentences varied considerably in length, hypothesis sentences tended to be as

[2] Issues of coreference are not completely solved, but greatly mitigated. For example, with the premise sentence *A dog is lying in the grass*, a worker could safely assume that the dog is the most prominent thing in the photo, and very likely the only dog, and build contradicting sentences assuming reference to the same dog.

[3] We additionally include about 4k sentence pairs from a pilot study in which the premise sentences were instead drawn from the VisualGenome corpus (under construction; `visualgenome.org`). These examples appear only in the training set, and have pair identifiers prefixed with `vg` in our corpus.

Data set sizes:	
Training pairs	550,152
Development pairs	10,000
Test pairs	10,000
Sentence length:	
Premise mean token count	14.1
Hypothesis mean token count	8.3
Parser output:	
Premise 'S'-rooted parses	74.0%
Hypothesis 'S'-rooted parses	88.9%
Distinct words (ignoring case)	37,026

Table 2: Key statistics for the raw sentence pairs in SNLI. Since the two halves of each pair were collected separately, we report some statistics for both.

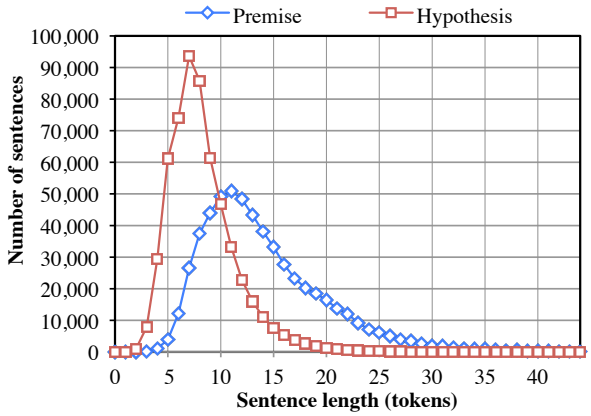

Figure 2: The distribution of sentence length.

short as possible while still providing enough information to yield a clear judgment, clustering at around seven words. We also observed that the bulk of the sentences from both sources were syntactically complete rather than fragments, and the frequency with which the parser produces a parse rooted with an 'S' (sentence) node attests to this.

2.2 Data validation

In order to measure the quality of our corpus, and in order to construct maximally useful testing and development sets, we performed an additional round of validation for about 10% of our data. This validation phase followed the same basic form as the Mechanical Turk labeling task used to label the SICK entailment data: we presented workers with pairs of sentences in batches of five, and asked them to choose a single label for each pair. We supplied each pair to four annotators, yielding five labels per pair including the label used by the original author. The instructions were similar to the instructions for initial data collection shown in Figure 1, and linked to a similar FAQ. Though we initially used a very restrictive qualification (based on past approval rate) to select workers for the validation task, we nonetheless discovered (and deleted) some instances of random guessing in an early batch of work, and subsequently instituted a fully closed qualification restricted to about 30 trusted workers.

For each pair that we validated, we assigned a gold label. If any one of the three labels was chosen by at least three of the five annotators, it was chosen as the gold label. If there was no such consensus, which occurred in about 2% of cases, we assigned the placeholder label '-'. While these unlabeled examples are included in the corpus distribution, they are unlikely to be helpful for the standard NLI classification task, and we do not include them in either training or evaluation in the experiments that we discuss in this paper.

The results of this validation process are summarized in Table 3. Nearly all of the examples received a majority label, indicating broad consensus about the nature of the data and categories. The gold-labeled examples are very nearly evenly distributed across the three labels. The Fleiss κ scores (computed over every example with a full five annotations) are likely to be conservative given our large and unevenly distributed pool of annotators, but they still provide insights about the levels of disagreement across the three semantic classes. This disagreement likely reflects not just the limitations of large crowdsourcing efforts but also the uncertainty inherent in naturalistic NLI. Regardless, the overall rate of agreement is extremely high, suggesting that the corpus is sufficiently high quality to pose a challenging but realistic machine learning task.

2.3 The distributed corpus

Table 1 shows a set of randomly chosen validated examples from the development set with their labels. Qualitatively, we find the data that we collected draws fairly extensively on commonsense knowledge, and that hypothesis and premise sentences often differ structurally in significant ways, suggesting that there is room for improvement beyond superficial word alignment models. We also find the sentences that we collected to be largely

General:	
Validated pairs	56,951
Pairs w/ unanimous gold label	58.3%
Individual annotator label agreement:	
Individual label = gold label	89.0%
Individual label = author's label	85.8%
Gold label/author's label agreement:	
Gold label = author's label	91.2%
Gold label ≠ author's label	6.8%
No gold label (no 3 labels match)	2.0%
Fleiss κ:	
contradiction	0.77
entailment	0.72
neutral	0.60
Overall	0.70

Table 3: Statistics for the validated pairs. The *author's label* is the label used by the worker who wrote the premise to create the sentence pair. A *gold label* reflects a consensus of three votes from among the author and the four annotators.

fluent, correctly spelled English, with a mix of full sentences and caption-style noun phrase fragments, though punctuation and capitalization are often omitted.

The corpus is available under a CreativeCommons Attribution-ShareAlike license, the same license used for the Flickr30k source captions. It can be downloaded at:
`nlp.stanford.edu/projects/snli/`

Partition We distribute the corpus with a prespecified train/test/development split. The test and development sets contain 10k examples each. Each original ImageFlickr caption occurs in only one of the three sets, and all of the examples in the test and development sets have been validated.

Parses The distributed corpus includes parses produced by the Stanford PCFG Parser 3.5.2 (Klein and Manning, 2003), trained on the standard training set as well as on the Brown Corpus (Francis and Kucera 1979), which we found to improve the parse quality of the descriptive sentences and noun phrases found in the descriptions.

3 Our data as a platform for evaluation

The most immediate application for our corpus is in developing models for the task of NLI. In particular, since it is dramatically larger than any existing corpus of comparable quality, we expect it to be suitable for training parameter-rich models like neural networks, which have not previously been competitive at this task. Our ability to evaluate standard classifier-base NLI models, however, was limited to those which were designed to scale to SNLI's size without modification, so a more complete comparison of approaches will have to wait for future work. In this section, we explore the performance of three classes of models which could scale readily: (i) models from a well-known NLI system, the Excitement Open Platform; (ii) variants of a strong but simple feature-based classifier model, which makes use of both unlexicalized and lexicalized features, and (iii) distributed representation models, including a baseline model and neural network sequence models.

System	SNLI	SICK	RTE-3
Edit Distance Based	71.9	65.4	61.9
Classifier Based	72.2	71.4	61.5
+ Lexical Resources	**75.0**	**78.8**	**63.6**

Table 4: 2-class test accuracy for two simple baseline systems included in the Excitement Open Platform, as well as SICK and RTE results for a model making use of more sophisticated lexical resources.

3.1 Excitement Open Platform models

The first class of models is from the Excitement Open Platform (EOP, Padó et al. 2014; Magnini et al. 2014)—an open source platform for RTE research. EOP is a tool for quickly developing NLI systems while sharing components such as common lexical resources and evaluation sets. We evaluate on two algorithms included in the distribution: a simple edit-distance based algorithm and a classifier-based algorithm, the latter both in a bare form and augmented with EOP's full suite of lexical resources.

Our initial goal was to better understand the difficulty of the task of classifying SNLI corpus inferences, rather than necessarily the performance of a state-of-the-art RTE system. We approached this by running the same system on several data sets: our own test set, the SICK test data, and the standard RTE-3 test set (Giampiccolo et al., 2007). We report results in Table 4. Each of the models

was separately trained on the training set of each corpus. All models are evaluated only on 2-class entailment. To convert 3-class problems like SICK and SNLI to this setting, all instances of *contradiction* and *unknown* are converted to nonentailment. This yields a most-frequent-class baseline accuracy of 66% on SNLI, and 71% on SICK. This is intended primarily to demonstrate the difficulty of the task, rather than necessarily the performance of a state-of-the-art RTE system. The edit distance algorithm tunes the weight of the three case-insensitive edit distance operations on the training set, after removing stop words. In addition to the base classifier-based system distributed with the platform, we train a variant which includes information from WordNet (Miller, 1995) and VerbOcean (Chklovski and Pantel, 2004), and makes use of features based on tree patterns and dependency tree skeletons (Wang and Neumann, 2007).

3.2 Lexicalized Classifier

Unlike the RTE datasets, SNLI's size supports approaches which make use of rich lexicalized features. We evaluate a simple lexicalized classifier to explore the ability of non-specialized models to exploit these features in lieu of more involved language understanding. Our classifier implements 6 feature types; 3 unlexicalized and 3 lexicalized:

1. The BLEU score of the hypothesis with respect to the premise, using an n-gram length between 1 and 4.
2. The length difference between the hypothesis and the premise, as a real-valued feature.
3. The overlap between words in the premise and hypothesis, both as an absolute count and a percentage of possible overlap, and both over all words and over just nouns, verbs, adjectives, and adverbs.
4. An indicator for every unigram and bigram in the hypothesis.
5. Cross-unigrams: for every pair of words across the premise and hypothesis which share a POS tag, an indicator feature over the two words.
6. Cross-bigrams: for every pair of bigrams across the premise and hypothesis which share a POS tag on the second word, an indicator feature over the two bigrams.

We report results in Table 5, along with ablation studies for removing the cross-bigram features (leaving only the cross-unigram feature) and for removing all lexicalized features. On our large corpus in particular, there is a substantial jump in accuracy from using lexicalized features, and another from using the very sparse cross-bigram features. The latter result suggests that there is value in letting the classifier automatically learn to recognize structures like explicit negations and adjective modification. A similar result was shown in Wang and Manning (2012) for bigram features in sentiment analysis.

System	SNLI		SICK	
	Train	Test	Train	Test
Lexicalized	99.7	**78.2**	90.4	**77.8**
Unigrams Only	93.1	71.6	88.1	77.0
Unlexicalized	49.4	50.4	69.9	69.6

Table 5: 3-class accuracy, training on either our data or SICK, including models lacking cross-bigram features (Feature 6), and lacking all lexical features (Features 4–6). We report results both on the test set and the training set to judge overfitting.

It is surprising that the classifier performs as well as it does without any notion of alignment or tree transformations. Although we expect that richer models would perform better, the results suggest that given enough data, cross bigrams with the noisy part-of-speech overlap constraint can produce an effective model.

3.3 Sentence embeddings and NLI

SNLI is suitably large and diverse to make it possible to train neural network models that produce distributed representations of sentence meaning. In this section, we compare the performance of three such models on the corpus. To focus specifically on the strengths of these models at producing informative sentence representations, we use sentence embedding as an intermediate step in the NLI classification task: each model must produce a vector representation of each of the two sentences without using any context from the other sentence, and the two resulting vectors are then passed to a neural network classifier which predicts the label for the pair. This choice allows us to focus on existing models for sentence embedding, and it allows us to evaluate the ability of those models to learn useful representations of meaning (which may be independently useful for subsequent tasks), at the cost of excluding from con-

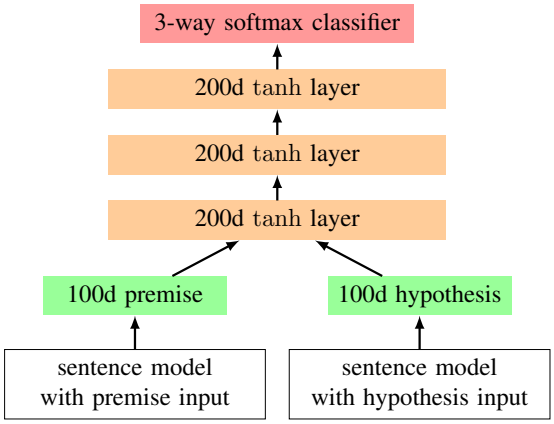

Figure 3: The neural network classification architecture: for each sentence embedding model evaluated in Tables 6 and 7, two identical copies of the model are run with the two sentences as input, and their outputs are used as the two 100d inputs shown here.

sideration possible strong neural models for NLI that directly compare the two inputs at the word or phrase level.

Our neural network classifier, depicted in Figure 3 (and based on a one-layer model in Bowman et al. 2015), is simply a stack of three 200d tanh layers, with the bottom layer taking the concatenated sentence representations as input and the top layer feeding a softmax classifier, all trained jointly with the sentence embedding model itself.

We test three sentence embedding models, each set to use 100d phrase and sentence embeddings. Our baseline sentence embedding model simply sums the embeddings of the words in each sentence. In addition, we experiment with two simple sequence embedding models: a plain RNN and an LSTM RNN (Hochreiter and Schmidhuber, 1997).

The word embeddings for all of the models are initialized with the 300d reference GloVe vectors (840B token version, Pennington et al. 2014) and fine-tuned as part of training. In addition, all of the models use an additional tanh neural network layer to map these 300d embeddings into the lower-dimensional phrase and sentence embedding space. All of the models are randomly initialized using standard techniques and trained using AdaDelta (Zeiler, 2012) minibatch SGD until performance on the development set stops improving. We applied L2 regularization to all models, manually tuning the strength coefficient λ for each, and additionally applied dropout (Srivastava et al., 2014) to the inputs and outputs of the sentence embedding models (though not to its internal connections) with a fixed dropout rate. All models were implemented in a common framework for this paper, and the implementations will be made available at publication time.

Sentence model	Train	Test
100d Sum of words	79.3	75.3
100d RNN	73.1	72.2
100d LSTM RNN	84.8	**77.6**

Table 6: Accuracy in 3-class classification on our training and test sets for each model.

The results are shown in Table 6. The sum of words model performed slightly worse than the fundamentally similar lexicalized classifier—while the sum of words model can use pretrained word embeddings to better handle rare words, it lacks even the rudimentary sensitivity to word order that the lexicalized model's bigram features provide. Of the two RNN models, the LSTM's more robust ability to learn long-term dependencies serves it well, giving it a substantial advantage over the plain RNN, and resulting in performance that is essentially equivalent to the lexicalized classifier on the test set (LSTM performance near the stopping iteration varies by up to 0.5% between evaluation steps). While the lexicalized model fits the training set almost perfectly, the gap between train and test set accuracy is relatively small for all three neural network models, suggesting that research into significantly higher capacity versions of these models would be productive.

3.4 Analysis and discussion

Figure 4 shows a learning curve for the LSTM and the lexicalized and unlexicalized feature-based models. It shows that the large size of the corpus is crucial to both the LSTM and the lexicalized model, and suggests that additional data would yield still better performance for both. In addition, though the LSTM and the lexicalized model show similar performance when trained on the current full corpus, the somewhat steeper slope for the LSTM hints that its ability to learn arbitrarily structured representations of sentence meaning may give it an advantage over the more constrained lexicalized model on still larger datasets.

We were struck by the speed with which the lexicalized classifier outperforms its unlexicalized

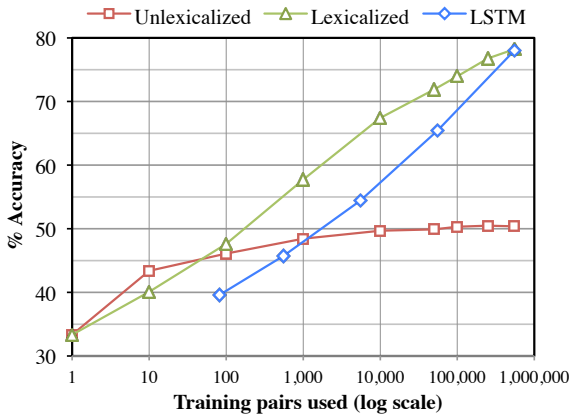

Figure 4: A learning curve showing how the baseline classifiers and the LSTM perform when trained to convergence on varied amounts of training data. The y-axis starts near a random-chance accuracy of 33%. The minibatch size of 64 that we used to tune the LSTM sets a lower bound on data for that model.

counterpart. With only 100 training examples, the cross-bigram classifier is already performing better. Empirically, we find that the top weighted features for the classifier trained on 100 examples tend to be high precision entailments; e.g., *playing* → *outside* (most scenes are outdoors), *a banana* → *person eating*. If relatively few spurious entailments get high weight—as it appears is the case—then it makes sense that, when these do fire, they boost accuracy in identifying entailments.

There are revealing patterns in the errors common to all the models considered here. Despite the large size of the training corpus and the distributional information captured by GloVe initialization, many lexical relationships are still misanalyzed, leading to incorrect predictions of *independent*, even for pairs that are common in the training corpus like *beach/surf* and *sprinter/runner*. Semantic mistakes at the phrasal level (e.g., predicting contradiction for *A male is placing an order in a deli/A man buying a sandwich at a deli*) indicate that additional attention to compositional semantics would pay off. However, many of the persistent problems run deeper, to inferences that depend on world knowledge and context-specific inferences, as in the entailment pair *A race car driver leaps from a burning car/A race car driver escaping danger*, for which both the lexicalized classifier and the LSTM predict *neutral*. In other cases, the models' attempts to shortcut this kind of inference through lexical cues can lead them astray. Some of these examples have qualities reminiscent of Winograd schemas (Winograd, 1972; Levesque, 2013). For example, all the models wrongly predict entailment for *A young girl throws sand toward the ocean/A girl can't stand the ocean*, presumably because of distributional associations between *throws* and *can't stand*.

Analysis of the models' predictions also yields insights into the extent to which they grapple with event and entity coreference. For the most part, the original image prompts contained a focal element that the caption writer identified with a syntactic subject, following information structuring conventions associating subjects and topics in English (Ward and Birner, 2004). Our annotators generally followed suit, writing sentences that, while structurally diverse, share topic/focus (theme/rheme) structure with their premises. This promotes a coherent, situation-specific construal of each sentence pair. This is information that our models can easily take advantage of, but it can lead them astray. For instance, all of them stumble with the amusingly simple case *A woman prepares ingredients for a bowl of soup/A soup bowl prepares a woman*, in which prior expectations about parallelism are not met. Another headline example of this type is *A man wearing padded arm protection is being bitten by a German shepherd dog/A man bit a dog*, which all the models wrongly diagnose as *entailment*, though the sentences report two very different stories. A model with access to explicit information about syntactic or semantic structure should perform better on cases like these.

4 Transfer learning with SICK

To the extent that successfully training a neural network model like our LSTM on SNLI forces that model to encode broadly accurate representations of English scene descriptions and to build an entailment classifier over those relations, we should expect it to be readily possible to adapt the trained model for use on other NLI tasks. In this section, we evaluate on the SICK entailment task using a simple transfer learning method (Pratt et al., 1991) and achieve competitive results.

To perform transfer, we take the parameters of the LSTM RNN model trained on SNLI and use them to initialize a new model, which is trained from that point only on the training portion of SICK. The only newly initialized parameters are

Training sets	Train	Test
Our data only	42.0	46.7
SICK only	100.0	71.3
Our data and SICK (transfer)	99.9	**80.8**

Table 7: LSTM 3-class accuracy on the SICK train and test sets under three training regimes.

softmax layer parameters and the embeddings for words that appear in SICK, but not in SNLI (which are populated with GloVe embeddings as above). We use the same model hyperparameters that were used to train the original model, with the exception of the L2 regularization strength, which is re-tuned. We additionally transfer the accumulators that are used by AdaDelta to set the learning rates. This lowers the starting learning rates, and is intended to ensure that the model does not learn too quickly in its first few epochs after transfer and destroy the knowledge accumulated in the pre-transfer phase of training.

The results are shown in Table 7. Training on SICK alone yields poor performance, and the model trained on SNLI fails when tested on SICK data, labeling more *neutral* examples as *contradiction*s than correctly, possibly as a result of subtle differences in how the labeling task was presented. In contrast, transferring SNLI representations to SICK yields the best performance yet reported for an unaugmented neural network model, surpasses the available EOP models, and approaches both the overall state of the art at 84.6% (Lai and Hockenmaier, 2014) and the 84% level of interannotator agreement, which likely represents an approximate performance ceiling. This suggests that the introduction of a large high-quality corpus makes it possible to train representation-learning models for sentence meaning that are competitive with the best hand-engineered models on inference tasks.

We attempted to apply this same transfer evaluation technique to the RTE-3 challenge, but found that the small training set (800 examples) did not allow the model to adapt to the unfamiliar genre of text used in that corpus, such that no training configuration yielded competitive performance. Further research on effective transfer learning on small data sets with neural models might facilitate improvements here.

5 Conclusion

Natural languages are powerful vehicles for reasoning, and nearly all questions about meaningfulness in language can be reduced to questions of entailment and contradiction in context. This suggests that NLI is an ideal testing ground for theories of semantic representation, and that training for NLI tasks can provide rich domain-general semantic representations. To date, however, it has not been possible to fully realize this potential due to the limited nature of existing NLI resources. This paper sought to remedy this with a new, large-scale, naturalistic corpus of sentence pairs labeled for entailment, contradiction, and independence. We used this corpus to evaluate a range of models, and found that both simple lexicalized models and neural network models perform well, and that the representations learned by a neural network model on our corpus can be used to dramatically improve performance on a standard challenge dataset. We hope that SNLI presents valuable training data and a challenging testbed for the continued application of machine learning to semantic representation.

Question-Answer Driven Semantic Role Labeling: Using Natural Language to Annotate Natural Language

Luheng He **Mike Lewis** **Luke Zettlemoyer**

Abstract

This paper introduces the task of question-answer driven semantic role labeling (QA-SRL), where question-answer pairs are used to represent predicate-argument structure. For example, the verb "introduce" in the previous sentence would be labeled with the questions "What is introduced?", and "What introduces something?", each paired with the phrase from the sentence that gives the correct answer. Posing the problem this way allows the questions themselves to define the set of possible roles, without the need for predefined frame or thematic role ontologies. It also allows for scalable data collection by annotators with very little training and no linguistic expertise. We gather data in two domains, newswire text and Wikipedia articles, and introduce simple classifier-based models for predicting which questions to ask and what their answers should be. Our results show that non-expert annotators can produce high quality QA-SRL data, and also establish baseline performance levels for future work on this task.

1 Introduction

Semantic role labeling (SRL) is the widely studied challenge of recovering predicate-argument structure for natural language words, typically verbs. The goal is to determine "who does what to whom," "when," and "where," etc. (Palmer et al., 2010; Johansson and Nugues, 2008). However, this intuition is difficult to formalize and fundamental aspects of the task vary across efforts, for example FrameNet (Baker et al., 1998) models a large set of interpretable thematic roles (AGENT, PATIENT, etc.) while PropBank (Palmer et al., 2005) uses a small set of verb-specific roles (ARG0, ARG1, etc.). Existing task definitions can be complex and require significant linguistic expertise to understand,[1] causing challenges for data annotation and use in many target applications.

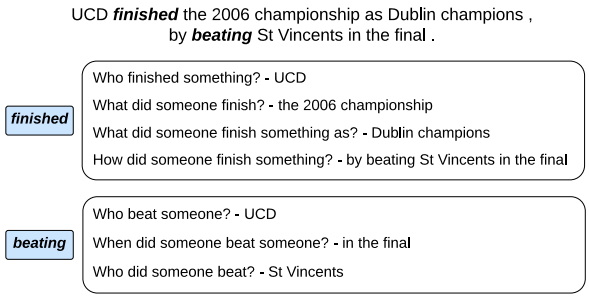

Figure 1: QA-SRL annotations for a Wikipedia sentence.

In this paper, we introduce a new question-answer driven SRL task formulation (QA-SRL), which uses question-answer pairs to label verbal predicate-argument structure. For example, for the sentence in Figure 1, we can ask a short question containing a verb, e.g. *"Who finished something?"*, and whose answer is a phrase from the original sentence, in this case *"UCD."* The answer tells us that *"UCD"* is an argument of "finished," while the question provides an indirect label on the role that *"UCD"* plays. Enumerating all such pairs, as we will see later, provides a relatively complete representation of the original verb's arguments and modifiers.

The QA-SRL task formulation has a number of advantages. It can be easily explained to non-expert annotators with a short tutorial and a few examples. Moreover, the formulation does not depend on any pre-defined inventory of semantic roles or frames, or build on any existing gram-

[1]The PropBank annotation guide is 89 pages (Bonial et al., 2010), and the FrameNet guide is 119 pages (Ruppenhofer et al., 2006). Our QA-driven annotation instructions are 5 pages.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 643–653,
Lisbon, Portugal, 17-21 September 2015.

mar formalisms. Nonetheless, as we will show, it still represents the argument and modifier attachment decisions that have motivated previous SRL definitions, and which are of crucial importance for semantic understanding in a range of NLP tasks, such as machine translation (Liu and Gildea, 2010) and coreference resolution (Ponzetto and Strube, 2006). The annotations also, perhaps surprisingly, capture other implicit arguments that cannot be read directly off of the syntax, as was required for previous SRL approaches. For example, in *"It was his mother's birthday, so he was going to play her favorite tune"*, annotators created the QA pair *"When would someone play something? His mother's birthday"* which describes an implicit temporal relation. Finally, QA-SRL data can be easily examined, proofread, and improved by anyone who speaks the language and understands the sentence; we use natural language to label the structure of natural language.

We present a scalable approach for QA-SRL annotation and baseline models for predicting QA pairs. Given a sentence and target word (the verb), we ask annotators to provide as many question-answer pairs as possible, where the question comes from a templated space of wh-questions[2] and the answer is a phrase from the original sentence. This approach guides annotators to quickly construct high quality questions within a very large space of possibilities. Given a corpus of QA-SRL annotated sentences, we also train baseline classifiers for both predicting a set of questions to ask, and what their answers should be. The question generation aspect of QA-SRL is unique to our formulation, and corresponds roughly to identifying what semantic role labels are present in previous formulations of the task. For example, the question *"Who finished something"* in Figure 1 corresponds to the AGENT role in FrameNet. Table 1 also shows examples of similar correspondences for PropBank roles. Instead of pre-defining the labels, as done in previous work, the questions themselves define the set of possibilities.

Experiments demonstrate high quality data annotation with very little annotator training and establish baseline performance levels for the task. We hired non-expert, part-time annotators on Upwork (previously oDesk) to label over 3,000 sentences (nearly 8,000 verbs) across two domains (newswire and Wikipedia) at a cost of approximately $0.50 per verb. We show that the data is high quality, rivaling PropBank in many aspects including coverage, and easily gathered in non-newswire domains.[3] The baseline performance levels for question generation and answering reinforce the quality of the data and highlight the potential for future work on this task.

In summary, our contributions are:

- We introduce the task of question-answer driven semantic role labeling (QA-SRL), by using question-answer pairs to specify verbal arguments and the roles they play, without predefining an inventory of frames or semantic roles.
- We present a novel, lightweight template-based scheme (Section 3) that enables the high quality QA-SRL data annotation with very little training and no linguistic expertise.
- We define two new QA-SRL sub-tasks, question generation and answer identification, and present baseline learning approaches for both (Sections 4 and 5). The results demonstrate that our data is high-quality and supports the study of better learning algorithms.

2 Related Work

The success of syntactic annotation projects such as the Penn Treebank (Marcus et al., 1993) has led to numerous efforts to create semantic annotations for large corpora. The major distinguishing features of our approach are that it is not tied to any linguistic theory and that it can be annotated by non-experts with minimal training.

Existing SRL task formulations are closely related to our work. FrameNet (Baker et al., 1998) contains a detailed lexicon of verb senses and thematic roles. However, this complexity increases the difficulty of annotation. While the FrameNet project is decades old, the largest fully annotated corpus contains about 3,000 sentences (Chen et al., 2010). We were able to annotate over 3,000 sentences within weeks. PropBank (Kingsbury and Palmer, 2002), NomBank (Meyers et al., 2004) and OntoNotes (Hovy et al., 2006) circumvent the need for a large lexicon of roles, by defin-

[2] Questions starting with a wh-word, such as *who*, *what*, *when*, *how*, etc.

[3] Our hope is that this approach will generalize not only across different domains in English, as we show in this paper, but also to other languages. We will leave those explorations to future work.

Sentence	CoNLL-2009		QA-SRL	
(1) Stock-fund managers , meantime , went into October with less cash on hand than they **held** earlier this year .	A0	they	Who had held something?	Stock-fund managers / they
	AM-TMP	year	When had someone held something?	earlier this year
			What had someone held?	less cash on hand
			Where had someone held something?	on hand
(2) Mr. Spielvogel **added** pointedly : " The pressure on commissions did n't begin with Al Achenbaum . "	A0	Spielvogel	Who added something?	Mr. Spielvogel
	A1	did	What was added?	" The pressure on commissions did n't begin with Al Achenbaum . "
	AM-MNR	pointedly	How was something added?	pointedly
(3) He claimed losses totaling $ 42,455 – and the IRS **denied** them all .	A0	IRS	Who denied something?	IRS
	A1	them	What was denied?	losses / them
(4) The consumer - products and newsprint company said net **rose** to $ 108.8 million , or $ 1.35 a share , from $ 90.5 million , or $ 1.12 a share , a year ago .	A1	net	What rose?	net
	A3	$/ago	What did something rise from?	$ 90.5 million , or $ 1.12 a share
	A4	to	What did something rise to?	$ 108.8 million , or $ 1.35 a share
			When did something rise?	a year ago
(5) Mr. Agnew was vice president of the U.S. from 1969 until he **resigned** in 1973 .	A0	he	Who resigned from something?	Mr. Agnew
	AM-TMP	in	When did someone resign from something?	1973
			What did someone resign from?	vice president of the U.S.
(6) Mr. Gorbachev badly **needs** a diversion from the serious economic problems and ethnic unrest he faces at home .	A0	Gorbachev	Who needs something?	Gorbachev/he
	A1	diversion	What does someone need?	a diversion from the serious economic problems and ethnic unrest he faces at home
	AM-ADV	badly	How does someone need something?	badly
			What does someone need something from?	the serious economic problems and ethnic unrest he faces at home .
(7) Even a federal measure in June allowing houses to **add** research fees to their commissions did n't stop it .	A0	houses	What added something?	houses
	A1	fees	What was added?	research fees
	A2	to		
			When was something added?	June
(8) This year , Mr. Wathen says the firm will be able to **service** debt and still turn a modest profit .	A0	firm	Who will service something?	the firm
	A1	debt	What will be serviced?	debt
			When will something be serviced?	this year
(9) Clad in his trademark black velvet suit , the soft - spoken clarinetist announced that . . . and that it was his mother 's birthday , so he was going to **play** her favorite tune from the record .	A0	he	Who would play something?	the soft - spoken clarinetist / he
	A1	tune	What would be played?	her favorite tune from the record
			When would someone play something?	his mother 's birthday

Table 1: Comparison between CoNLL-2009 relations and QA-SRL annotations. While closely related to PropBank predicate-argument relations, QA pairs also contain information about within-sentence coreference (Ex 3, 5, 6, 9), implicit or inferred relations (Ex 4, 7, 8, 9) and roles that are not defined in PropBank (Ex 1, 5). Annotation mistakes are rare, but for example include missing pronouns (Ex 5) and prepositional attachment errors (Ex 6).

ing the core semantic roles in a predicate-specific manner. This means that frames need to be created for every verb, and it requires experts to distinguish between different senses and different roles.

Our work is also related to recent, more general semantic annotation efforts. Abstract Meaning Representation (Banarescu et al., 2013) can be viewed as an extension of PropBank with additional semantic information. Sentences take 8-13 minutes to annotate—which is slower than ours, but the annotations are more detailed. Universal Cognitive Conceptual Annotation (UCCA) (Abend and Rappoport, 2013) is an attempt to create a linguistically universal annotation scheme by using general labels such as *argument* or *scene*. The UCCA foundational layer does not distinguish semantic roles, so *Frogs eat herons* and *Herons eat frogs* will receive identical annotation — thereby discarding information which is potentially useful for translation or question answering. They report similar agreement with PropBank to our approach (roughly 90%), but annotator training time was an order-of-magnitude higher (30-40 hours). The Groningen Meaning Bank (Basile et al., 2012) project annotates text by manually correcting the output of existing semantic parsers. They show that some annotation can be crowdsourced using "games with a purpose" — however, this does not include its predicate-argument structure, which requires expert knowledge of their syntactic and semantic formalisms. Finally, Reisinger et al. (2015) study crowdsourcing semantic role labels based on Dowty's proto-roles, given gold predicate and argument mentions. This work directly complements our focus on labeling predicate-argument structure.

The idea of expressing the meaning of natural language in terms of natural language is related to natural logic (MacCartney and Manning, 2007), in which they use natural language for logical inference. Similarly, we model predicate-argument structure of a sentence with a set of question-

Field	Description	Example of Values	No. Values
WH*	Question words (wh-words)	who, what, when, where, why, how, how much	7
AUX	Auxiliary verbs	is, have, could, is n't	36
SBJ	Place-holding words for the subject position	someone, something	2
TRG*	Some form of the target word	built, building, been built	≈ 12
OBJ1	Place-holding words for the object position	someone, something	2
PP	Frequent prepositions (by, to, for, with, about) and prepositions (unigrams or bigrams) that occur in the sentence	to, for, from, by	≈ 10
OBJ2	Similar to OBJ1, but with more options	someone, something, do, do something, doing something	9

Table 2: Fields in our question annotation template, with descriptions, example values, and the total number of possible values for each. **WH*** and **TRG*** are required; all other fields can be left empty.

WH*	AUX	SBJ	TRG*	OBJ1	PP	OBJ2	
Who			built	something			?
What	had	someone	said				?
What	was	someone	expected		to	do	?
Where	might	something	rise		from		?

Table 3: Four example questions written with our question annotation template.

answer pairs. While existing work on natural logic has relied on small entailment datasets for training, our method allows practical large-scale annotation of training data.

Parser evaluation using textual entailment (Yuret et al., 2010) is a method for evaluating syntactic parsers based on entailment examples. In a similar spirit to our work, they abstract away from linguistic formalisms by using natural language inference. We focus on semantic rather than syntactic annotation, and introduce a scalable method for gathering data that allows both training and evaluation. Stern and Dagan (2014) applied textual entailment to recognize implicit predicate-argument structure that are not explicitly expressed in syntactic structure.

3 QA-based Semantic Dataset

This section describes our annotation process in more detail, and discusses agreement between our annotations and PropBank. Table 1 shows examples provided by non-expert annotators.[4]

3.1 Annotation Task Design

We annotate verbs with pairs of questions and answers that provide information about predicate-argument structure. Given a sentence s and a verbal predicate v in the sentence, annotators must produce a set of wh-questions that contain v and whose answers are phrases in s.

To speed annotation and simplify downstream processing, we define a small grammar over possible questions. The questions are constrained with a template with seven fields, $q \in$ **WH** $\times$ **AUX** $\times$ **SBJ** $\times$ **TRG** $\times$ **OBJ1** $\times$ **PP** $\times$ **OBJ2**, each associated with a list of possible options. Descriptions for each field are shown in Table 2. The grammar is sufficiently general to capture a wide-range of questions about predicate-argument structure—some examples are given in Table 3.

The precise form of the question template is a function of the verb v and sentence s, for two of the fields. For the **TRG** field, we generate a list of inflections forms of v using the Wiktionary dictionary. For the **PP** field, the candidates are all the prepositions that occurred in the sentence s, and some frequently-used prepositions - *by*, *to*, *for*, *with*, and *about*. We also include preposition bigrams (e.g., *out for*) from s.

Answers are constrained to be a subset of the words in the sentence but do not necessarily have to be contiguous spans. We also allow questions to have multiple answers, which is useful for annotating graph structured dependencies such as those in examples 3 and 6 in Table 1.

3.2 Data Preparation

We annotated over 3000 sentences (nearly 8,000 verbs) in total across two domains: newswire (PropBank) and Wikipedia. Table 4 shows the full data statistics. In the newswire domain, we sampled sentences from the English training data of CoNLL-2009 shared task (Hajič et al.,

[4] Our dataset is freely available at: `https://dada.cs.washington.edu/qasrl`.

Dataset	Sentences	Verbs	QAs
newswire-train	744	2020	4904
newswire-dev	249	664	1606
newswire-test	248	652	1599
Wikipedia-train	1174	2647	6414
Wikipedia-dev	392	895	2183
Wikipedia-test	393	898	2201

Table 4: Annotated data statistics.

2009), excluding questions and sentences with fewer than 10 words. For the Wikipedia domain, we randomly sampled sentences from the English Wikipedia, excluding questions and sentences with fewer than 10 or more than 60 words.

In each sentence, we need to first identify the candidates for verbal predicates. In principle, a separate stage of annotation could identify verbs—but for simplicity, we instead used POS-tags. We used gold POS-tags for newswire, and predicted POS-tags (using Stanford tagger (Toutanova et al., 2003)) in Wikipedia. Annotators can choose to skip a candidate verb if they are unable to write questions for it. Annotators skipped 136 verbs (3%) in Wikipedia data and 50 verbs (1.5%) in PropBank data.

3.3 Annotation Process

For annotation, we hired 10 part-time, non-expert annotators from Upwork (previously oDesk) and paid $10 per hour for their work. The average cost was $0.58 per verb ($1.57 per sentence) for newswire text and $0.45 per verb ($1.01 per sentence) on the Wikipedia domain. The annotators are given a short tutorial and a small set of sample annotations (about 10 sentences). Annotators were hired if they showed good understanding of English and our task. The entire screening process usually took less than 2 hours.

Writing QA pairs for each sentence takes 6 minutes on average for Wikipedia and 9 minutes on newswire, depending on the length and complexity of the sentence and the domain of the text.

3.4 Agreement with Gold PropBank Data (CoNLL-2009)

PropBank is the most widely used annotation of predicate-argument structure. While our annotation captures different information from PropBank, it is closely related. To investigate the similarity between the annotation schemes, we measured the overlap between the newswire domain (1241 sentences) of our QA-SRL dataset and the PropBank dataset.

	All Roles	Core	Adjuncts
Precision	81.4	85.9	59.9
Recall	86.3	89.8	63.6

Table 5: Agreement with gold PropBank (CoNLL-2009) for all roles, core roles, and adjuncts. Precision is the percentage of QA pairs covering exactly one PropBank relation. Recall is the percentage of PropBank relations covered by exactly one QA pair.

For each PropBank predicate that we have annotated with our scheme, we compute the agreement between the PropBank arguments and the QA-SRL answers. We ignore modality, reference, discourse and negation roles, as they are outside the scope of our current annotation. An annotated answer is judged to match the PropBank argument if either (1) the gold argument head is within the annotated answer span, or (2) the gold argument head is a preposition and at least one of its children is within the answer span.

We measure the macro-averaged precision and recall of our annotation against PropBank, with the proportion of our QA-pairs that are match a PropBank relation, and the proportion of PropBank relations covered by our annotation. The results are shown in Table 5, and demonstrate high overall agreement with PropBank. Agreement for core arguments [5] is especially strong, showing much of the expert linguist annotation in PropBank can be recovered with our simple scheme. Agreement for adjuncts is lower, because the annotated QAs often contain inferred roles, especially for *why*, *when* and *where* questions (See examples 4, 7 and 8 in Table 1). These inferred roles are typically correct, but outside of the scope of PropBank annotations; they point to exciting opportunities for future work with QA-SRL data. On the other hand, the adverbial arguments in PropBank are sometimes neglected by annotators, thus becoming a major source of recall loss.

Table 6 shows the overlap between our annotated question words and PropBank argument labels. There are many unsurprising correlations—*who* questions are strongly associated with Prop-

[5] In PropBank, A0-A5 are the core arguments. In QA-SRL, the core arguments include QA pairs with a question that starts with *Who* or *What*.

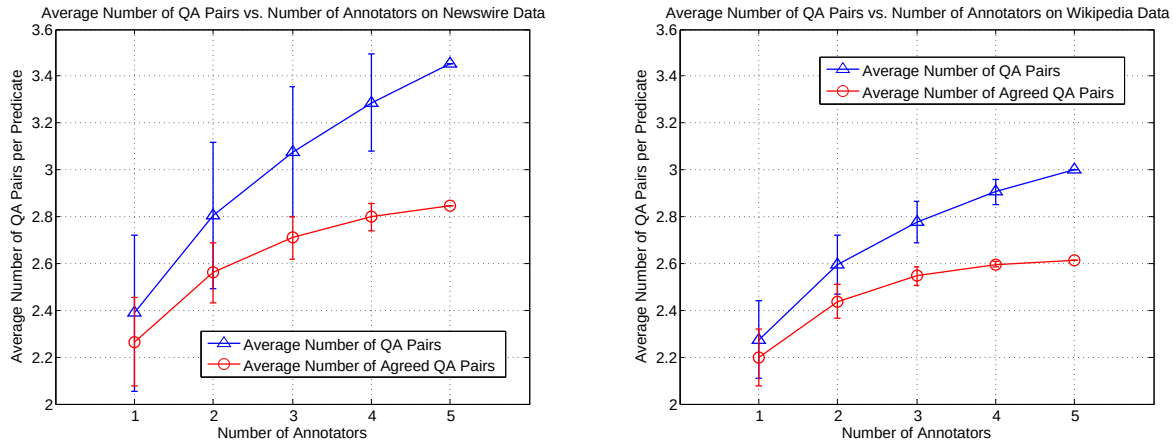

Figure 2: Inter-annotator agreement measured on 100 newswire sentences and 108 Wikipedia sentences, comparing the total number of annotators to the number of unique QA pairs produced and the number of agreed pairs. A pair is considered agreed if two or more annotators produced it.

Table 6: Co-occurrence of wh-words in QA-SRL annoations and role labels in PropBank.

Bank agents (A0), and *where* and *when* questions correspond to PropBank temporal and locative roles, respectively. Some types of questions are divided much more evenly among PropBank roles, such as *How much*. These cases show how our questions can produce a more easily interpretable annotation than PropBank labels, which are predicate-specific and can be difficult to understand without reference to the frame files.

Together, these results suggest that non-experts can annotate much of the information contained in PropBank, and produce a more easily interpretable annotation.

3.5 Inter-Annotator Agreement

To judge the reliability of the data, we measured agreement on a portion of the data (100 sentences in the newswire domain and 108 sentences in the Wikipedia domain) annotated by five annotators.

Measuring agreement is complicated by the fact that the same question can be asked in multiple ways—for example *"Who resigned?"* and *"Who resigned from something?"*—and annotators may choose different, although usually highly overlapping, answer spans. We consider two QA pairs to be equivalent if (1) they have the same wh-word and (2) they have overlapping answer spans. In this analysis, *Who* and *What* are considered to be the same wh-word.

Figure 2 shows how the number of different QA pairs (both overall and agreed) increases with number of annotations. A QA pair is considered to be agreed upon if it is proposed by at least two of the five annotators. After five annotators, the number of agreed QA pairs starts to asymptote. A single annotator finds roughly 80% of the agreed QA pairs that are found by five annotators, suggesting that high recall can be achieved with a single stage of annotation. To further improve precision, future work should explore a second stage of annotation where annotators check each other's work, for example by answering each other's questions.

4 Question Generation

Given a sentence s and a target verb v, we want to automatically generate a set of questions containing v that are answerable with phrases from s. This task is important because generating answerable questions requires understanding the predicate-argument structure of the sentence. In

essence, questions play the part of semantic roles in our approach.[6]

We present a baseline that breaks down question generation into two steps: (1) we first use a classifier to predict a set of roles for verb v that are likely present in the sentence, from a small, heuristically defined set of possibilities and then (2) generate one question for each predicted role, using templates extracted from the training set.

Mapping Question Fields to Semantic Roles To generate questions, we first have to decide the primary role we want to target; each question's answer is associated with a specific semantic role. For example, given the sentence *UCD finished the 2006 championship* and target verb *finished*, we could ask either: (Q1) *Who finished something?* or (Q2) *What did someone finish?*. Q1 targets the role associated with the person doing the finishing, while Q2 focuses on the thing being finished. To generate high quality questions, it is also often necessary to refer to roles other than the primary role, with pronouns. For example, Q2 uses "someone" to refer to the finisher.

Although it is difficult to know a priori the ideal set of possible roles, our baseline uses a simple discrete set, and introduces heuristics for identifying the roles a question refers to. The roles $\mathcal{R}$ include:

$$\begin{aligned}\mathcal{R} =& \{\text{R0}, \text{R1}, \text{R2}, \text{R2}[p], w, w[p]\}\\ w \in& \{\textbf{Where}, \textbf{When}, \textbf{Why}, \textbf{How}, \textbf{HowMuch}\}\\ p \in& \text{Prepositions}\end{aligned}$$

We then normalize the annotated questions by mapping its fields **WH**, **SBJ**, **OBJ1** and **OBJ2** to the roles $r \in \mathcal{R}$, using a small set of rules listed in Table 7. In our example, the **WH** field of the Q1 (*Who*) and the **SBJ** of Q2 (*someone*) are both mapped to role R0. The **WH** of Q2 (*What*) and the **OBJ1** of Q1 (*something*) are mapped to role R1. Some roles can be subclassed with prepositions. For example, the **WH** field of the question *What did something rise from?* is mapped to R2[from].

In most cases, R0 is related to the A0/AGENT roles in PropBank/FrameNet, and R1/R2 are related to A1/PATIENT roles. Since our questions are defined in a templated space, we are able to do this mapping heuristically with reasonable accuracy. In the future, we might try to induce the set of possible roles given each target verb, following the semantic role induction work of Titov and Klementiev (2012) and Lang and Lapata (2011), or use crowdsourcing to label proto-roles, following Reisinger et al. (2015).

[6]The task also has applications to semi-automatic annotation of sentences with our scheme, if we could generate questions with high enough recall and only require annotators to provide all the answers. We leave this important direction to future work.

$wh \in$ {Who, What} $\wedge$ voice = active		
WH $\rightarrow$ R0	WH $\rightarrow$ R1	WH $\rightarrow$ R2[p]
SBJ $= \phi$	SBJ $\rightarrow$ R0	SBJ $\rightarrow$ R0
OBJ1 $\rightarrow$ R1	OBJ1 $= \phi$	OBJ1 $\rightarrow$ R1
OBJ2 $\rightarrow$ R2[p]	OBJ2 $\rightarrow$ R2[p]	OBJ2 $= \phi$
$wh \in$ {Who, What} $\wedge$ voice = passive		
WH $\rightarrow$ R1	WH $\rightarrow$ R2	
SBJ $= \phi$	SBJ $\rightarrow$ R1	
OBJ1 $\rightarrow$ R2	OBJ1 $= \phi$	
OBJ2 $\rightarrow$ R2[p]	OBJ2 $\rightarrow$ R2[p]	
$wh \in$ {When, Where, Why, How, HowMuch} $\wedge$ voice = active		
WH $\rightarrow wh[p]$	WH $\rightarrow wh$	
SBJ $\rightarrow$ R0	SBJ $\rightarrow$ R0	
OBJ1 $\rightarrow$ R1	OBJ1 $\rightarrow$ R1	
OBJ2 $= \phi$	OBJ2 $\rightarrow$ R2[p]	
$wh \in$ {When, Where, Why, How, HowMuch} $\wedge$ voice = passive		
WH $\rightarrow wh[p]$	WH $\rightarrow wh$	
SBJ $\rightarrow$ R1	SBJ $\rightarrow$ R1	
OBJ1 $\rightarrow$ R2	OBJ1 $\rightarrow$ R2	
OBJ2 $= \phi$	OBJ2 $\rightarrow$ R2[p]	

Table 7: Mapping question fields to roles in $\mathcal{R}$. The mapping is based on whether certain question fields are empty and the voice of the verb in the question (active or passive). ϕ indicates that a field is either an empty string or equals "do/doing". If a question is in passive voice and contains the preposition "by", then **OBJ2** is tagged with R0 instead, as in *What is built by someone?*

Predicting Question Roles Given this space of possible roles, our first step in generation is to determine which roles are present in a sentence, and select the pronouns that could be used to refer to them in the resulting questions. We formulate this task as a supervised multi-label learning problem. We define the set of possible labels $\mathcal{L}$ by combining the roles in $\mathcal{R}$ with different pronoun values:

$$\begin{aligned}\mathcal{L} =& \{role{:}val \mid role \in \mathcal{R}\}\\ val \in& \{\phi, \text{someone}, \text{something}, \text{do something},\\ & \text{doing something}\}\end{aligned}$$

For example, to support the generation of the questions *Who finished something?* and *What did someone finish?*, we need to first predict the labels R0:someone and R1:something. Adjunct roles, such as *When* and *How*, always take an empty pronoun value.

Question	Abstract Question				
	WH	SBJ	Voice	OBJ1	OBJ2
Who finished something?	R0	/	active	R1	/
What did someone finish?	R1	R0	active	/	/

Table 8: Example surface realization templates from abstract questions.

For each sentence s and verb v, the set of positive training samples corresponds to the set of labels in the annotated questions, and the negative samples are all the other labels in $\mathcal{L}_{train}$, the subset of labels appeared in training data.[7] We train a binary classifier for every label in $\mathcal{L}_{train}$ using L2-regularized logistic regression by Liblinear (Fan et al., 2008), with hyper-parameter $C = 0.1$. Features of the binary classifiers are listed in Table 10. For each sentence s and verb v in the test data, we take the k highest-scoring labels, and generate questions from these.

Question Generation After predicting the set of labels for a verb, we generate a question to query each role. First, we define the concept of an *abstract question*, which provides a template that specifies the role to be queried, other roles to include in the question, and the voice of the verb. Abstract questions can be read directly from our training data.

We can map an abstract question to a surface realization by substituting the slots with the pronoun values of the predicted labels. Table 8 shows the abstract questions we could use to query roles R0 and R1; and the generated questions, based on the set of predicted labels $\{\text{R0:someone}, \text{R1:something}\}$.

Therefore, to generate a question to query a role $r \in \mathcal{R}$, we simply return the most frequent abstract question that occurred in training data that matches the role being queried, and the set of other predicted labels.

Experiments Native English speakers manually evaluated 500 automatically generated questions (5 questions per verb). Annotators judged whether the questions were grammatical [8] and answerable from the sentence.

We evaluated the top k questions produced by our baseline technique. The results in Table 9 show that our system is able to produce questions which are both grammatical and answerable. The average number of QA pairs per verb collected by human annotator is roughly 2.5, demonstrating significant room for improving these results.

[7] We pruned the negative samples that contain prepositions that are not in the sentence or in the set of frequently-used prepositions (by, to, for, with, about).

[8] Some automatically generated questions are ungrammatical because of label prediction errors, such as *Who sneezed someone?*, where the label R1:someone shouldn't be predicted.

5 Answer Identification

The goal of the answer identification task is to predict an answer a given sentence s, target verb v and a question q. Our annotated answers can be a series of spans, so the space of all possible answers is $2^{|s|}$. To simplify the problem, we transform our span-based answer annotation to answer head words, thus reducing the answer space to $|s|$. We model whether a word is the head of an answer as a binary classification problem.

Each training sample is a tuple $\langle s, v, q, a, \pm 1 \rangle$. The answer head a is extracted from the k-best dependency parses and the annotated answer span. Given a dependency tree, if any word in the annotated answer span has a parent coming from outside the span, then it is considered an answer head. Therefore, a gold question-answer pair can be transformed into multiple positive training samples. The negative samples come from all the words in the sentence that are not an answer head. For learning, we train a binary classifier for every word in the sentence (except for the verb v).

Experiments We use L2-regularized logistic regression by Liblinear (Fan et al., 2008) for binary classification. Features are listed in Table 10.

The performance of our answer identification approach is measured by accuracy. For evaluation, given each test sentence s, verb v and question q, we output the word with highest predicted score using the binary classifier. If the predicted word is contained inside the annotated answer span, it is considered a correct prediction. We also use the

Feature Class	Question Generation	Answer Identification
Predicate	Token, Predicted POS-tag, Lemma extracted from Wiktionary	
	Dependency parent and edge label, dependency children and edge label	
Question	Question role label, Wh-word, Preposition	
Answer Word	/	Syntactic parent and edge label, Left/Right-most syntactic children,
Predicate-Answer	/	Relative position (left or right), Syntactic relation, Syntactic path

Table 10: Indicator features that are included in our role classifiers for question generation (Section 4) and the answer identification classifier (Section 5). Many come from previous work in SRL (Johansson and Nugues, 2008; Xue and Palmer, 2004). To mitigate syntactic errors, we used 10-best dependency parses from the Stanford parser (Klein and Manning, 2003).

	Newswire	Wikipedia
Classifier	78.7	82.3
Random	26.3	26.9

baseline method that predicts a random syntactic child from the 1-best parse for each question.

In each of the two domains, we train the binary classifiers on the training set of that domain (See Table 4 for dataset size). Table 11 shows experiment results for answer identification. Our classifier-based method outputs a correct answer head for 80% of the test questions, establishing a useful baseline for future work on this task.

6 Discussion and Future Work

We introduced the task of QA-SRL, where question-answer pairs are used to specify predicate-argument structure. We also presented a scalable annotation approach with high coverage, as compared to existing SRL resources, and introduced baselines for two core QA-SRL subtasks: question generation and answering.

Our annotation scheme has a number of advantages. It is low cost, easily interpretable, and can be performed with very little training and no linguistic expertise. These advantages come, in large part, from the relatively open nature of the QA-SRL task, which does not depend on any linguistic theory of meaning or make use of any frame or role ontologies. We are simply using natural language to annotate natural language.

Although we studied verbal predicate-argument structure, there are significant opportunities for future work to investigate annotating nominal and adjectival predicates. We have also made few language-specific assumptions, and believe the annotation can be generalized to other languages—a major advantage over alternative annotation schemes that require new lexicons to be created for each language.

The biggest challenge in annotating sentences with our scheme is choosing the questions. We introduced a method for generating candidate questions automatically, which has the potential to enable very large-scale annotation by only asking the annotators to provide answers. This will only be possible if performance can be improved to the point where we achieve high recall question with acceptable levels of precision.

Finally, future work will also explore applications of our annotation. Most obviously, the annotation can be used for training question-answering systems, as it directly encodes question-answer pairs. More ambitiously, the annotation has the potential to be used for training parsers. A joint syntactic and semantic parser, such as that of Lewis et al. (2015), could be trained directly on the annotations to improve both the syntactic and semantic models, for example in domain transfer settings. Alternatively, the annotation could be used for active learning: we envisage a scheme where parsers, when faced with ambiguous attachment decisions, can generate a human-readable question whose answer will resolve the attachment.

Abstract

Target entity disambiguation (TED), the task of identifying target entities of the same domain, has been recognized as a critical step in various important applications. In this paper, we propose a graph-based model called TremenRank to collectively identify target entities in short texts given a name list only. TremenRank propagates trust within the graph, allowing for an arbitrary number of target entities and texts using inverted index technology. Furthermore, we design a multi-layer directed graph to assign different trust levels to short texts for better performance. The experimental results demonstrate that our model outperforms state-of-the-art methods with an average gain of 24.8% in accuracy and 15.2% in the F1-measure on three datasets in different domains.

1 Introduction

Currently, a growing number of people prefer to express their views and comments online. These messages, which are updated at the rate of millions per day, become a potentially rich source of information. From such a large number of texts, entity disambiguation is a critical step when extracting text information from these messages, and for various applications, such as natural language processing and knowledge acquisition (Dredze et al., 2010). Take the application of customer feedback analysis (CFA) as an example. An enterprise is typically interested in public reviews of its own products as well as those of its competitors'; the identification of these entities is thus critical for further analysis.

The product names comprise a list of entities to be identified. We refer to these entities of the same domain as **target entities**, and the identification process is called **target entity disambiguation** (Wang et al., 2012). All of target entities (e.g., *car brands*) share a common domain, which we refer to as the **target domain**. The target domain is the only constraint to target entities, which implies that the entities are in a specific domain, rather than being general things. In the case of entity recognition from short texts, the disambiguation can be performed on the document level. Given a collection of short documents, our goal is to determine which documents contain the target entities.

Challenge and Related Work

In contrast to traditional entity disambiguation tasks, TED in short texts can require as little information as a name list. There are three types of information that are utilized in Named Entity Disambiguation related tasks: knowledge resources, the context in which a target word occurs and statistical information (Navigli, 2009). However, the lack of the first two types of information makes this problem more challenging.

Knowledge Sparsity A large number of methods focus on using knowledge bases (KBs) like Wikipedia or YAGO to enrich the named entities (e.g., *in-links and out-links*) (Hoffart et al., 2011; Bunescu and Pasca, 2006; Milne and Witten, 2008; Kulkarni et al., 2009; Han et al., 2011; Mihalcea and Csomai, 2007; Shen et al., 2012). These methods compared the context of the entities and their reference pages in the KBs through a similarity measurement. However, we tested 32 different names of General Motors (GM) car brands, and only four of the brands exist in Wikipedia. This circumstance is not unusual. For another larger dataset that included 2468 stock names, we found only 340 of them had their reference pages in Wikipedia. Thus, the methods that rely heavily on KBs might not be appropriate here.

Shortness of the Texts The context in which a

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 654–664,
Lisbon, Portugal, 17-21 September 2015.

target entity occurs plays an important role in disambiguation. (Cassidy et al., 2012; Li et al., 2013) applied the underlying topical coherence information to a set of mentions for entity linking. In (Wang et al., 2012), mentionRank leverages some additional features, such as co-mention; however, people prefer to share their comments in brief or even informal words on social media platforms, such as Twitter, which becomes increasingly important as an information source. We have counted 350,498 microblogs, 37,379 tweets and 34,018 text snippets in various domains in Chinese and English from Twitter, Sina Weibo and Google. After preprocessing, their average length are 16, 5 and 11 words, respectively. To alleviate the shortness issue, additional information has been used to expand the context, such as the user's interest (Shen et al., 2013) and related documents (Guo et al., 2013). Such information is still sparse or unavailable in this case, and thus, the existing methods might not be suitable.

Large Scale Hundreds of millions of tweets are posted daily on Twitter (Liu et al., 2013). When scaling to a large document collection, the disambiguation task becomes increasingly important as the ambiguity increases (Cucerzan, 2007). MentionRank, the only state-of-the-art method for TED, is a graph-based model that focuses on a small set of entities (e.g., 50 or 100 entities) and conducts experiments on thousands of documents (Wang et al., 2012). However, the graph has a quadratic growth as the number of documents increases. In our experiments, a dataset that included 2,468 target entities and 350,498 microblogs generated a directed graph with billions of edges, which required more computer memory than was available even when using a sparse matrix. Therefore, the scalability remains a challenge.

Contributions

To address these challenges, we propose a collective method called TremenRank to disambiguate the target entities simultaneously. The main idea is to propagate trust within a graph based on our observations that true mentions are more similar in context than false mentions in a specific domain. Specifically, inverted indexes is used to construct the graph locally that allows for an arbitrary number of target entities and documents. Furthermore, a multi-layer directed graph is designed to assign different trust levels to documents, which significantly improves the performance. The contributions of our work can be summarized as follows:

- We propose a novel graph-based method, TremenRank, to collectively identify target entities in short texts. This method constructs the graph locally to avoid storing the entire graph in memory, which provides a linear scale up with respect to the number of target entities and documents.
- We design a multi-layer directed (MLD) graph for modeling short texts that possess different trust levels during propagation, which significantly improves the performance.
- We conduct a series of experiments on three practical datasets from different domains. The experimental results demonstrate that TremenRank has a similar performance to the state-of-the-art when addressing the TED problem at a large scale, and the use of MLD graph significantly improves our method.

2 Problem Definition

Example *Suppose that GM wants to collect tweets that talk about its cars. As shown in Figure 1, we take (i) a list of car brands (target entities), and (ii) a collection of tweets (i.e., short texts) as inputs. "Car" is the target domain, and "Sonic" appears in documents d_1 and d_2, which can be characterized as two* ***mentions*** *and the latter is a* ***true mention****. The goal is to find as many true mentions as possible.*

Our method models the collection of documents as a directed graph and outputs a trust score for each document via propagation. The trust score indicates the likelihood of a document containing a true mention. For flexibility, the trust scores lie within the range of 0 to 1 and are globally comparable; thus, we can obtain the top-k documents or choose an appropriate cut-off value to balance the precision and recall for different application requirements. For example, in the application of CFA, a company expects a higher *recall* to achieve a comprehensive understanding of its product, whereas a recommendation system must provide as many *precise* microblogs as possible.

Formally, the problem of TED in short texts is defined as follows:

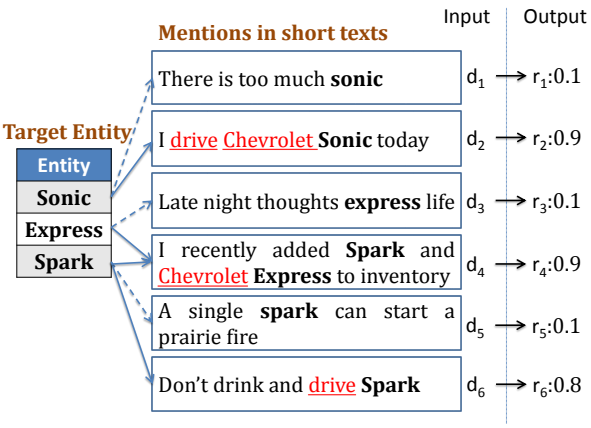

Figure 1: Illustration of TED. True mentions are shown as solid arrows, and the underlined words are their overlapping context.

Target Entity Disambiguation in Short Texts Given a list of target entities $E = \{e_i|i = 1, \ldots, m\}$, and a collection of text documents $D = \{d_j|j = 1, \ldots, n\}$, $E^{d_j} = \{e_1^j, \ldots, e_k^j\}$ is the set of target entities contained in d_j. The goal is to output the trust score $r_j \in [0, 1]$ for each document $d_j \in D$. All the target entities in E^{d_j} share the same trust score r_j.

All of the mentions in one document have the same score because they share a common context. In the graph, the context similarity between documents is computed and used as the edges normally, where the width of the context window that surround the target entity in the document is typically chosen to be 10, 20 or 50 words. However, the documents considered here are limited in length, and a user seldom changes the topic in so few words; thus, we regard the entire document as the context of its target entities. When multiple target entities occur in one document, all of them are more likely to refer to the entities in the target domain. Thus, the trust score for the document is higher, as indicated by d_4 (Figure 1).

The only constraint for the target entities is that they are in the same target domain. This constraint is reasonable in practice. The majority of applications identify a set of entities in one domain at a time. For example, a computer company focuses its attentions on the brands in the computer area, whereas an investment company is mainly interested in stocks. Additionally, even if the target domain is general and contains several small domains, an intuitive solution is to split it into several subproblems, where each subproblem focuses on the target entities in one small domain. Then, the task can be achieved by solving the subproblems individually.

3 Our Approach

TremenRank is a graph-based method that identifies target entities collectively. It propagates trust scores on the graph where each vertex denotes one document and an edge indicates the similarity between them. Considering the large scale of the problem, we obtain the neighbors of one vertex when propagating by searching two indexes instead of storing the entire graph in memory. This approach allows an arbitrary number of target entities and documents to be processed. To further improve the performance, a multi-layer directed graph is designed to treat the documents at different trust levels based on prior estimations.

3.1 Hypotheses

The documents within a domain share the characteristic of unitary similarity. This characteristic implies that all of the true mentions have a similar context due to the target domain constraint and that false mentions are distinct because their meanings belong to diversified domains. We investigated the ambiguity of 2468 stock names (target entities in experiments), and manually labeled 301 of those names. As shown in Figure 2, there are many different meanings for these names outside of the target domain, such as plant, bank, media and animal. The distribution of meanings are long-tailed; thus, we gathered a group of meanings together (the class "others").

Based on the statistical results, we can make the following hypotheses:

- The context of true mentions are similar to one another.
- The context of a false mention is different from any of the true mention.
- False mentions have distinct contexts across different entities.

For example, the true mentions in d_2, d_4 and d_6 (Figure 1) describe car brands of GM and share common pieces of text: "drive" or "Chevrolet". However, "sonic", "express" and "spark" in d_1, d_3 and d_5 are all false mentions; in their contexts, they refer to sound, giving opinions, and a small amount of fire, respectively. These false mentions are different in context from one another and from any true mention.

The assumptions resemble the main insight of MentionRank except the co-mention (multiple entities occur in one document). Co-mention seldom happens in short texts, and can be treated as the same because they share a common context. In conclusion, the assumptions suggest that a collective method could perform better than a method that disambiguates entities separately, because more comprehensive information on the entities from multiple "collaborators" (i.e., the mentions have similar contexts) has been used (Chen and Ji, 2011; Kulkarni et al., 2009; Pennacchiotti and Pantel, 2009; Will et al., 2010; Fernandez et al., 2010; Cucerzan, 2011; Guo et al., 2011; Han and Sun, 2011; Ratinov et al., 2011; Kozareva et al., 2011; Dalton and Dietz, 2013).

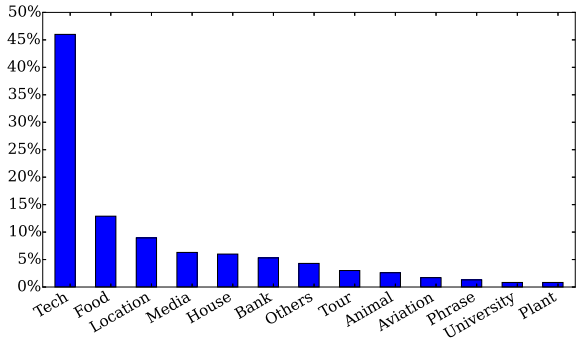

Figure 2: Statistics on the ambiguity in stocks.

3.2 Graph-based Method

Based on these assumptions, we build a graph to represent the documents and their relations, and we perform a TrustRank-like algorithm on the graph. We are given a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ that consists of a set $\mathcal{V}$ of N documents (vertices) and a set $\mathcal{E}$ of directed edges, where each edge $(d_i, d_j) \in \mathcal{E}$ denotes that d_i points to d_j, and $o(d_i)$ is the out-neighbors of d_i.

3.2.1 Similarity Measurement

We constructed the edges of the graph according to the similarity relations between documents. Most similarity measurements (Artiles et al., 2010; Miller, 1995) could be used in the proposed method. After some exploration, we found that Jaccard similarity performs better. It can be efficiently calculated through simple set operations:

$$\omega_{ij}^J = J(d_i, d_j) = \frac{\left|\mathcal{W}^{d_i} \bigcap \mathcal{W}^{d_j}\right|}{\left|\mathcal{W}^{d_i} \bigcup \mathcal{W}^{d_j}\right|} \quad (1)$$

where ω_{ij}^J denotes the weight of edge (d_i, d_j) using Jaccard similarity, and $\mathcal{W}^{d_i}$ is the set of words contained in d_i. ω_{ij} varies from 0 to 1, where a value closer to 1 indicates that its two nodes are more similar. We link only similar nodes by choosing an appropriate threshold η. In other words, we have $(d_i, d_j) \in \mathcal{E}$, only if $\omega_{ij}^J > \eta$. This is the foundation to construct the graph locally using inverted indexes.

3.2.2 Inverted Index

When the scale becomes excessively large, such as the 350,000 pieces in our dataset, the number of edges will increase into the billions, producing computational and storage-based difficulties. Considering that the propagation begins with document d_i and that we are required to find all of its out-neighbors $o(d_i)$ through a traversal of the entire dataset, then the complexity is $O(n^2)$. Alternatively, we can represent the entire graph with a matrix; however, its billions of elements would be difficult to store and calculate.

To address the large scale problem, we construct the graph locally via inverted index technology. During propagation, the neighbors of the documents are obtained by searching the indexes in real time. Two types of indexes are used: the document-to-word index and the word-to-document index. The former index records $\mathcal{W}^{d_i}$ of each document $d_i \in D$; the latter index records the occurrence of each word $\mathcal{D}^{w_k} = \{d_j | w_k \in W\}$, where $W = \{w_1, \ldots, w_N\}$ is the word dictionary. Combining these two indexes, the total out-neighbors of a document can be obtained in constant time as follows:

1. Obtain all of the words $\mathcal{W}^{d_i}$ of d_i via searching the document-to-word index.
2. Find the occurrences of each word $w_k \in \mathcal{W}^{d_i}$ in the word-to-document index: $D^{d_i} = \{d_j | \cup_{w_t \in \mathcal{W}^{d_i}} \mathcal{D}^{w_t}\}$. Each document $d_j \in D^{d_i}$ shares at least one common word with d_i.
3. Count the frequency of d_j, which indicates the number of overlapping words between d_i and d_j. Then, the frequency $f_{ij} = |\mathcal{W}^{d_i} \cap \mathcal{W}^{d_j}|, i \neq j$ and Equation 1 becomes:

$$\omega_{ij}^{J} = \frac{f_{ij}}{|\mathcal{W}^{d_i}| + |\mathcal{W}^{d_j}| - f_{ij}} \quad (2)$$

4. Calculate the similarity weight. We obtain the out-neighbors $o(d_i) = \{d_j | \omega_{ij}^{J} \geq \eta\}$.

3.2.3 Trust Propagation

Similar to TrustRank, an individual document propagates the trust score to its neighbors and those who have more neighbors will receive more trust. Intuitively, trust attenuates along the edge. There are several ways for attenuation to take place, such as trust dampening, trust splitting, and a combination of them (Gyöngyi et al., 2004). For example, each document $d_i \in D$ has a trust score r_i, and its out-neighbors obtain $\alpha \cdot r_i$ (or $\frac{r_i}{|o(d_i)|}$) through trust dampening (or splitting). We adopt the third method, in which a document dampens its split trust with the attenuation coefficient α.

The final trust score is determined by two parts: the trust from a document's neighbors and its prior estimation. Then, TremenRank can iteratively propagate via the following function:

$$r_i = \alpha \cdot \sum_{o(d_i)} \frac{r_j}{|o(d_j)|} + (1 - \alpha) \cdot \mathcal{T}(d_i) \quad (3)$$

where $\mathcal{T}(d_i)$ is the prior estimation of the document d_i and is a constant during iterative propagation. Here we simply assign a uniform distribution to all of the documents $\mathcal{T}(d_i) = \frac{1}{|D|}$. A more precise estimation will be discussed later.

At the beginning of the propagation, we initialize the trust scores of the documents with the prior estimation. Then, the trust scores of the documents are updated iteratively until convergence[1]. True mentions receive high scores because they are likely to connect with more trustworthy documents and thus receive more trust through the first term in Equation 3. In contrast, false mentions are dissimilar to most other documents; thus, their scores gradually attenuate (the second term in Equation 3). These scores are globally comparable. One can normalize the final scores by dividing them by the largest score, but the relative ordering of the documents will not change. Thus, one document that is more likely to contain any true mention will receive a higher trust score and be ranked higher.

3.3 Multi-layer Directed Graph

During propagation, all of the documents are initialized with the same trust score and attenuate their trust at the same level. However, different documents should be treated differently. For example, the tweet "*I drive a big car* ***suburban***" is more trustworthy than "*doctors use* ***GMC*** *report system to process harmful patients*", because the former tweet contains the credible context feature "car", which is the name of the target domain. The latter clearly irrelevant text should not be trusted or even be regarded as noise. In this subsection, we first discuss how to make more precise prior estimation of documents based on some of the characteristics of the target domain. Additionally, based on the prior estimation, an MLD graph is built to assign different trust levels to the documents.

3.3.1 Prior Estimation

Ideally, a true mention is similar to true mentions only. To take advantage of the approximate isolation of true mentions, we first extract a set of true mentions to start the propagation. The documents that contain these true mentions are called seeds.

Formally, the entire set of documents D is divided into two groups: (i) the seed set $D^s = \{d_1, \ldots, d_s\}$, and (ii) a subset $D^* = \{d_{s+1}, \ldots, d_n\}$. We estimate a prior trust score for each document via the function $\mathcal{T}$:

$$\mathcal{T}(d_i) = \begin{cases} \frac{1-\epsilon}{|D^*|} & d_i \in D^*, \\ \frac{\epsilon}{|D^s|} & d_i \in D^s. \end{cases} \quad (4)$$

where $|D^s|$ and $|D^*|$ represent the size of the two sets for normalization. $\epsilon \in (0, 1]$ is used for smoothing and indicates the likelihood that we can trust the seeds that actually contain true mentions. In the experiments, we set $\epsilon = 0.9$ based on the accuracy of the seeds extraction method.

There are several methods for extracting seeds, such as manual annotation and pattern-based method. Patterns could be easily derived from the characteristics of the target domain, such as the domain name, product type or unique ID[2]. These methods can typically identify entities with a high accuracy, but their low recall limits the portion of

[1] We select the attenuation coefficient $\alpha = 0.85$ and the number of iterations to be 20, which have been regarded as the standards in the PageRank literature(Page et al., 1999; Krishnan and Raj, 2006). Our experiments also show that 20 iterations are sufficient to achieve convergence.

[2] The exact patterns used in our datasets are detailed in Section 4

true mentions that can be found. We use the results of the pattern-based method as our seeds, which have an accuracy higher than 90%. We do not present the experimental results here due to space limitations.

3.3.2 Graph Construction

The similarity measurement does not consider directions, and thus, the documents are mutually connected. In this section, we construct a layered structure in the graph, where each layer denotes a document trust level that contains any true mention. Thus, we define that the propagation direction from the high trust level to the low trust level.

Figure 3 shows an example of an MLD graph. The blue nodes of the seeds in the top layer are the most trustworthy, and the other white nodes in the higher layer are less similar to the seeds which implies that they are at lower trust levels. Thus, as we move farther away from the seeds, trust attenuates at a constant speed α along with the layers. The nodes in the same layer are also connected.

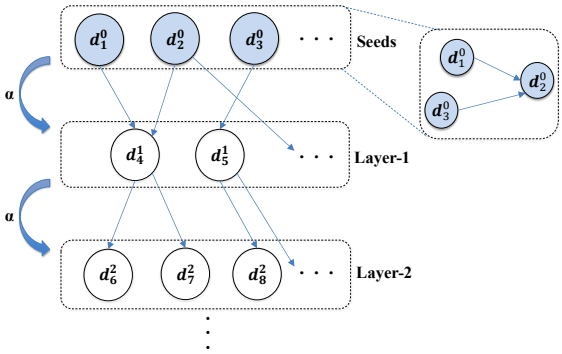

Figure 3: Example of an MLD graph.

The construction algorithm[3] is presented in Algorithm 1, where $D^l = \{d_i^l | l \geq 0\}$ is the set of nodes in layer l, and the nodes in $\bar{D} = \{\bar{d}_j | \bar{d}_j \notin D^l, l \geq 0\}$ are not connected. To simplify our notation, the seeds are set to be in layer 0. Note that $(\cap_{l \geq 0} D^l) \cap \bar{D} = D$.

TremenRank is different from the standard TrustRank and MentionRank in several respects. First, TremenRank is designed to process short texts at a large scale. Second, through a well-designed MLD graph, we consider documents to consist of different trust levels rather than be represented by a unified distribution. Third, TrustRank randomly samples a set of seeds and checks them manually, which limits the number of seeds available; however, the proposed method extracts the seeds automatically and uses large amounts of seeds to produce better prior estimations. Finally, disambiguation occurs at the document level in the proposed method; we assign the same scores to the entities that occur in one document, because they typically share common context features in short texts.

Algorithm 1: Construction of an MLD graph.

Input: D^s, D^*, η, indexes $\mathcal{W}^D, \mathcal{D}^W$
Output: $\mathcal{G}$
Initialize seeds in layer $l = 0$, $\bar{D} = D^*$;
foreach *layer* $l \geq 0$ **do**
  Find the out-neighbors of D^l from $\bar{D}$;
  foreach *document* $d_i^l \in D^l$ **do**
    put $o(d_i^l)$ in the next layer D^{l+1};
    update $\bar{D} = \bar{D} - D^{l+1}$;
  end
  if $|\bar{D}| = 0$ *or* $|D^{l+1}| = 0$ **then**
    break;
  else
    $l = l + 1$;
  end
end

4 Empirical Evaluation

4.1 Data Preparation

Because there is no publicly available benchmark dataset for TED, we constructed three datasets of different domains: Stock, Car and Herb[4]. All of these datasets came from the needs of real-life projects.

1. **Stock** - We collected 2,468 stock names from a stock exchange website, and identified their candidate mentions by string matching from Sina Weibo (Counterpart of Twitter in China). Each stock has a unique ID, which has little ambiguity. Thus, we used this regular expression pattern to extract seeds.

2. **Car** - We collected 32 car brands of General Motors and a group of tweets that contain at least one mention of these brands via the Twitter API. In the seeds extraction step, we use the domain name "car" as the patterns.

[3] A key parameter for the structure of MLD Graph is η, which will be discussed in Section 4.2.

[4] All of the dataset related sources used in this study are listed at http://newsminer.org/TEDs.

3. **Herb** - We randomly selected 1,119 Chinese herb names and collected 40 pieces of text descriptions in the search results per entity from Google. To extract the seeds, we simply added the domain name to the key words (e.g., *"天虫(Worms)* 中草药*(Chinese Medical Herb)"*).

Table 1: Statistics on the datasets.

	E	D	#edges	Positive(%)
Stock	2,468	350,498	2.049B	43
Car	32	37,379	4.91M	7
Herb	1,119	34,018	9.66M	68

Table 1 shows some of the statistics of the datasets created. We chose these datasets because (i) the identification of entities in these domains meets the practical requirements of many applications, (ii) the target entities are ambiguous and (iii) there is little information in the existing KBs. Before applying TremenRank, we preprocessed the plain texts through word segmentation, low frequency words filtering and stop words filtering.

4.2 Experiment

Baseline Methods TED in short texts is a relatively new problem, and there are few specific methods for solving it. To validate the performance of TremenRank and the improvement produced by the MLD graph, we selected the baseline from three different perspectives: (i) a context-based method that identifies target entities separately; (ii) a classic supervised method SVM to classify a document by whether it contains any true mentions; and (iii) the only state-of-the-art MentionRank for TED, which is a collective ranking method.

- **The Context-based method** mines a frequent item set of true mentions and identifies the documents that contain more frequent items.

- **SVM** classifies the documents into two classes: documents that are in the target domain and those that are not. Using context words as features, we train and test SVM on the labeled set with a 10-fold cross validation.

- **MentionRank** is a graph-based method that disambiguates at the entity level. Difficult to apply to the entire large datasets directly, it has been applied to the labeled set.

Evaluation Metrics The performance of the disambiguation task is typically evaluated by *accuracy*, but in TEDs we are also interested in *precision*, *recall* and the *F1-measure* because different applications focus on different aspects. For example, in the application of CFA, a company expects a higher *recall* to collect as many reviews as possible, while in financial news recommendations, users prefer to read more *accurate* microblogs. Because the entire dataset is too large to evaluate directly, we randomly sampled 800 mentions for each dataset and labelled them manually to calculate the performance metrics[5].

Results and Analysis

The overall performances of TremenRank and those of the baseline methods on all of the datasets are shown in Table 2. The following is indicated in the results:

- TremenRank+MLD outperforms all of the baselines with all of the datasets, because it collectively identifies target entities and treats the documents differently based on a precise prior estimation.

- The collective methods tend to perform better. Although, on the Car dataset, SVM achieves the second best performance, the use of MLD graph in TremenRank outperforms all of the methods tested. This is because false mentions that occupy a large proportion of the dataset produce too much noise, whose negative impacts can be reduced through the train set in the supervised method or a precise prior estimations.

- Compared with MentionRank, TremenRank processes a larger number of entities and documents while achieving a similar performance. Combined with a MLD graph, TremenRank shows significant improvements including an average gain of 24.8% in accuracy and 15.2% in the F1-measure on the three datasets.

We also investigate the influence of the main elements in TremenRank below.

Similarity Threshold Different similarity thresholds result in various structures of the MLD graph, and have a great impact on the performance of our

[5] A detailed explanation about these metrics can be found in http://en.wikipedia.org/wiki/Precision_and_Recall.

Table 2: Overall results on the three datasets

Method	Stock				Car				Herb			
	Accu	Prec	Recall	F-score	Accu	Prec	Recall	F-score	Accu	Prec	Recall	F-score
Context	0.704	0.332	0.545	0.410	0.733	0.333	0.256	0.476	0.670	0.200	0.074	0.108
SVM	0.746	0.377	0.998	0.547	0.839	0.371	0.923	0.529	0.567	0.988	0.564	0.718
MentionRank	0.458	0.424	0.828	0.561	0.464	0.301	0.715	0.423	0.644	0.691	0.824	0.752
TremenRank	0.477	0.424	0.803	0.555	0.542	0.310	0.720	0.433	0.737	0.736	0.827	0.779
TremenRank+MLD	0.683	0.575	0.844	**0.684**	0.827	0.624	0.731	**0.673**	0.800	0.774	0.908	**0.836**

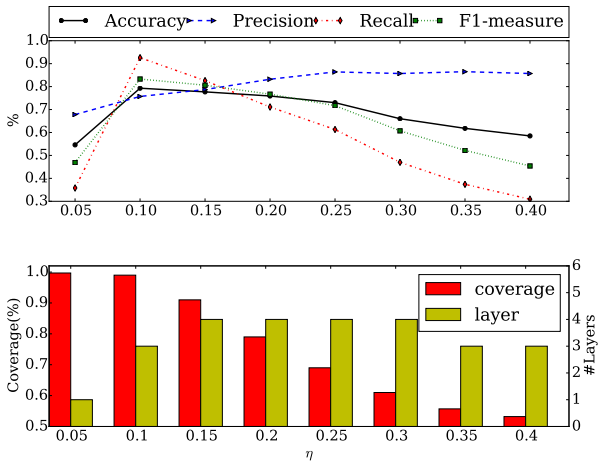

Figure 4: Selection of the Similarity Threshold

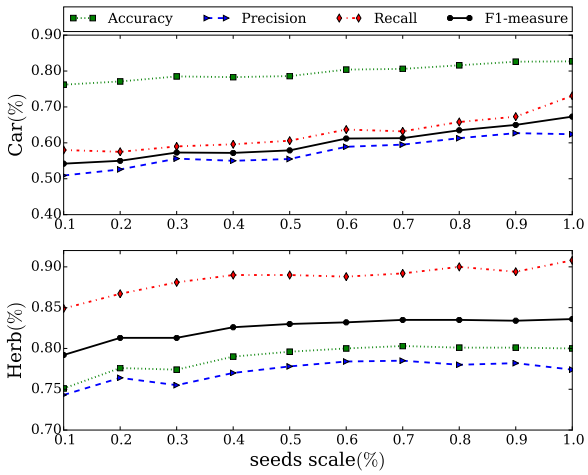

Figure 5: Influence of Seed Scale

method. In this subsection, we study a heuristical method that help choose the best eta according two factors (Both of them can be obtained before propagation). Figure 4 presents the experimental results for different values of η on the dataset of Herb. The performance of TremenRank is showed on the top, and the bottom is the corresponding graph structure represented by two factors: the graph coverage and the number of layers. We can see that precision increases until it becomes steady with the growth of η, and other measurements reach their peaks when $\eta = 0.1$.

This is in accordance with the change of the graph structure. On one hand, the number of layers l declines sharply when η is less than 0.1, this indicates little difference in the trust level of documents in the propagation. On the other hand, our method has no effect on the vertices outside of the graph, so the performance is directly proportional to the graph coverage rate. Therefore, a proper η should ensure a high coverage as well as adequate layers. In experiments, we choose η as 0.1, 0.15, 0.1 for the datasets of Stock, Car and Herb respectively.

Influence of the Seed Scale As the basis of the prior estimation, the seeds have significant influence on the performance of the proposed method via the MLD graph. Intuitively, a larger set of seeds should lead to a more precise estimation and thus better performance. In the experiments on the Car and Herb datasets, we split their seed set into ten parts, and add one part each time. As Figure 5 shows, when increasing the percentage of the seeds gradually, the performance has an overall upward trend (e.g., a 14.6% and 4.4% gain in the F1-measure for the Car and Herb datasets, respectively). This trend occurs because the potential context features of the seeds utilized for propagation increase as the absolute number of seed documents rises. For example, the tweet *"Cadillac Uber airport is classy"* obtains a low score of 0.013 with 50% of the seeds, whereas it is identified successfully with the score of 0.588 when all of the seeds are used for propagation because more context features are introduced, such as *"airport" and "Uber"*. Thus, the proposed method achieves better performance as the seed set grows. This arrangement is helpful for a company that seldom changes its business area and then accumulates seeds continuously to improve performance.

Robustness to Noise Because seeds play an important role in the MLD graph, we further test the

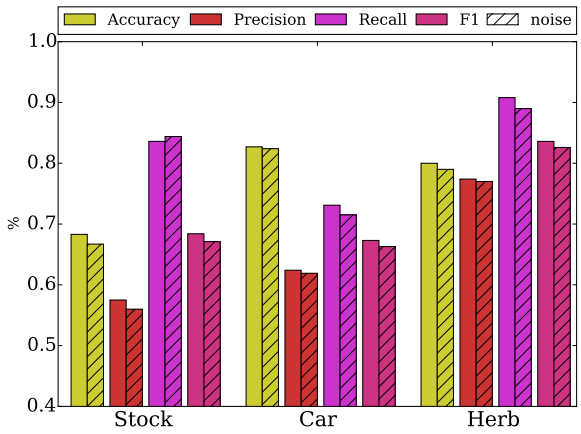

Figure 6: Robustness to Noise

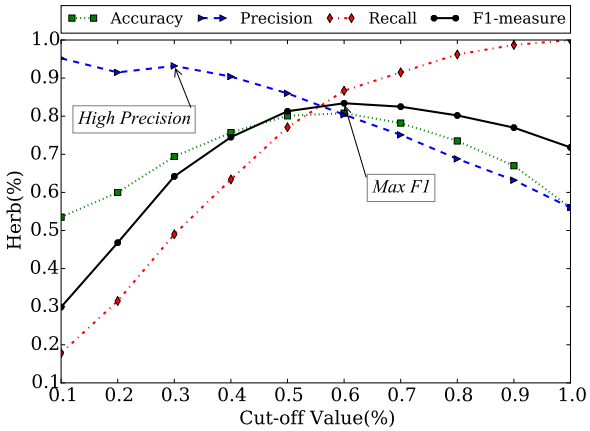

Figure 7: Cut-off Value

robustness of our method with respect to the quality of the seeds. We randomly sample documents outside of the seed set (considered as noise) to replace 20% of the seeds on all the datasets; these results are shown in Figure 6. The introduced noise only leads to a limited decrease in performance (average 1.3%, 1% and 1% in the F1), which is much better than when only using TremenRank (Table 2). More specifically, the experiments that use artificial noise occasionally achieve a higher recall (e.g., on the Stock dataset); this result could occur because the unknown true mentions add some useful edges to the graph, which is helpful when finding more true mentions of the target entities.

Cut-off Value According to the globally comparable trust scores, we can (i) rank all of the documents, and trade off the performance metrics by choosing an appropriate cut-off value γ for various applications, or (ii) rank the documents of an individual entity separately and obtain its top-k mentions.

In the experiments, we set γ as different percentage of the ranked documents. As Figure 7 shows, the recommendation system could use $\gamma = 30\%$ to achieve a 93.2% precision and a 64.2% recall, or a company could use $\gamma = 60\%$ for more reviews that have a relatively high precision.

Efficiency We implemented TremenRank in Java and ran it on a single PC with the Windows 8.1 64-bit operation system. With an Intel(R) Core(TM) i3-3240 (3.40GHz) CPU and 4GB memory, our program converges within 5 iterations, and only consumes approximately 700MB of memory when running steadily. The overall identification times of the Stock, Car and Herb datasets are 12h, 5min and 18min, respectively. The computation time increases exponentially with the increase of the amount of data due to the excessive computations required to search the indexes, which can be optimized in future work.

5 Conclusions and Future Work

In this paper, we addressed a new and increasingly important problem in social content analysis in a challenging scenario: disambiguation of a list of homogenous entities in short texts using names only. We proposed a graph-based method called TremenRank to identify target entities collectively; this method can also hold an arbitrary number of target entities and documents. The performance of this method can be further improved via a well-designed MLD graph. The experimental results show that the proposed method has a significant improvement compared to other approaches.

In the future, we are interested in refining the prior estimation by using the ontology and extending this work to detect the target entities that are not in a list while performing the disambiguation task.

Acknowledgments We'd like to acknowledge Lei Hou, Chi Wang and Hongzhao Huang for their impressive discussions on this paper. Abstract

Knowledge Base Population (KBP) tasks, such as slot filling, show the particular importance of entity-oriented automatic relevant document acquisition. Rich, diverse and reliable relevant documents satisfy the fundamental requirement that a KBP system explores the nature of an entity. Towards the bottleneck problem between comprehensiveness and definiteness of acquisition, we propose a collaborative archiving method. In particular we introduce topic modeling methodologies into entity biography profiling, so as to build a bridge between fuzzy and exact matching. On one side, we employ the topics in a small-scale high-quality relevant documents (i.e., exact matching results) to summarize the life slices of a target entity (i.e., biography), and on the other side, we use the biography as a reliable reference material to detect new truly relevant documents from a large-scale partially complete pseudo-feedback (i.e., fuzzy matching results). We leverage the archiving method to enhance slot filling systems. Experiments on KBP corpus show significant improvement over state-of-the-art.

1 Introduction

Entity archiving is an entity-oriented document retrieval task. Towards a target entity of a specific type, such as the ones discussed in this paper, a person or an organization, the goal of entity archiving is to search and collect all relevant documents from large-scale data sets under limited prior knowledge of the entity. We limit our study to the regular English entity archiving, in which the prior knowledge contains the commonly used full name (formatted by English entity naming criteria) along with a gold-standard reference document, such as a news story on President "*George W. Bush*".

Entity archiving plays a fundamental role in KBP tasks. It narrows down the range of the data source for knowledge discovery to small-scale closely related documents. Such documents, on one hand, contain informative content on a target entity, which is extremely favorable for background knowledge extraction. On the other hand, the documents provide definitive evidence for verifying the claimed identity of the entity.

As for KBP slot filling and verification tasks (Surdeanu and Ji, 2014), the archived relevant documents to an entity provide sufficient contexts (provenances) of the concrete instances (fillers) of the entity attributes (slots). See Figure 1, in which both the *provenances* support filler extraction, meanwhile the *provenance 1* additionally provides the evidence to verify the fillers (e.g., is *episcopalism* the true religion of *Bush*?).

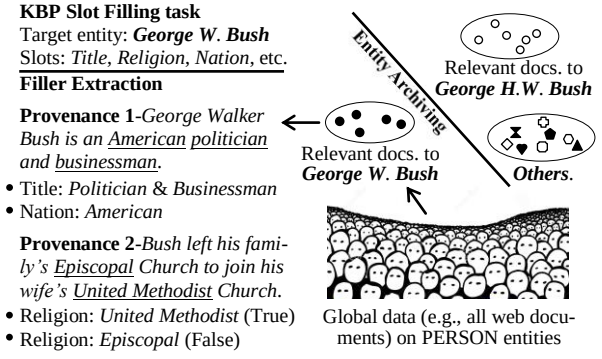

Figure 1**:** Use of entity archiving in slot filling

The main challenges of entity archiving are as

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 665–675,
Lisbon, Portugal, 17-21 September 2015.

follows: 1) it is difficult to retrieve all relevant documents through exact matching at the level of entity name, because an entity can be mentioned in various forms, such as alternate names and abbreviations; 2) in contrast, fuzzy matching introduces a large amount of noise into retrieval results (see the examples in Figure 1), although it is capable of recalling an overwhelming majority of relevant documents; 3) inadequate prior knowledge makes it difficult to generate a full profile of an entity; 4) although pseudo-feedback is helpful to enrich the prior knowledge, traditional entity profiling (e.g., bag-of-words) methods establish vague boundaries among different life slices of an entity. For example, they are incapable of distinguishing the slice of the "*Church Scientologist in Sea Organization*" of *Mark Fisher*[1] from the freelance career as the "*Corporate liaison to Miscavige*". As a result it is difficult to enhance the independent effects of different slices on the entity-document relevance determination.

To solve these problems, we propose a collaborative entity archiving (CEA) method. It employs the exact-matching based document retrieval to obtain a few high-quality reference documents, and leverages fuzzy matching for high-speed acquisition of adequate candidate documents (section 3). In addition, CEA uses the reference documents as prior knowledge to model the topic-level biography of an entity, and identifies the truly relevant documents from the candidates based on biography-document relevance (section 4). Experiments show that CEA has substantial advantages over traditional retrieval methods (section 5.1). We apply CEA to state-of-the-art slot filling systems. Experimental results show that CEA provides consistent gains (section 5.2).

2 Related Work

- **Entity Search**

One research topic similar to entity archiving is entity search. Entity search aims to seek, collect, and rank entities associated with specific information needs (Balog et al, 2011). The TREC Enterprise track featured an *expert finding* task (Balog et al, 2008a): given a topic, return a ranked list of experts on the topic. In response to this problem, there have been considerable efforts on content based retrieval models, as well as feature selection, such as proximity (Petkova and Croft, 2007), document priors (Hu et al, 2006; Zhu et al, 2010), expert-document associations (Balog and De-Rijke, 2008) and external evidence (Serdyukov and Hiemstra, 2008).

Since INEX was launched in 2002, which is an entity ranking task specific to structured data and multimedia (Demartini et al, 2010), structured features have been widely used in entity search, such as the most recent studies on Wikipedia links and categories (Vercoustre et al, 2008; Zhu et al, 2008; Jiang et al, 2009; Weerkamp et al, 2009; Kaptein and Kamps, 2009; Balog et al, 2011) and web link structure (Balog et al, 2008b; You et al, 2011; Blanco et al, 2011; Neumayer et al, 2012; Bron et al, 2013).

- **Slot Filling**

The goal of slot filling is to seek and extract the concrete instances (fillers) specific to multiple entity attributes (slots) from a large-scale textual data set (Ji et al., 2010 and 2011; Surdeanu, 2013; Surdeanu and Ji, 2014). The quality of the fillers largely depends on the performance of entity archiving and information extraction.

Related studies on archiving mainly employed traditional retrieval techniques, including query expansion and string matching (Ji and Grishman, 2011). A few studies involved document ranking and prioritizing by using probability model (Byrne and Dunnion, 2010; Roth et al, 2014) and statistical language model (Chrupala et al, 2010).

For filler extraction, great efforts were made to generate effective patterns and structure perceptrons by supervised learning and reasoning (Chen et al, 2010; Grishman and Min, 2010; Gao et al, 2010; Surdeanu et al, 2011; Louis et al, 2011; Kisiel et al, 2013). And effective feature selection and distant-supervision based classifiers have been explored (Lehmann et al, 2010; Artiles et al, 2011; Sun et al, 2011; Roth and Klakow, 2013; Roth et al, 2014). Recently active learning (Angeli et al, 2014), truth-finding (Yu et al, 2014) as well, scanning (Yu et al., 2015) and ensemble learning (Viswanathan et al., 2015) were introduced to this field.

- **Brief Summary**

In all, entity search concentrates on the analysis of a single specific aspect of an entity, which is of interest or related to a domain. In the *expert finding* task, only *academic career*s of person entities (potential experts) are of concern in entity-document relevance determination. By contrast, for the sake of comprehensive understanding of an entity, entity archiving necessarily

1 Mark Fisher: a PERSON query name in Slot Filing evaluation of 2014, ID=SF14_ENG_031

takes multiple and diverse aspects into account, such as a person's career, family, religion, sociality, academics, etc. Due to the difference in goals, entity search techniques cannot be used directly to solve entity archiving problems.

The performance of conventional retrieval techniques was generally limited due to the lack of precise modeling of the characteristics of an entity. Sparse prior knowledge and absence of effective profiling methods cause difficulties in characterizing the entity. The rest of the paper will be about knowledge acquisition and partition, as well as the collaborative method, along with a topic-level biographical profiling method.

3 Prior Knowledge Acquisition

We use string matching based retrieval methods to acquire relevant documents. It is worth considering that the acquired documents are not straightforwardly defined as the final entity archiving results. As we will show in this section, some of them are reliable, while others are full of noise. Instead, we regard them as the prerequisite knowledge for a coarse-to-fine processing.

In the retrieval phase, a query *Q* is formulated as the full name of the target entity, while a document *D* is represented as a string of words. *D* is determined to be relevant only if it contains some words that match *Q*. Accordingly we name such words as entity mentions. Both *Q* and *D* are preprocessed by tokenization and stop-word filtering. Other commonly used preprocessing steps (stemming and lemmatization) are disabled because they may cause confusion between entity mentions and common words. Table 1 shows the examples where the underlined words in <1> denotes an entity mention but <2> does not.

<2>The 24 *guards divide* up into 2 groups. After lemmatization: ***guard divide***

Table 1: Inappropriate use of preprocessing

We employ two matching methods for the relevance determination: exact and fuzzy matching.

Exact matching (EM) requires that a sequence of successive words in *D* exactly matches *Q*. By EM, entity archiving regards a full entity name as an indivisible word-order-fixed unit. Accordingly it only acquires the documents which contain the entity mentions in the form of completely-preserved full name.

Fuzzy matching (FM) relaxes the conditions to a large extent, allowing *Q* to be split into nonadjacent words. In particular, it supports the change in word order as well as partial match. By FM, entity archiving is able to retrieve documents that contain the entity mentions in the form of separated, pruned and/or reordered names. Table 2 shows some examples of using these matching methods, where the mark "•" denotes the available methods for a certain form of entity mention.

Mark Fisher (PER) <ID: SF14_ENG_031 >

Table 2: Examples of string matching results

EM and FM have substantially different advantages and disadvantages in entity archiving. Table 3 shows the performance of EM and FM based entity archiving on KBP corpus (Surdeanu, 2013). We will introduce the corpus in details in Section 5. EM yields precise archiving results because the constraint conditions are helpful to reduce uncertainty in string matching. In contrast FM-based archiving is able to match entity name mentions with various forms, and thus it achieves higher recall.

	Precision	Recall	F-measure
EM	**72.5**	52.6	61.0
FM	10.8	**86.8**	19.2

Table 3: Effects of EM and FM on archiving

However FM generally introduces much noise, namely those mistakenly retrieved irrelevant documents. The documents are recalled because some pseudo entity mentions they contain can easily satisfy the constraints of fuzzy matching. See examples of the pseudo mentions in Table 4. As a result, FM yields a very low precision score.

Mark Fisher (PER) <ID: SF14_ENG_031 >

Deutsche *Mark* was the currency in Germany (**pruning**)
Iconic *Fisher*-Price *mark*. (**reordering**)

Table 4: Examples of pseudo entity mentions obtained by using FM

Undoubtedly it is helpful for global optimization of entity archiving to make full use of the advantages of EM and FM. In view of the above-mentioned investigation, we partition the string matching results into two parts, exact and fuzzy ones, which are used as reliable prior knowledge (named *reference source*) and unrefined prior knowledge (*candidate source*) respectively. Most documents in the *reference* are truly related to the target entity but the scale is not big (see Recall of EM in Table 3), while the *candidate* is full of both true answers and noise (see Precision and Recall of FM in Table 3), respectively. As we will show in the next section, the final archiving results are generated by synthesizing the sources in a collaborative coarse-to-fine way.

4 Collaborative Entity Archiving (CEA)

We propose a Collaborative Entity Archiving approach (CEA for short). CEA synthesizes the reference source and candidate source in a collaborative manner (section 4.1) through a biography-document relevance determination method (section 4.2 and 4.3). In addition, CEA involves mention disambiguation and query expansion in pre-processing to optimize the quality of both sources (section 4.4)

4.1 Overall Framework of CEA

CEA models the biography of an entity by using the topics in the reference source, in which, each topic serves as the description of a slice of life of the target entity (*life slice* for short), as shown in Figure 2. The *Life slice* means an episode in the whole story of the entity, which may represent an event, state or scenario at a certain moment, such as a person's *birth* or an organization's *establishment*.

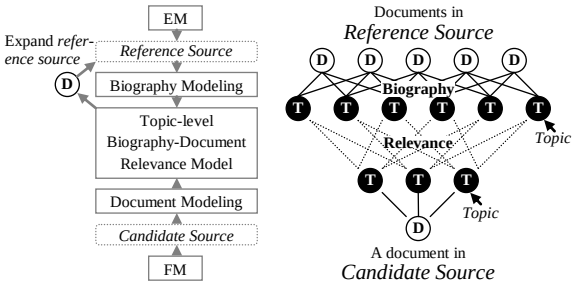

Figure 2**:** Framework of collaborative archiving

CEA pulls out a document from the candidate source, one by one, and measures the biography-document relevance at the topic level. By using a relevance threshold as the discrimination factor, CEA either preserves the document if it is relevant, or filters otherwise. Meanwhile, CEA adds the newly found relevant documents to the reference source, and updates the biography by reshaping life slices (i.e., topics). CEA iteratively goes through the process of biography formulation, biography-document relevance measurement and determination until a condition is satisfied. Finally CEA selects all the preserved documents in the reference source as the final output. Figure 2 shows the framework.

4.2 Biography-Document Relevance Models

We design a generative approach to estimate the biography-document relevance *r*, which calculates the conditional probability that a candidate document *D* generates the biography *B*:

$$r = P(B|D) \quad (1)$$

In total we leverage three probabilistic models for modeling *B* and *D*, including relevance model, topic model and context-level topic model. Then we introduce Hellinger Distance (Lindsay, 1994) into relevance measurement.

- *Relevance Model* **(*RM*)**

Generally, *Relevance Model* (RM) (Huang and Croft, 2009) refers to the probability distribution over all words conditioned on their occurrences in a set of previously-known relevant documents (or high-quality pseudo-relevant documents), i.e., $\forall w \in V, P(w|R)$, where *V* is the vocabulary, *R* is the document set, and *P*(*w*|*R*) can be estimated by TF-IDF. RM is often used in combination with *Document Model* (DM). Similar to RM, DM refers to the probability distribution over words in a particular document, i.e., $\forall w \in V, P(w|D)$. The relevance between *R* and *D* is normally determined by the agreement of RM and DM. The agreement can be estimated with Hellinger Distance between the models:

$$H(RM|DM) = \sum_{w \in V} (\sqrt{P(w|R)} - \sqrt{P(w|D)})^2 \quad (2)$$

RM is a widely-used probabilistic model for information retrieval. It determines the relevance of a document to an object in accordance with homogeneousness in content between the document and the relevant documents of the object.

For an entity, in our case, we generate RM on the reference source, and regard it as the probabilistic model of a macro-level all-embracing biography *B* over the prior knowledge *R*. For a candidate document *D*, the biography-document relevance *r* is measured with Hellinger Distance between RM and DM: *P*(*B*|*D*)=*H*(*RM*|*DM*). We

will demonstrate the effect of RM heavily relies on the quality of reference source in experiments.

- *Topic Model* **(*TM*)**

Empirically, RM is coarse-grained. It mixes up different, separate and incoherent life slices of an entity. A more serious problem is that RM assigns uneven weights to life slices, giving excessive weights to the words about the popular slices, but low or even zeroth weights to the unpopular ones. A popular slice is defined as the slice of greater concern, which is normally frequently mentioned in the reference source, such as the slice of "*the career of George W. Bush* as *the President*" (high weight) versus "*his childhood*" (low weight). As a result, the RM based biography-document relevance is only helpful to identify and recall the documents relevant to the popular slices but not to the unpopular ones.

As a modification, we employ *Topic Model* (TM) for biography modeling. We define a topic in the reference source as an independent fine-grained representation for a microscopic life slice. Accordingly we treat the biography as a bucket of topics. We leverage Latent Dirichlet Allocation (LDA) (Blei et al, 2003; Wei and Croft, 2006) for topic discovery and modeling in the reference source. A topic is modeled as a probability distribution over all words in lexicon conditioned on the association of the words with the topic, denoted as $\forall w \in V$, $P(w|t_R)$, in which t_R refers to a topic in the reference source, representing a life slice *s*. Table 5 shows partial topic models (slices) in the reference source of *Mark Fisher*, where the highlighted probability values by a box reveal the words that well characterize a topic (slice). In the same way, we survey the topics t_C in the *candidate source*, modeled as $\forall w \in V$, $P(w|t_C)$. It is worth noting that those topics (t_C) may represent anything, namely the slices of the target entity or namesakes, related or unrelated events, etc. It means they are full of noise.

Mark Fisher (Slice Modeling) <ID: SF14_ENG_031>			
Slice 1(***s1***), topic t_{s1}: ***political*** *career*			
$P(w\|t_{s1})=0.003$ "*Parliament*"	$P(w\|t_{s1})=8E-5$ "*screenwriter*"	$P(w\|t_{s1})=8E-5$ "*film*"	$P(w\|t_{s1})=4E-5$ "*Bear Fisher*" …
Slice 2(***s2***), topic t_{s2}: ***artistic*** *career*			
$P(w\|t_{s2})=6E-5$ "*Parliament*"	$P(w\|t_{s2})=0.003$ "*screenwriter*"	$P(w\|t_{s2})=0.001$ "*film*"	$P(w\|t_{s2})=3E-5$ "*Bear Fisher*" …
Slice 3(***s3***), topic t_{s3}: ***family***			
$P(w\|t_{s3})=9E-5$ "*Parliament*"	$P(w\|t_{s3})=1E-5$ "*screenwriter*"	$P(w\|t_{s3})=5E-6$ "*film*"	$P(w\|t_{s3})=0.001$ "*Bear Fisher*" …

Table 5: Example of life slice modeling by TM

In practice, given a target entity, its reference source (exact matching results) is a subset of the candidate source (fuzzy matching results). We picked the *reference source* out of the candidate to parse topics independently, forming the set of t_R. Meanwhile, we parse topics in the candidate source to form the set of t_C. Benefitting from the separate treatment, some of the truly related topics (t_R) to the entity (correct slices) can be collected along with less noise. Using the topics as references, we detect the relevant documents in the *candidate source* in terms of the topic-level biography-document relevance $P(B|D)$.

Given a document D in the candidate source, we transform $P(B|D)$ into the combination of topic-document relevance of all topics in the *reference source*. We measure the topic-document relevance with the conditional probability $P(t_R|D)$ that the topic t_R occurs in the document D. Accordingly, $P(B|D)$ is estimated by:

$$r = P(B \mid D) = \prod_{t_R} P(t_R \mid D)$$
$$\log(r) = \sum_{t_R} \log P(t_R \mid D) \quad (3)$$

where, we incorporate the log likelihood into the numerical calculation for the sake of nonzero joint probability.

Due to the separate topic modeling procedures for the reference and candidate sources, the probability $P(t_R|D)$ − a topic t_R in the *reference source* occurs in a candidate document D − cannot be obtained directly. To solve the problem, we introduce the joint probability of topic-topic relevance between topics (t_R) in reference and topics (t_C) in candidate (see the mode in Figure 2) into the probability calculation:

$$\forall t_R \in T_R,\ P(t_R \mid D) = \prod_{t_C \in T_C} P(t_R \mid t_C) P(t_C \mid D) \quad (4)$$

where T_R is the set of all topics in the reference source while T_C is the candidate. The topic-topic relevance $P(t_R|t_C)$ is approximated by Hellinger distance estimation between the topic models of t_R and t_C. As a whole, we measure the biography-document relevance as:

$$\begin{aligned} \log(r) &= \log \prod_{t_R \in T_R} \prod_{t_C \in T_C} P(t_R \mid t_C) P(t_C \mid D) \\ &= \sum_{t_R \in T_R} \sum_{t_C \in T_C} \log P(t_R \mid t_C) P(t_C \mid D) \\ &= \sum_{t_R \in T_R} \sum_{t_C \in T_C} \log H(t_R \mid t_C) P(t_C \mid D) \\ &= \sum_{t_R \in T_R} \sum_{t_C \in T_C} \sum_{w \in V} \log(\sqrt{P(w \mid t_R)} - \sqrt{P(w \mid t_C)})^2 P(t_C \mid D) \end{aligned} \quad (5)$$

We employ the toolkit GibbsLDA++[2] in topic modeling, which is an implementation of LDA using Gibbs sampling (Porteous et al, 2008). GibbsLDA++ makes it easy to parse the topics in a document set as well as estimate topic models $P(w|t)$. Besides, GibbsLDA++ offers the probability over topics in generating a specific document, facilitating the estimation of $P(t_C|D)$ in equation (5). Table 6 shows the operating parameters what we set in experiments, where the ones $\{\alpha, \beta\}$ were set as the default values while the iterative number *num* is an empirical value.

α= 1	*num*= 200
β= 0.1	N_t←HDP

Table 6: Operating parameters of GibbsLDA++

The necessary precondition for GibbsLDA++ in topic partition is to define the number N_t of potential topics in a set of documents. We execute the Hierarchical Dirichlet Processes (Teh et al, 2005), abbr., HDP, to predict N_t. HDP is similar to current hierarchical information organization methods, such as the hierarchical clustering (Kummamuru et al, 2004), unsupervised and coarse-to-fine grained. Hence HDP is useful in exploring the basic rules of topic partition in an automatic way, such as number and granularity. We employ HDP to estimate the number (N_t) of all possible topics in *reference source* and *candidate* separately, acquiring two N_t for each target entity, one per source.

- *Context-level Topic Model* **(*CTM*)**

In consideration of the reliability of contexts in representing closely-related life slices to the entity, we use the contexts around entity mentions to improve the slice-oriented topic modeling.

SEN: A sentence where an entity mention occurs **NEB**: Left and right neighbor sentences of SEN **DEP**: Words dependent on entity mention **SYN**: Words in maximum syntactic subtree in SEN
Context 1: SEN **Context 2**: DEP + SYN **Context 3**: SEN + left NEB + Right NEB

Table 7: Instructions of various types of contexts

A context consists of the words co-occurring with an entity mention in a radius-fixed text span or syntactic or dependent structure (see instructions in Table 7). Given a target entity, the entity mention in the *reference source* is its full name. The union of all contexts in the source defines the vocabulary V_R that most probably represent the slices of the entity. In the *candidate sourc*e, on the contrary, the entity mention can be a reordered, separated or pruned entity name, as well as abbreviation or alias, such as *GWB* (abbr.) and *Dubya* (alias) of *George W. Bush*. Different from the cases in *reference*, the vocabulary V_C obtained from the contexts in *candidate* are closely related to diverse entities or other objects with the same name (see Table 2&4).

CTM measures the biography-document relevance in the same way with *TM*, estimating the topic-level $P(B|D)$ by equation (5). The only difference lies in the available words in topic model $P(w|t)$. For the ones not included in V_R and V_C, CTM assigns a weight zero in topic model no matter what GibbsLDA++ does.

4.3 Unsupervised Threshold Estimation

For each target entity, CEA measures the biography-document relevance for all documents in the candidate source. In the light of the relevance scores, CEA ranks the documents and sets a clear threshold θ to cut off the long tail in the ranking list, in other words, filtering the documents that have a relevance score lower than θ. The preserved documents will be added to the reference source for both biography reformulation and archiving result output.

We estimate the threshold by learning density distribution of documents over relevance scores (Arampatzis et al, 2009). *Density* means the number of documents that have similar relevance scores. The *distribution* is produced by densities within all interval ranges of relevance score. Our empirical findings show that the density distribution fits a mixture of two Gaussians, where the highly relevant documents and the irrelevant ones distribute in two separate Gaussian peaks respectively. Accordingly we define the threshold as the range of relevance score at the extreme point between the peaks, as shown in Figure 3.

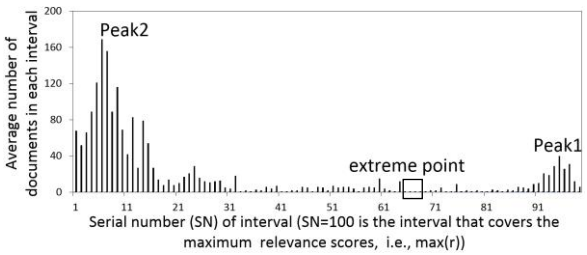

Figure 3: Extremum detection for threshold selection. (Note: Y-axis indicates the density in a specific interval range of relevance score)

In order to detect the extreme point, we firstly use a cubic polynomial function to approximate

2 http://gibbslda.sourceforge.net/

the density distribution. Second, we go through the integral solution of the function in every fine-grained interval range of relevance score (interval is set as max(r)/100). We finally detect the extremum between peaks. The threshold is initialized during runtime exclusively for each target entity, without training. It is re-estimated every time when the biography is reformulated.

4.4 Termination Criterion for Iteration

CEA identifies relevant documents in *candidate source* and moves them to *reference*. Then CEA reshapes statistical models (RM, TM or CTM) over the updated sources. In terms of the reformed models, CEA starts a new round of relevance determination, data movement, and statistical modeling. CEA keeps it going until meeting any of the following termination criterions:

- T1: No more new topic occurs in the *reference source* (N_t doesn't change).
- T2: The number of the documents in Peak1 (Figure 3) begins to increase continuously.

T2 is triggered if T1 loses its efficacy. The invalidation happens when some general slices (i.e., general topics) are mistakenly introduced into the *reference source*, causing large-scale irrelevant document to be recalled and moved to *reference*. It will dramatically increase the number (N_t) of topics in a long term in the iterative procedure, driving CEA to capture more irrelevant documents. Thus Peak1 will be enlarged continuously. However, if as expected, Peak1 should be narrowed with increasing the iteration times because:

- Fewer new related slices appear.
- The number of documents related to the slices is less than that in previous iterations.

4.5 Optimization of EM and FM

In the preprocessing phase, we improve the precision of EM because higher-quality EM results can offer more reliable reference documents for biography modeling. In addition, we expand queries for FM to recall a larger number of relevant documents. It is helpful to minimize the loss of relevant documents before proceeding to CEA.

To improve EM, we focus on identifying the common words that completely match the full name of the target entity. The words normally are elusive and easily treated as a correct entity name, called deceptive name, see that in (1).

(1) *Countrywide Financial* <ORG>
True: *Countrywide Financial Corporation*.
Deceptive: *Bank of America purchased the failing countrywide financial for $4.1 billion*.

To reduce EM errors caused by deceptive names, we use name tagging (Miller et al, 2004) to distinguish deceptive names and true names. Further, we filter the documents that are mistakenly retrieved based on the match between a deceptive name and the full-entity-name based query Q.

We leverage an *Alternate Name Table* (ANT) for query expansion. ANT is a mapping table between entity name and alternate name. An alternate name is either generated according to the naming conventions (Burman et al, 2011), such as abbreviation, suffixation and revivification. Some alternative names were extracted from knowledge base through redirect links (Nia et al, 2014), such as nicknames in Wikipedia dumps. For an entity, we reformulate query Q by the combination of the pre-assigned full entity name and all possible alternate names in ANT, see (2).

(2) **Initial** Q: *Countrywide Financial Corporation.*
Expanded: *Countrywide Financial+Corporation +Corp. +Company +Co. +Ltd. +Co Ltd. +CFC.*

We use the expanded query for FM to increase the number of relevant documents in the candidate source, regardless of whether or not it will introduce a larger scale of new noises.

5 Experiments

We evaluate our methods on KBP 2013 corpus. The corpus contains 2.1M texts collected from web pages, newswires and discussion forums. From this corpus, a slot filling system is required to find fillers for 41 types of slots that represent the attributes of the target entities. There are 25 slot types of person and 16 slot types of organization, such as a Person's *birth date* and an Organization's *founder* (Ji et al., 2010 and 2011).

KBP 2013 includes 100 target entities and ground-truth fillers and provenances, where the ground-truth data was obtained by manual verification and annotation on the pool of system outputs. The provenances contain the IDs of documents relevant to target entities and fine-grained text spans which illustrate the eligibility of fillers.

In total there are 1,851 gold standard relevant documents available for the evaluation of entity archiving. However the data is far from enough because it only covers a small portion of all relevant documents in the pool. Most are excluded since KBP annotators ignore relevant documents in which there isn't any filler for the assigned slots or, although exists, the fillers were inexactly identified by Slot Filling systems. Therefore, we manually went over the pool and extracted 4,405 relevant documents as our ground-truth.

Sources / Archiving	**Before** Optimization of EM & FM (%)						**After** Optimization of EM & FM (%)					
	Micro-Average			Macro-Average			Micro-Average			Macro-Average		
	P	R	F	P	R	F	P	R	F	P	R	F
EM	65.4	40.1	49.7	72.5	52.6	61.0	78.8	24.6	37.5	81.1	46.9	59.4
FM	9.4	74.6	16.7	10.8	86.8	19.2	6.3	92.9	11.8	6.9	94.2	12.9
Baseline	29.1	50.6	36.9	36.1	62.9	45.9	22.6	33.3	26.9	25.1	52.6	34.0
CEA(RM)	49.7	86.5	63.1	62.3	85.8	72.2	59.5	84.3	69.7	64.9	87.4	74.5
CEA(TM)	52.6	87.7	65.8	63.2	86.1	72.9	60.6	82.9	70.0	65.7	85.8	74.4
CEA(CTM1)	63.9	81.7	71.7	69.7	82.7	75.7	65.1	75.6	70.0	69.8	84.4	76.4
CEA(CTM2)	63.9	81.7	71.7	69.7	82.7	75.7	65.1	75.6	70.0	69.8	84.4	76.4

Table 8: Archiving results (CTM1, 2 &3 are CTM using different types of contexts, context1, 2 &3 in Table 7)

5.1 Archiving Results and Analysis

We evaluate the entity archiving methods by micro and macro Precision (P), Recall (R) and F metrics. Table 8 shows the main results.

- *Overall Archiving Results*

Overall, the proposed CEA methods perform much better than the string matching based entity archiving methods (i.e., EM and FM).

In addition the methods outperform a random-sampling based CEA (baseline), which randomly selects a certain number of documents (candidates) from the candidate source to combine with reference source straightforwardly (for final archiving results generation). The sampling number is set to be the same as the number of candidates eventually archived by RM-based CEA.

Random	RM	TM	CTM1	CTM2	CTM3
5,901	5,901	5,578	3,866	3.866	4,243
5,158	5,158	4,943	4,032	4,032	3,655

Table 9: The number of candidates added to reference source for archiving results generation (the second row indicates the number before optimizing EM and FM, while the third row indicates after optimization)

Table 9 shows the number of candidates archived from the candidate source by all kinds of CEA methods. It demonstrates that the biography-based CEAs yield higher precision (Table 8) after introducing the same or smaller number of candidates in the reference source, revealing the positive effect of biography modeling on entity-oriented document relevance determination.

- *Reliability versus Comprehensiveness*

CEA achieves higher precision by using the optimized EM results as reference source. It demonstrates the importance of reliable prior knowledge for entity understanding as well as detecting relevant documents. However, the reference source causes lower recall scores of all CEA methods. The reason lies in reduction of prior knowledge. As shown in Table 8, the refined reference source (i.e., optimized EM results) covers only 24.6% of all relevant documents, which is far less than the coverage before optimization (nearly 40%).

The reduced prior knowledge provides fewer available life slices of an entity for constructing an informative biography, inevitably resulting in missing some relevant documents. In order to confirm this, we regard the 41 KBP slot types as some readily-made visible life slices, and use the manual annotations of the slot fillers to verify whether a life slice appears in a relevant document. For example, the filler "*Corporate liaison* of the slot *Title* reveals the slice of *freelance career* of *Mark Fisher*. Then we figure out the coverage rate of life slices for both the original reference source and the refined.

Figure 4 exhibits the coverage rates for 5 most frequently occurred life slices. The coverage rate is calculated by the number of reference sources that contain a specific life slice versus 100, i.e., the number of reference sources for the 100 KBP entities (one per entity). It can be found that the refined reference sources miss lots of life slices.

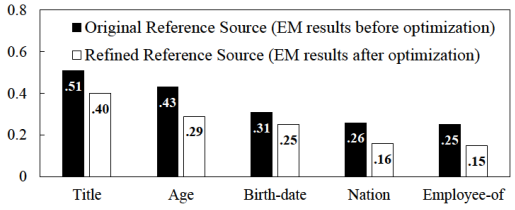

Figure 4: Coverage rates of life slices (for top 5)

- *Comparison among Biography Models*

RM is biased towards the popular life slices in biography modeling. The reasons are as following: 1) RM gives greater weights to the high-frequency words, and 2) popular slices are of much greater public interest and hence frequently mentioned in relevant documents. However, some entities not only share similar names but similar popular slices, such as the *religious vocation* of different *church scientologists*. Therefore

RM is extremely likely to acquire the documents related to the namesakes if they have similar popular background as the target entity, causing a greater loss of precision.

Table 10 shows the top highly-weighted words in RM for the target *Mark Fisher* (a *church scientologist*), along with 2 namesakes who occur most frequently in the incorrect archiving results.

Keywords in RM	The most similar entities
church *committee* *religious* *Sea Org* *policy*	***Miles Mark Fisher*** *Church historian, Educator, Baptist minister and writer* ***Mark Fisher*** *Senior Pastor*

Table 10: Entities of similar background

By contrast, TM independently represents different life slices and combines the effects of the slices on biography-document relevance determination, evenly and exhaustively. Comprehensive and unbiased measurement of every known life slices is helpful in disambiguating entities that have similar backgrounds (definitely not the same in all). As a result, TM improves the precision. And the context-based TM goes further.

5.2 Slot Filling Results and Analysis

We apply our entity archiving methods to two top-ranked slot filling systems in the evaluation of KBP 2013, including LSV (Roth and Klakow, 2013) and Blender (Yu et al 2013).

The LSV incorporates a string matching based entity archiving and a SVM classifier based filler extraction. LSV's archiving model expands queries by using suffixes and Wikipedia anchor texts, and uses mutual information based relevance measure in document ranking and filtering.

Blender employs a hybrid retrieval model for archiving relevant documents. It combines Boolean and VSM models and expands query by an alternate name table similar to ours. For filler extraction, Blender implements truth finding over conflicting claims from multiple rule-based extraction systems.

Methods	P	R	F
LSV's archiving	53.0	88.2	66.2
Blender's archiving	54.6	71.7	62.0

Table 11: Archiving performance of LSV &BLD

Table 11 shows entity archiving performances of LSV and Blender (Macro-Average P, R and F). All CEA methods perform better than the both. With the aim to optimize provenances of fillers, we modify the slot filling systems by substituting their archiving methods with ours. Table 12 exhibits the performance gains after replacement.

Slot Filling / Archiving	LSV (%)			Blender (%)		
	P	R	F	P	R	F
Original system	40.8	30.0	34.6	34.1	22.1	26.8
Mod. (RM)^{CEA}	42.1	30.0	35.0	35.6	23.9	28.6
Mod. (TM)^{CEA}	**42.2**	**30.6**	**35.5**	35.6	23.9	28.6
Mod. (CTM3)^{CEA}	42.7	29.3	34.7	**36.0**	**23.8**	**28.7**

Table 12: Slot filling performance gains

Both LSV and Blender achieve significant gains. The most interesting finding is on the different performance gains. It should reveal the fact that the well-supervised classification based filler extraction of LSV has a better capability of noise resistance, while by contrast, the truth-finding in Blender is capable of identifying valid fillers if the quality of archiving results is high, otherwise easily makes mistake.

6 Conclusion

We doubt that it is easy to maintain the stability of current entity-oriented knowledge acquisition methods, including ours, in dealing with ordinary entities. Most target entities now in use for the evaluation are made to stand as "out of the ordinary", such as well-known enterprises, celebrities or domain experts. As a result, a corpus contains abundant relevant documents of the entities but less about the little-known namesakes. It greatly reduces the interference of namesakes and thus the difficulty of the task.

In future work, we will make the task critical for success by employing the little known namesakes as targets. In addition to verifying the robustness of the CEA method, we will work on the relationship among entities (ACE entity relation types, Doddington et al, 2004) and related events (e.g., causal, temporal and sub-event relations), by which to build graph-based biography.

Abstract

ListNet is a well-known listwise learning to rank model and has gained much attention in recent years. A particular problem of ListNet, however, is the high computation complexity in model training, mainly due to the large number of object permutations involved in computing the gradients. This paper proposes a stochastic ListNet approach which computes the gradient within a bounded permutation subset. It significantly reduces the computation complexity of model training and allows extension to Top-k models, which is impossible with the conventional implementation based on full-set permutations. Meanwhile, the new approach utilizes partial ranking information of human labels, which helps improve model quality. Our experiments demonstrated that the stochastic ListNet method indeed leads to better ranking performance and speeds up the model training remarkably.

1 Introduction

Learning to rank aims to learn a model to rerank a list of objects, e.g., candidate documents in document retrieval. Recent studies show that listwise learning delivers better performance in general than traditional pairwise learning (Liu, 2009), partly attributed to its capability of learning human-labelled scores as a full rank list. A potential disadvantage of listwise learning, however, is the high computation complexity in model training, which is mainly caused by the large number of permutations of the objects to rank.

A typical listwise learning method is the ListNet model proposed by Cao et al. (2007). This model has been utilized to tackle many ranking problems, e.g. modeling the hiring behavior in online labor markets (Kokkodis et al., 2015), ranking sentences in document summarization (Jin et al., 2010), improving detection of musical concepts (Yang et al., 2009) and ranking the results in video search (Yang and Hsu, 2008). Basically, ListNet implements the rank function as a neural network (NN), with the objective function set to be the cross entropy between two probability distributions over the object permutations, one derived from the human-labelled scores and the other derived from the model prediction (network output). In order to deal with the high computation complexity associated with the large number of permutations, Cao et al. (2007) proposed a Top-k approach, which clusters the permutations by the first k objects, so the number of distinct probabilities that need to evaluate in model training reduces from $n!$ to $\frac{n!}{(n-k)!}$, where n is the number of objects in the list.

To ensure efficiency, $k = 1$ was selected in the seminal paper (Cao et al., 2007) and in the open source implementation of RankLib (Dang, 2013). This Top-1 approach is a harsh approximation to the full listwise learning and may constrain the power of the ListNet method. We therefore seek to extend the Top-1 approximation to Top-k (k $>$ 1) models.

The major obstacle for the Top-k extension is the large number of permutations, or more precisely, permutation classes in the Top-k setting. A key idea of this paper is that the rank information involved in the permutation classes is highly redundant and so a small number such permutation classes are sufficient to convey the rank information required to train the model. Meanwhile, the partial rank information associated with the subset of permutation classes may represent more detailed knowledge for model training, leading to better ListNet models.

Based on these two conjectures, we propose a stochastic ListNet method, which samples a subset

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 676–684,
Lisbon, Portugal, 17-21 September 2015.

of the permutation classes (object lists) in model training and based on this subset to train the ListNet model. Three methods are proposed to conduct the sampling. In the uniform distribution method, the candidate objects are selected following a uniform distribution; in the fixed distribution method, the candidate objects are selected following a distribution derived from the human-labeled scores; in the adaptive distribution method, the candidates are selected following a distribution defined by the rank function, i.e., the neural network output. Experimental results demonstrated that the stochastic ListNet method can significantly reduce the computation cost in model training. In fact, if the size of the permutation subset is fixed, the computation complexity is bounded, which allows training Top-k models where k is large. Meanwhile, better performance was obtained with the stochastic ListNet approach, probably due to the learning of partial rank information.

The contributions of the paper are three-fold: (1) proposes a stochastic ListNet method that significantly reduces the training complexity and delivers better ranking performance; (2) investigates Top-k models based on the stochastic ListNet, and studies the impact of a large k; (3) provides an open source implementation based on RankLib.

The rest of the paper is organized as follows. Section 2 introduces some related works, and Section 3 presents the stochastic ListNet method. Section 4 presents the experiments, and the paper is concluded by Section 6.

2 Related Work

This work is an extension of the Top-k ListNet method proposed by Cao et al. (2007). The novelty is that we propose a stochastic learing method which not only speeds up the model training but also produces stronger models. The code is based on the Top-1 ListNet implementation of RankLib (Dang, 2013).

Another related work is the SVM-based pairwise learning to rank model based on stochastic gradient descent (SGD) (Sculley, 2009). In this approach, training instances (queries) are selected randomly and for each query, a number of object pairs are sampled from the object list. These pairs are used to train the SVM model. In the stochastic ListNet method proposed in this paper, the randomly selected training samples are permutation classes (object lists) rather than pairs of objects, and a set of object lists rather than a single pair forms a training sample.

3 Methods

3.1 Review of ListNet

The ListNet approach proposed by Cao et al. (2007) trains a neural network which predicts the scores $z^{(i)}$ of a list of candidate objects $x^{(i)}$ given a query $q^{(i)}$, formulated by $z^{(i)} = f_w(x^{(i)})$, where f_w stands for the scoring function defined by the NN. The objective function is given by:

$$\begin{aligned}\mathcal{L} &= \sum_i \mathcal{L}(y^{(i)}, z^{(i)}) \\ &= \sum_i \sum_{\forall g \in \mathscr{G}_k} P_{y^{(i)}}(g) log(P_{z^{(i)}}(g)) \quad (1)\end{aligned}$$

where $y^{(i)}$ denotes the human-labelled scores, and $\mathscr{G}_k$ is the set of permutation classes defined by:

$$\begin{aligned}\mathscr{G}_k &= \{\mathscr{G}_k(j_1, j_2, ..., j_k) | j_t = 1, 2, ..., n, \\ &\quad s.t.\ j_u \neq j_v \quad for\ \ \forall u \neq v\} \quad (2)\end{aligned}$$

where n is the number of candidate objects, j_t is the object ranked at the t-th position, and $\mathscr{G}_k(j_1, j_2, ..., j_k)$ is a permutation class which involves all the permutations whose first k objects are exactly $(j_1, j_2, ..., j_k)$. Following Cao et al. (2007), the probability of $\mathscr{G}_k(j_1, j_2, ..., j_k)$ can be computed by:

$$P_s(\mathscr{G}(j_1, j_2, ..., j_k)) = \prod_{t=1}^{k} \frac{e^{s_{j_t}}}{\sum_{l=t}^{n} e^{s_{j_l}}}. \quad (3)$$

where s_{j_t} is the score of object at position $j_t (t = 1, 2, , , k)$ at a certain permutation. By this definition of permutation probability, Eq. (1) defines a cross entropy between the distributions over permutations (precisely, permutation classes) derived from the human-labelled scores and the NN-predicted scores. Therefore, optimizing the objective function Eq. (1) with respect to the NN model f_w leads to a scoring function that approximates the human-labelled ranking.

3.2 Stochastic Top-k ListNet

A particular difficulty of the Top-k ListNet method is that it requires very demanding computation in model training. Refer to Eq. (2), the permutation set $\mathscr{G}_k$ involves $\frac{n!}{(n-k)!}$ members, and for each member, computing its probability involves $\frac{(2n-k+1)k}{2}$ summations plus k multiplications and

divisions. To let the algorithm practical, k=1 was selected in (Cao et al., 2007), as well as the public toolkit RankLib (Dang, 2013). Although this is a good solution and reduces computation dramatically, we argue that this approach largely buries the power of ListNet. In fact, setting k=1 effectively marginalizes all the probabilities over the candidate objects of a permutation class except the top one. By this approximation, Eq. (3) reduces to a softmax over the candidate objects, which means that it actually focuses on how the probabilities are distributed over *individual* objects, rather than how the probabilities are distributed over *object lists*. This potentially loses much rank information involved in the human labels.

Another disadvantage of the Top-1 model is that it learns the rank information of the *full list*, but ignores the rank information of *partial sequences*, which may lead to ineffective learning. As an example, considering an object list where the score of the most relevant object is much higher than the scores of others, then the learning is dominated by the highest score, and largely throws away the rank information conveyed by the scores of other objects. It would be quite helpful if the rank information involved in partial sequences of the candidate objects can be learned. Top-k models place distributions over object lists (in length k), and so can learn partial sequences of objects.

We are interested in how to learn Top-k ($k > 1$) models while keeping the computation tractable. To achieve the goal, we propose a stochastic ListNet approach, which samples a small set of the Top-k permutation classes (object lists), and train the Top-k model based on this small set instead of the full set of permutation classes. As a comparison, the full set of permutation classes of the Top-k model is $\frac{n!}{(n-k)!}$, which is computationally prohibitive if $k > 1$. With stochastic ListNet, a subset of the permutation classes that involves only l members are randomly selected. Training the Top-k model based on this subset greatly reduces the computation cost, even with a large k. In fact, the subset approach imposes a bound of the computation cost that is largely determined by the the size of the subset (l), while independent of the total number of objects n and the model order k.

Interestingly, the stochastic approach offers not only quick learning, but also a chance of learning partial ranks. This is obvious because only a subset of the object lists are selected in model training, and so the rank information involved in the subset of the permutation classes can be learned. With the Top-1 model, partial ranks reduces to partial sequences since each object list involves only one object. As we have discussed, learning partial sequences is an advantage of Top-k models with $k > 1$. This means that stochastic Top-1 ListNet possesses some advantages of Top-k ListNet, while the computation cost is much lower.

3.3 Sampling methods for stochastic ListNet

The training process of stochastic ListNet starts from sampling l permutation classes, or object lists. For each object list, k objects are sampled following a particular distribution. As mentioned in Section 1, three distributions are studied in this paper: uniform distribution, fixed distribution and adaptive distribution. They are presented as follows.

Uniform distribution sampling: In this method, all the k objects of a particular object list are sampled with an equal probability. This sampling method is simple but biased towards irrelevant candidates, since there are much more irrelevant objects than relevant ones in the training data. A re-sampling approach is proposed to remedy the bias, as will be discussed in Section 4.

Fixed distribution sampling: In this method, the objects are sampled following a distribution proportional to the human-labelled scores. For instance, in the LETOR dataset that is used in this study, each candidate object (document) is labelled as 2 (very relevant), 1 (relevant) or 0 (irrelevant). These scores are normalized by softmax and are used as the probability distribution when sampling objects. Because the probabilities of relevant objects are larger than those of irrelevant objects, more relevant objects would be selected by this sampling approach in model training.

Adaptive distribution sampling: The fixed distribution sampling mentioned above relies on human-labelled scores, which may be impacted by label errors. Moreover, the absolute values of human labels are not good measures of object relevance. To solve these problems, we choose the outputs of the 'current' neural network as the relevance scores, and sample the objects according to these scores. Note that the network outputs are natural measures of object relevance based on the present ranking model. As the model (the neural network) keeps updated during model training, the

relevance scores are accordingly changed. In each iteration, the relevance scores are re-calculated, and the sampling is based on the new scores in the next iteration.

3.4 Gradients with linear networks

Cao et al. (2007) optimized the ListNet model by gradient descent. For each query, the learn rule is formuated by:

$$w = w - \eta \Delta w$$

where η is the learning rate, and w denotes the parameters of the model f_w. Δw denotes the gradient and it can be computed as follows:

$$\Delta w = \sum_{\forall g \in \mathscr{G}_k} \frac{\partial P_{z^{(i)}(f_w)}(g)}{\partial w} \frac{P_{y^{(i)}}(g)}{P_{z^{(i)}(f_w)}(g)}.$$

For simplicity, a linear NN model was used by Cao et al. (2007). This has been adopted in our study as well, written by $z^{(i)} = f_w(x_j^{(i)}) = w^T x_j^{(i)}$, where $x_j^{(i)}$ denotes the feature vector of the j-th object of the i-th query. In the case of the Top-1 model, it shows that:

$$\Delta w = \sum_j [\sigma(z^{(i)}, j) - \sigma(y^{(i)}, j)] x_j^{(i)}$$

where $\sigma(s, j)$ is the j-th value of the softmax function of the score vector s, given by:

$$\sigma(s^{(i)}, j) = \frac{e^{s_j^{(i)}}}{\sum_{t=1}^{n^{(i)}} e^{s_t^{(i)}}}.$$

In the case of the Top-k model, the gradient(Derivative of cross entropy between $P_{z^{(i)}}$ and $P_{y^{(i)}}$ when $k >= 2$) is a bit complex, but still manageable:

$$\begin{aligned} \Delta w = \sum_{g \in \mathscr{G}_k} [(\prod_{t=1}^{k} \hat{\sigma}(y^{(i)}, t)) \cdot \\ (\sum_{f=1}^{k} \{x_{j_f}^{(i)} - \sum_{v=f}^{n^{(i)}} \hat{\sigma}(z^{(i)}, v) x_{j_v}^{(i)}\})] \end{aligned} \quad (4)$$

where $\hat{\sigma}(\cdot)$ defines a 'partial' softmax(The partial softmax means that the $\sigma(s, f)$ has a similar form as softmax, however when computing the value for each f, the denominator is not the summation from 1 to n, instead a partial sequence from f to n.), given by:

$$\hat{\sigma}(s^{(i)}, f) = \frac{e^{s_{j_f}^{(i)}}}{\sum_{t=f}^{n^{(i)}} e^{s_{j_t}^{(i)}}}.$$

3.5 Stochastic Top-k ListNet algorithm

We present the stochastic Top-k ListNet algorithm, by employing the techniques described above. The gradient descent (GD) approach is adopted. All the training samples are processed sequentially in an iteration. The training runs several iterations until the convergence criterion is reach. Another detail is that the learning rate is multiplied by 0.1 whenever the objective function is worse than the previous iteration. The procedure is illustrated in Algorithm 1, where $\mathcal{L}(t)$ denotes value of the objective function after the t-th iteration.

Algorithm 1 Stochastic Top-k ListNet

Require:

Input:
$\mathscr{D} = \{(q^{(1)}, x^{(1)}, y^{(1)}), ..., (q^{(m)}, x^{(m)}, y^{(m)})\}$: training data
T: number of iterations
η: learning rate

Procedure:

```
Randomly initialize w
for t = 1 to T do
    for i = 1 to m do
        select the i-th training instance (q^(i), x^(i), y^(i)) ∈ D
        Sample the permutation classes G_k
        Compute Δw according to Eq. (4)
        Update f_w: w = w − ηΔw
    end for
    if L(t) < L(t − 1) then
        η = 0.1η
    end if
end for
```

4 Experiments

4.1 Data

The proposed stochastic Top-k ListNet method is tested on the document retrieval task based on the MQ2008 dataset of LETOR 4.0 (Liu et al., 2007). This database was released in early 2007 and has been widely used in learning to rank studies. It contains queries and corresponding candidate documents. The human-labelled scores are among three values $\{0, 1, 2\}$, representing little, medium, and strong relevance between queries and candidate documents, respectively. The training set, validation set and test data all contain 784 queries. The document features used in this study include term frequency, inverse document frequency, B-

M25, and language model scores for IR. Some new features proposed recently are also included, such as HostRank, feature propagation, and topical PageRank.

4.2 Experiment Setup

In our experiments, we consider Top-k models where k = 1, 2, 3, and 4. Although any k is possible with the proposed stochastic ListNet, we will show that simply increasing the model order k does not improve performance. The P@1 and P@10 performance is used as the evaluation metric.

Specially, for all the three distribution sampling methods, the sampling process involves two steps: pre-selection and re-sampling. The pre-selection step samples a list of documents following three distributions mentioned above, and in the re-sampling step, document lists including more relevant documents are retained with a higher probability. For example, denoting the pre-selected document list by (v_1,v_2,...,v_k) where k is the length of the list, and denoting the corresponding human-labelled scores by (s_1, s_2,...,s_k), the probability that the list is retained is given by

$$\frac{\sum_{i=1}^{k} s_i}{kS}$$

where S is the maximum value of the human-labelled scores, which is 2 in our case. The re-sampling approach is designed to encourage document lists containing more relevant documents, which is the most important for the uniform distribution sampling.

In stochastic Top-k ListNet, the learning rate is set as 10^{-3} for k = 1, and 10^{-5} for $k > 1$. These values are set to achieve the best performance on the validation set. Another important parameter of the stochastic Top-k ListNet approach is the number of samples of the document lists (or the size of subset of permutation classes selected), denoted by l. Various settings of l are experimented with in this study. To eliminate randomness in the results, all the experiments are repeated 20 times and the averaged performance is reported.

4.3 Experimental results

The P@1 results on the test dataset with different orders of Top-k ListNet are reported in Figure 1 to Figure 4. In each figure, the number of document lists varies from 5 to 500. For comparison, the results with the conventional ListNet are also presented. Note that the re-sampling approach was not applied to the Top-1 model as we found it caused performance reduction. This is perhaps because the sampling space is small with the Top-1 model, and so re-sampling tends to cause over-emphasis on relevant documents.

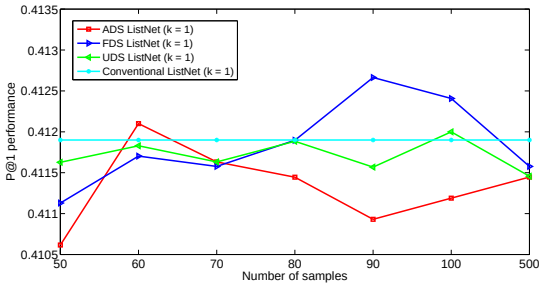

Figure 1: The P@1 performance on the test data with the Top-1 ListNet utilizing the three sampling approaches. The size of the permutation subset varies from 50 to 500.

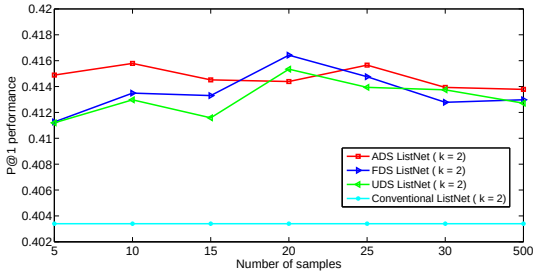

Figure 2: The P@1 performance on the test data with the Top-2 ListNet utilizing the three sampling approaches. The size of the permutation subset varies from 5 to 500.

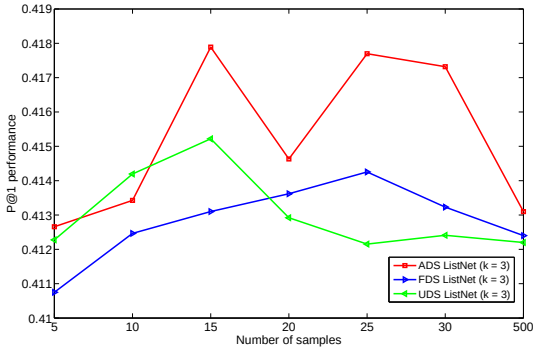

Figure 3: The P@1 performance on the test data with the Top-3 ListNet utilizing the three sampling approaches. The size of the permutation subset varies from 5 to 500.

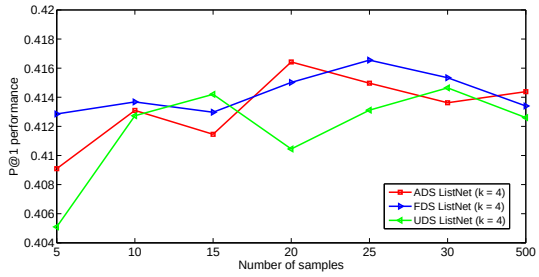

Figure 4: The P@1 performance on the test data with the Top-4 ListNet utilizing the three sampling approaches. The size of the permutation subset varies from 5 to 500.

From these results, we first observe that stochastic ListNet with either fixed or adaptive distribution sampling tends to outperform the conventional ListNet approach, particularly with a large k. This confirms our argument that rank information can be learned from a subset of the permutation classes that are randomly selected, and the partial rank learning can lead to even better performance than the full rank learning, the case of conventional ListNet. This is an interesting result and demonstrates the stochastic ListNet is both faster and better than the conventional ListNet. It is also seen that the adaptive distribution sampling performs slightly better than the fixed distribution sampling. This is not surprising as the adaptive distribution sampling uses a more reasonable relevance score (neural network output) to balance relevant and irrelevant documents. The uniform distribution sampling performs a little worse than the other two sampling methods, probably caused by the less informative uniform distribution.

Another observation is that in all the four figures, the performance of the stochastic ListNet methods increases with more samples of the object lists. However if there are too many samples, the performance starts to decrease. This can be explained by the fact that the sampling prefers relevant documents which are more informative. A larger sample set often includes more informative documents; however if the set is too large, many irrelevant documents will be selected and the performance is reduced. In the case that the number of samples is very large (500 for example for Top-1), the stochastic ListNet falls back to the conventional ListNet, and their performance becomes similar.

Comparing the results with different k, it can be seen that a larger k leads to a better performance with stochastic ListNet. This confirms that high-order Top-k models can learn more ranking information. However, this is not necessarily the case with the conventional ListNet. For example, the Top-2 model does not offer better performance than the Top-1 model. This is perhaps because high-order Top-k models consider a large number of document lists and most of them are not informative, which leads to ineffective learning. Remind that the conventional ListNet is a special case of the stochastic ListNet with a very large sample set, and we have discussed that an over large sample set actually reduces performance.

The averaged training time and the performance in precession are presented in Table 1. For precession, both P@1 and P@10 results are reported, though we focus on P@1 since it is more concerned for applications such as QA. Note that for stochastic ListNet, the optimal number of samples (document lists) has been selected according to the P@1 performance on the validate set.

From these results, it can be seen that the conventional Top-1 ListNet is rather fast, however the Top-2 model is thousands of times slower. With $k > 2$, the training time becomes prohibitive and so they are not listed in the Table. This is expected since the conventional ListNet considers the full set of permutations which is a huge number with a large k. With the stochastic ListNet, the training time is dramatically reduced. Even with a large k, the computation cost is still manageable, because the computation is mostly determined by the number of object lists, rather than the value of k. When comparing the three sampling methods, it can be found the convergence speed of the uniform distribution approach is the slowest, probably due to the ineffective selection for relevant documents. The adaptive distribution sampling is the fastest, probably attributed to the collaborative update of the model and the distribution.

As for the P@1 performance, the stochastic ListNet method generally outperforms its non-stochastic counterpart, particularly with the adaptive distribution sampling. For example, the best P@1 results obtained on the test data with the stochastic Top-1 ListNet is 0.4127, which outperforms the conventional Top-1 ListNet (0.4119). This advantage of stochastic ListNet, as we argued, is largely attributed to its capability of learning partial rank information with samples of partial sequences of the rank list.

Comparing the results with different k values, it can be seen that a larger k tends to offer better P@1 performance on the training set, with either the conventional ListNet or the stochastic ListNet. For example, with the conventional ListNet, the results are 0.4101 vs. 0.4119 with the Top-1 and Top-2 models respectively. However, the performance gap is rather marginal, and the advantage with the large k does not propagate to the results on the test data (as has been seen in Figure 1 and Figure 2). This indicates that for the conventional ListNet, the Top-1 model is not the only choice in the sense of computation complexity, but also the best choice in the sense of P@1 performance.

For stochastic ListNet, the performance improves with k increases. In contrast to the conventional ListNet, this improvement propagates to the results on the test data. For example, with the adaptive distribution sampling, the P@1 results on the training set are 0.4102 vs. 0.4184 with the Top-1 and Top-3 models respectively, and the results on the test data are 0.4121 vs. 0.4177 respectively.

Nevertheless, the P@1 performance improvement with a large k is rather marginal, and an over large k simply reduces the performance. To make it clear, we vary the value of k from 1 to 100 and plot the P@1 results in Figure 5). It can be seen that larger k (> 4) does not offer any merit but causes performance instability, particularly with the adaptive sampling approach. As we have discussed, with the stochastic ListNet, partial rank information can be learned with simple Top-k models, even the Top-1 model. This capability of partial rank learning with simple models reduces the necessity of employing complex Top-k models. This is a highly valuable conclusion, and it suggests that a simple Top-1 or Top-2 model is sufficient for the ListNet method, if the stochastic method is applied. Considering the trade-off between computation cost and model strength, we recommend stochastic Top-2 ListNet which delivers better P@1 performance than the Top-1 model consistently, with sufficiently fast computing. If more computation is affordable, stochastic Top-3 ListNet can be used to obtain better performance.

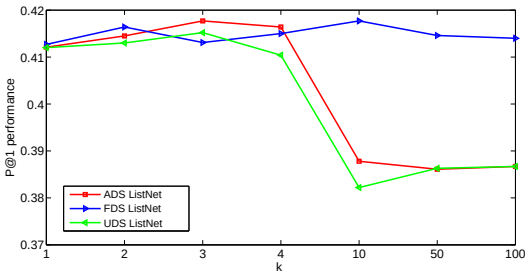

Figure 5: The P@1 performance on the test data with the stochastic Top-k ListNet approach, where k varies from 1 to 100.

Finally, we highlight that the conclusions ob-

Table 1: Averaged training time (in seconds), P@1 and P@10 on training, validation (Val.) and test data with different Top-k methods. 'C-ListNet' stands for conventional ListNet, 'S-ListNet' stands for stochastic ListNet.

tained from the P@1 results and the P@10 results perfectly match. In fact, the P@10 results look more consistent between training and test data, and the advantage of the stochastic approach seems more clear, particularly with the adaptive sampling. This is not surprising as the optimization goal of ListNet is essentially to form a good rank that involves multiple candidates, and so P@10 is apt to measure the superiority of a better rank approach.

5 Discussion

An interesting observation with the stochastic ListNet approach is that sampling more relevant documents improves performance. This can be explained by the data imbalance between relevant and irrelevant documents, i.e., there are much more irrelevant documents than relevant documents in the training data. This imbalance leads to biased models that tend to classify all documents as irrelevant. The re-sampling approach can be regarded as a way of balancing the two classes, and the fixed and adaptive distribution sampling can be regarded as another way to achieve the goal. Note that in the fixed distribution sampling, the distribution is solely dependent on the human-labeled scores. These scores are good measures of the *rank* of relevance but not good measures of the relevance itself. A possible way to solve this problem is to learn a scoring function that maps human-labelled scores to more reasonable measures of document relevance, though we took a different way that employs the network outputs as the relevance measures, which is what the adaptive distribution sampling method does. Note that the network output is a natural measure of document relevance, so the adaptive distribution sampling works the best in our experiments.

Another related issue is the harsh labelling of the AM2008 dataset. In this dataset, documents are labelled by only three values $\{0, 1, 2\}$, which is rather imprecise and the rank information is very limited. This harsh labeling is another reason why the uniform distribution sampling does not work: by uniform distribution sampling, there is a large probability that the sampled object lists involve documents that are all labelled by 0. This leads to an inefficient learning. Another consequence of the harsh labeling is that the power of complicated ranking models is largely constrained. For example, with the Top-k ($k > 1$) ListNet model, many of the k documents in a candidate list are labelled as the same score, resulting in limited rank information for the Top-k model to learn. This is why Top-k models did not exhibit much superiority to the Top-1 model in our experiments. We argue that top-k models would provide more contributions with more thorough labels (e.g., scores in real values). This is an ongoing research of our group.

Finally, we highlight that the stochastic approach is not limited to the ListNet model, but any model for listwise learning. It is well known that listwise learning outperforms pairwise learning, due to it is capability of learning full ranks (Liu, 2009). However learning full ranks requires unaffordable computation and so is infeasible in practice, even with the Top-k approximation. Our work demonstrated that learning full ranks can be approximated by learning partial ranks, and a limited number samples of such partial ranks is sufficient to convey the rank information. This stochastic learning is very fast, and even delivers better performance. It can be regarded as a general framework that treats both the pair-wise learning and the full rank learning as two special cases. In fact, if the set of partial ranks involves all the permutation classes, it reduces to the conventional listwise learning, and if the set of partial ranks involves all object pairs, it resembles the pairwise learning. A wide range of listwise learning methods can benefit from the idea of stochastic learning provided in this paper.

6 Conclusion

This paper proposed a stochastic ListNet method to speed up the training of ListNet models and improve the ranking performance. The basic idea is to approximate the full rank learning by learning a small number of partial ranks. Three sampling approaches were proposed to select the partial ranks, and Top-k ListNet models with various complexity (k values) were investigated.

Our preliminary results on the MQ2008 dataset confirmed that the stochastic ListNet approach can dramatically speeds up the model training, and more interestingly, it can produce better ranking performance than the conventional ListNet. Especially, the adaptive distribution sampling method delivered the best P@1 performance. An appealing observation is that the simple Top-2 model is very effective and more complex Top-k models

seem not very necessary, considering the trade-off between training complexity and model strength. This observation, however, is purely based on the MQ2008 dataset. As have been discussed, more detailed human labels may require more complex models, for which the stochastic method proposed in this paper is essential to conduct the model training. For the future work, we plan to study Top-k ListNet models with other databases and apply the stochastic learning approach to other listwise learning to rank methods.

Abstract

Elementary-level science exams pose significant knowledge acquisition and reasoning challenges for automatic question answering. We develop a system that reasons with knowledge derived from textbooks, represented in a subset of first-order logic. Automatic extraction, while scalable, often results in knowledge that is incomplete and noisy, motivating use of reasoning mechanisms that handle uncertainty.

Markov Logic Networks (MLNs) seem a natural model for expressing such knowledge, but the exact way of leveraging MLNs is by no means obvious. We investigate three ways of applying MLNs to our task. First, we simply use the extracted science rules directly as MLN clauses and exploit the structure present in hard constraints to improve tractability. Second, we interpret science rules as describing prototypical entities, resulting in a drastically simplified but brittle network. Our third approach, called Praline, uses MLNs to align lexical elements as well as define and control how inference should be performed in this task. Praline demonstrates a 15% accuracy boost and a 10x reduction in runtime as compared to other MLN-based methods, and comparable accuracy to word-based baseline approaches.

1 Introduction

We consider the problem of answering questions in standardized science exams (Clark et al., 2013), which are used as a benchmark for developing knowledge acquisition and reasoning capabilities. The 4th grade science exam dataset from Clark et al. (2013) tests for a wide variety of knowledge and its application to specific scenarios. In particular we focus on a subset that test students' understanding of various kinds of general rules and principles (e.g., *gravity pulls objects towards the Earth*) and their ability to apply these rules to reason about specific situations or scenarios (e.g., *which force is responsible for a ball to drop?*).

Answering these questions can be naturally formulated as a reasoning task given the appropriate form of knowledge. Prior work on reasoning based approaches has largely relied on manually input knowledge (Lenat, 1995). We present an investigation of a reasoning approach that operates over knowledge automatically extracted from text.

In order to effectively reason over knowledge derived from text, a QA system must handle incomplete and potentially noisy knowledge, and allow for reasoning under uncertainty. We cast QA as a reasoning problem in weighted-first order logic. While many probabilistic formalisms exist, we use Markov Logic Networks for the ease of specification of weighted rules. MLNs have been adopted for many NLP tasks (Singla and Domingos, 2006a; Kok and Domingos, 2008; Poon and Domingos, 2009). Recently, Beltagy et al. (2013) and Beltagy and Mooney (2014) have shown that MLNs can be used to reason with rules derived from natural language. While MLNs appear to be a natural fit, it is a priori unclear how to effectively formulate the QA task as an MLN problem. We find that unique characteristics of this domain pose new challenges in efficient inference. Moreover, it is unclear how MLNs might perform on automatically extracted noisy rules and how they would fare against simpler baselines that do not rely as much on structured logical representations.

Our goal is to build a high accuracy reasoning-based QA system that can answer a question in near real time. To this end, we investigate three MLN-based formulations: (1) A natural formulation that is intuitive but suffers from inefficient in-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 685–694,
Lisbon, Portugal, 17-21 September 2015.

ference (e.g., over 10 minutes on 31% of the questions); (2) an extension that improves efficiency by using prototypical constants, but is brittle to variation in structure; and (3) a formulation with improved flexibility to handle variation in text and structure that is 15% more accurate and 10x faster than the other approaches.

Despite significant improvements over two natural MLN formulations, the best reasoning-based configuration still does not outperform a simpler word-based baseline. We surmise that without effective salience models on text-derived rules, reasoning is unable to leverage the systematic advantages of the MLN-based models. The improved flexibility in the MLN-based models essentially appears to approximate word-based approaches due to the noisy and incomplete nature of the input knowledge. Nevertheless, the reasoning based method shows improved performance when adding multiple rules, which provides a principled way to inject additional knowledge and control inference for further improvements.

2 Background: QA Task

Following Clark et al. (2014), we formulate QA as a reasoning task over knowledge derived from textual sources. A multiple choice question with k answer options is turned into k true-false questions, each of which asserts some known facts (the $setup$) and posits a $query$. The reasoning task is to determine whether the $query$ is true given the $setup$ and the input knowledge.

The input knowledge is derived from 4th-grade science texts and augmented with a web search for terms appearing in the texts. Much of this knowledge is in terms of generalities, expressed naturally as IF-THEN rules. We use the representation and extraction procedures of Clark et al. (2014), recapitulated briefly here for completeness.

Rule Representation: The generalities in text convey information about classes of entities and events. Following the neo-davidsonian reified representation (Curran et al., 2007), we encode information about events (e.g, falling) and entities (e.g., ball or stone) using variables. Predicates such as $agent$, $cause$, $function$, $towards$, and in define semantic relationships between variables. Rather than committing to a type ontology, the variables are associated with their original string representation using an isa predicate.

The "if" or $antecedent$ part of the rule is semantically interpreted as being universally quantified (omitted below for conciseness) whereas every entity or event mentioned only in the "then" or $consequent$ part of the rule is treated as existentially quantified. Both $antecedent$ and $consequent$ are interpreted as conjunctions. For example, "Growing thicker fur in winter helps some animals to stay warm" translates into:

$$\begin{aligned} &isa(g, \text{grow}), isa(a, \text{some animals}), \\ &isa(f, \text{thicker fur}), isa(w, \text{the winter}), \\ &agent(g, a), object(g, f), in(g, w) \\ &\Rightarrow \exists s, r : isa(s, \text{stays}), isa(r, \text{warm}), \\ &\quad enables(g, s), agent(s, a), object(s, r) \end{aligned} \quad (1)$$

Question Representation: The question representation is computed similarly except that we use fixed constants (represented as block letters) rather than variables. For example, consider the question: "A fox grows thick fur as the season changes. This helps the fox to (A) hide from danger (B) attract a mate (C) find food (D) keep warm?" The T/F question corresponding to option (D) translates into:

$$\begin{aligned} setup :& isa(F, \text{fox}), isa(G, \text{grows}), isa(T, \\ & \quad \text{thick fur}), agent(G, F), object(G, T) \\ query :& isa(K, \text{keep warm}), enables(G, K), \\ & \quad agent(K, F) \end{aligned}$$

Lexical Reasoning: Since entity and event variables hold textual values, reasoning must accommodate lexical variability and textual entailment. For example, the surface forms "thick fur" and "thicker fur" are semantically equivalent. Also, the string "fox" entails "some animal". We use a lexical reasoning component based on textual entailment to establish lexical equivalence or entailment between variables.

Most Likely Answer as Inference: Given KB rules and the question as input, we formulate a probabilistic reasoning problem by adding lexical reasoning probabilities and incorporating uncertainties in derived rules. Given setup facts S and k answer options Q_i, we seek the most likely answer option: $\arg\max_{i \in \{1,\ldots,k\}} \Pr[Q_i \mid S, KB]$. This is a Partial MAP computation which is known to be #P-hard (Park, 2002). Hence methods such as Integer Linear Programming are not directly applicable.

2.1 Challenges

Reasoning with text-derived knowledge presents challenges that expose the *brittleness* and *rigidity* inherent in pure logic-based frameworks. Text-derived rules are incomplete and include lexical items as logical elements, making rule application in a pure logical setting extremely brittle: Many relevant rules cannot be applied because their preconditions are not fully satisfied due to poor alignment. For example, naive matching of rule (1) with the facts in the $setup$ would not conclude the $query$ since the rule requires "in the winter" to be true. A robust inference mechanism must allow for rule application with partial evidence. Further, a single text-derived rule may be insufficient to answer a question. For example, "Animals grow thick fur in winter" and "Thick fur helps keep warm" may need to be chained.

3 Probabilistic Formulations

Statistical Relational Learning (SRL) models (Getoor and Taskar, 2007) are a natural fit for QA reasoning. They provide probabilistic semantics over knowledge in first-order logic, thereby handling uncertainty in lexical reasoning and incomplete matching. While there are many SRL formalisms including Stochastic Logic Programs (SLPs) (Muggleton, 1996), ProbLog (Raedt et al., 2007), and PRISM (Sato and Kameya, 2001), we use Markov Logic Networks (MLNs) for their ease of specification and ability to naturally handle potentially cyclic rules.

Markov Logic Networks (MLNs) are relational models represented using weighted first-order logic rules. The rules provide a template for generating a Markov network by grounding the variables to all the constants in the rules. Each rule f_i forms a clique in the ground network and its weight w_i determines the potential for the clique. Since all cliques generated by grounding the same clause have the same weight, the probability of a given assignment is calculated as:

$$P(\mathbf{X} = \mathbf{x}) = \frac{1}{Z} \exp\left(\sum_i w_i n_i(\mathbf{x})\right)$$

where $n_i(\mathbf{x})$ is the number of times the ith formula is satisfied by the world $\mathbf{x}$ and Z is a normalization constant. Intuitively, a rule with a positive weight is more likely to be true than false.Higher the weight of a rule, more likely it is to be true.

We explore three MLN formulations:

a) First-order MLN: Given a question and relevant first-order KB rules, we convert them into an MLN program and let MLN inference automatically handle rule chaining. While a natural first-order formulation of the QA task, this struggles with long conjunctions and existentials in rules, as well as relatively few atoms and little to no symmetries. This results in massive grounding sizes, not remedied easily by existing solutions such as lazy, lifted, or structured inference. We exploit the structure imposed by hard constraints to vastly simplify groundings and bring them to the realm of feasibility, but performance remains poor.

b) Entity Resolution MLN: Instead of reasoning with rules that express generalities over classes of individuals, we replace the variables in the previous formulation with prototypical constants. This reduces the number of groundings, while retaining the crux of the reasoning problem defined over generalities. Combining this idea with existing entity resolution approaches substantially improves scalability. However, this turns out to be too brittle in handling lexical mismatches, especially in the presence of differences in parse structures

c) Praline MLN: Both of the above MLNs rely on exactly matching the relations in the KB and question representation, making them too sensitive to syntactic differences. In response, PRobabilistic ALignment and INferencE (Praline) performs inference using primarily the string constants but guided by the edge or relational structure. We relax the rigidity in rule application by explicitly modeling the desired QA inference behavior instead of relying on MLN's semantics.

3.1 First-Order MLN Formulation

For a set R of first-order KB rules, arguably the most natural way to represent the QA task of computing $\Pr[Q_i \mid S, R]$ as an MLN program M is to simply add R essentially verbatim as first-order rules in M. For all existentially quantified variables, we introduce a new domain constant. Predicates of M are those in R, along with a binary $entails$ predicate representing the lexical entailment blackbox, which allows M to probabilistically connect lexically related constants such as "thick_fur" and "thicker_fur" or "fox" and "some_animals". $entails$ is defined to be closed-world and is not necessarily transitive.

Evidence: Soft evidence for M consists of $entails$ relations between every ordered pair of entity (or event) strings, e.g., $entails(\text{fox}, \text{some\_animals})$. Hard evidence for M comprises grounded atoms in S.

Query: The query atom in M is $result()$, a new zero-arity predicate $result()$ that is made equivalent to the conjunction of the predicates in Q_i that have not been included in the evidence. We are interested in computing $\Pr[result() = \text{true}]$.

Semantic Rules: In addition to KB science rules, we add *semantic rules* that capture the intended meaning of our predicates, such as every event has a unique agent, $cause(x, y) \rightarrow effect(y, x)$, etc. Semantic predicates also enforce natural restrictions such as non-reflexivity, $!r(x, x)$, and anti-symmetry, $r(x, y) \rightarrow !r(y, x)$.

Finally, to help bridge lexical gaps more, we use a simple external lexical alignment algorithm to estimate how much does the $setup$ entail $antecedent_r$ of each KB rule r, and how much does $consequent_r$ entail $query$. These are then added as two additional MLN rules per KB rule.

Our rules have a specific first-order logic form:

$$\forall x_1, .., x_k \bigwedge_i R_i(x_{i_1}, x_{i_2}) \rightarrow \exists x_{k+1}, .., x_{k+m} \bigwedge_j R_j(x_{j_1}, x_{j_2})$$

Existentials spanning conjunctions in the consequent of this rule form can neither be directly fed into existing MLN systems nor naively translated into a standard form without incurring an exponential blowup. We introduce a new "existential" predicate $E_j^{\alpha}(x_1, \ldots, x_k, x_{k+j})$ for each existential variable x_{k+j} in each such rule α. This predicate becomes the consequent of α, and hard MLN rules make it equivant to the original consequent.

3.1.1 Boosting Inference Efficiency.

A bottleneck in using MLN solvers out-of-the-box for this QA formulation is the prohibitively large grounded network size. For example, 34 out of 108 runs timed out during MLN grounding phase after 6 minutes. On average, the ground networks in these runs were of the order of 1.4×10^6 ground clauses. Such behavior has also been observed, perhaps to a lesser degree, in related NLP tasks such as RTE (Beltagy and Mooney, 2014) and STS (Beltagy et al., 2014).

Existing techniques address large grounding size by focusing on relevant atoms (Singla and Domingos, 2006b; Shavlik and Natarajan, 2009) or grouping atoms into large classes of interchangeable atoms (de Salvo Braz et al., 2005; Gogate and Domingos, 2011; Venugopal and Gogate, 2012). Our QA encoding has very few atoms (often under 500) but very long clauses and highly asymmetric structure. This makes existing methods ineffective. For example, lazy inference in Alchemy-1[1] reduced ∼70K ground clauses to ∼56K on a question, while our method, described next, brought it down to only 951 clauses. Further, Lifted Blocked Gibbs and Probabilistic Theorem Proving, as implemented in Alchemy-2, were slower than basic Alchemy-1.

We utilize the combinatorial structure imposed by the set H of hard constraints (e.g., semantic rules, definition style rules, some science rules) present in the MLN, and use it to simplify the grounding of *both* hard and soft constraints. Importantly, this does not alter the first-order MLN semantics. The approach thus embraces hard clauses rather than relaxing them, as is often done in probabilistic inference techniques, especially when avoiding infinite energy barriers in MCMC based methods. Assuming an arbitrary constraint ordering in H, let F_i denote the first i constraints. Starting with $i = 1$, we generate the propositional grounding G_i of F_i, use a propositional satisfiability (SAT) solver to identify the set B_i of *backbone variables* of G_i (i.e., variables that take a fixed value in all solutions to G_i), freeze values of the corresponding atoms in B_i, increment i, and repeat until $G_{|H|}$ has been processed. Although the end result can be described simply as freezing atoms corresponding to the backbone variables in the grounding of H, the incremental process helps us control the intermediate grounding size as a propositional variable is no longer generated for a frozen atom. Once the freezing process is complete, the full grounding of H is further simplified by removing frozen variables. Finally, the soft constraints S are grounded much more efficiently by taking frozen atoms into account. Our approach may also be seen as an extension of a proposal by Papai et al. (2011).

[1] http://alchemy.cs.washington.edu

3.2 Entity Resolution Based MLN

Representing generalities as quantified rules defined over classes of entities or events appears to be a natural formulation, but is also quite inefficient leading to large grounded networks. Despite the drastically reduced number of groundings by our inference approach, the first-order MLN formulation still timed out on 31% of the questions. Hence we consider an alternative formulation that treats generalities as relations expressed over *prototypical* entities and events. This formulation leverages the fact that elementary level science questions can often be answered using relatively simple logical reasoning over exemplar objects and homogeneous classes of objects. The only uncertainty present in our system is what's introduced by lexical variations and extraction errors, which we handle with probabilistic equality.

KB Rules and Question: We define rules over prototypical entity/event *constants*, rather than first-order variables. These constants are tied to their respective string representations, with the understanding that two entities behave similarly if they have lexically similar strings. For example,

$$agent(Grow, Animals), object(Grow, Fur) \Rightarrow enables(Grow, StayWarm)$$

What was a first-order rule in FO-MLN is now already fully grounded! Entities/events in the question are also similarly represented by constants. Note that the efficiency boost using hard constraints (Section 3.1.1) is orthogonal to using prototypical constants and can be applied here as well.

Equivalence or Resolution Rules: Using a simple probabilistic variant of existing Entity/Event Resolution frameworks (Singla and Domingos, 2006a; Kok and Domingos, 2008), we ensure that (a) two entities/events are considered similar when they are tied to lexically similar strings and (b) similar entities/events participate in similar relations w.r.t. other entities/events. This defines soft *clusters* or equivalence classes of entities/events. We use a probabilistic $sameAs$ predicate which is reflexive, symmetric, and transitive, and interacts with the rest of the MLN as follows:

$$isa(x, s), entails(s, s') \rightarrow isa(x, s').$$
$$isa(x, s), isa(y, s) \rightarrow sameAs(x, y).$$
$$w: \ isa(x, s), !isa(y, s) \rightarrow !sameAs(x, y)$$
$$r(x, y), sameAs(y, z) \rightarrow r(x, z).$$

r in the last rule refers to any of the MLN predicates other than $entails$ and isa. The $sameAs$ predicate, as before, is implemented in a typed fashion, separately for entities and events. We will refer to this formulation as ER-MLN.

Partial Match Rules: Due to lexical variability, often not all conjuncts in a rule's $antecedent$ are present in the question's $setup$. To handle incomplete matches, for each KB derived MLN rule of the form $(\wedge_{i=1}^{k} L_i) \rightarrow R$, we also add k soft rules of the form $L_i \rightarrow R$. This adds flexibility, by helping "fire" the rule in a soft manner. This differs from FO-MLN which uses an external alignment system to find parts of the $antecedent$ mentioned in the $setup$, L' and creates one rule $L' \Rightarrow R$.

Comparison with FO-MLN: Long KB rules and question representation now no longer have quantified variables, only the binary or ternary rules above do. These mention at most 3 variables each and thus have relatively manageable groundings. On the other hand, as discussed in the next section, ER-MLN can fail on questions that have distinct entities with similar string representations (e.g. two distinct plants in a question would map to the same entity). Further, it fails to apply valid rules in the presence of syntactic differences such as $agent(\text{Fall}, \text{Things})$ generated by "things fall due to gravity" and $object(\text{Dropped}, \text{Ball})$ for "a student dropped a ball". Although "drop" entails "fall" and "ball" entails "object", ER-MLN cannot reliably bridge the structural difference involving $object$ and $agent$, as these two relationships typically aren't equivalent. Despite these limitations, ER-MLN provides a substantial scalability advantage over FO-MLN on a vast majority of the questions that remain within its scope.

3.3 PRobabilistic ALignment and INferencE

ER-MLN handles some of the word-level lexical variation via *resolution* and soft *partial match* rules that break long antecedents. However, it is still rigid in two respects:

(1) ER-MLN primarily relies on the predicates (also referred to as links or edges) for inference. As a result, even if the words in the $antecedent$ and $setup$ have high entailment scores, the rule will still not "fire" if the edges do not match.

(2) As entities bound to lexically equivalent strings are forced to "behave" identically, ER-

MLN fails on questions that involve two different entities that are bound to equivalent string representations. Consider the question: "A student puts two identical plants in the same type and amount of soil. She puts one of these plants near a sunny window and the other in a dark room. This experiment tests how the plants respond to (A) light (B) air (C) water (D) soil." The entities corresponding to the two plants will be bound to equivalent string representations and hence will be treated as the same entity. To avoid this, we do not force the entailment-based clusters of constants to behave similarly. Instead, as discussed below, we use the clusters to guide inference in a softer manner.

To introduce such flexibility, we define an MLN to directly control how new facts are inferred given the KB rules. The flexibility to control inference helps address two additional QA challenges:

Acyclic inference: While knowledge is extracted from text as a set of directed rules each with an $antecedent$ and a $consequent$, there is no guarantee that the rules taken together are acyclic. For example, a rule stating "Living things → depend on the sun" and "Sun → source of energy for living things" may exist side-by-side. Successful inference for QA must avoid feedback loops.

False unless proven: While MLNs assume atoms not mentioned in any rule to be true with probability 0.5, elementary level science reasoning is better reflected in a system that assumes all atoms to be false unless stated in the question or proven through the application of a rule. This is similar to the semantics of Problog (Raedt et al., 2007) and PRISM (Sato and Kameya, 2001).

While acyclic inference and false unless proven can be handled by setting high negative priors in MLNs, inference behavior is susceptible to variations in these weights. By using hard rules to control the direction of inference, we can explicitly enforce these constraints.

We introduce a unary predicate called $holds$ over string constants to capture the probability of a string constant being true given the $setup$ is true ($\forall x \in setup, holds(x) = true$) and the KB rules hold. Instead of using edges for inference, we use them as factors influencing alignment: similar constants have similar local neighborhoods. With n string constants, this reduces the number of unobserved groundings from $O(n^2)$ edges in the ER-MLN to $O(n)$ existence predicates. For the example rule (1), Praline can be viewed as using the following rule for inference:

$$holds(Grow), holds(Animals), holds(Fur),$$
$$holds(Winter) \Rightarrow holds(Stays), holds(Warm)$$

If we view KB rules and question as a labeled graph G (Figure 1), alignment between string constants corresponds to node alignment in G. The nodes and edges of G are the input to the MLN, and the $holds$ predicate on each node captures the probability of it being true given the $setup$. We now use MLNs (as described below) to define the inference procedure for any such input graph G.

Evidence: We represent the graph structure of G using predicates $node(nodeid)$ and $edge(nodeid, nodeid, label)$. We use $setup(nodeid)$ and $query(nodeid)$ to represent the question's $setup$ and $query$, resp. Similarly, we use $inLhs(nodeid)$ and $inRhs(nodeid)$ to represent rules' $antecedent$ and $consequent$, resp.

Graph Alignment Rules: Similar to the previous approaches, we use entailment scores between words and short phrases to compute the alignment. In addition, we also expect *aligned* nodes to have similar edge structures:

$$aligns(x, y), edge(x, u, r), edge(y, v, s) \Rightarrow aligns(u, v)$$

That is, if node x aligns with y then their children/ancestors should also align. We create copies of these rules for edges with the same label, $r = s$, with a higher weight and for edges with different labels, $r \neq s$, with a lower weight.

Inference Rules: We use MLNs to define the inference procedure to prove the $query$ using the alignments from $aligns$. We assume that any node y that $aligns$ with a node x that $holds$, also $holds$:

$$holds(x), aligns(x, y) \Rightarrow holds(y) \qquad (2)$$

For example, if the setup mentions "fox", all nodes that entail "fox" also hold. As we also use the edge structure during alignment, we would have a lower probability of "fox" in "fox finds food" to align with "animal" in "animal grows fur" as compared to "animal" in "animal finds food".

We use KB rules to further infer new facts that should hold based on the rule structure. We compute $lhsHolds$, the probability of the rule's

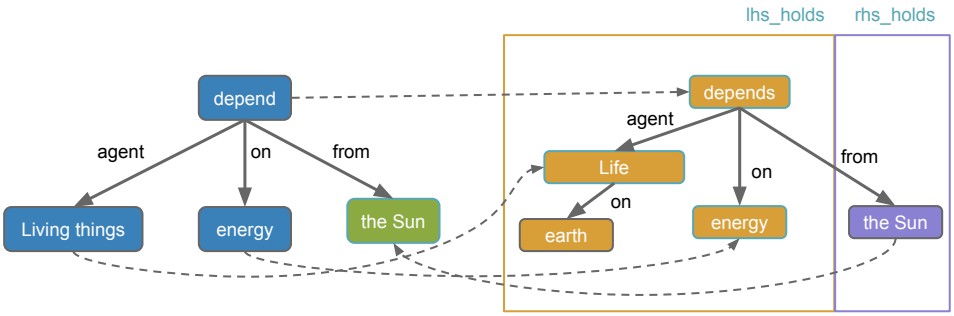

Figure 1: KB rule and question as a graph where blue:$setup$; green:$query$; orange:$antecedent$; purple:$consequent$; dotted lines: alignments. $lhsHolds$ combines individual probabilities of $antecedent$ nodes and $rhsHolds$ captures the probability of the $consequent$.

$antecedent$ holding, and use it to infer $rhsHolds$, the probability of the $consequent$. Similar to ER-MLN, we break the rule into multiple small rules.[2]

$$w : holds(x), inLhs(x, r) \Rightarrow lhsHolds(r)$$
$$w : !holds(x), inLhs(x, r) \Rightarrow !lhsHolds(r)$$
$$lhsHolds(r) \Rightarrow rhsHolds(r).$$
$$rhsHolds(r), inRhs(r, x) \Rightarrow holds(x).$$

Acyclic inference: We use two predicates, $proves(nodeid, nodeid)$ and $ruleProves(rule, rule)$, to capture the inference chain between nodes and rules, resp. To ensure acyclicity in inference, we add transitive clauses over these predicates and disallow reflexivity, i.e., $!proves(x, x)$, and update rule (2):

$$w_p : proves(x, y), holds(x) \Rightarrow holds(y)$$
$$w_a : aligns(x, y) \Rightarrow proves(x, y)$$

We capture inference direction between rules by checking consequent and antecedent alignments:

$$proves(x, y), inrhs(x, r1), inlhs(y, r2) \Rightarrow ruleProves(r1, r2).$$

False unless proven: To ensure that nodes hold only if they can be proven from $setup$, we add bidirectional implications to our rules. An alternative is to introduce a strong negative prior on $holds$ and have a higher positive weight on all other clauses that conclude $holds$. However, the performance of our MLNs was very sensitive to the choice of the weight. We instead model this constraint explicitly. Figure 1 shows a sample inference chain using dotted lines.

[2] An intuitive alternative for the 2nd clause doesn't capture the intending meaning, $-w : !holds(x), inLhs(x, r) \Rightarrow lhsHolds(r)$

Praline defines a meta-inference procedure that is easily modifiable to enforce desired QA inference behavior, e.g. $w : aligns(x, y), setup(x) \Rightarrow !query(y)$ would prevent a term from the $setup$ to align with the $query$. Further, by representing the input KB and question as evidence, we can define a single static first-order MLN for all the questions instead of a compiled MLN for every question. This opens up the possibility of learning weights of this static MLN, which would be challenging for the previous two approaches.[3]

4 Empirical Evaluation

We used Tuffy 0.4[4] (Niu et al., 2011) as the base MLN solver[5] and extended it to incorporate the hard-constraint based grounding reduction technique discussed earlier, implemented using the SAT solver Glucose 3.0[6] (Audemard and Simon, 2009) exploiting its "solving under assumptions" capability for efficiency. We used a 10 minute timelimit, including a max of 6 minutes for grounding. Marginal inference was performed using MC-SAT (Poon and Domingos, 2006), with default parameters and 5000 flips per sample to generate 500 samples for marginal estimation.

We used a 2-core 2.5 GHz Amazon EC2 linux machine with 16 GB RAM. We selected 108 elementary-level science questions (non-diagram, multiple-choice) from 4th grade New York Regents exam as our benchmark (Dev-108) and used another 68 questions from the same source as a blind test set (Unseen-68)[7].

[3] In this work, we have set the weights manually.

Question Set	MLN Formulation	#Answered (some / all)	Exam Score	#MLN Rules	#Atoms	#Ground Clauses	Runtime (all)
Dev-108	FO-MLN	106 / 82	33.6%	35	384*	524*	280 s
	ER-MLN	107 / 107	34.5%	41	284	2,308	188 s
	PRALINE	108	**48.8%**	51	182	219	**17 s**
Unseen-68	FO-MLN	66	33.8%	-	-	-	288 s
	ER-MLN	68	31.3%	-	-	-	226 s
	PRALINE	68	**46.3%**	-	-	-	**17 s**

Table 1: QA performance of various MLN formulations. #MLN-Rules, #GroundClauses, and Runtime per multiple-choice question are averaged over the corresponding dataset. #Answered column indicates questions where at least one answer option didn't time out (left) and where no answer option timed out (right). Of the 432 Dev MLNs (108×4), #Atoms and #GroundClauses for FO-MLN are averaged over the 398 MLNs where grounding finished; 34 remaining MLNs timed out after processing 1.4M clauses.

The KB, representing roughly 47,000 sentences, was generated in advance by processing the New York Regents 4th grade science exam syllabus, the corresponding Barron's study guide, and documents obtained by querying the Internet for relevant terms. Given a question, we use a simple word-overlap based matching algorithm, referred to as the *rule selector*, to retrieve the top 30 matching sentences to be considered for the question. Textual entailment scores between words and short phrases were computed using WordNet (Miller, 1995), and converted to "desired" probabilities for soft $entails$ evidence. The accuracy reported for each approach is computed as the number of multiple-choice questions it answers correctly, with a partial credit of $1/k$ in case of a k-way tie between the highest scoring options if they include the correct answer.

4.1 MLN Formulation Comparison

Table 1 compares the effectiveness of our three MLN formulations: FO-MLN, ER-MLN, and Praline. For each question and approach, we generate an MLN program for each answer option using the most promising KB rule for that answer option.

In the case of FO-MLN, Tuffy exceeded the 6 minute time limit when generating groundings for 34 of the 108×4 MLNs for the Dev-108 question set, quitting after working with 1.4×10^6 clauses on average, despite starting with only around 35 first-order MLN rules. In the remaining MLNs, where our clause reduction technique successfully finished, the ground network size reduced dramatically to 524 clauses and 384 atoms on average.

Tuffy finished inference for all 4 answer options for 82 of the 108 questions; for other questions, it chose the most promising answer option among the ones it finished processing. Overall, this resulted in a score of 33.6% with an average of 280 seconds per multiple-choice question on Dev-108, and similar performance on Unseen-68.

ER-MLN, as expected, did not result in any timeouts during grounding. The number of ground clauses here, 2,308 on average, is dominated not by KB rules but by the binary and ternary entity resolution clauses involving the $sameAs$ predicate. ER-MLN was roughly 33% faster than FO-MLN, but overall achieved similar exam scores.

Praline resulted in a 10x speedup over ER-MLN, explained in part by much smaller ground networks with only 219 clauses on average. It boosted exam performance by roughly 15%, pushing it up to 48.8% on Dev-108 and 46.3% on Unseen-68 (statistically significantly better than FO-MLN with p-value < 0.05). This demonstrates the value that the added flexibility and control Praline brings.

4.2 Praline: Improvements and Ablation

We evaluate Praline when using multiple KB rules as a chain or multiple inference paths. Simply using the top two rules for inference turns out to be ineffective as they are often very similar. Instead, we use *incremental inference* where we add one rule, perform inference to determine which additional facts now hold and which $setup$ facts haven't yet been used, and then use this information to select the next best rule. This, as the Chain=2 entries in the first row of Table 2 show, improves Praline's accuracy on both datasets. The improvement comes at the cost of a modest runtime increase from 17 seconds per question to 38.

Finally, we evaluate the impact of Praline's additional rules to handle acyclicity (Acyclic) and the false unless proven (FUP) constraint. As Table 2 shows, Praline's accuracy drops upon removing

MLN	One rule		Chain=2	
	Dev-108	Unseen	Dev-108	Unseen
Praline	48.8%	46.3%	**50.3%**	**52.7%**
-Acyclic	44.7%	36.0%	43.6%	30.9%
-FUP	35.0%	30.9%	42.1%	29.4%
-FUP -Acyclic	37.3%	34.2%	36.6%	24.3%

Table 2: QA performance of Praline MLN variations.

	Dev-108	Unseen-68	Dev-170	Unseen-176
Praline	50.3%	**52.7%**	33.2%	36.6%
Word-based	**57.4%**	51.5%	**40.3%**	**43.3%**

Table 3: QA performance: Praline vs. word-based.

either of these constraints, highlighting their importance. Specifically, when using only one KB rule, dropping FUP clauses has a bigger influence that dropping Acyclic constraint clauses. With a single rule, there is still a possibility of cyclic inference within a rule, leading to a small drop in score there as well. When chaining multiple rules, however, the possibility of incorrect cyclic inference is higher and we see a correspondingly larger drop in score when dropping Acyclic constraints.

4.3 Comparison to baseline approaches

Table 3 compares Praline to a baseline word-based method on two question sets. The new set here is from 4th and 5th grade, with 170 Dev and 176 unseen questions. The word-based approach calculates the entailment score, using the same methods as for the soft $entails$ evidence earlier, between the words in the T/F question and words in a rule in the KB. It then uses the maximum entailment score from all selected rules as the confidence measure i.e. $\max_{r \in R} entailment(q, r)$. While the scores of the two approaches are statistically similar (p-value > 0.05), the simple word-based approach does have a slight edge over Praline. Automatic extraction of knowledge from text provides additional information (e.g., rule structure) that MLNs are capable of exploiting. However, we found this additional flexibility to not pay off with the current knowledge-base and questions.

5 Conclusions

Reasoning with automatically extracted knowledge presents significant challenges. Our investigation of MLN-based formulations for elementary-level science exams highlights two key issues: 1) Natural translations of text derived knowledge into first-order representations are highly inefficient, resulting in large ground networks. 2) When the logical elements in the rules largely mirror the constructs in the source text, reasoning is hampered because of structural variability. In response, we proposed, Praline, an alignment based solution that is both efficient and accurate. Praline reasons with prototypical constants, and provides greater flexibility in how inference is performed and is therefore more robust to structural mismatches.

MLNs provided a flexible, structured framework to define inference for the QA task, while also providing reasoning chains used to arrive at an answer. While models such as MLNs seem a perfect fit for textual reasoning tasks such as RTE and QA, their performance on these tasks is still not up to par with textual feature-based approaches (Beltagy and Mooney, 2014). We conjecture that the increased flexibility of complex relational models results in increased susceptibility to noisy input, and the systematic advantages of MLN models are difficult to exploit with text-derived rules. Automatically learning weights of these models may allow leveraging their flexibility to address these issues, but weight learning remains challenging with only distant supervision.

We hope our datasets, knowledge bases, and MLN models[8] will help push NLP and SRL communities towards designing improved structured reasoning QA systems.

Abstract

Linking named mentions detected in a source document to an existing knowledge base provides disambiguated entity referents for the mentions. This allows better document analysis, knowledge extraction and knowledge base population. Most of the previous research extensively exploited the linguistic features of the source documents in a supervised or semi-supervised way. These systems therefore cannot be easily applied to a new language or domain. In this paper, we present a novel unsupervised algorithm named Quantified Collective Validation that avoids excessive linguistic analysis on the source documents and fully leverages the knowledge base structure for the entity linking task. We show our approach achieves state-of-the-art English entity linking performance and demonstrate successful deployment in a new language (Chinese) and two new domains (Biomedical and Earth Science). Experiment datasets and system demonstration are available at http://tw.rpi.edu/web/doc/hanwang_emnlp_2015 for research purpose.

1 Introduction and Motivation

The entity linking (EL) task aims at analyzing each named entity mention in a source document and linking it to its referent in a knowledge base (KB). Consider the following example: "*One day after released by the **Patriots**, **Florida** born **Caldwell** visited the **Jets**. ..... **The New York Jets** have six receivers on the roster: **Cotchery**, **Coles**, ...*". Here "*Caldwell*" is an ambiguous mention because not only are there thousands of people with different professions named "*Caldwell*", but even if as an American football player, as most people would recognize it from the context, there are several "*Caldwell*"s who are/were associated with either "*the Patriots*" or "*the Jets*". An EL system should be able to disambiguate the mention by carefully examining the context and then identify the correct KB referent, which is `Reche Caldwell` in this case.

Although EL has attracted a lot of community attention in the recent years, most research efforts have been focused on developing systems only effective for generic English corpora. When these systems are migrated to a new language or domain, their performance will usually suffer from a noticeable decline due to the following reasons:

1) State-of-the-art EL systems have developed comprehensive linguistic features from the source documents to generate advanced representations of the mentions and their context. While this methodology has been proved rewarding for a resource-rich language such as English, it prevents the systems from being adopted to a new language, especially to one with limited linguistic resources. One can imagine that it would be very difficult, if not impossible, for an English EL system that benefits from the part-of-speech tagging, dependency parsing, and named entity recognition to be deployed to a new language such as Chinese that has quite different linguistic characteristics.

2) The current EL approaches mostly target at people, organizations, and geo-political entities which are widely present in a general KB such as Wikipedia. However, domain-specific EL tends to pay more attention to entities beyond the above three types. For instance, in the biomedical science domain, protein is a major class of entities that greatly interest scientists. Conventional EL systems are very likely to fail in linking protein mentions in the text due to the lack of labeled

[*]These authors contributed equally to this work.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 695–704,
Lisbon, Portugal, 17-21 September 2015.

training data. Moreover, their reliance on general reference KBs seems insufficient for a specific domain. Take "*A20*", a type of protein as an example. Wikipedia has more than a few items listed under the name of "*A20*" and their types range from aircrafts to roads. This diversified information inevitably introduces noise for a biomedical EL application.

One potential solution to tackle these limitations is, instead of concentrating on the source documents, to conduct more deliberate study on the KB. Structured KBs such as DBpedia[1] typically offer detailed descriptions about entities, a large collection of named relations between entities, and a growing number of multi-lingual entity surface forms. By embracing these ready-for-use information and linked structures, we will be able to obtain sufficient contextual information for disambiguation without generating a full list of linguistic features from the source documents, and therefore eliminate the language dependency. Moreover, currently there exist numerous publicly available domain ontology repositories such as BioPortal[2] and OBO Foundry[3] which provide significantly more domain knowledge than general KBs for EL to leverage. By incorporating these domain ontologies, we can easily increase the entity coverage and reduce noise for deploying EL in various new domains.

In order to make the most of the KB structure, the mention context should be matched against the KB such that the relevant KB information can be extracted. A collective way of aligning co-occurred mentions to the KB graph has been proved to be a successful strategy to better represent the source context (Pennacchiotti and Pantel, 2009; Fernández et al., 2010; Cucerzan, 2011; Han et al., 2011; Ratinov et al., 2011; Dalton and Dietz, 2013; Zheng et al., 2014; Pan et al., 2015). We take a further step to consider quantitatively differentiating entity relations in the KB in order to evaluate entity candidates more precisely. Meanwhile, we jointly validate these candidates by aligning them back to the source context and integrating multiple ranking results. This novel EL framework deeply exploits the KB structure with a light weight representation of the source context, and thus enables a smooth migration to new languages and domains.

The main novel contributions of this paper are summarized as follows: 1) We design an unsupervised EL algorithm, namely, Quantified Collective Validation (QCV) that builds KB entity candidate graphs with quantified relations for the purpose of collective disambiguation and inference. 2) We develop a procedure of building language and domain independent EL systems by incorporating various ontologies into the QCV component. 3) We demonstrate that our system is able to achieve state-of-the-art performance in English EL, and it can also produce promising results for Chinese EL as well as EL in Biomedical Science and Earth Science.

2 Baseline Collective EL

As a baseline, we adopt a competitive unsupervised collective EL system (Zheng et al., 2014) utilizing structured KBs. It defines entropy based weights for the KB relations, and embeds them in a two-step candidate ranking process to produce the EL results.

Structured KB Terminologies: In a structured KB, a fact is usually expressed in the form of a triple: (e_h, r, e_t) where e_h, e_t are called the head entity and the tail entity, respectively, and r is the relation between e_h and e_t.

Entropy Based KB Relation Weights: The goal is to leverage various levels of granularity of KB relations. The calculation of the relation weight $H(r)$ is given in Equation (1):

$$H(r) = -\sum_{e_t \in E_t(r)} P(e_t) \log(P(e_t)) \qquad (1)$$

where $E_t(r)$ is the tail entity set for r in the KB, and $P(e_t)$ is the probability of e_t appearing as the tail entity for r in the KB.

Salience Ranking: As the first ranking step, we examine the candidates without the context and prefers those with higher importance in the KB. Equation (2) computes the salience score $S_a(c)$ for a candidate c:

$$S_a(c) = \sum_{r \in R(c), e_t \in E_t(r)} H(r) \frac{S_a(e_t)}{L(e_t)} \qquad (2)$$

where $R(c)$ is the relation set for c in the KB; $H(r)$ is given by Equation (1); $E_t(r)$ is the tail entity set with c being the head entity and r being the connecting relation in the KB; $L(e_t)$ denotes the

[1] http://wiki.dbpedia.org
[2] http://bioportal.bioontology.org
[3] http://www.obofoundry.org

cardinality of the tail entity set with e_t being the head entity in the KB. $S_a(c)$ is recursively computed until convergence.

Collective Ranking: The similarity $Sim^F(m, c)$ between a candidate c and its mention m is defined using Equation (3) as the final ranking score:

$$Sim^F(m,c) = \alpha \cdot JS(m,c) \cdot S_a(c) + \beta \cdot \sum_{r \in R(c)} H(r) \cdot \sum_{n \in E_t(r) \cap C(m)} S_a(n) \quad (3)$$

where $JS(m, c)$ is the Jaccard similarity between the string surface forms of m and c; $S_a(c)$ and $S_a(n)$ are both evaluated by Equation (2); $C(m)$ denotes the candidate set for mention m; α and β are hyperparameters.

3 Quantified Collective Validation

Incorporating the KB relation weighing mechanism of the baseline system, our QCV algorithm constructs a number of candidate graphs for a given set of collaborative mentions, and then performs a two-level ranking followed by a collective validation on those candidate graphs to acquire the linking results. Because this procedure minimally relies on linguistic analysis of the source documents while mainly uses the KB structure which by nature keeps detached from any specific language or domain, we claim that QCV comes with language and domain independence.

3.1 Candidate Graph Construction

The KB entity candidate graphs are constructed based on a mention context graph and a KB graph. We will introduce them in order as follows.

Mention Context Graph: To avoid abusing linguistic knowledge from the source documents, we construct a mention context graph G_m simply involving mention co-occurrence. Figure 1 depicts a constructed G_m for the *Caldwell* example at the beginning of Section 1. In this figure, mentions "*New York Jets*", "*Cotchery*" and "*Coles*" are brought into G_m through the coreference between "*Jets*" and "*New York Jets*" since the three of them are outside the context window of "*Caldwell*", "*Florida*", "*Patriots*", and "*Jets*". G_m contains a set of vertices representing the mentions extracted from the source document and a set of undirected edges. There will be an edge between two mention vertices if both of them fall into a context window with width w_m in the source document. Ideally, w_m should cover a single discourse according to the one sense per discourse assumption (Gale et al., 1992), but for simplicity we heuristically set w_m to be 7-sentence wide as a hyperparameter. Two mention vertices will be connected via a dashed edge if they are coreferential but are not located in the same context window. Here we determine the coreference by performing substring matching and abbreviation expansion. The dashed edge indicates the out-of-context coreferential mention together with its neighbors will be indirectly included in G_m as extended context to later facilitate the candidate graph collective validation. Note that all of these loose settings comply with our intention of generating a light-weight source context representation born with domain and language independence.

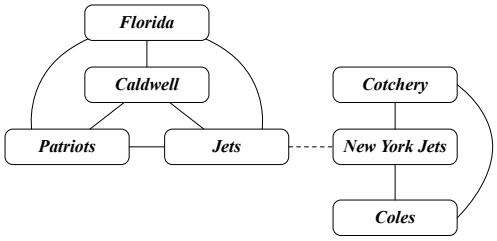

Figure 1: Mention context graph for the *Caldwell* example.

KB Graph: A structured KB such as DBpedia can be represented as a weighted graph G_k that consists of a set of vertices representing the entities and a set of directed edges labeled with relations between entities. The weights of relations are computed using Equation (1). In order to further enrich the KB relations, we add a type of relation named "wiki link" between two entities if one of them appears in the Wikipedia article of the other. Figure 2 presents a subgraph of the DBpedia KB graph containing the relevant entities in the *Caldwell* example.

Candidate Graph: The candidate graph is a set of graphs G_c^i $(i = 1, 2, ...)$ used for computing ranking scores for the KB entity candidates. For each of the mentions extracted from the source context, we first select a list of entity candidates from G_k with heuristic rules such as fuzzy string matching, synonyms, Wikipedia redirect, etc. Then we pick one candidate for each of the mentions to constitute the vertices of a G_c^i. In each G_c^i, we add an edge between two vertices if they are connected in G_k by some relation r and their mentions are connected in G_m. The edge label r from G_k is transferred to G_c^i. Upon comple-

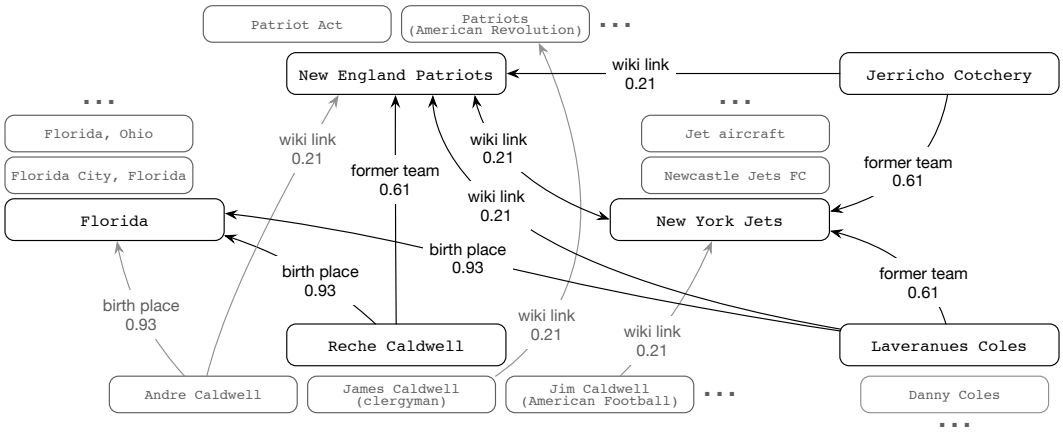

Figure 2: KB graph for the *Caldwell* example.

tion, every G_c^i represents a collective linking solution to the given mention set. Figure 3 shows three of the constructed candidate graphs for the *Caldwell* example. One can see that the first two graphs are very likely to be good solutions since they inherit many of the relation edges from G_K, while the third one is probably a poor collection as the candidates barely connect to one another. In the next section, we will more formally reveal how to rank these candidate graphs to obtain the optimal linking results.

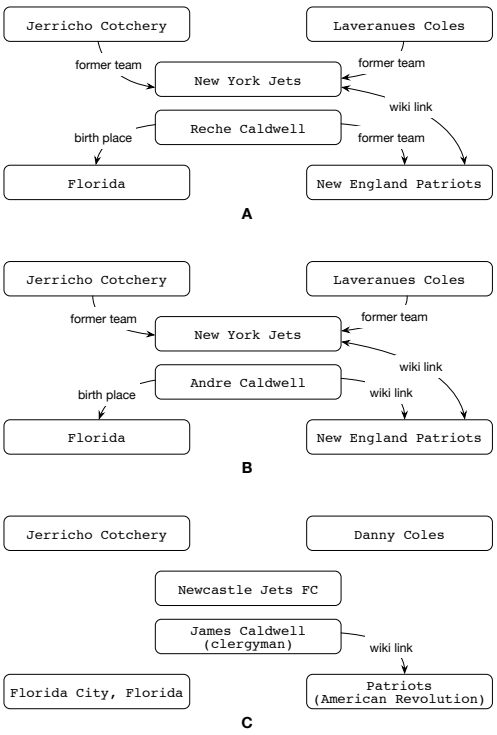

Figure 3: Candidate graphs for the *Caldwell* example.

3.2 Candidate Ranking

With the constructed candidate graphs, QCV performs two levels of ranking. First, it uses Equation (2) to compute the candidates' salience scores as a priori ranking. Then it compares each candidate graph with the mention context graph, and evaluates their vertex set similarity for context similarity ranking. Finally, by considering the relation weights in the candidate graphs as well as previous ranking scores, QCV collectively validates all the candidates and assembles the linking results. Below we will focus on introducing the context similarity ranking and the collective validation since the salience ranking resembles that of our baseline system.

Context Similarity Ranking: As shown in Figure 3, among the constructed candidate graphs, some of them contain many connected vertices while some are otherwise quite disconnected. Intuitively we would like to measure this structure difference by comparing each candidate graph G_c^i with its mention context graph G_m. Granted, we can only assert co-occurrence between two connected mentions in G_m, but it should be of great probability that two co-occurring mentions have their entity referents connected by some relation in the KB. In other words, the more a G_c^i is structurally similar to its G_m, the better the candidates in this G_c^i represent their mentions in G_m. Therefore, we define the context similarity $S_m(m_c, c)$ between a candidate c and its mention m_c using Jaccard similarity in Equation (4):

$$S_m(m_c, c) = \frac{|\Theta^{G_m}(m_c) \cap \Theta^{G_c^i}(c)|}{|\Theta^{G_m}(m_c) \cup \Theta^{G_c^i}(c)|} \quad (4)$$

where $\Theta^{G_m}(m_c)$ and $\Theta^{G_c^i}(c)$ denote m_c's neighbor set in G_m and c's neighbor set in G_c^i, respectively. The intersection takes the candidates of those mentions in $\Theta^{G_m}(m_c)$ that appear in $\Theta^{G_c^i}(c)$, and the union is equivalent to $\Theta^{G_m}(m_c)$ due to the way we construct G_c^i. We rank G_c^i using the summation of the context similarity of every c in G_c^i. Note that our baseline system uses Jaccard similarity to achieve approximate string match between the surface forms of a mention and a candidate, while we alternatively use it to capture the graph's structural similarity. After ranking with the context similarity, those G_c^i with more connected vertices such as Figure 3A and Figure 3B will get closer to the top of the ranked candidate graph list.

Candidate Graph Collective Validation: Besides the salience, the context similarity provides another ranking score for each candidate c in G_c^i, and it promotes those candidates remaining connected in G_c^i. However, it fails to differentiate how two candidates are connected. In Figure 3A, `Reche Caldwell` is a former player of `New England Patriots`, and in Figure 3B, `Andre Caldwell`'s Wikipedia article includes a hyperlink pointing to `New England Patriots`. The former seems a "tighter" relation than the latter. Although these two distinct relations imply that these two candidate pairs are related with different relation types, the context similarity rankings for these two candidate graphs are identical. Based on this observation, assuming that a "tighter" relation between two candidates is more likely to be an appropriate representation of the relation between their co-occurring mentions in the source context, we propose a novel validation step that not only considers the two previous ranking scores of each candidate but also quantitatively examines the relations between candidates. We transfer the calculated relation weights from G_k to G_c^i as positive indicators of how tightly two candidates are related, and then define the composite graph weight $W(G_c^i)$ for each G_c^i in Equation (5) as the final ranking metric:

$$W(G_c^i) = \sum_{c \in V(G_c^i)} S_a(c) S_m(m_c, c) + \sum_{r \in E(G_c^i)} H(r) \quad (5)$$

where $V(G_c^i)$ and $E(G_c^i)$ are the vertex set and the edge set of G_c^i; $S_a(c)$, $S_m(m_c, c)$, and $H(r)$ are given by Equation (2), Equation (4), and Equation (1), respectively. With this composite graph weight, since the relation "*former team*" has a greater weight than "*wiki link*", the candidate graph in Figure 3A outweighs that in Figure 3B, and therefore is ranked to the top.

4 Experiments

In this section, we first show QCV's performance on generic English corpora and compare it with our baseline together with other state-of-the-art EL systems. Then we move to a new language (Chinese) and two new domains (Biomedical Science and Earth Science) to demonstrate the language and domain independent nature of our algorithm.

4.1 EL on Generic English Corpora

For this evaluation, we used the TAC-KBP2013 EL dataset[1], which contains 2,190 mentions extracted from English newswire, web blogs, and discussion forums. We selected a subset of 1,090 linkable mentions that have entity referents in the KB for our experiment. DBpedia 3.9, which was generated from the Wikipedia dump in early 2013 and includes more than 4 million entities and more than 470 million facts[2], was used as our KB. We followed the KBP EL track using `B-Cubed+` (Ji et al., 2011) as the evaluation metric. Table 1 presents the results of QCV, our baseline system, as well as the top 3 supervised participant systems[3]and the top 3 unsupervised participant systems[3] of the TAC-KBP2013 EL track.

System	B^3+ F_1
Supervised 1st	0.724[4]
Supervised 2nd	0.721[4]
Supervised 3rd	0.718[4]
Unsupervised 1st	0.632[4]
Unsupervised 2nd	0.576[4]
Unsupervised 3rd	0.573[4]
Baseline (unsupervised)	0.697
QCV (unsupervised)	**0.749**

Table 1: Performance on the TAC-KBP2013 EL Dataset (1,090 linkable mentions).

[1]http://www.nist.gov/tac/2013/KBP/data.html

[2]http://wiki.dbpedia.org/services-resources/datasets/dataset-39

[3]Due to NIST policy, the names of the TAC-KBP2013 participant systems are not revealed.

[4]http://www.nist.gov/tac/publications/2013/papers.html

As shown in Table 1, QCV not only substantially outperforms the best unsupervised systems but also beats the best supervised systems from the KBP participants. In order to understand this notable advancement, we broke down our system into components and evaluated them accumulatively using the same dataset as above. The experiment results are summarized in Table 2.

Components	B^3+ P	B^3+ R	B^3+ F_1
SR	0.680	0.598	0.636
SR + CS	0.699	0.624	0.659
SR + CS + CV	**0.789**	**0.712**	**0.749**

Table 2: QCV Performance by Component.

In Table 2, *SR*, *CS*, and *CV* correspond to the Salience Ranking, the Context Similarity Ranking, and the Collective Validation in our QCV algorithm, respectively. It can be seen that *SR* already outperforms the best KBP unsupervised systems from Table 1. This is mainly attributed to the engagement of the entropy based relation weights which injects the impact of different relations into the entity salience. Notwithstanding being somewhat effective, *SR* solely depends on the KB and plays its role without the source context. It should be straightforward that the system performance gets improved after enabling *CS* since the source context has been incorporated. However, it was a little puzzling that the performance boost by enabling *CS* turned out to be relatively small. We took a careful look at the intermediate experiment results and discovered that although *CS* did not produce a lot more correct linking results than *SR* did, it did promote a great number of good candidates to the top of the ranking list. For example, in the *Caldwell* case, *CS* successfully raised the rankings of the context-related candidates such as `Reche Caldwell`, `Andre Caldwell`, and `Jim Caldwell`, despite the fact that it delivered `Andre Caldwell` instead of `Reche Caldwell` as the final linking result. This convincingly implies that *CS* is able to well capture the context of the target mentions, but meanwhile it is deficient in recognizing the subtle contextual difference among similar candidates. In Table 2 there is a significant performance gain after enabling *CV*. As described in Section 3.2, *CV* collectively validates the candidates of the target mention "*Caldwell*" and the mentions in its context such as "*Florida*", "*Patriots*", and "*Jets*" by integrating their *SR* and *CS* scores as well as the weights of the KB relations between them. Therefore this improvement is reasonably substantial.

By investigating the remaining errors, we identified several potential causes: 1) Our system occasionally could not capture enough context for the target mention. This happened more frequently for web blogs and discussion forums, where the language was informal and casual. Without any linguistic analysis on the source documents, it was difficult for us to extract additional context words. 2) Our simple coreference rules sometimes failed to work correctly and introduced false candidates, which, without clear context to disambiguate, could lead to linking errors. 3) Our KB had limited knowledge about some entities in a way that certain relations were missing. This kept us from creating necessary links in the candidate graphs and further effectively validating the graphs.

4.2 EL on Generic Chinese Corpora

Using Chinese as a case study, we evaluate the language portability of our approach. We used the TAC-KBP2012 Chinese EL dataset[1], and selected a subset of 1,240 linkable mentions out of the total 2,122 mentions extracted from Chinese newswire, web blogs, and discussion forums. For KB, we still used DBpedia because it contains multilingual surface forms for its entities. For instance, the entity `Barack Obama` has surface forms in over 30 languages including the Chinese one: "贝拉克·奥巴马". This cross-lingual surface form mapping naturally provides us with a convenient translation tool. Table 3 shows the linking performance comparison among QCV, our baseline system, and the top 3 participant systems of the KBP Chinese EL track. Again, we employed the `B-Cubed+` metric.

System	B^3+ F_1
Clarke et al. (2012) (supervised)	0.493
Monahan and Carpenter (2012) (supervised)	0.660
Fahrni et al. (2012) (supervised)	**0.736**
Baseline (unsupervised)	0.648
QCV (unsupervised)	0.671

Table 3: Performance on the TAC-KBP2012 Chinese EL Dataset (1240 linkable mentions).

As shown in Table 3, the best performance is

[1]http://www.nist.gov/tac/2012/KBP/data.html

achieved by Fahrni et al. (2012), a supervised system using over 20 fine-tuned features and many linguistic resources. In contrast, our QCV is an unsupervised approach without using any labeled data or linguistic resources. During the error analysis, we found that in this dataset multiple mentions are often the variants of the surface form of a single KB entity. For example, "奥巴马" and "欧巴马", being just different Chinese transliterations, both refer to "*Obama*". This fact tends to result in a low recall for our system because one or more of the mention variants may not exist in the KB. We decided to heuristically apply a substring matching in addition to the Wikipedia redirection mapping to boost the recall. However, as one can imagine, this simple strategy will impair the system precision due to the introduced noise. Take "奥巴马" again for example. If we only match its second and third characters, "欧巴马" will be correctly picked, but "巴马镇" (a small town in China) will also be falsely included. Fortunately, our QCV algorithm was able to select and rank candidates complying with the source context. Consequently most of this kind of noise got filtered out, and we thus could produce balanced precision and recall.

We acknowledge that, without performing deeper linguistic analysis on the source documents, the cross-language surface form mapping of the KB plays a crucial role in our approach. One can replace it with any machine translation product which, however, is not always available especially for a low-resource language. We should take advantage of the existing KBs where such cross-lingual mapping has already been widely created. The latest DBpedia provides localized versions in 125 languages[1], for instance.

4.3 EL in Biomedical Science

To demonstrate the domain portability of our approach, we first take the biomedical science domain as a case study. We conducted our experiment using the evaluation dataset created by Zheng et al. (2014) which contains 208 linkable mentions extracted from several biomedical publications. We built our KB with over 300 domain ontologies downloaded from BioPortal. Table 4 compares the linking accuracy of QCV and our baseline system.

As shown in Table 4, our approach achieves similar performance to our baseline system which is the state-of-the-art to our knowledge. However, we were curious why QCV did not improve the baseline system in the biomedical domain as much as it did in the general domain. After some in-depth analysis of the experiment results, we discovered that in this dataset the candidates of the related mentions (*i.e.* those mentions within the same context window) mostly have similar relations in the KB. In other words, for each mention, the candidate entity types are not as diverse as those in the general domain. As a consequence, the collective validation step in QCV does not take much effect since the weights of the involved relations are quite close to one another. On such a dataset, the context similarity ranking will play a major part for the disambiguation, and QCV will not be able to function at its full power. Nonetheless, from the results we can see that our approach can be efficiently and effectively adapted to this new domain.

System	Correct	Total	Accuracy
Baseline	173	208	83.17%
QCV	177	208	**85.10%**

Table 4: Biomedical Science EL Performance.

4.4 EL in Earth Science

Now we move to another new domain, Earth Science. As far as we know, we are the first to study EL in this domain. In order to create an evaluation dataset, our domain expert selected three scientific papers about Early Triassic discovery, Global Stratotype Section, and Triassic crisis, which are three different aspects of Earth Science related discovery, and then identified 296 mentions that can be linked to DBpedia entities. Table 5 presents the linking accuracy comparison between QCV and our baseline system. We can see that QCV provided significant gains.

System	Correct	Total	Accuracy
Baseline	221	296	74.66%
QCV	236	296	**79.73%**

Table 5: Earth Science EL Performance.

The linking errors were mainly caused by the following reasons: 1) As a general KB, DBpedia has introduced certain noise for our domain-

[1] http://wiki.dbpedia.org/about

specific EL. For example, in Geology, the term "*Beds*" mostly refers to "*Geology Bed*", which is a division of a geologic formation. But in general, "*Beds*" usually means the beds people sleep on. Much more common in the KB, the latter had such a significantly higher salience score than the former that the final ranking score of our system got biased. 2) Some relations between Earth Science related entities are not clearly defined in DBpedia. For instance, in geology time scale, the period "*Chattian*" is immediately preceded by the period "*Rupelian*". An explicit relation such as "*preceded by*" should be inserted between these two period entities. Instead, only a vague "*wiki link*" relation is present in our KB. This directly diminishes the differentiating power of our system on the KB relations.

It is worth mentioning that there exists a large number of well established ontologies for different sub-domains of Earth Science. SWEET ontologies[1], for example, widely capture Earth and Environmental terminologies. By adopting these ontologies, we will be able to considerably improve our domain EL performance, and the benefits of EL in the domain will further get revealed.

4.5 System Complexity

We indexed our KB and ontologies in the format of triples using Apache Lucene[2] such that retrieving entity candidates of a mention is $O(1)$. We precomputed all the entropy-based relation weights and entity salience scores with complexities of $O(n_r \cdot n_e)$ and $O(n_e \cdot k)$, respectively, where n_r is the number of KB relations, n_e is the number of KB entities, and k is the number of iterations it took for the salience score to get converged. For the final QCV score computation, the upper bound of the computing time to link all the mentions in a document is $O(n_m \cdot n_c \cdot n_{n_c} \cdot n_{n_m})$, where n_m is the number of linkable mentions in the document, n_c is the number of candidates for each mention, and n_{n_c} is the number of neighbor nodes of a candidate, and n_{n_m} is the number of neighbors of a mention.

5 Related Work

In recent years, collective inference methods for EL have become increasingly popular. Many efforts have been devoted to encoding linguistic features from the source documents in order to precisely select collaborator mentions for collective inference. These features include topic modeling (Xu et al., 2012; Cassidy et al., 2012), relation constraint (Cheng and Roth, 2013), coreferential chaining (Nguyen et al., 2012; Huang et al., 2014), and dependency restriction (Ling et al., 2014). Some recent work utilized multi-layer linguistic analysis integration to capture contextual properties for better mention collection (Pan et al., 2015). While many of these approaches have been proved to be effective, the dependency on deep linguistic knowledge makes it difficult to migrate them to a new language or domain. In contrast to these methods, we establish a very loose setting for the mention selection, and rely on the quantified information computed from the structured KB to collectively evaluate and validate the entity candidates. Since the KB is relatively universal to languages and domains, our approach inherently is language and domain independent.

Recent cross-lingual EL approaches can be divided into two types. The first type (McNamee et al., 2011; Cassidy et al., 2011; McNamee et al., 2012; Guo et al., 2012; Miao et al., 2013) translated entity mentions and source documents from the new language into English and then ran English mono-lingual EL to link to English KB. The second type (Monahan et al., 2011; Fahrni et al., 2011; Fahrni et al., 2012; Monahan and Carpenter, 2012; Clarke et al., 2012; Fahrni et al., 2013) developed EL systems on the new language and used cross-lingual KB links to map the link results back to English KB. While the bottleneck of the former method usually is on translation errors, the latter approach heavily relies on the linguistic resources and the KB of the new language. In comparison, our system mainly uses the English KB and a mention surface form mapping that can either come from translation or cross-lingual KB links, and requires minimal linguistic resources from the new language.

There is a limited amount of research work in the literature that focused solely on domain-specific EL (Zheng et al., 2014). In the biomedical domain, a few studies have been found on EL-related tasks such as scientific name discovery (Akella et al., 2012), gene name normalization (Hirschman et al., 2005; Fang et al., 2006; Dai et al., 2010), biomedical named entity recognition (Usami et al., 2011; Van Landeghem et al.,

[1] http://sweet.jpl.nasa.gov

[2] https://lucene.apache.org/

2012) and concept mention extraction (Tsai et al., 2013). The baseline system (Zheng et al., 2014) in this paper is the work most similar to ours in a sense of collectively aligning mentions to structured KBs. However, our system differs by integrating a context similarity ranking and a candidate validation to conduct a two-way collective inference with better performance.

6 Conclusions and Future Work

Language and domain independence is a new requirement to EL systems and this capability is particularly welcome by low-resource language related applications and domain scientists. In this paper we demonstrated a high-performance EL approach that can be easily migrated to new languages and domains due to the minimal reliance on linguistic analysis and the deep utilization of structured KBs. In the future, we plan to improve the source document processing such that the system can better extract the mention context without involving extensive linguistic knowledge. We are also experimenting with our collective validation algorithm to incorporate the impact of more distant KB entities other than just the neighbors.

Abstract

Representation learning of knowledge bases aims to embed both entities and relations into a low-dimensional space. Most existing methods only consider direct relations in representation learning. We argue that multiple-step relation paths also contain rich inference patterns between entities, and propose a path-based representation learning model. This model considers relation paths as translations between entities for representation learning, and addresses two key challenges: (1) Since not all relation paths are reliable, we design a path-constraint resource allocation algorithm to measure the reliability of relation paths. (2) We represent relation paths via semantic composition of relation embeddings. Experimental results on real-world datasets show that, as compared with baselines, our model achieves significant and consistent improvements on knowledge base completion and relation extraction from text. The source code of this paper can be obtained from `https://github.com/mrlyk423/relation_extraction`.

1 Introduction

People have recently built many large-scale knowledge bases (KBs) such as Freebase, DBpedia and YAGO. These KBs consist of facts about the real world, mostly in the form of triples, e.g., (*Steve Jobs*, `FounderOf`, *Apple Inc.*). KBs are important resources for many applications such as question answering and Web search. Although typical KBs are large in size, usually containing thousands of relation types, millions of entities and billions of facts (triples), they are far from complete. Hence, many efforts have been invested in relation extraction to enrich KBs.

Recent studies reveal that, neural-based representation learning methods are scalable and effective to encode relational knowledge with low-dimensional representations of both entities and relations, which can be further used to extract unknown relational facts. TransE (Bordes et al., 2013) is a typical method in the neural-based approach, which learns vectors (i.e., embeddings) for both entities and relations. The basic idea behind TransE is that, the relationship between two entities corresponds to a translation between the embeddings of the entities, that is, $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$ when the triple (h, r, t) holds. Since TransE has issues when modeling 1-to-N, N-to-1 and N-to-N relations, various methods such as TransH (Wang et al., 2014) and TransR (Lin et al., 2015) are proposed to assign an entity with different representations when involved in various relations.

Despite their success in modeling relational facts, TransE and its extensions only take direct relations between entities into consideration. It is known that there are also substantial multiple-step relation paths between entities indicating their semantic relationships. The relation paths reflect complicated inference patterns among relations in KBs. For example, the relation path $h \xrightarrow{\texttt{BornInCity}} e_1 \xrightarrow{\texttt{CityInState}} e_2 \xrightarrow{\texttt{StateInCountry}} t$ indicates the relation `Nationality` between h and t, i.e., (h, `Nationality`, t).

In this paper, we aim at extending TransE to model relation paths for representation learning of KBs, and propose path-based TransE (PTransE). In PTransE, in addition to direct connected relational facts, we also build triples from KBs using entity pairs connected with relation paths. As shown in Figure 1, TransE only considers direct relations between entities, e.g., $h \xrightarrow{r} t$, builds a triple (h, r, t), and optimizes the objec-

*Corresponding author: Z. Liu (liuzy@tsinghua.edu.cn)

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 705–714, Lisbon, Portugal, 17-21 September 2015.

tive $\mathbf{h} + \mathbf{r} = \mathbf{t}$. PTransE generalizes TransE by regarding multiple-step relation paths as connections between entities. Take the 2-step path $h \xrightarrow{r_1} e_1 \xrightarrow{r_2} t$ for example as shown in Figure 1. Besides building triples (h, r_1, e_1) and (e_1, r_2, t) for learning as in TransE, PTransE also builds a triple $(h, r_1 \circ r_2, t)$, and optimizes the objective $\mathbf{h} + (\mathbf{r}_1 \circ \mathbf{r}_2) = \mathbf{t}$, where $\circ$ is an operation to join the relations r_1 and r_2 together into a unified relation path representation.

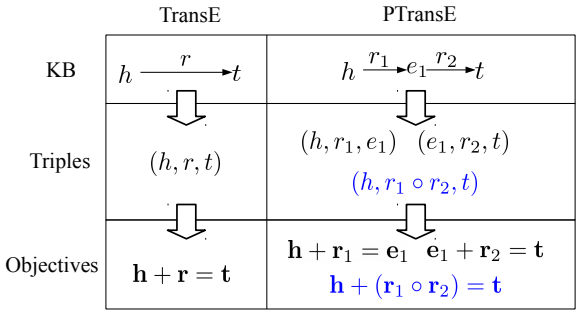

Figure 1: TransE and PTransE.

As compared with TransE, PTransE takes rich relation paths in KBs for learning. There are two critical challenges that make PTransE nontrivial to learn from relation paths:

Relation Path Reliability. Not all relation paths are meaningful and reliable for learning. For example, there is often a relation path $h \xrightarrow{\texttt{Friend}} e_1 \xrightarrow{\texttt{Profession}} t$, but actually it does not indicate any semantic relationship between h and t. Hence, it is inappropriate to consider all relation paths in our model. In experiments, we find that those relation paths that lead to lots of possible tail entities are mostly unreliable for the entity pair. In this paper, we propose a path-constraint resource allocation algorithm to measure the reliability of relation paths. Afterwards, we select the reliable relation paths for representation learning.

Relation Path Representation. In order to take relation paths into consideration, relation paths should also be represented in a low-dimensional space. It is straightforward that the semantic meaning of a relation path depends on all relations in this path. Given a relation path $p = (r_1, \ldots, r_l)$, we will define and learn a binary operation function ($\circ$) to obtain the path embedding $\mathbf{p}$ by recursively composing multiple relations, i.e., $\mathbf{p} = \mathbf{r}_1 \circ \ldots \circ \mathbf{r}_l$.

With relation path selection and representation, PTransE learns entity and relation embeddings by regarding relation paths as translations between the corresponding entities. In experiments, we select a typical KB, Freebase, to build datasets and carry out evaluation on three tasks, including entity prediction, relation prediction and relation extraction from text. Experimental results show that, PTransE significantly outperforms TransE and other baseline methods on all three tasks.

2 Our Model

In this section, we introduce path-based TransE (PTransE) that learns representations of entities and relations considering relation paths. In TransE and PTransE, we have entity set $\mathbf{E}$ and relation set $\mathbf{R}$, and learn to encode both entities and relations in $\mathbb{R}^k$. Given a KB represented by a set of triples $\mathbf{S} = \{(h, r, t)\}$ with each triple composed of two entities $h, t \in \mathbf{E}$ and their relation $r \in \mathbf{R}$. Our model is expected to return a low energy score when the relation holds, and a high one otherwise.

2.1 TransE and PTransE

For each triple (h, r, t), TransE regards the relation as a translation vector $\mathbf{r}$ between two entity vectors $\mathbf{h}$ and $\mathbf{t}$. The energy function is defined as

$$E(h, r, t) = ||\mathbf{h} + \mathbf{r} - \mathbf{t}||, \quad (1)$$

which is expected to get a low score when (h, r, t) holds, and high otherwise.

TransE only learns from direct relations between entities but ignores multiple-step relation paths, which also contain rich inference patterns between entities. PTransE take relation paths into consideration for representation learning.

Suppose there are multiple relation paths $P(h, t) = \{p_1, \ldots, p_N\}$ connecting two entities h and t, where relation path $p = (r_1, \ldots, r_l)$ indicates $h \xrightarrow{r_1} \ldots \xrightarrow{r_l} t$. For each triple (h, r, t), the energy function is defined as

$$G(h, r, t) = E(h, r, t) + E(h, P, t), \quad (2)$$

where $E(h, r, t)$ models correlations between relations and entities with direct relation triples, as defined in Equation (1). $E(h, P, t)$ models the inference correlations between relations with multiple-step relation path triples, which is defined as

$$E(h, P, t) = \frac{1}{Z} \sum_{p \in P(h,t)} R(p|h, t) E(h, p, t), \quad (3)$$

where $R(p|h, t)$ indicates the reliability of the relation path p given the entity pair (h, t), Z =

$\sum_{p \in P(h,t)} R(p|h,t)$ is a normalization factor, and $E(h,p,t)$ is the energy function of the triple (h,p,t).

For the energy of each triple (h,p,t), the component $R(p|h,t)$ concerns about relation path reliability, and $E(h,p,t)$ concerns about relation path representation. We introduce the two components in detail as follows.

2.2 Relation Path Reliability

We propose a path-constraint resource allocation (PCRA) algorithm to measure the reliability of a relation path. Resource allocation over networks was originally proposed for personalized recommendation (Zhou et al., 2007), and has been successfully used in information retrieval for measuring relatedness between two objects (Lü and Zhou, 2011). Here we extend it to PCRA to measure the reliability of relation paths. The basic idea is, we assume that a certain amount of resource is associated with the head entity h, and will flow following the given path p. We use the resource amount that eventually flows to the tail entity t to measure the reliability of the path p as a meaningful connection between h and t.

Formally, for a path triple (h,p,t), we compute the resource amount flowing from h to t given the path $p = (r_1, \ldots, r_l)$ as follows. Starting from h and following the relation path p, we can write the flowing path as $S_0 \xrightarrow{r_1} S_1 \xrightarrow{r_2} \ldots \xrightarrow{r_l} S_l$, where $S_0 = h$ and $t \in S_l$.

For any entity $m \in S_i$, we denote its direct predecessors along relation r_i in S_{i-1} as $S_{i-1}(\cdot, m)$. The resource flowing to m is defined as

$$R_p(m) = \sum_{n \in S_{i-1}(\cdot,m)} \frac{1}{|S_i(n,\cdot)|} R_p(n), \quad (4)$$

where $S_i(n,\cdot)$ is the direct successors of $n \in S_{i-1}$ following the relation r_i, and $R_p(n)$ is the resource obtained from the entity n.

For each relation path p, we set the initial resource in h as $R_p(h) = 1$. By performing resource allocation recursively from h through the path p, the tail entity t eventually obtains the resource $R_p(t)$ which indicates how much information of the head entity h can be well translated. We use $R_p(t)$ to measure the reliability of the path p given (h,t), i.e., $R(p|h,t) = R_p(t)$.

2.3 Relation Path Representation

Besides relation path reliability, we also need to define energy function $E(h,p,t)$ for the path triple (h,p,t) in Equation (2). Similar with the energy function of TransE in Equation (1), we will also represent the relation path p in the embedding space.

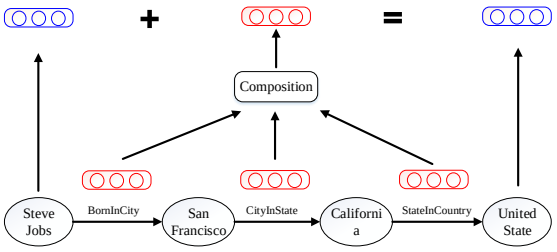

Figure 2: Path representations are computed by semantic composition of relation embeddings.

The semantic meaning of a relation path considerably relies on its involved relations. It is thus reasonable for us to build path embeddings via semantic composition of relation embeddings. As illustrated in Figure 2, the path embedding $\mathbf{p}$ is composed by the embeddings of `BorninCity`, `CityInState` and `StateInCountry`.

Formally, for a path $p = (r_1, \ldots, r_l)$, we define a composition operation $\circ$ and obtain path embedding as $\mathbf{p} = \mathbf{r}_1 \circ \ldots \circ \mathbf{r}_l$. In this paper, we consider three types of composition operation:

Addition (ADD). The addition operation obtains the vector of a path by summing up the vectors of all relations, which is formalized as

$$\mathbf{p} = \mathbf{r}_1 + \ldots + \mathbf{r}_l. \quad (5)$$

Multiplication (MUL). The multiplication operation obtains the vector of a path as the cumulative product of the vectors of all relations, which is formalized as

$$\mathbf{p} = \mathbf{r}_1 \cdot \ldots \cdot \mathbf{r}_l. \quad (6)$$

Both addition and multiplication operations are simple and have been extensively investigated in semantic composition of phrases and sentences (Mitchell and Lapata, 2008).

Recurrent Neural Network (RNN). RNN is a recent neural-based model for semantic composition (Mikolov et al., 2010). The composition operation is realized using a matrix W:

$$c_i = f(W[c_{i-1}; r_i]), \quad (7)$$

where f is a non-linearity or identical function, and $[a;b]$ represents the concatenation of two vec-

tors. By setting $c_1 = r_1$ and recursively performing RNN following the relation path, we will finally obtain $p = c_n$. RNN has also been used for representation learning of relation paths in KBs (Neelakantan et al., 2015).

For a multiple-step relation path triple (h, p, t), we could have followed TransE and define the energy function as $E(h, p, t) = ||\mathbf{h} + \mathbf{p} - \mathbf{t}||$. However, since we have minimized $||\mathbf{h} + \mathbf{r} - \mathbf{t}||$ with the direct relation triple (h, r, t) to make sure $\mathbf{r} \approx \mathbf{t} - \mathbf{h}$, we may directly define the energy function of (h, p, t) as

$$E(h, p, t) = ||\mathbf{p} - (\mathbf{t} - \mathbf{h})|| = ||\mathbf{p} - \mathbf{r}|| = E(p, r), \tag{8}$$

which is expected to be a low score when the multiple-relation path p is consistent with the direct relation r, and high otherwise, without using entity embeddings.

2.4 Objective Formalization

We formalize the optimization objective of PTransE as

$$L(\mathbf{S}) = \sum_{(h,r,t)\in\mathbf{S}} \Big[L(h, r, t) + \frac{1}{Z} \sum_{p\in P(h,t)} R(p|h, t) L(p, r) \Big]. \tag{9}$$

Following TransE, $L(h, r, t)$ and $L(p, r)$ are margin-based loss functions with respect to the triple (h, r, t) and the pair (p, r):

$$L(h, r, t) = \sum_{(h',r',t')\in\mathbf{S}^-} [\gamma + E(h, r, t) - E(h', r', t')]_+, \tag{10}$$

and

$$L(p, r) = \sum_{(h,r',t)\in\mathbf{S}^-} [\gamma + E(p, r) - E(p, r')]_+, \tag{11}$$

where $[x]_+ = \max(0, x)$ returns the maximum between 0 and x, γ is the margin, $\mathbf{S}$ is the set of valid triples existing in a KB and $\mathbf{S}^-$ is the set of invalid triples. The objective will favor lower scores for valid triples as compared with invalid triples.

The invalid triple set with respect to (h, r, t) is defined as

$$\mathbf{S}^- = \{(h', r, t)\} \cup \{(h, r', t)\} \cup \{(h, r, t')\}. \tag{12}$$

That is, the set of invalid triples is composed of the original valid triple (h, r, t) with one of three components replaced.

2.5 Optimization and Implementation Details

For optimization, we employ stochastic gradient descent (SGD) to minimize the loss function. We randomly select a valid triple from the training set iteratively for learning. In the implementation, we also enforce constraints on the norms of the embeddings h, r, t. That is, we set

$$\|\mathbf{h}\|_2 \leq 1, \quad \|\mathbf{r}\|_2 \leq 1, \quad \|\mathbf{t}\|_2 \leq 1. \quad \forall h, r, t. \tag{13}$$

There are also some implementation details that will significantly influence the performance of representation learning, which are introduced as follows.

Reverse Relation Addition. In some cases, we are interested in the reverse version of a relation, which may not be presented in KBs. For example, according to the relation path $e_1 \xrightarrow{\texttt{BornInCity}} e_2 \xleftarrow{\texttt{CityOfCountry}} e_3$ we expect to infer the fact that $(e_1, \texttt{Nationality}, e3)$. In this paper, however, we only consider the relation paths following one direction. Hence, we add reverse relations for each relation in KBs. That is, for each triple (h, r, t) we build another (t, r^{-1}, h). In this way, our method can consider the above-mentioned path as $e_1 \xrightarrow{\texttt{BornInCity}} e_2 \xrightarrow{\texttt{CityOfCountry}^{-1}} e_3$ for learning.

Path Selection Limitation. There are usually large amount of relations and facts about each entity pair. It will be impractical to enumerate all possible relation paths between head and tail entities. For example, if each entity refers to more than 100 relations on average, which is common in Freebase, there will be billions of 4-step paths. Even for 2-step or 3-step paths, it will be time-consuming to consider all of them without limitation. For computational efficiency, in this paper we restrict the length of paths to at most 3-steps and consider those relation paths with the reliability score larger than 0.01.

2.6 Complexity Analysis

We denote N_e as the number of entities, N_r as the number of relations and K as the vector dimension. The model parameter size of PTransE is $(N_e K + N_r K)$, which is the same as TransE. PTransE follows the optimization procedure introduced by (Bordes et al., 2013) to solve Equation (9). We denote S as the number of triples for learning, P as the expected number of relation paths between two entities, and L as the expected

length of relation paths. For each iteration in optimization, the complexity of TransE is $O(SK)$ and the complexity of PTransE is $O(SKPL)$ for ADD and MUL, and $O(SK^2PL)$ for RNN.

3 Experiments and Analysis

3.1 Data Sets and Experimental Setting

We evaluate our method on a typical large-scale KB Freebase (Bollacker et al., 2008). In this paper, we adopt two datasets extracted from Freebase, i.e., FB15K and FB40K. The statistics of the datasets are listed in Table 1.

Table 1: Statistics of data sets.

Dataset	#Rel	#Ent	#Train	#Valid	# Test
FB15K	1,345	14,951	483,142	50,000	59,071
FB40K	1,336	39,528	370,648	67,946	96,678

We evaluate the performance of PTransE and other baselines by predicting whether testing triples hold. We consider two scenarios: (1) Knowledge base completion, aiming to predict the missing entities or relations in given triples only based on existing KBs. (2) Relation extraction from texts, aiming to extract relations between entities based on information from both plain texts and KBs.

3.2 Knowledge Base Completion

The task of knowledge base completion is to complete the triple (h, r, t) when one of h, t, r is missing. The task has been used for evaluation in (Bordes et al., 2011; Bordes et al., 2012; Bordes et al., 2013). We conduct the evaluation on FB15K, which has $483,142$ relational triples and $1,345$ relation types, among which there are rich inference and reasoning patterns.

In the testing phase, for each testing triple (h, r, t), we define the following score function for prediction

$$S(h, r, t) = G(h, r, t) + G(t, r^{-1}, h), \quad (14)$$

and the score function $G(h, r, t)$ is further defined as

$$G(h, r, t) = ||\mathbf{h} + \mathbf{r} - \mathbf{t}|| + \frac{1}{Z} \sum_{p \in P(h,t)} \Pr(r|p) R(p|h, t) ||\mathbf{p} - \mathbf{r}||. \quad (15)$$

The score function is similar to the energy function defined in Section 2.1. The difference is that, here we consider the reliability of a path p is also related to the inference strength given r, which is quantified as $\Pr(r|p) = \Pr(r, p)/\Pr(p)$ obtained from the training data.

We divide the stage into two sub-tasks, i.e., entity prediction and relation prediction.

3.2.1 Entity Prediction

In the sub-task of entity prediction, we follow the setting in (Bordes et al., 2013). For each testing triple with missing head or tail entity, various methods are asked to compute the scores of $G(h, r, t)$ for all candidate entities and rank them in descending order.

We use two measures as our evaluation metrics: the mean of correct entity ranks and the proportion of valid entities ranked in top-10 (Hits@10). As mentioned in (Bordes et al., 2013), the measures are desirable but flawed when an invalid triple ends up being valid in KBs. For example, when the testing triple is (*Obama*, `PresidentOf`, *USA*) with the head entity *Obama* is missing, the head entity *Lincoln* may be regarded invalid for prediction, but in fact it is valid in KBs. The evaluation metrics will under-estimate those methods that rank these triples high. Hence, we can filter out all these valid triples in KBs before ranking. The first evaluation setting was named as "Raw" and the second one as "Filter".

For comparison, we select all methods in (Bordes et al., 2013; Wang et al., 2014) as our baselines and use their reported results directly since the evaluation dataset is identical.

Ideally, PTransE has to find all possible relation paths between the given entity and each candidate entity. However, it is time consuming and impractical, because we need to iterate all candidate entities in $|E|$ for each testing triple. Here we adopt a re-ranking method: we first rank all candidate entities according to the scores from TransE, and then re-rank top-500 candidates according to the scores from PTransE.

For PTransE, we find the best hyperparameters according to the mean rank in validation set. The optimal configurations of PTransE we used are $\lambda = 0.001$, $\gamma = 1$, $k = 100$ and taking L_1 as dissimilarity. For training, we limit the number of epochs over all the training triples to 500.

Evaluation results of entity prediction are shown in Table 2. The baselines include RESCAL (Nickel et al., 2011), SE (Bordes et al., 2011), SME (linear) (Bordes et al., 2012), SME (bilinear)

Table 2: Evaluation results on entity prediction.

Metric	Mean Rank		Hits@10 (%)	
	Raw	Filter	Raw	Filter
RESCAL	828	683	28.4	44.1
SE	273	162	28.8	39.8
SME (linear)	274	154	30.7	40.8
SME (bilinear)	284	158	31.3	41.3
LFM	283	164	26.0	33.1
TransE	243	125	34.9	47.1
TransH	212	87	45.7	64.4
TransR	**198**	77	48.2	68.7
TransE (Our)	205	63	47.9	70.2
PTransE (ADD, 2-step)	200	**54**	**51.8**	83.4
PTransE (MUL, 2-step)	216	67	47.4	77.7
PTransE (RNN, 2-step)	242	92	50.6	82.2
PTransE (ADD, 3-step)	207	58	51.4	**84.6**

(Bordes et al., 2012), LFM (Jenatton et al., 2012), TransE (Bordes et al., 2013) (original version and our implementation considering reverse relations), TransH (Wang et al., 2014), and TransR (Lin et al., 2015).

For PTransE, we consider three composition operations for relation path representation: addition (ADD), multiplication (MUL) and recurrent neural networks (RNN). We also consider relation paths with at most 2-steps and 3-steps. With the same configurations of PTransE, our TransE implementation achieves much better performance than that reported in (Bordes et al., 2013).

From Table 2 we observe that: (1) PTransE significantly and consistently outperforms other baselines including TransE. It indicates that relation paths provide a good supplement for representation learning of KBs, which have been successfully encoded by PTransE. For example, since both *George W. Bush* and *Abraham Lincoln* were presidents of *the United States*, they exhibit similar embeddings in TransE. This may lead to confusion for TransE to predict the spouse of *Laura Bush*. In contrast, since PTransE models relation paths, it can take advantage of the relation paths between *George W. Bush* and *Laura Bush*, and leads to more accurate prediction. (2) For PTransE, the addition operation outperforms other composition operations in both Mean Rank and Hits@10. The reason is that, the addition operation is compatible with the learning objectives of both TransE and PTransE. Take $h \xrightarrow{r_1} e_1 \xrightarrow{r_2} t$ for example. The optimization objectives of two direct relations $\mathbf{h} + \mathbf{r}_1 = \mathbf{e}_1$ and $\mathbf{e}_1 + \mathbf{r}_2 = \mathbf{t}$ can easily derive the path objective $\mathbf{h} + \mathbf{r}_1 + \mathbf{r}_2 = \mathbf{t}$. (3) PTransE of considering relation paths with at most 2-step and 3-step achieve comparable results. This indicates that it may be unnecessary to consider those relation paths that are too long.

As defined in (Bordes et al., 2013), relations in KBs can be divided into various types according to their mapping properties such as 1-to-1, 1-to-N, N-to-1 and N-to-N. Here we demonstrate the performance of PTransE and some baselines with respect to different types of relations in Table 3. It is observed that, on all mapping types of relations, PTransE consistently achieves significant improvement as compared with TransE.

3.2.2 Relation Prediction

Relation prediction aims to predict relations given two entities. We also use FB15K for evaluation. In this sub-task, we can use the score function of PTransE to rank candidate relations instead of reranking like in entity prediction.

Since our implementation of TransE has achieved the best performance among all baselines for entity prediction, here we only compare PTransE with TransE due to limited space. Evaluation results are shown in Table 4, where we report Hits@1 instead of Hits@10 for comparison, because Hits@10 for both TransE and PTransE exceeds 95%. In this table, we report the performance of TransE without reverse relations (TransE), with reverse relations (+Rev) and considering relation paths for testing like that in PTransE (+Rev+Path). We report the performance of PTransE with only considering relation paths (-TransE), only considering the part in Equation (1) (-Path) and considering both (PTransE).

The optimal configurations of PTransE for relation prediction are identical to those for entity prediction: $\lambda = 0.001$, $\gamma = 1$, $k = 100$ and taking L_1 as dissimilarity.

From Table 4 we observe that: (1) PTransE outperforms TransE+Rev+Path significantly for relation prediction by reducing 41.8% prediction errors. (2) Even for TransE itself, considering relation paths for testing can reduce 17.3% errors as compared with TransE+Rev. It indicates that encoding relation paths will benefit for predicting relations. (3) PTransE with only considering relation paths (PTransE-TransE) gets surprisingly high mean rank. The reason is that, not all entity pairs in testing triples have relation paths, which will lead to random guess and the expectation of rank of these entity pairs is $|R|/2$. Meanwhile, Hits@1 of PTransE-TransE is relatively reasonable, which indicates the worth of modeling rela-

Table 3: Evaluation results on FB15K by mapping properties of relations. (%)

Tasks	Predicting Head Entities (Hits@10)				Predicting Tail Entities (Hits@10)			
Relation Category	1-to-1	1-to-N	N-to-1	N-to-N	1-to-1	1-to-N	N-to-1	N-to-N
SE	35.6	62.6	17.2	37.5	34.9	14.6	68.3	41.3
SME (linear)	35.1	53.7	19.0	40.3	32.7	14.9	61.6	43.3
SME (bilinear)	30.9	69.6	19.9	38.6	28.2	13.1	76.0	41.8

PTransE (RNN, 2-step)	1.9	1.4	68.3	93.2
PTransE (ADD, 3-step)	1.8	1.4	68.5	**94.0**

3.3 Relation Extraction from Text

Relation extraction from text aims to extract relational facts from plain text to enrich existing KBs. Many works regard large-scale KBs as distant supervision to annotate sentences as training instances and build relation classifiers according to features extracted from the sentences (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). All these methods reason new facts only based on plain text. TransE was used to enrich a text-based model and achieved a significant improvement (Weston et al., 2013), and so do TransH (Wang et al., 2014) and TransR (Lin et al., 2015). In this task, we explore the effectiveness of PTransE for relation extraction from text.

We use New York Times corpus (NYT) released by (Riedel et al., 2010) as training and testing data. NYT aligns Freebase with the articles in New York Times, and extracts sentence-level features such as part-of-speech tags, dependency tree paths for each mention. There are 53 relations (including non-relation denoted as NA) and 121,034 training mentions. We use FB40K as the KB, consisting all entities mentioned in NYT and 1,336 relations.

In the experiments, we implemented the text-based model Sm2r presented in (Weston et al., 2013). We combine the ranking scores from the text-based model with those from KB representations to rank testing triples, and generate precision-recall curves for both TransE and PTransE. For learning of TransE and PTransE, we set the dimensions of entities/relations embeddings $k = 50$, the learning rate $\lambda = 0.001$, the margin $\gamma = 1.0$ and dissimilarity metric as L1. We also compare with MIMLRE (Surdeanu et al., 2012) which is the state-of-art method using distant supervision. The evaluation curves are shown in Figure 3.

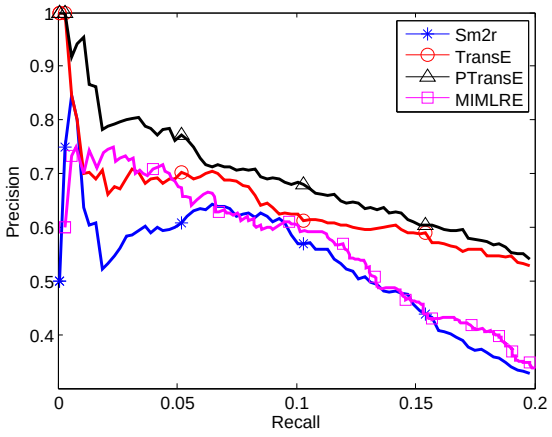

Figure 3: Precision-recall curves of Sm2r, TransE and PTransE combine with Sm2r.

From Figure 3 we can observe that, by combining with the text-based model Sm2r, the precision of PTransE significantly outperforms TransE especially for the top-ranked triples. This indicates that encoding relation paths is also useful for relation extraction from text.

Note that TransE used here does not consider reverse relations and relation paths because the performance does not change much. We analyze the reason as follows. In the task of knowledge base completion, each testing triple has at least one valid relation. In contrast, many testing triples in this task correspond to non-relation (NA), and there are usually several relation paths between two entities in these non-relation triples. TransE does not encode relation paths during the training phase like PTransE, which results in worse performance for predicting non-relation when considering relation paths in the testing phase, and compensates the improvement on those triples that do have relations. This indicates it is non-trivial to encode relation paths, and also confirms the effectiveness of PTransE.

3.4 Case Study of Relation Inference

We have shown that PTransE can achieve high performance for knowledge base completion and relation extraction from text. In this section, we present some examples of relation inference according to relation paths.

According to the learning results of PTransE, we can find new facts from KBs. As shown in Figure 4, two entities *Forrest Gump* and *English* are connected by three relation paths, which give us more confidence to predict the relation between the two entities to `LanguageOfFilm`.

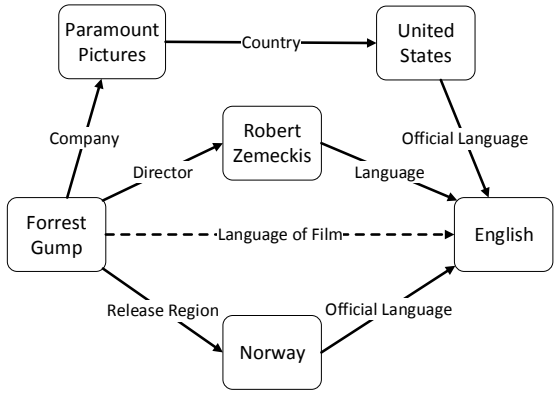

Figure 4: An inference example in Freebase.

4 Related Work

Recent years have witnessed great advances of modeling multi-relational data such as social networks and KBs. Many works cope with relational learning as a multi-relational representation learning problem, encoding both entities and relations in a low-dimensional latent space, based on Bayesian clustering (Kemp et al., 2006; Miller et al., 2009; Sutskever et al., 2009; Zhu, 2012), energy-based models (Bordes et al., 2011; Chen et al., 2013; Socher et al., 2013; Bordes et al., 2013; Bordes et al., 2014), matrix factorization (Singh and Gordon, 2008; Nickel et al., 2011; Nickel et al., 2012) . Among existing representation models, TransE (Bordes et al., 2013) regards a relation as translation between head and tail entities for optimization, which achieves a good trade-off between prediction accuracy and computational efficiency. All existing representation learning methods of knowledge bases only use direct relations between entities, ignoring rich information in relation paths.

Relation paths have already been widely considered in social networks and recommender systems. Most of these works regard each relation and path as discrete symbols, and deal with them using graph-based algorithms, such as random walks with restart (Tong et al., 2006). Relation paths have also been used for inference on large-scale KBs, such as Path Ranking algorithm (PRA) (Lao and Cohen, 2010), which has been adopted for expert finding (Lao and Cohen, 2010) and information retrieval (Lao et al., 2012). PRA has also been used for relation extraction based on KB structure (Lao et al., 2011; Gardner et al., 2013). (Neelakantan et al., 2015) further learns a recurrent neural network (RNN) to represent unseen relation paths according to involved relations. We note that, these methods focus on modeling relation paths for relation extraction without considering any information of entities. In contrast, by successfully integrating the merits of modeling entities and relation paths, PTransE can learn superior representations of both entities and relations for knowledge graph completion and relation extraction as shown in our experiments.

5 Conclusion and Future Work

This paper presents PTransE, a novel representation learning method for KBs, which encodes relation paths to embed both entities and relations

in a low-dimensional space. To take advantages of relation paths, we propose path-constraint resource allocation to measure relation path reliability, and employ semantic composition of relations to represent paths for optimization. We evaluate PTransE on knowledge base completion and relation extraction from text. Experimental results show that PTransE achieves consistent and significant improvements as compared with TransE and other baselines.

In future, we will explore the following research directions: (1) This paper only considers the inference patterns between direct relations and relation paths between two entities for learning. There are much complicated patterns among relations. For example, the inference form $\texttt{Queen}(e) \xRightarrow{\text{Inference}} \texttt{Female}(e)$ cannot be handled by PTransE. We may take advantages of first-order logic to encode these inference patterns for representation learning. (2) There are some extensions for TransE, e.g., TransH and TransR. It is non-trivial for them to adopt the idea of PTransE, and we will explore to extend PTransE to these models to better deal with complicated scenarios of KBs.

Corpus-level Fine-grained Entity Typing Using Contextual Information

Yadollah Yaghoobzadeh and **Hinrich Schütze**
Center for Information and Language Processing
University of Munich, Germany
yadollah@cis.lmu.de

Abstract

This paper addresses the problem of corpus-level entity typing, i.e., inferring from a large corpus that an entity is a member of a class such as "food" or "artist". The application of entity typing we are interested in is knowledge base completion, specifically, to learn which classes an entity is a member of. We propose FIGMENT to tackle this problem. FIGMENT is embedding-based and combines (i) a global model that scores based on aggregated contextual information of an entity and (ii) a context model that first scores the individual occurrences of an entity and then aggregates the scores. In our evaluation, FIGMENT strongly outperforms an approach to entity typing that relies on relations obtained by an open information extraction system.

1 Introduction

Natural language understanding (NLU) is not possible without knowledge about the world – partly so because world knowledge is needed for many NLP tasks that must be addressed as part of NLU; e.g., many coreference ambiguities can only be resolved based on world knowledge. It is also true because most NLU applications combine a variety of information sources that include both text sources and knowledge bases; e.g., question answering systems need access to knowledge bases like gazetteers. Thus, high-quality knowledge bases are critical for successful NLU.

Unfortunately, most knowledge bases are incomplete. The effort required to create knowledge bases is considerable and since the world changes, it will always continue. Knowledge bases are therefore always in need of updates and corrections. To address this problem, we present an information extraction method that can be used for knowledge base completion. In contrast to most other work on knowledge base completion, we focus on fine-grained *classification of entities* as opposed to *relations between entities*.

The goal of knowledge base completion is to acquire knowledge in general as opposed to detailed analysis of an individual context or sentence. Therefore, our approach is *corpus-level*: We infer the types of an entity by considering the set of all of its mentions in the corpus. In contrast, named entity recognition (NER) is *context-level* or *sentence-level*: NER infers the type of an entity in a particular context. As will be discussed in more detail in the following sections, the problems of corpus-level entity typing vs. context/sentence-level entity typing are quite different. This is partly because the objectives of optimizing accuracy on the context-level vs. optimizing accuracy on the corpus-level are different and partly because evaluation measures for corpus-level and context-level entity typing are different.

We define our problem as follows. Let K be a knowledge base that models a set E of entities, a set T of fine-grained classes or *types* and a membership function $m : E \times T \mapsto \{0, 1\}$ such that $m(e, t) = 1$ iff entity e has type t. Let C be a large corpus of text. Then, the problem we address in this paper is *corpus-level entity typing*: For a given pair of entity e and type t determine – based on the evidence available in C – whether e is a member of type t (i.e., $m(e, t) = 1$) or not (i.e., $m(e, t) = 0$) and update the membership relation m of K with this information.

We investigate two approaches to entity typing: a global model and a context model.

The *global model* aggregates all contextual information about an entity e from the corpus and then based on that, makes a classification decision on a particular type t – i.e., $m(e, t) = 0$ vs. $m(e, t) = 1$.

The *context model* first scores each individual

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 715–725,
Lisbon, Portugal, 17-21 September 2015.

context of e as expressing type t or not. A final decision on the value of $m(e,t)$ is then made based on the distribution of context scores. One difficulty in knowledge base completion based on text corpora is that it is too expensive to label large amounts of text for supervised approaches. For our context model, we address this problem using *distant supervision*: we treat *all* contexts of an entity that can have type t as contexts of type t even though this assumption will in general be only true for a *subset* of these contexts. Thus, as is typical for distant supervision, the labels are incorrect in some contexts, but we will show that the labeling is good enough to learn a high-quality context model.

The global model is potentially more robust since it looks at all the available information at once. In contrast, the context model has the advantage that it can correctly predict types for which there are only a small number of reliable contexts. For example, in a large corpus we are likely to find a few reliable contexts indicating that "Barack Obama" is a bestselling author even though this evidence may be obscured in the global distribution because the vast majority of mentions of "Obama" do not occur in author contexts.

We implement the global model and the context model as well as a simple combination of the two and call the resulting system FIGMENT: FIne-Grained eMbedding-based Entity Typing. A key feature of FIGMENT is that it makes extensive use of distributed vector representations or *embeddings*. We compute embeddings for words as is standard in a large body of NLP literature, but we also compute embeddings for *entities* and for *types*. The motivation for using embeddings in these cases is (i) better generalization and (ii) more robustness against noise for text types like web pages. We compare the performance of FIGMENT with an approach based on Open Information Extraction (OpenIE).

The main contributions of this paper can be summarized as follows.

- We address the problem of corpus-level entity typing in a knowledge base completion setting. In contrast to other work that has focused on learning *relations* between entities, we learn *types* of entities.
- We show that context and global models for entity typing provide complementary information and combining them gives the best results.
- We use embeddings for words, entities and types to improve generalization and deal with noisy input.
- We show that our approach outperforms a system based on OpenIE relations when the input corpus consists of noisy web pages.

In the following, we first discuss related work. Then we motivate our approach and define the problem setting we adopt. We then introduce our models in detail and report and analyze experimental results. Finally, we discuss remaining challenges and possible future work and present our conclusions.

2 Related work

Named entity recognition (NER) is the task of detecting and classifying named entities in text. While most NER systems (e.g., Finkel et al. (2005)) only consider a small number of entity classes, recent work has addressed fine-grained NER (Yosef et al., 2012; Ling and Weld, 2012). These methods use a variety of lexical and syntactic features to segment and classify entity mentions. Some more recent work assumes the segmentation is known and only classifies entity mentions. Dong et al. (2015) use distributed representations of words in a hybrid classifier to classify mentions to 20 types. Yogatama et al. (2015) classify mentions to more fine-grained types by using different features for mentions and embedding labels in the same space. These methods as well as standard NER systems try to maximize correct classification of mentions in individual contexts whereas we aggregate individual contexts and evaluate on accuracy of entity-type assignments inferred from the entire corpus. In other words, their evaluation is *sentence-level* whereas ours is *corpus-level*.

Entity set expansion (ESE) is the problem of finding entities in a class (e.g., medications) given a seed set (e.g., {"Ibuprofen", "Maalox", "Prozac"}). The standard solution is pattern-based bootstrapping (Thelen and Riloff, 2002; Gupta and Manning, 2014). ESE is different from the problem we address because ESE starts with a small seed set whereas we assume that a large number of examples from a knowledge base (KB) is available. Initial experiments with the system of Gupta

and Manning (2014) showed that it was not performing well for our task – this is not surprising given that it is designed for a task with properties quite different from entity typing.

More closely related to our work are the OpenIE systems NNPLB (Lin et al., 2012) and PEARL (Nakashole et al., 2013) for *fine-grained typing of unlinkable and emerging entities*. Both systems first extract relation tuples from a corpus and then type entities based on the tuples they occur in (where NNPLB only uses the subject position for typing). To perform typing, NNPLB propagates activation from known members of a class to other entities whereas PEARL assigns types to the argument slots of relations. The main difference to FIGMENT is that we do not rely on relation extraction. In principle, we can make use of any context, not just subject and object positions. FIGMENT also has advantages for noisy text for which relation extraction can be challenging. This will be demonstrated in our evaluation on web text. Finally, our emphasis is on making yes-no decisions about possible types (as opposed to just ranking possibilities) for all entities (as opposed to just emerging or unlinkable entities). Our premise is that even existing entities in KBs are often not completely modeled and have entries that require enhancement. We choose NNPLB as our baseline.

The fine-grained typing of entities performed by FIGMENT can be used for *knowledge base completion (KBC)*. Most KBC systems focus on *relations* between entities, not on *types* as we do. Some generalize the patterns of relationships within the KB (Nickel et al., 2012; Bordes et al., 2013) while others use a combination of within-KB generalization and information extraction from text (Weston et al., 2013; Socher et al., 2013; Jiang et al., 2012; Riedel et al., 2013; Wang et al., 2014). Neelakantan and Chang (2015) address entity typing in a way that is similar to FIGMENT. Their method is based on KB information, more specifically entity descriptions in Wikipedia and Freebase. Thus, in contrast to our approach, their system is not able to type entities that are not covered by existing KBs. We infer classes for entities from a large corpus and do not assume that these entities occur in the KB.

Learning embeddings for words is standard in a large body of NLP literature (see Baroni et al. (2014) for an overview). In addition to words, we also learn *embeddings for entities and types*. Most prior work on entity embeddings (e.g., Weston et al. (2013), Bordes et al. (2013)) and entity and type embeddings (Zhao et al., 2015) has mainly used KB information as opposed to text corpora. Wang et al. (2014) learn embeddings of words and entities in the same space by replacing Wikipedia anchors with their corresponding entities. For our global model, we learn entity embedding in a similar way, but on a corpus with automatically annotated entities. For our context model, we learn and use type embeddings jointly with corpus words to improve generalization, a novel contribution of this paper to the best of our knowledge. We learn all our embeddings using `word2vec` (Mikolov et al., 2013).

Our problem can be formulated as *multi-instance multi-label* (MIML) learning (Zhou and Zhang, 2006), similar to the formulation for relation extraction by Surdeanu et al. (2012). In our problem, each example (entity) can have several instances (contexts) and each instance can have several labels (types). Similar to Zhou and Zhang (2006)'s work on scene classification, we also transform MIML into easier tasks. The global model transforms MIML into a multi-label problem by merging all instances of an example. The context model solves the problem by combining the instance-label scores to example-label scores.

3 Motivation and problem definition

3.1 Freebase

Large scale KBs like Freebase (Bollacker et al., 2008), YAGO (Suchanek et al., 2007) and Google knowledge graph are important NLP resources. Their structure is roughly equivalent to a graph in which entities are nodes and edges are relations between entities. Each node is also associated with one or more semantic classes, called types. These types are the focus of this paper.

We use Freebase, the largest available KB, in this paper. In Freebase, an entity can belong to several classes, e.g., "Barack Obama" is a member of 37 types including "US president" and "author". One *notable type* is also defined for each entity, e.g., "US-president" for "Obama" since it is regarded as his most prominent characteristic and the one that would be used to disambiguate references to him, e.g., to distinguish him from somebody else with the same name.

There are about 1500 types in Freebase, or-

ganized by domain; e.g., the domain "food" has types like "food", "ingredient" and "restaurant". Some types like "location" are very general, some are very fine-grained, e.g., "Vietnamese urban district". There are types that have a large number of instances like "citytown" and types that have very few like "camera_sensor". Entities are defined as instances of types. They can have several types based on the semantic classes that the entity they are referring to is a member of – as in the above example of Barack Obama.

The types are not organized in a strict taxonomy even though there exists an *included type* relationship between types in Freebase. The reason is that for a user-generated KB it is difficult to maintain taxonomic consistency. For example, almost all instances of "author" are also instances of "person", but sometimes organizations author and publish documents. We follow the philosophy of Freebase and assume that the types do not have a hierarchical organization.

3.2 Incompleteness of knowledge base

Even though Freebase is the largest publicly available KB of its kind, it still has significant coverage problems; e.g., 78.5% of persons in Freebase do not have *nationality* (Min et al., 2013).

This is unavoidable, partly because Freebase is user-generated, partly because the world changes and Freebase has to be updated to reflect those changes. All existing KBs that attempt to model a large part of the world suffer from this incompleteness problem. Incompleteness is likely to become an even bigger problem in the future as the number of types covered by KBs like Freebase increases. As more and more fine-grained types are added, achieving good coverage for these new types using only human editors will become impossible.

The approach we adopt in this paper to address incompleteness of KBs is extraction of information from large text corpora. Text can be argued to be the main repository of the type of knowledge represented in KBs, so it is reasonable to attempt completing them based on text. There is in fact a significant body of work on corpus-based methods for extracting knowledge from text; however, most of it has addressed relation extraction, not the acquisition of type information – roughly corresponding to unary relations (see Section 2). In this paper, we focus on typing entities.

3.3 Entity linking

The first step in extracting information about entities from text is to reliably identify mentions of these entities. This problem of *entity linking* has some mutual dependencies with entity typing. Indeed, some recent work shows large improvements when entity typing and linking are jointly modeled (Ling et al., 2015; Durrett and Klein, 2014). However, there are constraints that are important for high-performance entity linking, but that are of little relevance to entity typing. For example, there is a large literature on entity linking that deals with coreference resolution and inter-entity constraints – e.g., "Naples" is more likely to refer to a US (resp. an Italian) city in a context mentioning "Fort Myers" (resp. "Sicily").

Therefore, we will only address entity typing in this paper and consider entity linking as an independent module that provides contexts of entities for FIGMENT. More specifically, we build FIGMENT on top of the output of an existing entity linking system and use FACC1,[1] an automatic Freebase annotation of ClueWeb (Gabrilovich et al., 2013). According to the FACC1 distributors, precision of annotated entities is around 80-85% and recall is around 70-85%.

3.4 FIGER types

Our goal is fine-grained typing of entities, but types like "Vietnamese urban district" are too fine-grained. To create a reliable setup for evaluation and to make sure that all types have a reasonable number of instances, we adopt the FIGER type set (Ling and Weld, 2012) that was created with the same goals in mind. FIGER consists of 112 tags and was created in an attempt to preserve the diversity of Freebase types while consolidating infrequent and unusual types through filtering and merging. For example, the Freebase types "dish", "ingredient", "food" and "cheese" are mapped to one type "food". See (Ling and Weld, 2012) for a complete list of FIGER types. We use "type" to refer to FIGER types in the rest of the paper.

4 Global, context and joint models

We address a problem setting in which the followings are given: a KB with a set of entities E, a set of types T and a membership function $m : E \times T \mapsto \{0, 1\}$ such that $m(e, t) = 1$ iff entity e has type t; and a large annotated corpus C

[1] lemurproject.org/clueweb12/FACC1

in which mentions of E are linked. As mentioned before, we use FACC1 as our corpus.

In this problem setting, we address the task of *corpus-level fine-grained entity typing*: we want to infer from the corpus for each pair of entity e and type t whether $m(e,t) = 1$ holds, i.e., whether entity e is a member of type t.

We use three scoring models in FIGMENT: global model, context model and joint model. The models return a score $S(e,t)$ for an entity-type pair (e,t). $S(e,t)$ is an assessment of the extent to which it is true that the semantic class t contains e and we learn it by training on a subset of E. The trained models can be applied to large corpora and the resulting scores can be used for learning new types of entities covered in the KB as well as for typing new or unknown entities – i.e., entities not covered by the KB. To work for new or unknown entities, we would need an entity linking system such as the ones participating in TAC KBP (McNamee and Dang, 2009) that identifies and clusters mentions of them.

4.1 Global model

The global model (GM) scores possible types of entity e based on a *distributed vector representation* or *embedding* $\vec{v}(e) \in \mathbb{R}^d$ of e. $\vec{v}(e)$ can be learned from the entity-annotated corpus C.

Embeddings of words have been widely used in different NLP applications. The embedding of a word is usually derived from the distribution of its context words. The hypothesis is that words with similar meanings tend to occur in similar contexts (Harris, 1954) and therefore cooccur with similar context words. By extension, the assumption of our model is that entities with similar types tend to cooccur with similar context words.

To learn a score function $S_{\text{GM}}(e,t)$, we use a multilayer perceptron (MLP) with one shared hidden layer and an output layer that contains, for each type t in T, a logistic regression classifier that predicts the probability of t:

$$S_{\text{GM}}(e,t) = G_t\Big(\tanh\left(\mathbf{W}_{\text{input}}\vec{v}(e)\right)\Big)$$

where $\mathbf{W}_{\text{input}} \in \mathbb{R}^{h\times d}$ is the weight matrix from $\vec{v}(e) \in \mathbb{R}^d$ to the hidden layer with size h. G_t is the logistic regression classifier for type t that is applied on the hidden layer. The shared hidden layer is designed to exploit the dependencies among labels. Stochastic gradient descent (SGD) with AdaGrad (Duchi et al., 2011) and minibatches are used to learn the parameters.

4.2 Context model

For the context model (CM), we first learn a scoring function $S_{\text{c2t}}(c,t)$ for individual contexts c in the corpus. $S_{\text{c2t}}(c,t)$ is an assessment of how likely it is that an entity occurring in context c has type t. For example, consider the contexts c_1 = "he served SLOT cooked in wine" and c_2 = "she loves SLOT more than anything". SLOT marks the occurrence of an entity and it also shows that we do not care about the entity mention itself but only its context. For the type t = "food", $S_{\text{c2t}}(c_1,t)$ is high whereas $S_{\text{c2t}}(c_2,t)$ is low. This example demonstrates that some contexts of an entity like "beef" allow specific inferences about its type whereas others do not. We aim to learn a scoring function S_{c2t} that can distinguish these cases.

Based on the context scoring function S_{c2t}, we then compute the corpus-level CM scoring function S_{CM} that takes the scores $S_{\text{c2t}}(c_i,t)$ for all contexts of entity e in the corpus as input and returns a score $S_{\text{CM}}(e,t)$ that assesses the appropriateness of t for e. In other words, S_{CM} is:

$$S_{\text{CM}}(e,t) = g(U_{e,t}) \tag{1}$$

where $U_{e,t} = \{S_{\text{c2t}}(c_1,t), \ldots, S_{\text{c2t}}(c_n,t)\}$ is the set of scores for t based on the n contexts $c_1 \ldots c_n$ of e in the corpus. The function g is a summary function of the distribution of scores, e.g., the mean, median or maximum. We use the mean in this paper.

We now describe how we learn S_{c2t}. For training, we need contexts that are labeled with types. We do not have such a dataset in our problem setting, but we can use the contexts of linked entities as distantly supervised data. Specifically, assume that entity e has n types. For each mention of e in the corpus, we generate a training example with n labels, one for each of the n types of e.

For training S_{c2t}, a context c of a mention is represented as the concatenation of two vectors. One vector is the *average* of the embeddings of the $2l$ words to the left and right of the mention. The other vector is the *concatenation* of the embeddings of the $2k$ words to the left and right of the mention. E.g., for $k = 2$ and $l = 1$ the context c is represented as the vector: $\Phi(c) = \left[x_{-2}, x_{-1}, x_{+1}, x_{+2}, \text{avg}(x_{-1}, x_{+1})\right]$ where $x_i \in \mathbb{R}^d$ is the embedding of the context word at position i relative to the entity in position 0.

We train S_{c2t} on context representations that consist of embeddings because our goal is a robust model that works well on a wide variety of genres, including noisy web pages. If there are other entities in the contexts, we first replace them with their notable type to improve generalization. We learn word and type embeddings from the corpus C by replacing train entities with their notable type.

The next step is to score these examples. We use an MLP similar to the global model to learn S_{c2t}, which predicts the probability of type t occurring in context c:

$$S_{\text{c2t}}(c,t) = G_t\Big(\tanh\left(\mathbf{W}_{\text{input}}\Phi(c)\right)\Big)$$

where $\Phi(c) \in \mathbb{R}^n$ is the feature vector of the context c as described above, $n = (2k+1) * d$ and $\mathbf{W}_{\text{input}} \in \mathbb{R}^{h \times n}$ is the weight matrix from input to hidden layer with h units. Again, we use SGD with AdaGrad and minibatch training.

4.3 Joint model

Global model and context model have complementary strengths and weaknesses.

The strength of CM is that it is a direct model of the only source of reliable evidence we have: the context in which the entity occurs. This is also the way a human would ordinarily do entity typing: she would determine if a specific context in which the entity occurs implies that the entity is, say, an author or a musician and type it accordingly. The order of words is of critical importance for the accurate assessment of a context and CM takes it into account. A well-trained CM will also work for cases for which GM is not applicable. In particular, if the KB contains only a small number of entities of a particular type, but the corpus contains a large number of contexts of these entities, then CM is more likely to generalize well.

The main weakness of CM is that a large proportion of contexts does not contain sufficient information to infer all types of the entity; e.g., based on our distant supervised training data, we label every context of "Obama" with "author", "politician" and Obama's other types in the KB. Thus, CM is trained on a noisy training set that contains only a relatively small number of informative contexts.

The main strength of GM is that it bases its decisions on the entire evidence available in the corpus. This makes it more robust. It is also more efficient to train since its training set is by a factor of $|M|$ smaller than the training set of CM where $|M|$ is the average number of contexts per entity.

The disadvantage of GM is that it does not work well for rare entities since the aggregated representation of an entity may not be reliable if it is based on few contexts. It is also less likely to work well for non-dominant types of an entity which might be swamped by dominant types; e.g., the author contexts of "Obama" may be swamped by the politician contexts and the overall context signature of the entity "Obama" may not contain enough signal to infer that he is an author. Finally, methods for learning embeddings like `word2vec` are bag-of-word approaches. Therefore, word order information – critical for many typing decisions – is lost.

Since GM and CM models are complementary, a combination model should work better. We test this hypothesis for the simplest possible joint model (JM), which adds the scores of the two individual models:

$$S_{\text{JM}}(e,t) = S_{\text{GM}}(e,t) + S_{\text{CM}}(e,t)$$

5 Experimental setup and results

5.1 Setup

Baseline: Our baseline system is the OpenIE system no-noun-phrase-left-behind (NNPLB) by Lin et al. (2012) (see Section 2). Our reimplementation performs on a par with published results.[2] We use NNPBL as an alternative way of computing scores $S(e,t)$. Scores of the four systems we compare – NNPBL, GM, CM, JM – are processed the same way to perform entity typing (see below).

Corpus: We select a subset of about 7.5 million web pages, taken from the first segment of ClueWeb12,[3] from different crawl types: 1 million Twitter links, 120,000 WikiTravel pages and 6.5 million web pages. This corpus is preprocessed by eliminating HTML tags, replacing all numbers with "7" and all web links and email addresses with "HTTP", filtering out sentences with length less than 40 characters, and finally doing a simple tokenization. We merge the text with the FACC1 annotations. The resulting corpus has 4 billion tokens and 950,000 distinct entities. We use the 2014-03-09 Freebase data dump as our KB.

[2] The precision of our implementation on the dataset of three million relation triples distributed by (Lin et al., 2012) is 60.7% compared to 59.8% and 61% for tail and head entities reported by Lin et al. (2012).

[3] `http://lemurproject.org/clueweb12`

Entity datasets: We consider all entities in the corpus whose notable types can be mapped to one of the 112 FIGER types, based on the mapping provided by FIGER. 750,000 such entities form our set of entities. 10 out of 112 FIGER types have no entities in this set.[4]

We run the OpenIE system Reverb (Fader et al., 2011) to extract relation triples of the form <subject, relation, object>. Since NNPLB only considers entities in the subject position, we filter out triples whose subject is not an entity. The size of the remaining set of triples is 4,000,000. For a direct comparison with NNPLB, we divide the 750,000 entities into those that occur in subject position in one of the extracted triples (about 250,000 *subject entities* or SE) and those that do not (about 500,000 *non-subject entities* or NSE). We split SE 50:20:30 into train, dev and test sets. The average and median number of FIGER types of the training entities are 1.8 and 2, respectively. We use NSE to evaluate performance of FIGMENT on entities that do not occur in subject position.[5]

Context sampling: For S_{c2t}, we create train', dev' and test' sets of *contexts* that correspond to train, dev and test sets of *entities*. Because the number of contexts is unbalanced for both entities and types and because we want to accelerate training and testing, we downsample contexts. For the set train', we use the notable type feature of Freebase: For each type t, we take contexts from the mentions of those entities whose notable type is t. Recall, however, that each context is labeled with all types of its entity – see Section 4.2.

Then if the number of contexts for t is larger than a minimum, we sample the contexts based on the number of training entities of t. We set the minimum to 10,000 and constrain the number of samples for each t to 20,000. Also, to reduce the effect of distant supervision, entities with fewer distinct types are preferred in sampling to provide discriminative contexts for their notable types. For test' and dev' sets, we sample 300 and 200 random contexts, respectively, for each entity.

System setup: As the baseline, we apply NNPLB to the 4 million extracted triples. To learn entity embeddings for GM, we run `word2vec` (skipgram, 200 dimensions, window size 5) on a version of the corpus in which entities have been replaced by their Freebase IDs, based on the FACC1 annotation. We then train MLP with number of hidden units h = 200 on the embeddings of training entities until the error on dev entities stops decreasing.

Our reasoning for the unsupervised training setup is that we do not use any information about the types of entities (e.g., no entities annotated by humans with types) when we run an unsupervised algorithm like `word2vec`. In a real-world application of FIGMENT to a new corpus, we would first run `word2vec` on the merger of our corpus and the new corpus, retrain GM on training entities and finally apply it to entities in the new corpus. This scenario is simulated by our setup.

Recall that the input to CM consists of $2k$ unit embeddings and the average of $2l$ unit embeddings where we use the term *unit* to refer to both words and types. We set k to 4 and l to 5. To learn embeddings for units, we first exclude lines containing test entities, and then replace each entity with its notable type. Then, we run `word2vec` (skipgram, 100 dimensions, window size 5) on this new corpus and learn embeddings for words and types.

Using the embeddings as input representations, we train S_{c2t} on train' until error on dev' stops decreasing. We set the number of hidden units to 300. We then apply the trained scoring function S_{c2t} to test' and get the scores $S_{\text{c2t}}(c,t)$ for test' contexts. As explained in Section 4.2, we compute the corpus-level scores $S_{\text{CM}}(e,t)$ for each entity by averaging its context-level scores (see Equation 1).

Ranking evaluation: This evaluation shows how well the models rank types for entities. The ranking is based on the scores $S(e,t)$ produced by the different models and baselines. Similar to the evaluation performed by Lin et al. (2012), we use precision at 1 (P@1) and breakeven point (BEP, Boldrin and Levine (2008)). BEP is F_1 at the point in the ranked list at which precision and recall have the same value.

Classification evaluation: This evaluation demonstrates the quality of the thresholded assignment decisions produced by the models. These measures more directly express how well FIGMENT would succeed in enhancing the KB with new information since for each pair (e,t), we have to make a binary decision about whether to put it in the KB or not. We compare our decisions with the gold KB information.

[4]The reason is that the FIGER mapping uses Freebase user-created classes. The 10 missing types are not the notable type of any entity in Freebase.

[5]The entity datasets are available at `http://cistern.cis.lmu.de/figment`

	all types	head types	tail types

Table 3: Effect of the context size $2k$ in CM (2k: context size, h: number of hidden units in MLP)

Our evaluation measures are (i) accuracy: an entity is correct if all its types and no incorrect types are assigned to it; (ii) micro average: F_1 of all type-entity assignment decisions; (iii) entity macro average F_1: F_1 of types assigned to an entity, averaged over entities; (iv) type macro average F_1: F_1 of entities assigned to a type, averaged over types.

The assignment decision is made based on thresholds, one per type, for each $S(e, t)$. We select the threshold that maximizes F_1 of entities assigned to the type on dev.

5.2 Results

Table 1 presents results for the ranking evaluation as well as for the first three measures of the classification evaluation. MFT is the most frequent type baseline that ranks types according to their frequency in train. We also show the results for head entities (frequency higher than 100) and tail entities (frequency less than 5). The performance of the systems is in this order: JM $>$ GM $>$ CM $>$ NNPLB $>$ MFT.

Table 2 shows the results of the fourth classification measure, type macro average F_1, for all, head (more than 3000 train entities, 11 types), and tail (less than 200 train entities, 36 types) types. The ordering of models for Table 2 is in line with Table 1: JM $>$ GM $>$ CM $>$ NNPLB $>$ MFT.

We can easily run FIGMENT for **non-subject entities** (NSE) exactly the same way we have run it for subject entities. We test our JM on the 67,000 NSE entities with a frequency of more than 10. The top ranked type returned for 73.5% of entities was correct. Thus, due to our ability to deal with NSE, we can type an additional 50,000 entities correctly.

6 Analysis

Effect of window size in CM: Table 3 explores the effect of using different context sizes. Recall that CM was trained with $2k$ = 8 for the concatenation and $2l$ = 10 for the average window size. We change $2k$ from 0 to 14 while keeping $2l$ = 10. The number of hidden units used in each model is also reported. The table shows that CM can leverage larger context sizes well.

Poor results of NNPLB: NNPLB is mostly hampered by Reverb, which did not work well on the noisy web corpus. As a result, the quality of the extracted relations – which NNPLB entity typing is based on – is too low for reliable typing decisions. The good results of NNPLB on their non-noisy published relation triples confirm that. On the three million relation triples, when mapping Freebase types to FIGER, P@1 of NNPLB is .684; when limiting entities to those with more than 10 relations, the results improve to .776.

GM performs better than CM and JM performs best: The fact that GM outperforms CM shows that decisions based on one global vector of an entity work better than aggregating multiple weak decisions on their contexts. That is clearest for tail entities – where one bad context can highly influence the final decision – and for tail types, which CM was not able to distinguish from other similar types. However, the good results of the simple JM confirm that the score distributions in CM do help. As an example, consider one of the test entities that is an "author". GM and CM wrongly predict "written_work" and "artist", respectively, but JM correctly outputs "author".

Errors of CM: Many CM errors are caused by its simple input representation: it has to learn all linguistic abstractions that it wants to rely on from the training set. One manifestation of this problem is that CM confuses the types "food" and "restaurant". There are only few linguistic contexts in which entities of these types can be exchanged for each other. On the other hand, the context words they cooccur with in a bag-of-words (BOW) sense are very similar. Thus, this indicates that CM pays too much attention to BOW information and that its representation of contexts is limited in terms of generalization.

	all entities					head entities					tail entities

Table 1: Ranking and classification results for SE entities. P@1 and BEP are ranking measures. Accuracy (acc), micro (mic) and macro (mac) are classification measures.

Assumptions that result in errors: The performance of all models suffers from a number of assumptions we made in our training / evaluation setup that are only approximately true.

The first assumption is that FACC1 is correct. But it has a precision of only 80-85% and this caused many errors. An example is the lunar crater "Buffon" in Freebase, a "location". Its predicted type is "athlete" because some FACC1 annotations of the crater link it to the Italian goalkeeper.

The second assumption of our evaluation setup is the completeness of Freebase. There are about 2,600 entities with the single type "person" in SE test. For 62% of the errors on this subset, the top predicted type is a subtype of person: "author", "artist" etc. We manually typed a random subset of 50 and found that the predicted type is actually correct for 44 of these entities.

The last assumption is the mapping from Freebase to FIGER. Some common Freebase types like "award-winner" are not mapped. This negatively affects evaluation measures for many entities. On the other hand, the resulting types do not have a balanced number of instances. Based on our training entities, 11 types (e.g., "law") have less than 50 instances while 26 types (e.g., "software") have more than 1000 instances. Even sampling the contexts could not resolve this problem and this led to low performance on tail types.

7 Future work

The performance of FIGMENT is poor for tail types and entities. We plan to address this in the future (i) by running FIGMENT on larger corpora, (ii) by refining the FIGER type set to cover more Freebase entities, (iii) by exploiting a hierarchy over types and (iv) by exploring more complex input representations of the context for the CM.

FIGMENT's context model can in principle be based on any system that provides entity-type assessment scores for individual contexts. Thus, as an alternative to our scoring model $S_{\text{c2t}}(c,t)$, we could use sentence-level entity classification systems such as FIGER (Ling and Weld, 2012) and (Yogatama et al., 2015)'s system. These systems are based on linguistic features different from the input representation we use, so a comparison with our embedding-based approach is interesting. Our assumption is that FIGMENT is more robust against noise, but investigation is needed.

The components of the version of FIGMENT we presented, in particular, context model and global model, do not use features derived from the mention of an entity. Our assumption was that such features are less useful for fine-grained entity typing. However, there are clearly some types for which mention-based features are useful (e.g., medications or organizations referred to by abbreviations), so we will investigate the usefulness of such features in the future.

8 Conclusion

We presented FIGMENT, a corpus-level system that uses contextual information for entity typing. We designed two scoring models for pairs of entities and types: a global model that scores based on aggregated context information and a context model that aggregates the scores of individual contexts. We used embeddings of words, entities and types to represent contextual information. Our experimental results show that global model and context model provide complementary information for entity typing. We demonstrated that, comparing with an OpenIE-based system, FIGMENT performs well on noisy web pages.

Abstract

We present KB-UNIFY, a novel approach for integrating the output of different Open Information Extraction systems into a single unified and fully disambiguated knowledge repository. KB-UNIFY consists of three main steps: (1) disambiguation of relation argument pairs via a sense-based vector representation and a large unified sense inventory; (2) ranking of semantic relations according to their degree of specificity; (3) cross-resource relation alignment and merging based on the semantic similarity of domains and ranges. We tested KB-UNIFY on a set of four heterogeneous knowledge bases, obtaining high-quality results. We discuss and provide evaluations at each stage, and release output and evaluation data for the use and scrutiny of the community[1].

1 Introduction

The breakthrough of the Open Information Extraction (OIE) paradigm opened up a research area where Web-scale unconstrained Information Extraction systems are developed to acquire and formalize large quantities of knowledge. However, while successful, to date most state-of-the-art OIE systems have been developed with their own type inventories, and no portable ontological structure. In fact, OIE systems can be very different in nature. Early approaches (Etzioni et al., 2008; Wu and Weld, 2010; Fader et al., 2011) focused on extracting a large number of relations from massive unstructured corpora, mostly relying on dependencies at the level of surface text. Systems like NELL (Carlson et al., 2010) combine a hand-crafted taxonomy of entities and relations with self-supervised large-scale extraction from the Web, but they require additional processing for linking and integration (Dutta et al., 2014).

More recent work has focused, instead, on deeper language understanding, especially at the level of syntax and semantics (Nakashole et al., 2012; Moro and Navigli, 2013). By leveraging semantic analysis, knowledge gathered from unstructured text can be adequately integrated and used to enrich existing knowledge bases, such as YAGO (Mahdisoltani et al., 2015), FREEBASE (Bollacker et al., 2008) and DBPEDIA (Lehmann et al., 2014). A large amount of reliable structured knowledge is crucial for OIE approaches based on distant supervision (Mintz et al., 2009; Riedel et al., 2010), even when multi-instance multi-learning algorithms (Surdeanu et al., 2012) or matrix factorization techniques (Riedel et al., 2013; Fan et al., 2014) come into play to deal with noisy extractions. For this reason a recent trend of research has focused on Knowledge Base (KB) completion (Nickel et al., 2012; Bordes et al., 2013), exploiting the fact that distantly supervised OIE and structured knowledge can complement each other. However, the majority of integration approaches nowadays are not designed to deal with many different resources at the same time.

We propose an approach where the key idea is to bring together knowledge drawn from an arbitrary number of OIE systems, regardless of whether these systems provide links to some general-purpose inventory, come with their own ad-hoc structure, or have no structure at all. Knowledge from each source, in the form of ⟨subject, predicate, object⟩ triples, is disambiguated and linked to a single large sense inventory. This enables us to discover alignments at a semantic level between relations from different KBs, and to generate a unified, fully disambiguated KB of entities and semantic relations. KB-UNIFY achieves state-of-the-art disambiguation and provides a general, resource-independent representation of semantic relations, suitable for any kind of KB.

The remainder of this paper is structured as follows: Section 2 reviews relevant related work; Sections 3, 4, 5 and 6 describe in detail each stage of the approach; Sections 7 and 8 describe the experiments carried out and the results obtained; and finally Section 9 summarizes our findings and discusses potential directions for future work.

2 Related Work

The integration of knowledge drawn from different sources has received much attention over the last decade. Among the most notable examples are resources like BabelNet (Navigli and Ponzetto, 2012), UBY (Gurevych et al., 2012) and YAGO (Mahdisoltani et al., 2015). While great effort has been put into aligning knowledge at the *concept level*, most approaches do not tackle the problem of integrating heterogeneous knowledge at the *relation level*, nor do they exploit effectively the huge amount of information harvested with OIE systems, even when this information is unambiguously linked to a structured resource, as in (Nakashole et al., 2012), or (Moro and Navigli, 2013). In fact, as the number of resources increases, KB alignment is already becoming an emergent research field: Dutta et al. (2014) describe a method for linking arguments in NELL triples to DBPEDIA by combining First Order Logic and Markov Networks; Grycner and Weikum (2014) semantify PATTY's pattern synsets and connect them to WordNet verbs; Lin et al. (2012) propose a method to propagate FREEBASE types across REVERB and deal with the problem of unlinkable entities. All these approaches achieve very competitive results in their respective settings, but unlike the approach being proposed here, they limit the task to 1-to-1 alignments. A few contributions have tried to broaden the scope and include different resources at the same time, but with rather different goals from ours. For example, Riedel et al. (2013) propose a universal schema that integrates structured data with OIE data by learning latent feature vectors for entities and relations; the KNOWLEDGE VAULT (Dong et al., 2014) uses a graph-based probabilistic framework where prior knowledge from existing resources (e.g. FREEBASE) improves Web extractions by predicting their reliability. However, in both cases the main objective is distantly supervised extraction from unstructured text, rather than KB unification. A recent trend of research focuses on learning embedding models for structured knowledge and their application to tasks like relation extraction and KB completion (Socher et al., 2013; Weston et al., 2013; Bordes et al., 2013). These approaches, however, leverage embeddings at surface level, which are suboptimal for our task, as will be discussed in Section 3. Since we require a common semantic framework for KB unification, we use vector representations based on word senses, which are mapped to a very large sense inventory. This shared sense inventory, then, constitutes the common ground in which disambiguation, alignment and final unification occurs.

3 Knowledge Base Unification: Overview

KB-UNIFY takes as input a set of KBs $\mathbf{K} = \{KB_1, ..., KB_n\}$ and outputs a single, unified and fully disambiguated KB, denoted as $\mathbf{KB}^*$. For our purposes we can define a KB KB_i as a triple $\langle E_i, R_i, T_i \rangle$, where E_i is a set of entities, R_i is a set of semantic relations, and T_i is a set of triples (facts) $\langle e_d, r, e_g \rangle$ with subject and object e_d, $e_g \in E_i$ and predicate $r \in R_i$. Depending on the nature of each KB_i, entities in E_i might be disambiguated and linked to an external inventory (e.g. the entity *Washington* linked to the Wikipedia page GEORGE WASHINGTON), or unlinked and only available as ambiguous mentions (e.g. the bare word *washington* might refer to the president, the city or the state). We can thus partition $\mathbf{K}$ into a subset of linked resources $\mathbf{K}_D$, and one of unlinked resources $\mathbf{K}_U$. In order to align very different and heterogeneous KBs at the semantic level, KB-UNIFY exploits:

- A unified sense inventory S, which acts as a superset for the inventories of individual KBs. We choose BabelNet (Navigli and Ponzetto, 2012) for this purpose: by merging complementary knowledge from different resources (e.g. Wikipedia, WordNet, Wikidata and Wiktionary, among others), BabelNet provides a wide coverage of entities and concepts whilst at the same time enabling convenient inter-resource mappings for KB_i in $\mathbf{K}_D$. For instance, each Wikipedia page (or Wikidata item) has a corresponding synset in BabelNet, which enables a one-to-one mapping between BabelNet's synsets and entries in, e.g., DBPEDIA or FREEBASE;

- A vector space model V_S that enables a semantic representation for every item in S. Current distributional models, like word em-

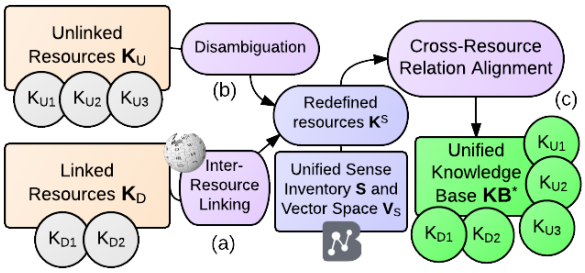

Figure 1: Unification algorithm workflow

beddings (Mikolov et al., 2013), are not suitable to our setting: they are constrained to surface word forms, and hence they inherently retain ambiguity of polysemous words and entity mentions. We thus leverage SENSEMBED (Iacobacci et al., 2015), a novel semantically-enhanced approach to embeddings. SENSEMBED is trained on a large annotated corpus and produces continuous representations for individual word senses (*sense embeddings*), according to an underlying sense inventory.

Figure 1 illustrates the workflow of our KB unification approach. Entities coming from any $KB_i \in \mathbf{K}_D$ can be directly (and unambiguously) mapped to the corresponding entries in S via BabelNet inter-resource linking (Figure 1(a)): in the above example, the entity *Washington* linked to the Wikipedia page GEORGE WASHINGTON is included in the BabelNet synset $\texttt{Washington}^4_{bn}$. In contrast, unlinked (and potentially ambiguous) entities need an explicit disambiguation step (Figure 1(b)) connecting them to appropriate entries, i.e. synsets, in S: this is the case, in the above example, for the ambiguous mention *washington* that has to be linked to either the president, the city or the state. Therefore, our approach comprises two successive stages:

- A **disambiguation** stage (Section 5) where all $KB_i \in \mathbf{K}$ are linked to S, either by inter-resource mapping (Figure 1(a)) or disambiguation (Figure 1(b)), and all E_i are merged into a unified set of entities E^*. As a result of this process we obtain a set $\mathbf{K}^S$ comprising all the KBs in $\mathbf{K}$ redefined using the common sense inventory S;
- An **alignment** stage (Section 6, Figure 1(c)) where, for each pair of KBs $KB_i^S, KB_j^S \in \mathbf{K}^S$, we compare any relation pair $\langle r_i, r_j \rangle$, $r_i \in R_i^S$ and $r_j \in R_j^S$, in order to identify cross-resource alignments and merge relations sharing equivalent semantics into relation clusters (*relation synsets*). This process yields a unified set of relation synsets R^*. The overall result is $\mathbf{KB}^* = \langle E^*, R^*, T^* \rangle$, where T^* is the set of all disambiguated triples redefined over E^* and R^*.

4 Background

The disambiguation stage of our approach is based on the interplay between two core components: a vector space model V_S, as introduced in Section 3, which provides an unambiguous semantic representation for each item in S; and a Word Sense Disambiguation/Entity Linking system, working on the same sense inventory S, which discovers and disambiguates concepts and entity mentions within a given input text. In this section we briefly describe our choice for these two components: SENSEMBED (Iacobacci et al., 2015) and BABELFY (Moro et al., 2014).

SENSEMBED is a knowledge-based approach for obtaining latent continuous representations of individual word senses. Unlike other sense-based embeddings approaches, like (Huang et al., 2012), which address the inherent polysemy of word-level representations relying solely on text corpora, SENSEMBED exploits the structured knowledge of a large sense inventory along with the distributional information gathered from text corpora. In order to do this, SENSEMBED requires a sense-annotated corpus; for each target word sense, then, a representation is computed by maximizing the log likelihood of the word sense with respect to its context within the annotated text, similarly to the word-based embeddings model. Following Iacobacci et al. (2015), we trained SENSEMBED using the English Wikipedia and, as sense inventory, BabelNet.

BABELFY[2] is a joint state-of-the-art approach to multilingual Entity Linking and Word Sense Disambiguation. Given the BabelNet lexicalized semantic network as underlying structure, BABELFY first models each concept in the network through its corresponding *semantic signature* by leveraging a graph random walk algorithm. Then, given an input text, the generated semantic signatures are used to construct a subgraph

[2] http://babelfy.org

of the semantic network representing the meaning of the content words in that text. BABELFY then searches this subgraph for the intended sense of each content word, by means of a densest-subgraph heuristic that identifies high-coherence interpretations. Given its unified approach that covers concepts and named entities alike, and its flexibility in disambiguating both bag-of-words and proper text, BABELFY constitutes the most convenient choice for linking relation triples to a high-coverage sense inventory like BabelNet.

5 Disambiguation

In the disambiguation phase (Figure 1(b)), all $KB_i \in \mathbf{K}_U$ are linked to the unified sense inventory S and added to the set of redefined KBs $\mathbf{K}^S$. As explained in Section 3, while each KB in $\mathbf{K}_D$ can be unambiguously redefined via BabelNet inter-resource links and added to $\mathbf{K}^S$, KBs in $\mathbf{K}_U$ require an explicit disambiguation step. Given $KB_i \in \mathbf{K}_U$, our disambiguation module (Figure 2) takes as input its set of unlinked triples T_i and outputs a set $T_i^S \subseteq T_i$ of disambiguated triples with subject-object pairs linked to S. The triples in T_i^S, together with their corresponding entity sets and relation sets, constitute the redefined KB_i^S which is then added to $\mathbf{K}^S$. However, applying a straightforward approach that disambiguates all triples in isolation might lead to very imprecise results, due to the lack of available context for each individual triple. We thus devised a disambiguation strategy that comprises three successive steps:

1. We identify a set of high-confidence seeds from T_i (Section 5.1), i.e. triples $\langle e_d, r, e_g \rangle$ where subject e_d and object e_g are highly semantically related, and disambiguate them using the senses that maximize their similarity in our vector space V_S;

2. We use the seeds to generate a ranking of the relations in R_i according to their degree of specificity (Section 5.2). We represent each $r \in R_i$ in our vector space V_S and assign higher specificity to relations whose arguments are closer in V_S;

3. We finally disambiguate the remaining non-seed triples in T_i (Section 5.3) starting from the most specific relations, and jointly using all participating argument pairs as context.

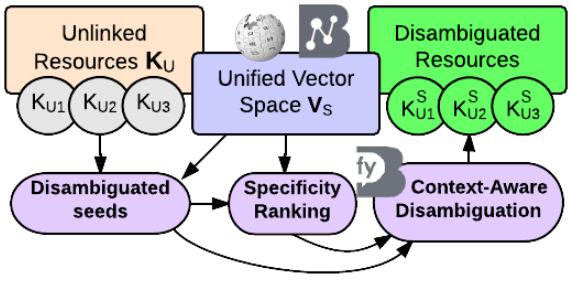

Figure 2: Disambiguation algorithm workflow

5.1 Identifying Seed Argument Pairs

The first stage of our disambiguation approach aims at extracting reliable seeds from T_i, i.e. triples $\langle e_d, r, e_g \rangle$ where subject e_d and object e_g can be confidently disambiguated without additional context. In order to do this we leverage the sense embeddings associated with each candidate disambiguation for e_d and e_g. We consider all the available senses for both e_d and e_g in S, namely $\mathbf{s}_d = \{s_d^1, ..., s_d^m\}$ and $\mathbf{s}_g = \{s_g^1, ..., s_g^{m'}\}$, and the corresponding sets of sense embeddings $\mathbf{v}_d = \{v_d^1, ..., v_d^m\}$ and $\mathbf{v}_g = \{v_g^1, ..., v_g^{m'}\}$. We then select, among all possible pairs of senses, the pair $\langle s_d^*, s_g^* \rangle$ that maximizes the cosine similarity between the corresponding embeddings $\langle v_d^*, v_g^* \rangle$:

$$\langle v_d^*, v_g^* \rangle = \text{argmax}_{v_d \in \mathbf{v}_d,\, v_g \in \mathbf{v}_g} \frac{v_d \cdot v_g}{\|v_d\| \, \|v_g\|} \quad (1)$$

For each disambiguated triple $\langle s_d^*, r, s_g^* \rangle$, the cosine similarity value associated with $\langle v_d^*, v_g^* \rangle$ represents the disambiguation confidence ζ_{dis}. We rank all such triples according to their confidence, and select those above a given threshold δ_{dis}. The underlying assumption is that, for high-confidence subject-object pairs, the embeddings associated with the correct senses s_d^* and s_g^* will be closest in V_S compared to any other candidate pair. Intuitively, the more the relation r between e_d and e_g is semantically well defined, the more this assumption is justified. As an example, consider the triple $\langle$*Armstrong*, *worked for*, *NASA*$\rangle$: among all the possible senses for *Armstrong* (the astronaut, the jazz musician the cyclist, etc.) and *NASA* (the space agency, the racing organization, a Swedish band, etc.) we expect the vectors corresponding to the astronaut and the space agency to be closest in the vector space model V_S.

5.2 Relation Specificity Ranking

The assumption that, given an ambiguous subject-object pair, correct argument senses are

the closest pair in the vector space (Section 5.1) is easily verifiable for general relations (e.g. *is a*, *is part of*). However, as a semantic relation becomes specific, its arguments are less guaranteed to be semantically related (e.g. *is a professor in the university of*) and a disambiguation approach based exclusively on similarity is prone to errors. On the other hand, specific relations tend to narrow down the scope of possible entity types occurring as subject and object. In the above example, *is a professor in the university of* requires entity pairs with professors as subjects and cities as objects. Our disambiguation strategy should thus vary according to the specificity of the relations taken into account. In order to consider this observation in our disambiguation pipeline, we first need to estimate the degree of specificity for each relation in the relation set R_i of the target KB to be disambiguated. Given R_i and a set of seeds from the previous stage (Section 5.1), we apply a specificity ranking policy and sort relations in R_i from the most general to the most specific. We compute the generality $Gen(r)$ of a given relation r by looking at the spatial dispersion of the sense embeddings associated with its seed subjects and objects. Let $\mathbf{v}_D$ ($\mathbf{v}_G$) be the set of sense embeddings associated with the domain (range) seed arguments of r. For both $\mathbf{v}_D$ and $\mathbf{v}_G$, we compute the corresponding centroid vectors μ_D and μ_G as:

$$\mu_k = \frac{1}{|\mathbf{v}_k|} \sum_{v \in \mathbf{v}_k} \frac{v}{\|v\|}, \quad k \in \{D, G\} \qquad (2)$$

Then, the variances σ_D^2 and σ_G^2 are given by:

$$\sigma_k^2 = \frac{1}{|\mathbf{v}_k|} \sum_{v \in \mathbf{v}_k} (1 - cos\,(v, \mu_k))^2 \qquad (3)$$

with $k \in \{D, G\}$ as before. We finally compute $Gen(r)$ as the average of σ_D^2 and σ_G^2. The result of this procedure is a *relation specificity ranking* that associates each relation r with its generality $Gen(r)$. Intuitively, we expect more general relations to show higher variance (hence higher $Gen(r)$), as their subjects and objects are likely to be rather disperse throughout the vector space; instead, arguments of very specific relations are more likely to be clustered together in compact regions, yielding lower values of $Gen(r)$.

5.3 Disambiguation with Relation Context

In the third step, both the specificity ranking and the seeds are exploited to disambiguate the remaining triples in T_i. To do this we leverage BABELFY (Moro et al., 2014) (introduced in Section 4). As we observed in Section 5.2, specific relations impose constraints on their subject-object types and tend to show compact domains and ranges in the vector space. Therefore, given a triple $\langle e_d, r, e_g \rangle$, knowing that r is specific enables us to put together all the triples in T_i where r occurs, and use them to provide meaningful context for disambiguation. If r is general, instead, its subject-object types are less constrained and additional triples do not guarantee to provide semantically related context.

At this stage, our algorithm takes as input the set of triples T_i, along with the associated disambiguation seeds (Section 5.1), the specificity ranking (Section 5.2) and a specificity threshold δ_{spec}. T_i is first partitioned into two subsets: T_i^{spec}, comprising all the triples for which $Gen(r) < \delta_{spec}$, and $T_i^{gen} = T_i \setminus T_i^{spec}$. We then employ two different disambiguation strategies:

- For each distinct relation r occurring in T_i^{spec}, we first retrieve the subset $T_{i,r}^{spec} \subset T_i^{spec}$ of triples where r occurs, and then disambiguate $T_{i,r}^{spec}$ as a whole with BABELFY. For each triple in $T_{i,r}^{spec}$, context is provided by all the remaining triples along with the disambiguated seeds extracted for r.

- We disambiguate the remaining triples in T_i^{gen} one by one in isolation with BABELFY, providing for each triple only the predicate string r as additional context.

6 Cross-Resource Relation Alignment

After disambiguation (Section 5) each KB in $\mathbf{K}$ is linked to the unified sense inventory S and added to $\mathbf{K}^S$. However, each $KB_i^S \in \mathbf{K}^S$ still provides its own relation set $R_i^S \subseteq R_i$. Instead, in the unified $\mathbf{KB}^*$, relations with equivalent semantics should be considered as part of a single relation synset even when they come from different KBs. Therefore, at this stage, we apply an alignment algorithm to identify pairs of relations from different KBs having equivalent semantics. We exploit the fact that each relation r is now defined over entity pairs linked to S, and we generate a semantic representation of r in the vector space V_S based on the centroid vectors of its domain and range. Due to representing the semantics of relations on this common ground, we can compare them by computing their domain and range similarity in V_S. We

first consider each $KB_i^S \in \mathbf{K}^S$ and, for each relation r_i in R_i^S, we compute the corresponding centroid vectors $\mu_d^{r_i}$ and $\mu_g^{r_i}$ using formula (2). Then, for each pair of KBs $\langle KB_i^S, KB_j^S \rangle \in \mathbf{K}^S \times \mathbf{K}^S$, we compare all relation pairs $\langle r_i, r_j \rangle \in R_i^S \times R_j^S$ by computing the cosine similarity between domain centroids s_D and between range centroids s_G:

$$s_k = \frac{\mu_k^{r_i} \cdot \mu_k^{r_j}}{\|\mu_k^{r_i}\| \, \|\mu_k^{r_j}\|} \quad (4)$$

where μ_k^r denotes the centroid associated with relation r and $k \in \{D, G\}$. The average of s_D and s_G gives us an *alignment confidence* ζ_{align} for the pair $\langle r_i, r_j \rangle$. If confidence is above a given threshold δ_{align} then r_i and r_j are merged into the same relation synset. Relations for which no alignment is found are turned into singleton relation synsets. As a result of this alignment procedure we obtain the unified set of relations R^*.

7 Experimental Setup

The setting for our experimental evaluation was the following:

- We used BabelNet 3.0[3] as our unified sense inventory for the unification procedure as well as the underlying inventory for both BABELFY and SENSEMBED. Currently, BabelNet contains around 14M synsets and represents the largest single multilingual repository of entities and concepts;
- We selected PATTY (Nakashole et al., 2012) and WISENET (Moro and Navigli, 2013) as linked resources. We used PATTY with FREEBASE types and pattern synsets derived from Wikipedia, and WISENET 2.0 with Wikipedia relational phrases;
- We selected NELL (Carlson et al., 2010) and REVERB (Fader et al., 2011) as unlinked resources. We used KB beliefs updated to November 2014 for the former, and the set of relation instances from ClueWeb09 for the latter.

Comparative statistics in Table 1 show that the input KBs are rather different in nature: NELL is based on 298 predefined relations and contains beliefs for about 2 million entities. The distribution of entities over relations is however very skewed, with 80.33% of the triples being instances of the `generalizations` relationship. In contrast, REVERB contains a highly sparse relation set (1,299,844 distinct relations) and more than 3 million distinct entities. PATTY features the largest (and, together with WISENET, sparsest) set of triples, with 1,631,531 distinct relations and less than 10 triples per relation on average.

8 Experiments

8.1 Disambiguation

We tested our disambiguation approach experimentally in terms of both disambiguated seed quality (Section 8.1.1) and overall disambiguation performance (Section 8.1.2). We created a development set by extracting a subset of 6 million triples from the largest linked KB in our experimental setup, i.e. PATTY. Triples in PATTY are automatically linked to YAGO, which is in turn linked to WordNet and DBPEDIA. Since both resources are also linked by BabelNet, we mapped the original triples to the BabelNet sense inventory and used them to tune our disambiguation module. We also provide two baseline approaches: (1) di-

	SENSEMBED			Baseline

rect disambiguation on individual triples with BABELFY alone (without the seeds) and (2) direct disambiguation of the seeds only (without BABELFY).

8.1.1 Results: Disambiguated Seeds

We tuned our disambiguation algorithm by studying the quality of the disambiguated seeds (Section 5.1) extracted from the surface text triples of PATTY. Figure 3 shows precision and coverage for increasing values of the confidence threshold δ_{dis}. We computed precision by checking each disambiguated seed against the corresponding linked triple in the development set, and coverage as the ratio of covered triples. We analyzed results for both the whole set of triples in PATTY (Fig. 3a) and the subset of ambiguous triples (Fig. 3b), i.e. those triples whose subjects and objects have at least two candidate senses each in the BabelNet inventory. In both cases, precision of disambiguated seeds increases rapidly with δ_{dis}, stabilizing above 90% with $\delta_{dis} > 0.25$. Coverage displays the opposite behavior, decreasing exponentially with more confident outcomes, from 6 million triples to less than a thousand (for seeds with confidence $\delta_{dis} > 0.95$). As a result, we chose $\delta_{dis} = 0.25$ as optimal threshold value throughout the rest of the evaluations.

In addition, we manually evaluated the disambiguated seeds extracted from both linked KBs (PATTY and WISENET) and unlinked KBs (NELL and REVERB). For each KB, we extracted up to three random samples of 150 triples according to different levels of confidence ζ_{dis}: the first sample included extraction with $0.5 \leq \zeta_{dis} < 0.7$, the second with $0.7 \leq \zeta_{dis} < 0.9$, and the third with $\zeta_{dis} \geq 0.9$. Each sample was evaluated by two human judges: for each disambiguated triple

	KB-UNIFY		Dutta et al.	Baseline

F-score	**.864**	.197	.857	.671

Table 4: Disambiguation results over NELL gold standard

$\langle e_d, r, e_g \rangle$, we presented our judges with the surface text arguments e_d, e_g and the relation string r, along with the two BabelNet synsets corresponding to the disambiguated arguments s_d^*, s_g^*, and we asked whether the association of each subject and object with the proposed BabelNet synset was correct. We then estimated precision as the average proportion of correctly disambiguated triples. For each sample we compared disambiguation precision using SENSEMBED, as in Section 5.1, against the first baseline with BABELFY alone. Results, reported in Table 2, show that our approach consistently outperforms the baseline and provides high precision over all samples and KBs.

8.1.2 Results: Disambiguation with Relation Context

We then evaluated the overall disambiguation output after specificity ranking (Section 5.2) and disambiguation with relation context using BABELFY (Section 5.3). We analyzed three configurations of the disambiguation pipeline, namely $\delta_{spec} \in \{0.8, 0.5, 0.3\}$. We ran the algorithm over both linked and unlinked KBs of our experimental setup, and computed the coverage for each KB as the overall ratio of disambiguated triples. Results are reported in Table 3 and compared to the coverage obtained from the disambiguated seeds only: context-aware disambiguation substantially increases coverage over all KBs. Table 3 also shows that a restrictive δ_{spec} results in lower coverage values, due to the increased number of triples disambiguated without context.

Finally, we evaluated the quality of disambiguation on a publicly available dataset (Dutta et al., 2014) comprising manual annotations for NELL. This dataset provides a gold standard of 1200 triples whose subjects and objects are manually assigned a proper DBpedia URI. We again used BabelNet's inter-resource links to express DBpedia annotations with our sense inventory and then sought, for each annotated triple in the dataset, the corresponding triple in our disambiguated version of NELL with $\delta_{dis} = 0.25$ and $\delta_{spec} = 0.8$. We then repeated this process con-

Table 6: Examples of general and specific relations for all KBs

sidering only the disambiguated seeds instead of the whole disambiguation pipeline. In line with (Dutta et al., 2014), we computed precision, recall and F-score for each setting. Results are reported in Table 4 and compared against those of Dutta et al. (2014) and against our first baseline with BABELFY alone. KB-UNIFY achieves the best result, showing that a baseline based on state-of-the-art disambiguation is negatively affected by the lack of context for each individual triple. In contrast, an approach that relies only on the disambiguated seeds affords very high precision, but suffers from dramatically lower coverage.

8.2 Specificity Ranking

We evaluated the specificity ranking (Section 5.2) generated by KB-UNIFY for all KBs of our experimental setup. First of all, we empirically validated our scoring function $Gen(r)$ over each resource: for each relation we computed the average cosine similarity among all its domain arguments $\bar{s}_D$ and among all its range arguments $\bar{s}_G$. We then plotted the average $\bar{s}$ of $\bar{s}_D$ and $\bar{s}_G$ against $Gen(r)$ for each relation r (Figure 4). As observed in Section 5.2, the average similarity among domain and range arguments decreases for increasing values of $Gen(r)$, indicating that more general relations allow less semantically constrained subject-object types. We then used human judgement to assess the quality of our specificity rankings. First, each ranking was split into four quartiles, and two human evaluators were presented with a sample from the top quartile (i.e. a relation falling into the most general category) and a sample from the bottom quartile (i.e. a relation falling into the most specific category). We shuffled each relation pair, showed it to our human judges, and then asked which of the two relations they considered to be the more specific. Ranking precision was computed by considering those pairs where human choice agreed with the ranking. Finally, we computed inter-annotator agreement on each specificity ranking (except for NELL, due to the small sample size) with Cohen's kappa coefficient (Cohen, 1968). Results for each ranking are reported in Table 5, while some examples of general and specific relations for each KB are shown in Table 6. Disagreement between human choice and ranking is higher in NELL (where the set of relations is quite small compared to other KBs) and in PATTY (due to a sparser set of relations, biased towards very specific patterns). Inter-annotator agreement is instead lower for REVERB, where unconstrained Web harvesting often results in ambiguous relation strings.

8.3 Alignment

Due to the novelty of our approach, and hence the lack of widely accepted gold standards and testbeds, we evaluated our cross-resource relation alignment algorithm (Section 6) by exploiting human judgement once again. Given the results of

Table 8: Examples of cross resource relation alignments

Section 8.1, we considered the top 10k frequent relations for each KB and ran the algorithm over each possible pair of KBs with two different configurations: $\delta_{align} = 0.7$ and $\delta_{align} = 0.9$. From each pair of KBs $\langle KB_i, KB_j \rangle$ we obtained a list of candidate alignments, i.e. pairs of relations $\langle r_i, r_j \rangle$ where $r_i \in KB_i$ and $r_j \in KB_j$. From each list we then extracted a random sample of 150 candidate alignments. We showed each alignment[4] $\langle r_i, r_j \rangle$ to two human judges, and asked whether r_i and r_j represented the same relation. The problem was presented in terms of paraphrasing: for each pair, we asked whether exchanging r_i and r_j within a sentence would have changed that sentence's meaning. In line with Section 8.2 we computed precision based on the agreement between human choice and automatic alignments. Results are reported in Table 7. Our alignment algorithm shows high precision in all pairings where $\delta_{align} = 0.9$. Alignment reliability decreases for lower δ_{align}, as relation pairs where r_i is a generalization of r_j (or vice versa) tend to have similar centroids in V_S. The same holds for pairs where r_i is the negation of r_j (or vice versa). Even though we could have utilized measures based on relation string similarity (Dutta et al., 2015) to reduce wrong alignments in these cases, by relying on a purely semantic criterion we removed any prior assumption on the format of input KBs. Some examples of alignments are shown in Table 8.

To conclude, we report statistics regarding the unified **KB*** produced from the initial set of resources in our experimental setup (cf. Section 7). We validated our thresholds for high-precision, and selected $\delta_{dis} = 0.25$, δ_{spec} = 0.8 and δ_{align} = 0.8. Our alignment algorithm produced 56,673 confident alignments, out of which 2,207 relation synsets were derived, with an average size of 16.82 individual relations per synset. As a result, we obtained a unified **KB*** comprising 24,221,856 disambiguated triples defined over 1,952,716 distinct entities and 2,675,296 distinct relations.

9 Conclusion and Future Work

We have presented KB-UNIFY, a novel, general approach for disambiguating and seamlessly unifying KBs produced by different OIE systems. KB-UNIFY represents entities and relations using a shared semantic representation, leveraging a unified sense inventory together with a semantically-enhanced vector space model and a disambiguation algorithm. This enables us to disambiguate unlinked resources (like NELL and REVERB) with high precision and coverage, and to discover relation-level cross-resource alignments effectively. One of the key features of our strategy is its generality: by representing each KB on a common ground, we need no prior assumption on the nature and format of the knowledge it encodes. We tested our approach experimentally on a set of four very different KBs, both linked and unlinked, and we evaluated disambiguation and alignment results extensively at every stage, exploiting both human evaluations and public gold standard datasets (when available). This work opens compelling avenues for future work. We plan to further exploit sense-enhanced unified representations of relations in various ways: providing an ontological structure for the unified KB, exploring complementary approaches for capturing semantic relation alignments, and incorporating multilinguality.

Acknowledgments

The authors gratefully acknowledge the support of the ERC Starting Grant MultiJEDI No. 259234.

[4] In the case of relation synsets, such as PATTY and WISENET, we selected up to three random relation strings from each synset.

Open-Domain Name Error Detection using a Multi-Task RNN

Hao Cheng **Hao Fang** **Mari Ostendorf**

Abstract

Out-of-vocabulary name errors in speech recognition create significant problems for downstream language processing, but the fact that they are rare poses challenges for automatic detection, particularly in an open-domain scenario. To address this problem, a multi-task recurrent neural network language model for sentence-level name detection is proposed for use in combination with out-of-vocabulary word detection. The sentence-level model is also effective for leveraging external text data. Experiments show a 26% improvement in name-error detection F-score over a system using n-gram lexical features.

1 Introduction

Most spoken language processing or dialogue systems are based on a finite vocabulary, so occasionally a word used will be out of the vocabulary (OOV), in which case the automatic speech recognition (ASR) system chooses the best matching in-vocabulary sequence of words to cover that region (where acoustic match dominates the decision). The most difficult OOV words to cover are names, since they are less likely to be covered by morpheme-like subword fragments and they often result in anomalous recognition output, e.g.

REF: what can we get at **Litanfeeth**
HYP: what can we get *it leaks on feet*

While these errors are rare, they create major problems for language processing, since names tend to be important for many applications. Thus, it is of interest to automatically detect such error regions for additional analysis or human correction.

Named entity recognition (NER) systems have been applied to speech output (Palmer and Ostendorf, 2005; Sudoh et al., 2006), taking advantage of local contextual cues to names (e.g. titles for person names), but as illustrated above, neighboring words are often affected, which obscures lexical cues to name regions. Parada *et al.* (2011) reduce this problem somewhat by applying an NER tagger to a word confusion network (WCN) based on a hybrid word/fragment ASR system.

In addition to the problem of noisy context, automatic name error detection is challenging because name errors are rare for a good recognizer. To learn the cues to name errors, it is necessary to train from the output of the target recognizer, so machine learning is faced with infrequent positive examples for which training data is very sparse. In addition, in an open domain system, automatically-learned lexical context features from one domain may be useless in another.

In this paper, we address these general problems – detecting rare events in an open-domain task – specifically for name error detection. Prior work addressed the problem of skewed priors by artificially increasing the error rate by holding names out of the vocabulary (Chen et al., 2013) or by factoring the problem into sentence-level name detection and OOV word detection (He et al., 2014) (since OOV errors in general are more frequent than name errors). Sentence-level features are also shown to be more robust than local context in direct name error prediction (Marin, 2015). While these techniques provide some benefit, the use of discrete lexical context cues is sensitive to the limited amount of training data available.

Our work leverages the factored approach, but improve performance by using a continuous-space sentence representation for predicting presence of a name. Specifically, we modify a recurrent neural network (RNN) language model (LM) to predict both the word sequence and a sentence-level name indicator. Combining the LM objective with name prediction provides a regularization effect in training that leads to improved sentence-level

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 737–746,
Lisbon, Portugal, 17-21 September 2015.

name prediction. The continuous-space model is also effective for leveraging external text resources to improve generalization in the open-domain scenario.

The overall framework for speech recognition and baseline name error detection system is outlined in Section 2, and the multi-task (MT) RNN approach for sentence-level name prediction is introduced in Section 3. Experimental results for both sentence-level name detection and name error detection are presented in Section 4, demonstrating the effectiveness of the approach on test data that varies in its match to the training data. As discussed in Section 5, the sentence-level model is motivated by similar models for other applications. The paper summarizes key findings and discusses potential areas for further improvement in Section 6.

2 System Overview and Tasks

The name error detection task explored in this work is a component in a bidirectional speech-to-speech translation system for English to/from Iraqi Arabic with human-computer dialogue interaction for error resolution (Ayan et al., 2013), developed during the DARPA BOLT project. The training data consists of a range of topics associated with activities of military personnel, including traffic control, military training, civil affairs, medical checkups, and so on. However, the system is expected to handle open-domain tasks, and thus the evaluation data covers a broader range of topics, including humanitarian aid and disaster relief, as well as more general topics such as sports, family and weather. The dialogues often contain mentions of names and places, many of which are OOV words to the ASR system. As illustrated in the previous section, ASR hypotheses necessarily have errors in OOV regions, but because specific names are infrequent, even in-vocabulary names can have these types of error patterns. Therefore, developing a robust name error detector for ASR hypotheses is an important component of the system to resolve errors and ambiguity.

Detecting OOV errors requires combining evidence of recognizer uncertainty and anomalous word sequences in a local region. For name errors, lexical cues to names are also useful, e.g. a person's title, location prepositions, or keywords such as "name". The baseline system for this work uses structural features extracted from a confusion network of ASR hypotheses plus ASR word confidence to represent recognizer uncertainty, and word n-gram context to the left and right of the target confusion network slot. These features are combined in a maximum entropy (ME) classifier trained to predict name errors directly. This is the same as the baseline used in (He et al., 2014; Marin, 2015; Marin et al., 2015), but with a different ASR system.

Training a classifier to predict whether a sentence has a name is easier than direct name error prediction, because the positive class is less rare, and it does not require recognizer output so more data can be used (e.g. speech transcripts without recognizer output, or written text). In addition, since the words abutting the name are less reliable in a recognition hypothesis, the information lost by working at the sentence level is minimal. The idea of using sentence-level name prediction is proposed in (He et al., 2014), but in that work the sentence name posterior is a feature in the ME model (optionally with word cues learned by the sentence-level predictor). In our work, the problem is factored to use the acoustic confusibility and local word class features for OOV error prediction, which is combined with the sentence-level name posterior for name error prediction. In other words, only two features (posteriors) are used in training with the sparse name error prediction data. An ME classifier is then used to combine the two features to predict the word-level name error. The word-level OOV detector is another ME binary classifier; the full set of features used for the word-level OOV detector can be found in (Marin, 2015).

The main innovation in this work is that we propose to use a multi-task RNN model for the sentence-level name prediction, where the training objective takes into account both the language modeling task and the sentence-level name prediction task, as described in the next section.

3 Multi-task Recurrent Neural Network

The RNN is a powerful sequential model and has proven to be useful in many natural language processing tasks, including language modeling (Mikolov et al., 2010) and word similarity (Mikolov et al., 2013c). It also achieves good results for a variety of text classification problems when combined with a convolutional neural network (CNN) (Lai et al., 2015). In this paper, we

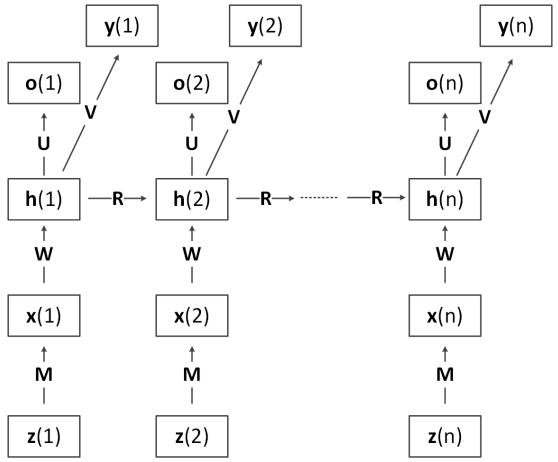

Figure 1: The structure of the proposed MT RNN model, which predicts both the next word $o(t)$ and whether the sentence contains a name $y(t)$ at each time step.

propose an MT RNN for the sentence-level name prediction task, which augments the word prediction in the RNN language model with an additional output layer for sentence-level name prediction. Formally, the MT RNN is defined over $t = 1, \ldots, n$ for a sentence of length n as:

$$\begin{aligned} \mathbf{x}(t) &= M\mathbf{z}(t), \\ \mathbf{h}(t) &= f\left(W\mathbf{x}(t) + R\mathbf{h}(t-1)\right), \\ \mathbf{o}(t) &= s\left(U\mathbf{h}(t) + \mathbf{b}_1\right), \\ \mathbf{y}(t) &= s\left(V\mathbf{h}(t) + \mathbf{b}_2\right). \end{aligned}$$

where $\mathbf{z}(t) \in \mathbb{R}^V$ is the 1-of-V encoding of the t-th word in the sentence; $\mathbf{x}(t) \in \mathbb{R}^d$ is the d-dimensional continuous word embedding corresponding to the t-th word; $\mathbf{h}(t) \in \mathbb{R}^k$ is a k-dimensional embedding that summarizes the word sequence through time t; and $\mathbf{o}(t)$ and $\mathbf{y}(t)$ are respectively the output layers for the language modeling task and the sentence-level prediction task. The parameters of the model (learned in multi-task training) include: $M \in \mathbb{R}^{d \times V}$, which is usually referred to as the word embedding matrix; projection matrices $U \in \mathbb{R}^{V \times d}$ and $V \in \mathbb{R}^{2 \times d}$; and bias terms $\mathbf{b}_1, \mathbf{b}_2 \in \mathbb{R}^d$. f and s are respectively the sigmoid and softmax functions. Note that the word sequence associated with a sentence includes start and end symbols.

The structure of the proposed MT RNN is shown in Fig. 1. At each time step, the hidden vector is used to predict both the next word and a sentence-level indicator of the presence of a name, providing a probability distribution for both variables. Thus, the hidden vector h_t provides a continuous representation of the word history that emphasizes words that are important for predicting the presence of a name. The vector at time n can be thought of as a sentence embedding. The sentence-level output y_t differs from the word-dependent label predictor typically used in named entity detection (or part-of-speech tagging) in that it is providing a sequentially updated prediction of a sentence-level variable, rather than a word-level indicator that specifies the location of a named entity in the sentence. The final prediction y_n is used as a feature in the name error detection system. The sentence-level output y_t does not always converge to y_n gradually nor is it always monotonic, since the prediction can change abruptly (either positively or negatively) as new words are processed. The sentence-level variable provides a mechanism for capturing long distance context, which is particularly useful for speech applications, where both the name of interest and the words in its immediate context may be in error.

The training objective is the combination of the log-likelihood of the word sequence and that of the sentence-level name prediction:

$$\sum_{t=1}^{n} \left[(1-\lambda)\log P(w(t)|h(t)) + \lambda \log P(y(t)|h(t))\right], \quad (1)$$

where $h(t) = [w(1), \ldots, w(t-1)]$ and λ is the weight on the log-likelihood of the sentence-level name labels.

Another way to train the model is to predict the sentence-level name label *only* at the end of the sentence, rather than at every time step. Preliminary experiment results show that this model has inferior performance. We argue that training with only the sentence-final name label output can result in unbalanced updates, i.e., information from the language modeling task is used more often than that from the sentence-level name prediction task, implying that balancing the use of information sources is an important design choice for multi-task models.

The training objective is optimized using stochastic gradient descent (SGD). We also experiment with AdaGrad (Duchi et al., 2011), which has shown to be more stable and converge faster for non-convex SGD optimization. Since language model training requires a normalization operation each time over the whole vocabulary (~60K) which is computationally intensive, we further speed up training by using noise contrastive esti-

mation (NCE) (Mnih and Teh, 2012). For all models using NCE, we fix the number of negative samples to 50.

All the weights are randomly initialized in the range of $[-0.1, 0.1]$. The hidden layer size k is selected from {50, 100, 200} and the task mixing weight λ is select in {0.2, 0.4, 0.6, 0.8}, based on development set performance. We set the initial learning rate to 1 and 0.1 for SGD with and without Adagrad respectively. In our experiments, we observe that models trained with AdaGrad achieve better performance, so we only report the models with AdaGrad in this paper. At each training epoch, we validate the objective on the development set. The learning rate is reduced after the first time the development set loglikelihood decreases, and the whole training procedure terminates when the development set loglikelihood decreases for the second time.

Domain	Topics
TRANSTAC	Traffic Control, Facilities Inspection, Civil Affairs, Medical, Combined Training, Combined Operations
HADR	Humanitarian Aid, Disaster Relief
General	Family, Gardening, Sports, Pets, Books, Weather, Language, Phone

Table 1: Topics in different domains.

Target Class	BOLT-Train	Dev1	Dev2	Test1	Test2
name sentences	7.6	7.5	8.2	8.1	14.0
name errors	0.8	1.1	0.9	0.7	0.8
OOVs	1.7	1.8	1.8	1.8	1.7

Table 2: Data splits and statistics, including the percentage of sentences containing names (name sentences), the percentage of hypothesized words that are name errors (name errors), and the percentage of words that are OOVs (OOVs).

4 Experiments

4.1 Data

There are two types of datasets used in this paper: the BOLT dataset and a collection of Reddit discussions. The first dataset was collected during the DARPA TRANSTAC and BOLT projects. The ASR hypotheses of totally 7088 spoken sentences makes up of the training dataset (BOLT-Train) for both sentence-level name prediction and word-level name error detection. There are two development sets: Dev1 and Dev2. Dev1 is used for parameter tuning for all models, and Dev2 is used for training the ME-based word-level name error detector using the word-level OOV posterior and sentence-level name posterior. For RNN models, we tune the hidden layer size and the multi-task weight λ; for the ME-based word-level name error detector, we tune the regularization parameter. Two test sets are used to evaluate sentence-level name prediction (Test1) and word-level name error detection (Test2), based on the BOLT phase 2 and 3 evaluations, respectively.

As shown in Table 1, the BOLT topics are categorized into three domains: TRANSTAC, HADR and General. The BOLT-Train, Dev1 and Dev2 sets contain only speech from the TRANSTAC domain, whereas the Test1 and Test2 sets contain all three domains. Detailed data split statistics and domain information are summarized in Table 2. Note that there are very few positive samples of name errors (roughly 1%), whereas for the sentence-level name prediction task and the word-level OOV prediction task, the data skewness is somewhat less severe (roughly 8% sentences with names in most of our data sets).

In order to address the issue of domain mismatch between the training data and the broad-domain subsets of the test data, we collect text from *Reddit.com* which is a very active discussion forum where users can discuss all kinds of topics. Reddit has thousands of user-created and user-moderated *subreddits*, each emphasizing a different topic. For example, there is a general ASKREDDIT subreddit for people to ask any questions, as well as subreddits targeted for specific interests, like ASKMEN, ASKWOMEN, ASKSCIENCE, etc. Although the Reddit discussions are different from BOLT data, they have a conversational nature and names are often observed within the discussions. Therefore, we hypothesize that they can help improve sentence-level name prediction in general. We collect data from 14 subreddits that cover different kinds of topics (such as politics, news, book suggestions) and vary in community size. The Stanford Name Entity Recognizer (Finkel et al., 2005) is used to detect names in each sentence, and a sentence-level name label is assigned if there are any names present.[1] The data are tokenized using Stanford

[1]The Stanford Name Entity Recognizer achieves 82.3% F-score on the references of Dev1. Thus, it is expected to

Model	TRANSTAC	HADR	General	All
BOW + ME	52.9	32.5	11.1	40.8
RNN + ME	11.2	21.7	30.5	15.0
SG + ME	14.7	12.6	16.3	14.6
ST RNN	40.3	37.5	**37.8**	39.3
MT RNN	**59.8**	**52.0**	23.8	**51.1**

Table 3: F-scores on Test1 for sentence-level name prediction for models trained on BOLT data.

CoreNLP tools (Manning et al., 2014) and are lowered cased after running the Stanford Name Entity Recognizer. In total, we obtain 135K sentences containing at least one name and 360K sentences without names.

4.2 Sentence-level Name Prediction

To evaluate the effectiveness of the proposed MT RNN model, we first apply it to the sentence-level name prediction task on ASR hypotheses. For this task, each sample corresponds to a hypothesized sentence generated by the ASR system and a ground-truth label indicating whether there are names in that sentence. We compare the MT RNN with four contrasting models for predicing whether a sentence includes a name.

- **BOW + ME**. An ME classifier using a bag-of-words (BOW) sentence representation.
- **SG + ME**. An ME classifier is used with the sentence embedding as features, where the embedding uses the skip-gram (SG) model (Mikolov et al., 2013a) to get word-level embeddings (with window size 10) and sentence embeddings are composed by averaging embeddings of all words in the sentence.
- **RNN + ME**. A simple RNN LM is trained (i.e., λ in (1) is set to 0), and the hidden layer for the last word in a sentence provides a sentence-level embedding that is used in an ME classifier trained to predict the sentence-level name label.
- **ST RNN**. A single-task (ST) RNN model is trained to directly predict the sentence-level name for each word (i.e., λ in (1) is set to 1).

All models are trained on either BOLT-Train or BOLT-Train + Reddit, and tuned on Dev1 including the dimension of embeddings, ℓ_2 regularization parameters for the ME classifiers, and so on.

The domain-specific F-scores on Test1 are summarized in Table 3 for training only with the BOLT

give useful labels for the Reddit data.

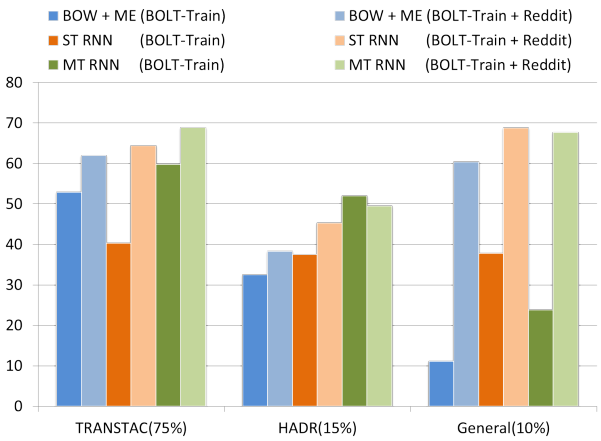

Figure 2: F-scores on Test1 for sentence-level name prediction for models trained with and without Reddit data. The number in the parenthesis indicates the portion of the domain in the data.

data. The proposed MT RNN achieves the best results on the TRANSTAC and HADR domains, and it has significant overall performance improvement over all baseline models. Not surprisingly, the two approaches that used unsupervised learning to obtain a sentence-level embedding (SG + ME, RNN + ME) have the worst performance on the TRANSTAC and HADR domains, with both having very low precision (6-18%), with best precision on the general domain. The BOW + ME and the ST RNN have similar performance in terms of overall F-score, but the BOW + ME model is much better on the TRANSTAC domain, whereas the ST RNN achieves the best results on the General domain. The main failing of the BOW + ME model is in recall on the General domain, though it also has relatively low recall on the HADR domain. Note that the General domain only accounts for 10% of the Test1 set, so the ST RNN gets lower F-score overall compared with the MT RNN, which performs best on the other two domains (90% of the Test1 set). On all domains, the MT RNN greatly improves precision compared to the ST RNN (at the expense of recall), and it improves recall compared to the BOW + ME approach (at the expense of precision).

In order to study the effectiveness of using external data, we also train all models on an enlarged training set including extra name-tagged sentences from Reddit. The improvement for each domain due to also using the Reddit data is shown in Fig. 2 for the three best configurations. (There is no benefit in the unsupervised learning cases.) Com-

pared with training only on the BOLT data, all three of these models get substantial overall performance improvement by utilizing the external domain training data. Since the external training data covers mostly topics in the General domain, the performance gain in that domain is most significant. For the MT RNN and BOW + ME classifiers, the additional training data primarily benefits recall, particulary for the General domain. In contrast, the ST RNN sees an improvement in precision for all domains. One reason that the added training text also benefits the models on the TRANSTAC domain is that over 90% of the words in the speech recognizer vocabulary are not seen in the small set of name-labeled speech training data, which means that the embeddings for these words are random in the RNNs trained only this data and the BOW + ME classifier will never use these words.

4.3 Word-level Name Error Detection

We next assess the usefulness of the resulting MT RNN model for word-level name error detection on ASR hypotheses. Here, several word-level name error detection approaches are compared, including direct name error prediction and factored name/OOV prediction approaches.

- **OOV thresholding**. This system simply uses the OOV prediction, but with the posterior threshold tuned for word-level name error based on the Dev1 set.
- **Word Context**. This is the baseline ME system described in Section 2 and also used as a baseline in (He et al., 2014; Marin et al., 2015), which directly predicts the word-level name error using WCN structural features, current word Brown class, and up-to trigram left and right word context information.
- **Word Class**. This system, from (Marin et al., 2015), also directly predicts the word-level name error, but replaces the word n-gram features with a smaller number of word class features to address the sparse training problem. The word classes are based on seed words learned from sentence-level name prediction which are expanded to classes using a nearest neighbor distance with RNN embeddings trained on the BOLT data.
- **Word Context + OOV**. This system uses an ℓ_2 regularized ME classifier to predict the word-level name error using two posteriors as features: a word-dependent posterior from the Word Context system and one from the OOV detection system.
- **MT RNN + OOV**. This system also uses an ℓ_2 regularized ME classifier to predict the word-level name error using two posteriors as features: the same word-dependent OOV posterior as above, and the posterior from the sentence-level name prediction using the MT RNN model described in Section 4.2, which is constant for all positions in the sentence.

All of the above models are trained on BOLT-Train and tuned on Dev1. The ME classifier used in the Word Context + OOV and the MT RNN + OOV systems are trained on Dev2, with regularization weights and decision boundaries tuned on Dev1.

Name error detection results (F-scores) are summarized in Table 4. The three systems that use discrete, categorical lexical context features (word or word class context) in direct name error prediction have worse results than the OOV thresholding approach overall, as well as on the TRANSTAC subset. Presumably this is due to over-fitting associated with the lexical context features. The factored MT RNN + OOV system, which uses a continuous-space representation of lexical context, achieves a gain in overall performance compared to the other systems and a substantial gain in performance on the TRANSTAC domain on which it is trained. Using the Reddit data further improves the overall F-score, with a slight loss on the TRANSTAC subset but substantial gains in the other domains. Although the performance improvement in the general domain is relatively small compared with sentence-level name prediction, utilizing external data makes the resulting representation more transferable across different domains and tasks. The best MT RNN + OOV system obtains 26% relative improvement over the baseline Word Context system (or 17% improvement over the simple OOV thresholding approach).

Looking at performance trade-offs in precision and recall, we find that the use of the RNN systems mainly improves precision, though there is also a small gain in recall overall. The added training data benefits recall for all domains, with a small loss in precision for the TRANSTAC and HADR sets. The use of the OOV posterior improves precision but limits recall, particularly for the general domain where recall of the OOV posterior alone

Model	TRANSTAC	HADR	General	All
OOV thresholding	41.6	31.2	16.5	30.9
Word Context	37.6	29.0	16.3	28.6
Word Class	33.6	35.9	11.9	27.9
Word Context + OOV	40.2	26.0	14.4	28.4
MT RNN + OOV	47.9	32.8	13.5	34.1
MT RNN† + OOV	46.4	37.5	18.0	36.2

Table 4: F-scores on Test2 for word-level name error prediction. MT RNN is trained on BOLT-Train, whereas MT RNN† is trained on BOLT-Train + Reddit.

is only 18% vs. 25% for the word context model with the OOV posterior information.

To better understand some of the challenges of this task, consider the following examples (R=reference, H=hypothesis):

R1: i'm doing good my name is captain **rodriguez**

H1: i'm doing good my name is captain *road radios*

R2: well it's got flying **lizards** knights and **zombies** and shit

H2: well it's gotta flying lives there it's nights and some bees and shia

R3: i live in a city called **omaha**

H3: i live in a city called *omar*

ASR tokens associated with name errors are underlined and italicized; tokens associated with non-name OOV errors are simply underlined. Name errors have a similar character to OOV erors in that they often have anomalous word sequences in the region of the OOV word (examples 1 and 2), which is why the OOV posterior is so useful. However, too much reliance on the OOV posterior leads to wrongly detecting general OOV errors as name errors ('lizards' and 'zombies' in example 2) and missed detection of name errors where the confusion network cues indicate a plausible hypothesis ('omaha' in example 3). Examples 1 and 3 illustrate the importance of lexical cues to names ('name ... captain', 'city called'), but word-based cues are unreliable for the systems trained only on the small amount of domain-specific data. Leveraging the reddit data allowed the MT RNN system to detect the error in example 1 (HADR domain) that was missed by the word context system. Example 3 was only detected by the word context system when no OOV posterior is used. Though this example was from the General domain, city names represent an important error class in the TRANSTAC data, so the term 'city' is learned as a useful cue.

4.4 Sentence Embedding

As discussed in Section 3, we postulate that by modeling words in a sentence in sequential order and simutaneously predicting sentence categorical information, the resulting hidden vector of the last word should be a good representation of the whole sentence, i.e., a sentence embedding. To provide support for this hypothesis and show the impact of external data, we present the sentence embeddings learned by the different RNN variants on Test2 using the t-Distributed Stochastic Neighbor Embedding (t-SNE) visualization (van der Maaten and Hinton, 2008) in Fig. 3. Four models are compared, including three RNNs trained on the BOLT data, and the MT RNN model trained on BOLT + Reddit data. Note the visualization method t-SNE does not take the label information into account during the learning.

As we can see in Fig. 3a, the positive and negative sentence embeddings learned by RNN LM are randomly scattered in the space, indicating that embeddings learned via unsupervised training (e.g., solely on word context) may fail to capture the sentence-level indicators associated with a particular task, in this case presence of a name. When the results are ploted in terms of domains, the embeddings are similarly broadly scattered – there is no obvious topic representation in the embeddings.

When comparing Fig. 3b to Fig. 3a, which is associated with the RNN using a sentence-final name indicator, we can see that a lot of positive vectors have moved to the bottom-left of the space, though there is still a relatively large overlap between positive and negative embeddings. In Fig. 3c, corresponding to the word-level MT RNN, there forms a separable subgroup of positive embeddings and the overlapping seems to be reduced as well in contrast to Figs. 3a and 3b. Finally, most of the positive sentence embeddings produced by the MT RNN model trained with external Reddit data gather at the botton-left of Fig. 3d. In general, the overlap between positive and negative sentences decreases from single task models to multi-task model. The external data make the proposed model produce more well-shaped groupings of sentence embeddings.

5 Related Work

Recently, due to the success of continuous representation methods, much work has been devoted to studying methods for learning word embeddings that capture semantic and syntactic meaning. Although these word embeddings are shown to be successful in some word-level tasks, such as word analogy (Mikolov et al., 2013b; Jeffery Pennington, 2014) and semantic role labeling (Collobert and Weston, 2008), it is still an open question how best to compose the word embeddings effectively and make use of them for text understanding.

Recent work on learning continuous sentence representations usually compose the word embeddings using either a convolutional neural network (CNN), a tree-structured recursive NN, or a variant of an RNN. A typical CNN-based structure composes word embeddings in a hierachical fashion (alternating between convolutional layers and pooling layers) to form the continuous sentence representation for sentence-level classification tasks (Kim, 2014; Kalchbrenner et al., 2014; Lai et al., 2015). These models usually build up the sentence representation directly from the lexical surface representation and rely on the pooling layer to capture the dependencies between words. Another popular method for continuous sentence representation is based on the recursive neural network (Socher et al., 2012; Socher et al., 2013; Tai et al., 2015). These models use a tree structure to compose a continuous sentence representation and have the advantages of capturing more fine-grained sentential structure due to the use of parsing trees. Note that the RNN-based sequential modeling used in this paper can be viewed as a linearized tree-structure model.

In this paper, we train the neural network model with a multi-task objective reflecting both the probability of the sequence and the probability that the sequence contains names. The general idea of multitask learning dates back to (Caruana, 1997), and is shown to be effective recently for neural network models in different natural language

processing tasks. Collobert and Weston (2008) propose a unified deep convolutional neural network for different tasks by using a set of task-independent word embeddings together with a set of task-specific word embeddings. For each task, it uses a *unique* neural network with its own layers and connections. Liu et al. (2015) propose a different neural network structure for search query classification and document retrieval where lower-level layers and connections are all shared but the high-level layers are task-specific. For tasks considered in (Collobert and Weston, 2008) and (Liu et al., 2015), training samples are task-dependent. Thus, both models are trained following the SGD manner by alternating tasks for each training samples with task-dependent training objectives. In this paper, we combine the language modeling task with the sentence-level name prediction task, and each training sample has labels for both tasks. Therefore, the SGD training can be done with the weighted sum of the task-specific objectives for each training sample, and the language model objective can be thought of as a regularization term. Similar settings of multitask learning for neural network models are employed in phoneme recognition for speech (Seltzer and Droppo, 2013) and speech synthesis (Wu et al., 2015) as well, but both of them use equal weights for all tasks.

6 Conclusion

In this paper, we address an open domain rare event detection problem, specifically, name error detection on ASR hypotheses. To alleviate the data skewness and domain mismatch problems, we adopt a factored approach (sentence-level name prediction and OOV error prediction) and propose an MT RNN for sentence-level name prediction. The factored model is shown to be more robust to the sparse training problem. For the problem of sentence-level name prediction, the proposed method of combining the language modeling and sentence-level name prediction objectives in an MT RNN achieves the best results among studied models for the domain represented by the training data as well as in the open-domain scenario. Visualization of sentence-level embeddings show how both the multi-task and the word-level name label update are important for achieving good results. The use of unrelated external training text (which can only be used in sentence-level name prediction) improves all models, particularly for the highly-mismatched general domain data.

The improvement in performance associated with using the external text is much smaller on the word-level name error detection task than on the sentence-level name prediction. This seems to be due to the high weight learned for the word-level posterior. For future work, it is worthwhile looking into whether continuous word and sentence representations can be combined in the name error detector to achieve further improvement.

In this work, we proposed a model for learning sentence representations that might be useful for other sentence classification tasks, such as review and opinion polarity detection, question type classification and so on. As discussed in Section 5, there are other models that have been found useful for obtaining continuous sentence embeddings. It would be of interest to investigate whether other structures are more or less sensitive to data skew and/or useful for incorporating multi-domain training data.

Extracting Relations between Non-Standard Entities using Distant Supervision and Imitation Learning

Abstract

Distantly supervised approaches have become popular in recent years as they allow training relation extractors without text-bound annotation, using instead known relations from a knowledge base and a large textual corpus from an appropriate domain. While state of the art distant supervision approaches use off-the-shelf named entity recognition and classification (*NERC*) systems to identify relation arguments, discrepancies in domain or genre between the data used for NERC training and the intended domain for the relation extractor can lead to low performance. This is particularly problematic for "non-standard" named entities such as album which would fall into the MISC category. We propose to ameliorate this issue by jointly training the named entity classifier and the relation extractor using imitation learning which reduces structured prediction learning to classification learning. We further experiment with Web features different features and compare against using two off-the-shelf supervised NERC systems, Stanford NER and FIGER, for named entity classification. Our experiments show that imitation learning improves average precision by 4 points over an one-stage classification model, while removing Web features results in a 6 points reduction. Compared to using FIGER and Stanford NER, average precision is 10 points and 19 points higher with our imitation learning approach.

1 Introduction

Factual answers to queries such as "What albums did The Beatles release?" are commonly stored in knowledge bases and can then be accessed by an information retrieval system, a commercial example for this being Google's knowledge vault (Xin et al., 2014). In order to keep knowledge bases up to date should new facts emerge, and to quickly adapt to new domains, there is a need for flexible and accurate information extraction (*IE*) approaches which do not require manual effort to be developed for new domains. A popular approach for creating IE methods to extract such relations is distant supervision (Craven and Kumlien, 1999; Mintz et al., 2009) which is a method for learning relation extractors using relations stored in a knowledge base combined with raw text to automatically generate training data.

An important first step in distant supervision is to identify named entities (*NEs*) and their types to determine if a pair of NEs is a suitable candidate for the relation. As an example, the album relation has a Musical Artist and an Album as arguments. Existing works use supervised named entity recognisers and classifiers (*NERC*) with either a small set of types such as the Stanford NER system (Manning et al., 2014), or fine-grained NE types (Ling and Weld, 2012; Liu et al., 2014). However, supervised NERCs typically focus on recognising persons, locations and organisations and perform poorly for other types of NEs, e.g. we find that Stanford NER only recognises 43% of all MISC NEs in our corpus. In addition, they do not always perform well if they are trained on a different type of text or for a different domain (Derczynski et al., 2015). This issue becomes more important as focus is shifting from using curated text collections such as Wikipedia to texts collected from the Web via search queries (Web-based distant supervision) which can provide better coverage (West et al., 2014).

In order to ameliorate this issue, we propose to recognise NEs with simple heuristics, then use the imitation learning algorithm DAGGER (Ross et al.,

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 747–757,
Lisbon, Portugal, 17-21 September 2015.

2011) to learn the NEC component jointly with relation extraction (*RE*), without requiring explicitly labeled data for NERC. Instead, training signal is obtained by assessing the predictions of the relation extraction component. In this paper we make the following contributions:

1. We learn jointly training a named entity classifier and a relation extractor for Web-based distant supervision. Our method does not rely on hand-labeled training data and is applicable to any domain, which is shown in our evaluation on 18 different relations.
2. We compare different methods for this purpose: (1) we use imitation learning to train separate classifiers for NEC and RE jointly; (2) we aggregate NEC features and RE features and train a one-stage classification model; (3) we train a one-stage classification model with only RE features; (4) we classify NEs with two supervised off-the-shelf NEC systems (Stanford NER and FIGER) and use the NE types as features in RE to achieve a soft NE type constraint.
3. We explore the effects of using different NEC and RE features, including Web features such as links and lists on Web pages, and show that Web-based features improve average precision by 7 points. We further find that high-precision, but low-frequency features perform better than low-precision and high-frequency features.
4. Our experiments show that joint learning of NEC and RE with imitation learning outperforms one-stage classification models by 4 points in average precision, and models based on Stanford NER and FIGER by 19 and 10 points respectively.

2 Distant Supervision

Distantly supervised RE is defined as automatically labelling a corpus with properties, P, and resources, R, where resources stand for entities from a knowledge base, KB, to train a classifier to learn to predict binary relations. The distant supervision paradigm is defined as (Mintz et al., 2009):

> If two entities participate in a relation, any sentence that contains those two entities might express that relation.

In general relations are of the form $(s, p, o) \in R \times P \times R$, consisting of a subject, a predicate and an object; during training, we only consider statements which are contained in a knowledge base, i.e. $(s, p, o) \in KB \subset R \times P \times R$. In any single extraction we consider only those subjects in a particular class $C \subset R$, i.e. $(s, p, o) \in KB \cap C \times P \times R$. Each resource $r \in R$ has a set of lexicalisations, $L_r \subset L$. Lexicalisations are retrieved from the KB, where they are represented as the name or alias, i.e. less frequent name of a resource.

3 Approach Overview

The input to the approach is a KB which contains entities and is partly populated with relations, the task is to complete the knowledge base. As an example, consider a KB about musical artists and their albums, which contains names of musical artists, and albums for some of them. The task is then to find albums for the remaining musical artists. Queries are automatically formulated containing C, s and o, e.g. "Musical Artist album 'The Beatles"' and we obtain Web pages using a search engine. For each sentence on the Web pages retrieved which contains s, all candidates for C are identified using NER heuristics (Section 4.2). Next, the distant supervision assumption is applied to all such sentences containing s (e.g. "Michael Jackson") and a candidate for that relation (e.g. "Music & Me"). If the candidate is an example of a relation according to the KB, it is used as a positive example, and if not, as a negative example. The examples are then used to train a model to recognise if the candidate is of the right type for the relation (NEC) and if it is of the correct relation (RE). The model is applied to the sentences of all the incomplete entries in the KB. Since different sentences could predict different answers to the query, all predictions are combined for the final answer.

4 Named Entity Recognition and Relation Extraction

The input to the learning task is a collection of training examples for a specific relation. The examples are sentences containing the subject of the relation and one further NE identified using simple heuristics. The examples are labeled as true (relation is contained in knowledge base) or as false (relation is not contained in the knowledge base).

We model the task in two binary classifica-

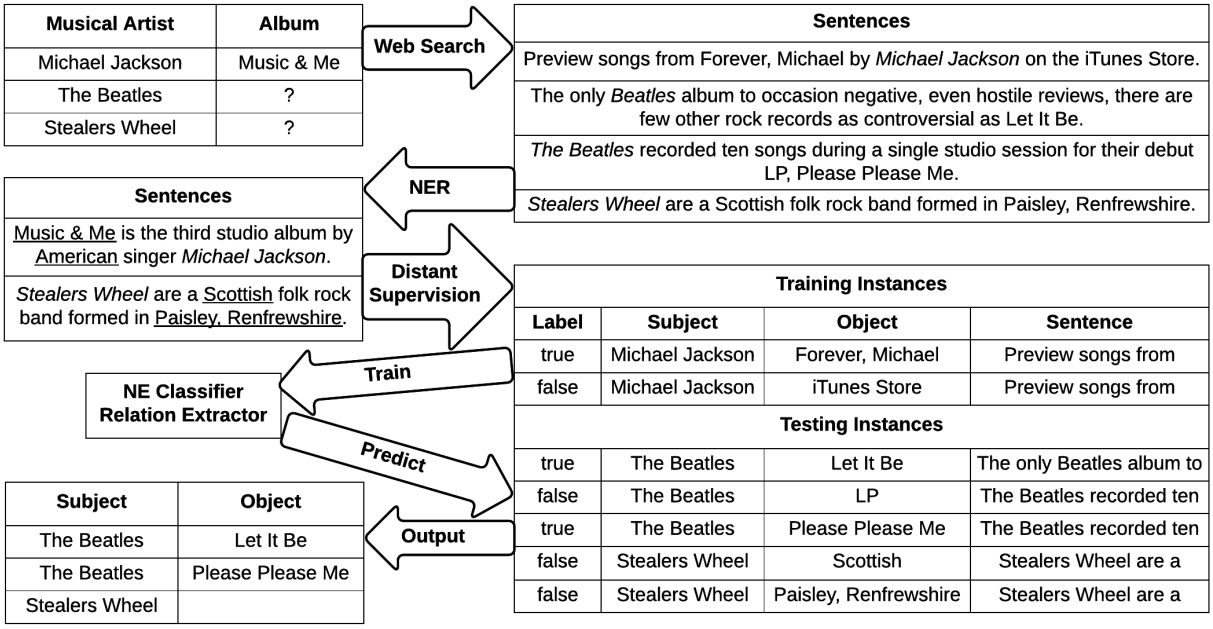

Figure 1: Overview of approach

tion stages: named entity classification (NEC) and relation extraction (RE). Existing approaches assume that named entity recognition and classification is done as part of the pre-processing. However, this is not possible domains for which NE classifiers are not readily available. To ameliorate this issue, existing approaches — e.g Mintz et al. (2009) — perform NEC to provide additional features for relation extraction. We use two such baselines with off-the-shelf NECs and add the NE labels to the relation features. The first baseline (**Stanf**) is with the Stanford NER 7-class (Time, Location, Organization, Person, Money, Percent and Date) model, the second (**FIGER**) is with the fine-grained FIGER (Ling and Weld, 2012).

An alternative approach is to simply add NEC features to relation extraction features, which we call **one-stage model (OS)** here. NEC features are typically morphological features extracted from the NE mention and features to model its context, whereas relation features typically model the path between the subject and object of the relation. While NEC features may be useful to determine if the NE has the correct type for the relation, such features are usually less sparse and also not directly related to the relation extraction task. Consider the following sentence, containing an example of the relation director:

"One of director <o>Steven Spielberg</o>'s greatest heroes was <o>Alfred Hitchcock</o>, the mastermind behind <s>Psycho</s>.

This sentence contains two relation candidates, "Steven Spielberg" and "Alfred Hitchcock", between which the decision for the final prediction has to be made. Both of the candidates are directors, but only one of them is the director of "Psycho". Because the context around "Steven Spielberg" is stronger (preceded by "director"), NEC features alone are more likely to indicate that as the correct candidate and also likely overpower relation features for the final prediction, as the latter tend to be sparser.

Ideally, we would like to train two models, one for NEC and one for RE, which would be applied in sequence. If the NEC stage concludes that the candidate is of the correct type for the relation, the RE stage determines whether the relation between the two entities is expressed. If the NEC stage concludes that the entity is not of the correct type, then the RE stage is not reached. However, distant supervision only provides positive labels for NEC, since if a sentence is labeled as false we do not know if it is due to the candidate not being of the correct type, or the relation not being true for the two entities. To overcome this, we learn models for the two stages, NEC and RE, jointly using the imitation learning algorithm DAGGER (Ross et al., 2011), as described in the next section.

4.1 Imitation Learning

Imitation learning[1] algorithms such as SEARN (Daumé III et al., 2009) and DAGGER (Ross et al., 2011) have been applied successfully to a variety of structured prediction tasks due to their flexibility in incorporating features and their ability to learn with non-decomposable loss functions. Sample applications include biomedical event extraction (Vlachos and Craven, 2011), dynamic feature selection (He et al., 2013), and machine translation (Grissom II et al., 2014).

Imitation learning algorithms for structured prediction decompose the prediction task into a sequence of actions; these actions are predicted by classifiers which are trained to take into account the effect of their predictions on the whole sequence by assessing their effect using a (possibly non-decomposable) loss function on the complete structure predicted. The dependencies between the actions are learnt via appropriate generation of training examples.

The ability to learn by assessing only the final prediction and not the intermediate steps is very useful in the face of missing labels, such as in the case of the labels for the NEC stage. Recall that the action sequence in our case consists of one NEC action and possibly one RE action, dependent on whether the NEC action is true, i.e. the entity is of the appropriate type for the relation. Following Vlachos and Clark (2014), for each training instance, we obtain supervision for the NEC stage by taking both options for this stage, true or false, obtaining the prediction from the RE stage in the former case and then comparing the outcomes against the label obtained from distant supervision. Thus the NEC stage is learned so that it enhances the performance of RE. In parallel, the RE stage is learned using only instances that actually reach this stage. The process is iterated so that the models learned adjust to each other. For more details on this we refer the reader to Vlachos and Clark (2014).

4.2 Relation Candidate Identification

To extract relations among NEs, the latter have to be detected first. Most distantly supervised approaches use supervised NER systems for this, which, especially for relations involving MISC NEs, achieve a low recall. High recall for NE identification is more important than high precision, since precision errors can be dealt with by the NEC stage. For a relation candidate identification stage with higher recall we instead rely on POS-based heuristics for detecting NEs[2] and HTML markup. We use the following POS heuristics:

- **Noun phrases:** Sequences of *N* tags
- **Capitalised phrases:** Those can be distinct from noun phrases, e.g. some album titles are capitalised verb phrases.

We further consider as relation candidates words which contain the following HTML markup:

- **Phrases from HTML markup:** All sequences of words marked as: `<ahref>` (links), `<li>` (list elements), `<h1>` or `<h2>` or `<h3>` (headers and subheaders, i.e. titles), `<strong>` or `<b>` (bold), `<em>` (emphasised), `<i>` (italics)

Different relation candidate identification strategies are then applied depending on the coarse NE types of objects of relation as defined in the KB (Table 2).

- **PER**: All capitalised noun phrases. We allow for a maximum of two characters to be surrounded by quotes to capture alternative first names, e.g. "Jerome David 'J. D.' Salinger".
- **LOC**: All capitalised noun phrases.
- **ORG**: All capitalised phrases and phrases from HTML markup. The latter is to capture ORG names which are not capitalised, e.g. the school "Woodrow Wilson School of Public and International Affairs" or the record label "Sympathy for the Record Industry".
- **MISC**: As for ORG, we use all capitalised phrases and phrases from HTML markup. MISC NEs are even more varied than ORG NEs and it is difficult to find the right balance between recognising most of them and generating unecessary candidates.

To assess how useful these strategies are, we randomly sample 30 instances of each Freebase class per coarse NE type of the object and manually examine all sentences which contain the subject of the relation. We used precision, i.e. how many of the relation candidates are appropriate

[1] Also referred to as search-based structured prediction or learning to search.

[2] The Stanford POS tagger uses Penn Treebank POS tags, see `http://www.ling.upenn.edu/courses/Fall_2003/ling001/penn_treebank_pos.html` for a list of tags

NE type	Model	R	P	F1
PER	heuristic	0.976	0.1287	0.227
PER	Stanford	0.774	0.1781	0.29
LOC	heuristic	0.963	0.1176	0.21
LOC	Stanford	0.889	0.1611	0.272727273
ORG	heuristic	0.95	0.0265	0.0516
ORG	Stanford	0.8	0.0505	0.095

MISC	Stanford	0.427	0.053	0.0943

Table 1: Results for POS-based candidate identification strategies compared to Stanford NER

for the relation, and recall to compare the relation candidate identification strategies described above against the identification of candidates by Stanford NER (ignoring the NE label). As shown in Table 1, while supervised identification of NE labels achieves a higher precision for all NE types, the recall is higher for all NE types using POS-based heuristics. The simple heuristics are especially helpful for MISC NEs, for which recall is twice as high compared to Stanford NER and precision only marginally higher. If we were to use the NE label to enforce hard constraints, recall would be reduced even further: 88% of all PER entities are correctly identified as persons, compared to 58% for locations and 87% for organisations. MISC NE are identified as PER (45%), LOC (40%) or ORG (15%). Overall, precision is not as important for candidate identification as recall, since choosing correct entities among the candidates can be dealt with in a NEC stage.

4.3 NEC features

For the one-stage and imitation learning model, we use the following **Web features** based on HTML markup, both as local features if the entity mention contains the markup, and as global features if a mention somewhere else in the document with the same lexicalisation contains that markup: is link, is list element, is header or subheader, is bold, is emphasised, is italics, is title, is in title.

In addition, the following NEC features are extracted, based on Nadeau et al. (2007) and Hoffmann et al. (2011):
Word features (mentfeats):

- Object occurrence
- Sequence and BOW of occurrence
- Sequence and bag of POS of occurrence
- Number of words, characters and digits of object
- Ends with period, is roman number, contains apostrophe, hyphen, ampersand, possessive
- Digit and capitalisation pattern

Context features, as 1-grams (1cont) and 2-grams, 2 words to left and right of occurrence (2cont): BOW, sequence, bag of POS, POS sequence.

4.4 RE Features

The following features are used for RE, based on Hoffman et al (2011) and Mintz et al. (2009):

- 1cont and 2cont features
- Flag indicating which entity came first in sentence
- Sequence of POS tags and bag of words (BOW) between the subject and the object occurrence

Parsing features as full sequences (parse):

- Dependency path between subject and object, POS tags of words on that path
- Lemmas on dependency path, same with NNP and CD tokens substituted by POS tags

4.5 Supervised NEC Features for RE

For the baselines with off-the-shelf NECs, sentences are preprocessed with the two NEC systems Stanford NER and FIGER. NE labels are then used in addition to the RE features listed in Section 4.4. For the Stanf baseline, Stanford NER 7-class labels are added as RE features. Those are: Time, Location, Organization, Person, Money, Percent, Date. FIGER classifies NEs according to 112 types, most of which are subtypes of Person, Organization, Location, Product, Art, Event and Building. Some of the types are relation types we evaluate (see Table 2 for relation types): educational institution, city, director, actor and author. Since FIGER performs multi-label classification, it annotates some of the relation candidates with more than one NE label. In that case, we add all NE labels returned as features, though more experiments on how best to integrate multiple NE labels as features could be performed, as shown by Liu et al. (2014).

Table 2: Relation types and corresponding coarse NE types

5 Evaluation

5.1 Corpus

To create a corpus[3] for Web RE, seven Freebase classes and two to four of their relations are selected (Table 2). The selected classes are subclasses of PER (Musical Artist, Politician), LOC (River), ORG (Business (Operation)), Education(al Institution)) or MISC (Film, Book). To avoid noisy training data, we only use entities which have values for all of those properties, which resulted in 1800 to 2200 entities per class. For each entity, 10 Web pages were retrieved via the Google Search API using the search pattern "'*subject_entity*" *class_name relation_name*', e.g. "'The Beatles" Musical Artist Origin'. In total, the corpus consists of around one million pages drawn from 76,000 different websites. Text content is extracted from HTML pages using the Jsoup API[4] and processed with Stanford CoreNLP[5].

5.2 Models and Metrics

We evaluate the following models: imitation learning (**IL**) as described in Section 4.1, a one-stage model (**OS**), a one-stage model with relation features only (**RelOnly**), and using Stanford (**Stanf**) and FIGER (**FIGER**) NE labels as features (Section 4). For all models we use linear classifiers learned with passive-aggressive updates (Crammer et al., 2006). For imitation learning, we use the learning algorithm DAGGER (Ross et al., 2011), which requires two parameters: the learning rate, i.e. how quickly the learning algorithm moves away from the optimal policy, and the number of iterations. We found empirically that the best learning rate for our prediction task is 0.25 and that the best number of iterations is 12.

Table 3: Results for best model for each relation, macro average over all relations.

The output of the models is a score for each relation example and stage, i.e. for the one-stage model, the output is one score and for the imitation learning model, there is a score each for the NEC stage and the RE stage. The default for deciding whether the relation label should be true or false depends on stage thresholds, which are 0 by default. Instead of using the default thresholds, we automatically pick thresholds for all models on 1/3 of the training set, which we set aside as a development set, then retrain on the whole training set and predict relations based on the learnt thresholds.

We use the metrics first best precision (P-top), first best recall (R-top), first best F1 (F1-top), all precision (P-all), all recall (P-all), and all average precision (P-avg). For top, only the top-ranked answer is considered, whereas for all all answers are returned until either the correct one is found or they are exhausted. Finally, in the all mode we evaluated precision at all recall points by varying the thresholds used in the respective classifiers and we report average precision (P-avg) (Manning et al., 2008). This evaluation measure provides an assessment of how well a system trades precision for recall. The number of all results for computing recall is the number of all relation tuples in the KB.

6 Results and Discussion

6.1 Comparison of Models

Overall results in Table 3 show that both of our models (**IL** and **OS**) outperform the baselines with off-the-shelf supervised NEC (**Stanf**, **FIGER**) for all metrics. Detailed results for different relations (Table 4) show that IL outperforms both OS and Base in terms of average precision. FIGER results fall in between Stanf and OS results. For some relations, there is a dramatic improvement by using fine-grained FIGER NE features over coarse-grained Stanford NE features; occasionally FIGER even outperforms OS, as for the relation author. This is because FIGER has a corresponding NE type (see Section 4.5).

For most relations, including those whose objects are of type MISC, IL shows a significant improvement in terms of F1 or average precision over OS (Table 5). This confirms our hypothesis that separating the NEC and relation extraction stages using imitation learning can achieve a higher precision and recall for non-standard relations than preprocessing sentences with a supervised NEC model. Furthermore, we show that it can also be useful for most standard relations. The main relations for which Stanf, FIGER or OS can have a benefit over IL are those for which entities are easy to classify, specifically LOC NEs, but also PER NEs. This is because, if NEs are easy to classify, a separate NEC is less likely to be useful.

6.2 Imitation Learning vs One-Stage

To give more insight into why **IL** is overall more successful than **OS**, common errors made by OS are shown here, along with an explanation of how those errors are prevented by using IL. One example of IL predicting correctly but OS incorrectly is from the following sentence, expressing the director relation:

"In 2010 he appeared in a leading role in <o>Alicia Duffy</o>'s <s>All Good Children</s>.

In that example, the NEC features extracted for <o>Alicia Duffy</o> are not very strong indicators, since neither the object string itself nor the surrounding context give any direct indication for the director relation. The RE features, which are based on the dependency path, are a stronger indicator. Since in the OS model all features are combined, the NEC features overpower the RE features. The IL model, on the other hand, learns a permissive NEC as a first stage, which filters NEs with respect to if they are generally appropriate for the relation or not, and then leaves the RE to the second stage.

Another example is a sentence for which OS incorrectly predicts the relation author, whereas IL correctly predicts "false":

"<o>Laura</o> and Mary went to school for the first time in Pepin rather than Walnut Grove, which is not included in <s>Little House in the Big Woods</s>."

Table 6: Imitation learning results for different NE and relation features, macro average over all relations.

For this example, OS relation features have small positive weights, which then overall lead to a positive prediction. For IL, the first stage predicts "false", since the one-token string <o>Laura</o> is not a likely candidate for author.

6.3 Comparison of Features

All different feature groups have an overall positive effect on the results (see Table 6). While low precision, high frequency features improve recall (1cont), they do not always improve precision. Both **OS** and **IL** benefit from high precision, low frequency features, e.g. for author and mouth, the best results are achieved with only sparse parsing features for RE.

Web features improve performance for 10 out of 18 relations. For n-ary relations the is list element feature is very useful because Web pages about musical artist, films or books often contain lists with their attributes, e.g. a Web page about a musical artist typically contains a list with their albums. For relations with persons as objects, is link and is bold is useful because Web pages often highlight persons or provide links to Web pages with more information about them. As an example, for the author relation, the strongest positive Web feature is is in title and the strongest negative feature is is list element. This makes sense since a book is frequently mentioned with its author and one of the most important attributes of a book, whereas lists on Web pages about books mention less important attributes, such as the characters.

6.4 Overall Comparison

Overall, we showed that using an off-the-shelf NEC as a pre-processing step for distant super-

vision as done by existing works often causes errors which can be prevented by instead separating NEC and RE with imitation learning. We also showed that using Web features increases precision for NEC. Finally, it is worth noting that the recall for some of the relations is quite low because they only infrequently occur in text, especially in the same sentence as the subject of the relation. These issues can be overcome by performing coreference resolution (Augenstein et al., 2014; Koch et al., 2014), by retrieving more Web pages or improving the information retrieval component of the approach (West et al., 2014) and by combining extractors operating on sentences with other extractors for semi-structured content on Web pages (Carlson et al., 2010).

7 Related Work

One of the first papers to introduce distant supervision was Mintz et al. (2009), which aims at extracting relations between entities in Wikipedia for the most frequent relations in Freebase. Most distant supervision research focuses on addressing the disadvantages of heuristic labelling, namely reducing false positive training data (Hoffmann et al., 2011; Surdeanu et al., 2012; Riedel et al., 2010; Riedel et al., 2013; Yao et al., 2010; Alfonseca et al., 2012; Roth and Klakow, 2013; Takamatsu et al., 2012; Xu et al., 2013) and dealing with false negatives due to missing entries in the knowledge base (Min et al., 2013), as well as combining distant supervision with active learning (Angeli et al., 2014)

Distant supervision has been researched for different domains, including newswire (Riedel et al., 2010; Riedel et al., 2013), Wikipedia (Mintz et al., 2009; Nguyen and Moschitti, 2011), the biomedical domain (Craven and Kumlien, 1999; Roller and Stevenson, 2014), the architecture domain (Vlachos and Clark, 2014) and the Web (Xin et al., 2014; Augenstein et al., 2014; Augenstein et al., 2015).

To date, there is very little research on improving NERC for distant supervision to extract relations between non-standard entities such as musical artists and albums. Some research has been done on improving distant supervision by using fine-grained named entity classifiers (Ling and Weld, 2012; Liu et al., 2014) and on using named entity linking for distant supervision (Koch et al., 2014). Liu et al. (2014) train a supervised fine-grained NERC on Wikipedia and show that using those types as entity contraints improves precision and recall for a distantly supervised RE on newswire. However, they assume that labeled training data is available, making it unsuitable for applying distant supervision to domains with relations involving non-standard entity types.

Vlachos and Clark (2014) also proposed a distantly supervised approach for joint learning of NEC and RE with imitation learning for the architecture domain. However, they only used two relations in their experiments which involved rather standard entity types and they did not compare against using off-the shelf NEC systems.

8 Conclusion and Future Work

In this paper, we proposed a method for extracting non-standard relations with distant supervision that learns a NEC jointly with relation extraction using imitation learning. Our proposed imitation learning approach outperforms models with supervised NEC for relations involving non-standard entities as well as relations involving persons, locations and organisations. We achieve an increase of 4 points in average precision over a simple one-stage classification model, and an increase in 10 points and 19 points over baselines with FIGER and Stanford NE labels. We further demonstrate that using specialised Web features, such as appearances of entities in lists and links to other Web pages, improves average precision by 7 points, which other Web search-based relation extraction approaches could also benefit from (Xin et al., 2014; Augenstein et al., 2014).

In future work, the proposed approach could be combined with other approaches to solve typical issues arising in the context of distant supervision, such as dealing with overlapping relations (Hoffmann et al., 2011), improving heuristic labelling of sentences (Takamatsu et al., 2012) or dealing with incomplete knowledge bases (Min et al., 2013).

Sieve-Based Spatial Relation Extraction with Expanding Parse Trees

Jennifer D'Souza and **Vincent Ng**

Abstract

A key challenge introduced by the recent SpaceEval shared task on spatial relation extraction is the identification of MOVELINKs, a type of spatial relation in which up to eight spatial elements can participate. To handle the complexity of extracting MOVELINKs, we combine two ideas that have been successfully applied to information extraction tasks, namely *tree kernels* and *multi-pass sieves*, proposing the use of an expanding parse tree as a novel structured feature for training MOVELINK classifiers. Our approach yields state-of-the-art results on two key tasks in SpaceEval.

1 Introduction

Spatial relation extraction is the task of determining the relation among a set of spatial elements. Although it has thus far received much less attention than temporal relation extraction, there has been a surge of interest in it in recent years, as evidenced by the organization of the three shared tasks on spatial relation extraction, namely the spatial role labeling tasks in 2012 (Kordjamshidi et al., 2012) and 2013 (Kolomiyets et al., 2013), as well as this year's SpaceEval task (Pustejovsky et al., 2015). The task has also evolved over the years, with new types of spatial elements and/or spatial relations being defined in each shared task. For instance, while the first two shared tasks have focused on extracting spatial relations between *stationary* objects, SpaceEval examines for the first time spatial relations on objects *in motion*.

Extracting spatial relations on objects in motion, or MOVELINKs, is very challenging. The challenge stems in part from the fact that a MOVELINK involves two *mandatory* participants (with roles $mover$ and $trigger$) and up to six *optional* participants (with other semantic roles). As an example, consider the MOVELINK that can be extracted from the sentence "John walked from Boston to Cambridge". As shown in Figure 1, this MOVELINK involves six spatial elements: "John" as the $mover$, "walked" as the $trigger$, "Boston" as the $source$, "Cambridge" as the $goal$, and "from" and "to" as the $motion_signal$s.

Figure 1: A MOVELINK example.

Given the complexity of MOVELINKs, any approach that attempts to *jointly* identify all the spatial elements involved in a MOVELINK and their roles is computationally infeasible. On the other extreme, one can tackle the task by identifying each element involved in a MOVELINK *independently* of the other elements. In fact, this is roughly the approach adopted by our participating system in SpaceEval (D'Souza and Ng, 2015), which achieved the best results in one of the SpaceEval tasks involving MOVELINK extraction. Specifically, this system trains one classifier for each *optional* role r to identify the filler for r in a MOVELINK independently of the other optional roles. Although this approach has achieved state-of-the-art performance, it is arguably not ideal: intuitively, dependencies exist among elements of different roles, and not capturing them may harm system performance.

Our goal in this paper is to advance the state of the art in spatial relation extraction, focusing on the extraction of MOVELINKs by addressing the aforementioned weakness. The key question is: how can we capture the dependencies among the spatial elements involved without sacrificing computational tractability? To address this question, we combine two ideas that have been successfully applied to a variety of information extraction tasks, namely multi-pass sieves (Raghu-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 758–768,
Lisbon, Portugal, 17-21 September 2015.

nathan et al., 2010; Lee et al., 2013) and tree kernels (Moschitti, 2004; Moschitti, 2006). Recall that a sieve-based approach is composed of a pipeline of *sieves* ordered by precision, where the decisions made by earlier sieves can be exploited by later sieves in order to incrementally construct a complex structure. When applied to MOVELINK identification, we can create a sieve for identifying each role, so that (1) spatial elements corresponding to different roles are incrementally added to a MOVELINK, and (2) earlier attachment decisions can be exploited as additional contextual information by later sieves. Hence, compared to a joint approach, a sieve-based approach achieves computational tractability by modeling *partial*, rather than *full* dependencies among the spatial elements.

While a sieve-based approach allows us to exploit additional contextual information provided by earlier sieves, we still have to specify how we encode such contextual information. Motivated by the successful application of tree kernels to relation extraction (e.g., Zelenko et al. (2003), Culotta and Sorensen (2004), Bunescu and Mooney (2005), Zhou et al. (2007)), we propose to (1) encode the *syntactic* context in which the spatial elements extracted by the sieves appear using a syntactic parse tree, and then (2) employ the tree as an (additional) structured feature for training the classifier associated with each sieve. This novel combination of sieves and tree-based structured features results in what we call an *expanding* parse tree. Specifically, as a spatial element for a MOVELINK is extracted by a (role-specific) sieve, it will be added to the structured feature for the classifier associated with the following sieve. In other words, the parse tree corresponding to the structured feature will keep expanding as we move along the sieves in the pipeline. This contrasts with previous applications of tree kernels, where a structured feature is created from a static parse subtree for extracting *exactly two* arguments involved in a relation. To our knowledge, this is the first attempt to combine sieves and parse trees to create expanding trees to extract complex relations involving multiple arguments.

2 Corpus and Task Definition

In this section, we introduce our corpus and the spatial relation extraction task. Owing to space limitations, we will only discuss those aspects that are relevant to the SpaceEval tasks we focus on.

2.1 The SpaceEval Corpus

We use as our corpus the SpaceEval training corpus, which is a subset of ISO-SpaceBank (Pustejovsky and Yocum, 2013). The corpus consists of 59 travel narratives annotated with seven types of spatial elements (Table 1) and three types of spatial relations (Table 2), following the ISO-Space (2012) annotation specifications. Different types of spatial elements have different attributes. The only attribute that is relevant to our work is *semantic type*, which is one of the attributes of a *spatial entity*. *Semantic type* expresses the type of the relation it triggers and can take one of three values: topological, directional, or both.

What is missing in Table 2 about spatial relations is that each element participating in a relation has a *role*. Each QSLINK/OLINK involves exactly three elements participating as $trajector$ (the object of interest), $landmark$ (the grounding location), and $trigger$ (the relation indicator). On the other hand, a MOVELINK has two fixed participants and up to six optional participants. The two mandatory MOVELINK participants are $mover$ (object in motion) and $trigger$ (verb denoting motion). Five of the optional participants express different aspects of the $mover$ in space, namely, $source$ (the spatial element at the beginning of the motion path), $midpoint$ (the spatial elements along the motion path), $goal$ (the spatial element at the end of the motion path), $path$ (the spatial element that reflects the path of motion), and $landmark$ (the grounding location). The sixth optional participant, $motion\_signal$, connects the spatial aspect to the $mover$. Note that all spatial relations are *intra-sentential*.

2.2 The Spatial Relation Extraction Task

Given a set of n spatial elements, the spatial relation extraction task aims to (1) determine whether the elements form a spatial relation of a particular type, and if so, (2) classify the roles of each participating element. For example, from the sentence "The cup is on the table", two relations can be extracted: QSLINK(cup$_{trajector}$, table$_{landmark}$, on$_{trigger}$) and OLINK(cup$_{trajector}$, table$_{landmark}$, on$_{trigger}$). As another example, from the sentence "John walked from Boston to Cambridge", a MOVELINK with participants John$_{mover}$, walked$_{trigger}$, from$_{motion_signal}$, Boston$_{source}$, to$_{motion_signal}$, and Cambridge$_{goal}$ can be extracted.

Type	Description
place	A geographic entity or region (e.g., *lakes*, *mountains*) or an administrative entity (e.g., *towns*, *countries*)
path	A location where the focus is on the potential for traversal (e.g., *road*)
spatial entity	A spatially relevant entity that is neither a *place* nor a *path* (e.g., *car*)
non-motion event	An event that does not involve movement but is directly related to another spatial element
motion event	A species of event that involves movement (e.g., *arrived*)
motion signal	A particle, preposition, verb, or adverb that encodes path or manner information about a *motion event*
spatial signal	A preposition/prepositional phrase that reveals the relationship between two locations (e.g., *north of*)

Table 1: Seven types of spatial elements in SpaceEval.

Relation	Description
QSLINK	Exists between stationary spatial elements with a regional connection. E.g., in "The cup is on the table", the regions of "cup" and "table" are *externally connected* and hence they are involved in a QSLINK.
OLINK	Exists between stationary spatial elements expressing their relative or absolute orientations. E.g., in the above sentence, "cup" and "table" are involved in an OLINK, which conveys that "cup" is oriented *above* "table".
MOVELINK	Exists between spatial elements in motion. E.g., in "John walked from Boston to Cambridge", there is a MOVELINK involving mover "John", motion verb "walked", source "Boston", and goal "Cambridge".

Table 2: Three types of spatial relations in SpaceEval.

3 Related Work

Broadly speaking, existing spatial relation extraction systems have adopted either a *pipeline* approach or a *joint* approach to these subtasks. Given a set of spatial elements, a pipeline spatial relation extraction system (1) extracts the $triggers$, (2) determines whether a spatial relation exists between each extracted $trigger$ and each of the remaining spatial elements, and (3) classifies the role of each non-$trigger$ in each pair of spatially-related elements (Kordjamshidi et al., 2011; Bastianelli et al., 2013; Kordjamshidi and Moens, 2015).

The major weakness of pipeline approaches is that errors in trigger identification can propagate to the relation classification component, whose errors can in turn propagate to the role labeling component. To address this weakness, Roberts et al. (2012; 2013) investigated *joint* approaches. Given a set of spatial elements with an assignment of roles to each element, a joint spatial relation extraction system uses a binary classifier to determine whether these elements form a spatial relation with the roles correctly assigned to all participating elements. In other words, the classifier will output a 1 if and only if (1) the elements in the set form a relation and (2) their roles in the relation are correct. The systems participating in SpaceEval all seem to be in favor of joint approaches (D'Souza and Ng, 2015; Nichols and Botros, 2015; Salaberri et al., 2015).

4 Baseline System

To ensure that we have a state-of-the-art baseline system for spatial relation extraction, we employ our SpaceEval participating system (D'Souza and Ng, 2015), which achieved the best results on task 3a in the official SpaceEval evaluation.[1]

This Baseline system performs *joint* role labeling and relation classification using an ensemble of classifiers. Specifically, it trains one classifier for extracting QSLINKs and OLINKs, and seven classifiers for extracting MOVELINKs. Creating these eight classifiers permits (1) separating the treatment of MOVELINKs from QSLINKs and OLINKs (because the former involves objects in motion while the latter involve stationary objects); and (2) simplifying the extraction of MOVELINKs (because its optional participants are extracted *independently* of each other by these classifiers).

4.1 Training the Baseline Classifiers

In this subsection, we describe how we train the Baseline classifiers, which include one classifier for identifying QSLINKs and OLINKs (Section 4.1.1) and seven classifiers for identifying MOVELINKs (Section 4.1.2).

4.1.1 The LINK Classifier

We collapse QSLINKs and OLINKs to a single relation type, LINK, identifying these two types of links using the LINK classifier. To understand why we can do this, recall from Section 2.1 that in QSLINKs and OLINKs, the $trigger$ has to be a *spatial signal* element having a semantic type attribute. If its semantic type is topological, it triggers a QSLINK; if it is directional, it triggers an OLINK; and

[1] Since the official annotated test data is not available to us, we cannot compare our results with the shared task systems' official results, but comparing against a state-of-the-art baseline will enable us to determine whether our approach is better than the best existing spatial relation extraction system.

if it is both, it triggers both relation types. Hence, if a LINK is identified by our classifier, we can simply use the semantic type of the relation's $trigger$ to determine whether the relation is a QSLINK, an OLINK, or both.

We create training instances for training a LINK classifier as follows. Following the joint approach described above, we create one training instance for each possible role labeling of each triplet of distinct spatial elements in each sentence in a training document. The role labels assigned to the spatial elements in each triplet are subject to the following constraints: (1) each triplet contains a $trajector$, a $landmark$, and a $trigger$; (2) neither the $trajector$ nor the $landmark$ are of type *spatial signal* or *motion signal*; and (3) the $trigger$ is a *spatial signal*. These role constraints are derived from the data annotation scheme. Note that a LINK may have at most one *implicit* participant. For instance, the relation LINK(balloon$_{trajector}$, up$_{trigger}$) extracted from the sentence "The balloon went up" has an implicit $landmark$. To allow for implicit participants, from each training instance we have created thus far, we create three additional training instances, where exactly one of the three participants has the value IMPLICIT.

A training instance is labeled as positive if and only if the elements in the triplet form a relation and their roles are correct. As an example, for the QSLINK and OLINK sentence in Table 2, exactly one positive instance, LINK(cup$_{trajector}$, table$_{landmark}$, on$_{trigger}$), will be created.

Each instance is represented using the 31 features, which can be broadly divided into seven types: lexical, grammatical, semantic, positional, distance, entity attributes, and entity roles.[2] We train the LINK classifier using the SVM learning algorithm as implemented in the SVM^{light} software package (Joachims, 1999). To optimize classifier performance, we tune two parameters, the regularization parameter C and the cost-factor parameter J, to maximize F-score on the development data.[3] Since joint tuning of these parameters is computationally expensive, we employ a hill-climbing algorithm to find a local maximum, altering one parameter at a time to optimize F-score by holding the other parameter fixed.

4.1.2 The Seven MOVELINK Classifiers

If we adopted the aforementioned joint method as is for extracting MOVELINKs, each instance would correspond to an octuple of the form ($trigger_i$, $mover_j$, $source_k$, $midpoint_m$, $goal_n$, $landmark_o$, $path_p$, $motion\_signal_r$), where each participant in the octuple is either a distinct spatial element with a role or the NULL element (if it is not present in the relation). However, generating role permutations for octuples from all spatial elements in a sentence is computationally infeasible. For this reason, we simplify MOVELINK extraction as follows. First, we decompose the MOVELINK octuple into seven smaller tuples including one pair and six triplets. These seven tuples are: [1] ($trigger_i$, $mover_j$); [2] ($trigger_i$, $mover_j$, $source_k$); [3] ($trigger_i$, $mover_j$, $midpoint_m$); [4] ($trigger_i$, $mover_j$, $goal_n$); [5] ($trigger_i$, $mover_j$, $landmark_o$); [6] ($trigger_i$, $mover_j$, $path_p$); and [7] ($trigger_i$, $mover_j$, $motion\_signal_r$). Then, we create seven separate classifiers for identifying these seven MOVELINK tuples, respectively.

Using this decomposition for MOVELINK instances, we can generate instances for each classifier using the aforementioned joint approach as is. For instance, to train classifier [1], we generate pairs of the form ($trigger_i$, $mover_j$), where $trigger_i$ and $mover_j$ are spatial elements proposed as a candidate $trigger$ and a candidate $mover$, respectively. Positive training instances are those ($trigger_i$, $mover_j$) pairs annotated as being part of a MOVELINK in the training data, while the rest of the candidate pairs are negative training instances. The instances for training the remaining six classifiers are generated similarly.

As in the LINK classifier, we enforce global role constraints when creating training instances for the MOVELINK classifiers. Specifically, the roles assigned to the spatial elements in each training instance of each MOVELINK classifier are subject to six constraints: (1) the $trigger$ has type *motion event*; (2) the $mover$ has type *place*, *path*, *spatial entity*, or *non-motion event*; (3) the $source$, the $goal$, and the $landmark$ can be NULL or have type *place*, *path*, *spatial entity*, or *non-motion event*; (4) the $midpoint$ can be NULL or have type *place*, *path*, or *spatial entity*; (5) the $path$ can be NULL or have type *path*; and (6) the $motion\_signal$ can

[2] Space limitations preclude a description of these features. See D'Souza and Ng (2015) for details.

[3] C is chosen from the set {0.01, 0.05, 0.1, 0.5, 1.0, 10.0, 50.0, 100.0}, and J is chosen from the set {0.01, 0.05, 0.1, 0.5, 1.0, 2.0, 4.0, 6.0}. All other learning parameters are set to their default values. In particular, a linear kernel is used.

be NULL or have type *motion signal*.

Our method for decomposing the octuple by role can be justified as follows. Since $trigger$ and $mover$ are mandatory MOVELINK participants, we have a classifier for classifying this core aspect of a MOVELINK. The next six classifiers, [2] to [7], aim to improve the core MOVELINK extraction by exploiting the contextual dependencies with each of its unique spatial aspects, namely $source$, $midpoint$, $goal$, $landmark$, $path$, and $motion\_signal$.

As an example, for the MOVELINK sentence in Table 2, we will create three positive instances: (John$_{mover}$, walked$_{trigger}$) for classifier [1], (John$_{mover}$, walked$_{trigger}$, Boston$_{source}$) for classifier [2], and (John$_{mover}$, walked$_{trigger}$, Cambridge$_{goal}$) for classifier [4].

We represent each training instance using the 31 features that were used to train the LINK classifier. We train each of the MOVELINK classifiers using SVM^{light}. We tune the C and J parameters to maximize F-score on the development data using the hill-climbing algorithm described earlier.[4]

4.2 Applying the Baseline Classifiers

After training, we apply the resulting classifiers to classify the test instances, which are created in the same way as the training instances. As noted before, each LINK extracted from a test document by the LINK classifier is further qualified as QSLINK, OLINK, or both based on the semantic type of its $trigger$. The MOVELINKs are extracted from a test document by combining the outputs from the seven MOVELINK classifiers.

There is a caveat, however: different MOVELINK classifiers can make conflicting decisions. For instance, classifier [1] might misclassify (John$_{mover}$, walked$_{trigger}$) as negative, whereas classifier [2] might correctly classify (John$_{mover}$, walked$_{trigger}$, Boston$_{source}$) as positive. To resolve these conflicting decisions, we give preference to positive decisions, meaning that in this case we will posit "John" and "walked" as having the roles of $mover$ and $trigger$ respectively. There are two more sources of conflicts. First, a spatial element may be assigned different roles for a given MOVELINK by different classifiers. Second, the global constraint that each MOVELINK can have at most one $source$, at most one $goal$, and at most one $landmark$ can be violated. To resolve these conflicts, we select for each spatial element the role that was predicted with highest confidence by the SVM classifiers subject to the global constraint.[5]

5 Our Multi-Pass Sieve Approach

In this section, we describe two methods for employing sieves for extracting spatial relations.

5.1 Using Sieves without Trees

To motivate our first method, recall that the Baseline resolves conflicting decisions in a heuristic manner. For instance, it prefers positive to negative decisions, effectively favoring recall over precision for spatial relation extraction. It is not clear whether this ad-hoc decision is good or not. As another example, when more than one role is assigned to the same spatial element in a MOVELINK, it favors the role associated with the highest SVM confidence. This, however, is also an ad-hoc decision: recall that each classifier's parameters are tuned independently of the others, so different confidence values assigned by different classifiers are not directly comparable.

Employing sieves for spatial relation extraction obviates the need for such ad-hoc decisions. In our implementation, we have eight sieves, each of which corresponds to exactly one of the eight classifiers employed by the Baseline. Recall from the introduction that these sieves are ordered as a pipeline. So, whenever a conflict arises, earlier sieves' decisions have precedence over later sieves' decisions. Returning to the conflicting decisions mentioned before, if sieve 1 misclassifies (John$_{mover}$, walked$_{trigger}$) as negative, whereas sieve 2 correctly classifies (John$_{mover}$, walked$_{trigger}$, Boston$_{source}$) as positive, then we will posit that no MOVELINK exists between "John" and "walked" because we have more confidence in sieve 1's decision than sieve 2's decision. As another example, if two classifiers assign different roles to the same spatial element, then we will choose the role assigned by the classifier associated with the earlier sieve.

Given the above discussion, it should be clear that the ordering of the sieves is important. Typically, sieves are ordered by *precision*, with the hope of reducing the number of erroneous deci-

[4] See Footnote 3 for the set of values of C and J used for parameter tuning.

[5] We use the distance from the hyperplane as a measure of an SVM classifier's confidence.

sions passed from the earlier sieves to the later sieves (e.g., Raghunathan et al. (2010), Lee et al. (2013), Chambers et al. (2014)). Motivated by this observation, we order the sieves as follows. We set sieve 0 to be the LINK classifier and sieve 1 to be the ($trigger$, $mover$) classifier, and then order the remaining sieves by precision. Specifically, we compute the precision of each sieve on the development data, then add sieves into the pipeline in decreasing order of precision.

5.2 Using Sieves with Trees

Next, we describe our second method for applying sieves to spatial relation extraction. To motivate this method, recall that one important property of a sieve-based approach is that later sieves can exploit earlier sieves' decisions when making their own decisions. However, our first method of using sieves makes limited use of the decisions made by earlier sieves. In particular, while each sieve exploits the knowledge of whether a spatial element has been assigned a role by an earlier sieve, it does not exploit the knowledge of what the role is.

Our second method exploits the role decisions made by earlier sieves, but another question arises: how can we encode these role decisions so that they can be best exploited by later sieves? One possibility is to employ them as additional features for training the classifiers associated with later sieves. Motivated by previous work on tree kernels for relation extraction, we employ parse trees as a *structured* feature to encode the syntactic relationships among the roles extracted so far for a given MOVELINK.

We create the structured feature as follows. To strike a better balance between having a rich representation of the context surrounding a spatial relation and improving the learner's ability to generalize, we extract a *subtree* from a parse tree and use it as the value of the structured feature. Specifically, given relation candidate triplet (e_1,e_2,e_3), where spatial elements e_1, e_2, and e_3 are posited in roles r_1, r_2, and r_3, respectively, and the associated syntactic parse tree T, we extract our parse subtree from T as follows. First, we identify the smallest subtree that covers all three spatial elements and call its root r. Second, for each path from each spatial element to r, we include in the parse subtree all the nodes that lie on the path and their immediate children. Third, we simplify the subtree by removing the POS nodes above each spatial element, effectively attaching it to its grandparent. Finally, for better generalization, we replace each spatial element with its role.

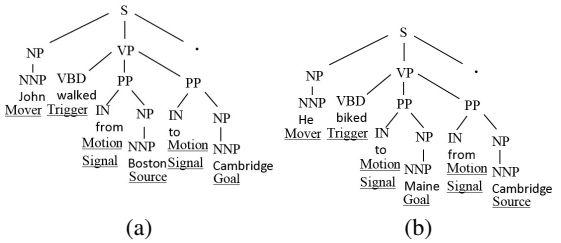

Figure 2: Syntactic parse trees for two example sentences containing MOVELINKs.

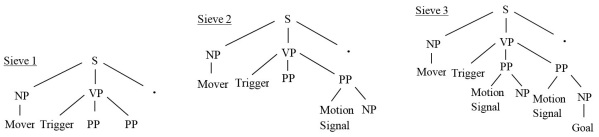
Since this subtree centers on a spatial relation, we call it a *spatial relation centered tree* (SRCT). As mentioned before, we will use SRCTs in combination with our sieve-based approach. This results in a novel application of structured features: to our knowledge, all trees that were previously used as structured features were *static*. By contrast, SRCTs expand as we move along the sieve pipeline. We will discuss examples of how to create SRCTs below.

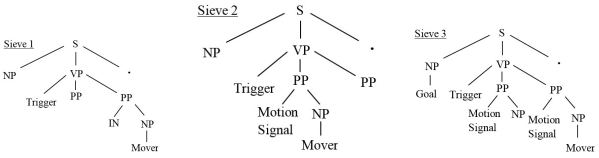
Creating training instances with structured features is straightforward. Recall that a structured feature is used as an additional feature when training each classifier. In other words, it will be used in combination with the original 31 features. The training instance creation method used by the Baseline remains unchanged. All we need to do is to add a SRCT as a structured feature to each training instance.

Consider the sentence "John walked from Boston to Cambridge", whose parse tree is shown in Figure 2(a). Since only one MOVELINK can be extracted from it, only one positive training instance will be created for each classifier. Assume that sieve 1 contains the ($trigger$, $mover$) classifier; sieve 2 contains the ($trigger$, $mover$, $motion\_signal$) classifier; and sieve 3 contains the ($trigger$, $mover$, $goal$) classifier. Figure 3(a) shows the SRCTs used in the corresponding positive instances, while Figure 3(b) shows the SRCTs associated with randomly chosen negative instances used to train the classifiers in these sieves.

To train a classifier on instances containing the original 31 features *and* SRCTs, we employ SVM$^{light-TK}$ (Moschitti, 2004; Moschitti, 2006), which (1) trains an SVM classifier using the 31 features with a linear kernel; (2) trains an SVM classifier using only the SRCTs with a convolution

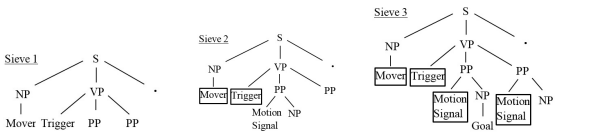


(a) SRCTs associated with positive training instances in sieves 1, 2, and 3.

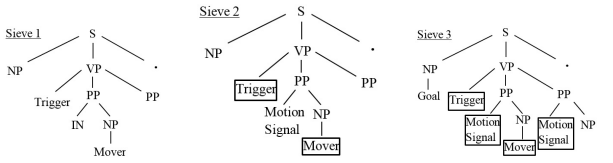


(b) SRCTs associated with randomly chosen negative training instances in sieves 1, 2, and 3.

Figure 3: SRCTs associated with training instances created for the sentence in Figure 2a.



(a) SRCTs associated with correctly classified test instances in sieves 1, 2, and 3.



(b) SRCTs associated with incorrectly classified test instances in sieves 1, 2, and 3.

Figure 4: SRCTs associated with test instances for the sentence in Figure 2b.

kernel; and (3) combines these two kernels using a composite kernel. Specifically, we define composite kernel K_c for combining linear kernel K_l and convolution kernel K_t as follows:

$$K_c(F_1, F_2) = K_l(F_1, F_2) + T \cdot K_t(T_1, T_2),$$

where F_1 and F_2 are the set of 31 features from two training instances, T_1 and T_2 are their SRCTs, and T is the combination parameter. We employ the hill-climbing algorithm described before to tune the C, J and T parameters to maximize F-score on the development data.[6]

The test instances with structured features are created in the same way as the training instances, with one notable difference. Note that roles are used to create structured features. While they are available in training, they are not available in the test documents. Hence, to create SRCTs for a test instance, we have to employ the roles *predicted* by preceding sieves. This is precisely how we exploit the role decisions made by earlier sieves in later sieves. This also explains why the SRCTs expand: more and more roles will be attached to a SRCT as it passes through the sieve pipeline.

As an example, consider the test sentence "He biked to Maine from Cambridge", whose parse tree is shown in Figure 2(b). Figure 4(a) shows the SRCTs generated when each sieve makes the correct decisions. Specifically, sieve 1 correctly identifies "He" as the $mover$ and "biked" as the $trigger$. The roles (correctly) extracted by sieve 1 (shown in boxes) are incorporated into the SRCT created in sieve 2. Similarly, the $motion_signal$s (correctly) extracted by sieve 2 are incorporated into the SRCT created in sieve 3. Figure 4(b) shows the SRCTs generated for misclassified instances. Assume that sieve 1 misclassifies the test instance underlying the SRCT (as positive). As we can see, this mistake is propagated to the SRCTs generated in later sieves.

Note that the precision of a sieve may change with the addition of SRCTs. For this reason, the sieves need to be reordered using the algorithm described in the previous subsection.

6 Evaluation

6.1 Experimental Setup

SpaceEval tasks. We evaluate our approach in tasks 1d and 3a of SpaceEval. These two tasks evaluate a system's ability to extract ($trajector$, $landmark$, $trigger$) triplets in QSLINKs and OLINKs as well as ($trigger$, $mover$) pairs in MOVELINKs using gold spatial elements (1d) and automatically extracted spatial elements (3a). To extract the spatial elements needed for task 3a, we follow Bastianelli et al.'s (2013) sequence labeling approach, except that we train the sequence labeler using a CRF rather than an HMM.[7]

Dataset. Since the annotated test set used in SpaceEval's official evaluation is not available

[6]To tune T, we attempted values between 0 and 2 in increments of 0.2. To tune C and J, we attempted the values specified in Footnote 3.

[7]We train two CRF models using CRF++ (`https://taku910.github.io/crfpp/`), one to extract *motion signal*s and the other to extract the remaining six types of spatial elements (see Table 1). The reason is that *motion signal* is the only type of spatial element that can overlap with other types. When predicting *spatial signal*s, we also predict their semantic types, since the LINK classifier needs this attribute to distinguish between QSLINKs and OLINKs (see Section 4.1.1). To increase recall, we use the 10-best outputs returned by the CRFs as candidate spatial elements.

Table 3: Results for extracting spatial relations.

to us at the time of writing, we conduct our evaluation on the SpaceEval training corpus, which contains 1890 spatial relations (886 QSLINKs, 225 OLINKs, and 779 MOVELINKs) and 1139 MOVELINK optional roles (95 $sources$, 65 $midpoints$, 310 $goals$, 77 $landmarks$, 100 $paths$, and 492 $motion\_signals$). We partition the 59 narratives in the corpus into five folds and report five-fold cross-validation results. In each fold experiment, we employ three folds for training, one fold for development, and one fold for testing.

Evaluation metrics. To evaluate the results for the two SpaceEval tasks, we employ the official SpaceEval scoring program, which reports results in terms of recall, precision, and F-score on the three types of spatial relations in isolation and in combination. To evaluate the results for extracting MOVELINK optional roles, we compute the recall, precision, and F-score for each role.

6.2 Results and Discussion

Tables 3a and 3b show the spatial relation extraction results for three systems — the Baseline (row 1), our Sieve approach without SRCTs (row 2), and our Sieve approach with SRCTs (row 3) — obtained using gold and extracted spatial elements, respectively.

The official scoring program reports spatial relation extraction results in terms of recall (R), precision (P), and F-score (F). For QSLINKs and OLINKs, it reports results on (1) extracting spatially-related ($trajector$, $landmark$, $trigger$) triplets (see the "True" columns) and (2) identifying that no spatial relation exists among a (candidate $trajector$, candidate $landmark$, candidate $trigger$) triplet (see the "False" columns). For MOVELINKs, it reports results on (1) extracting spatially-related ($trigger$, $mover$) pairs (see the "True" columns) and (2) identifying that no spatial relation exists between a (candidate $trigger$, candidate $mover$) pair (see the "False" columns). Since the pairs/triplets without links considerably outnumber those with links, the OVERALL scores are dominated by the performances on "False", which, as expected, are high.

Of particular interest are the MOVELINK scores under the "True" columns. When gold spatial elements are used, Sieve significantly outperforms Baseline ($p < 0.001$) owing to substantial gains in precision with smaller losses in recall.[8] Adding SRCTs to Sieve further boosts performance significantly ($p < 0.005$). As we can see, Sieve+SRCTs outperforms Baseline by 8.4% absolute F-score on extracting ($trigger$, $mover$) pairs. With respect to the OVERALL score, which also takes into account QSLINKs and OLINKs, Sieve+SRCTs outperforms Baseline significantly by 1.7% absolute F-score. Similar trends can be observed for the results obtained using extracted spatial elements. Note that Baseline and Sieve have the same QSLINK and OLINK results because the LINK classifier is associated with the first sieve.

Tables 4a and 4b show the results on extracting MOVELINK optional roles using gold and extracted spatial elements, respectively. When gold elements are used, Sieve insignificantly outperforms Baseline on $source$, $midpoint$, and $motion\_signal$. When used with SRCTs, Sieve insignificantly outperforms Baseline on $source$, $midpoint$, $path$, and $motion\_signal$. Overall, Sieve+SRCTs insignificantly outperforms Baseline by 3.0% absolute F-score.[9] While the results

[8] All statistical significance tests are paired t-tests, with p set to 0.05 unless otherwise stated.

[9] A closer examination of the results reveals why the improvement is insignificant: since many roles occur infrequently in the corpus, the parameters learned from the devel-

Table 4: Results for extracting MOVELINK optional roles.

obtained using extracted elements exhibit different trends, Sieve+SRCTs's OVERALL improvement of 6.1% absolute F-score over Baseline is significant ($p < 0.001$).

Table 5 shows the results of these systems on extracting entire MOVELINKs, where a MOVELINK is considered correctly extracted if *all* of its participating elements and their roles are correct. Note that none of the SpaceEval tasks employ this stringent but informative evaluation measure. As we can see, Sieve+SRCTs insignificantly outperforms Baseline by 2.3–3.0% absolute F-score, regardless of whether gold or extracted elements are used.

6.3 Error Analysis

In this subsection, we analyze the errors made by the best-performing system, Sieve+SRCTs, with respect to the extraction of MOVELINKs given our focus on this type of spatial relation.

Extracting ($mover$, $trigger$) pairs. The major source of recall error stems from the system's inability to extract $mover$s that are unseen in the training data. This error could be addressed using a named entity recognizer and WordNet categories related to people, places, animals, etc. The major source of precision error arises from *missing* gold annotations. Consider the sentence "I found myself biking..." Our system correctly extracted "biking" as the $trigger$ and "I" as the $mover$, but was considered wrong because "myself", not "I", was annotated as the $mover$ in the gold standard.

Extracting optional roles. A major source of recall/precision error stems from the system's inability to exploit contextual cues that are reliable indicators of a particular role. For instance, a statistical analysis of the training data reveals that $source$s are commonly preceded by prepositions such as "from" and "or", whereas $goal$s are commonly associated with verbs such as "return", "visit", "arrive", and "reach". This problem could be addressed by encoding these cues explicitly as additional features for training the role-specific classifiers. Another source of recall error can be attributed to the lack of background knowledge. Consider the sentence "We had only 70 more km to Cluj taking this way, but if getting back to Ciucea and on to Cluj the normal way would have been 25 km longer". Despite correctly extracting "Cluj" as the $goal$, the system failed to extract "Ciucea" as the $midpoint$. This problem could be alleviated by exploiting geographical knowledge concerning these cities in external knowledge sources such as Wikipedia.

	Gold			Extracted		
	R	P	F	R	P	F
Baseline	40.6	50.4	45.0	21.7	15.3	18.0

7 Conclusions

We have examined the under-studied task of spatial relation extraction, focusing on spatial relations of objects in motion. Our approach exploited expanding parse trees, which resulted from a novel combination of multi-pass sieves and tree kernels, achieving state-of-the-art results on two key SpaceEval tasks. To facilitate comparison with future work on this task, we released the source code of our spatial relation extraction system.[10]

Abstract

Characters are fundamental to literary analysis. Current approaches are heavily reliant on NER to identify characters, causing many to be overlooked. We propose a novel technique for character detection, achieving significant improvements over state of the art on multiple datasets.

1 Introduction

How many literary characters appear in a novel? Despite the seeming simplicity of the question, precisely identifying which characters appear in a story remains an open question in literary and narrative analysis. Characters form the core of many computational analyses, from inferring prototypical character types (Bamman et al., 2014) to identifying the structure of social networks in literature (Elson et al., 2010; Lee and Yeung, 2012; Agarwal et al., 2013; Ardanuy and Sporleder, 2014; Jayannavar et al., 2015). These current approaches have largely assumed that characters can be reliably identified in text using standard techniques such as Named Entity Recognition (NER) and that the variations in how a character is named can be found through coreference resolution. However, such treatment of character identity often overlooks minor characters that serve to enrich the social structure and serve as foils for the identities of major characters (Eder et al., 2010).

This work provides a comprehensive examination of literary character detection, with three key contributions. First, we formalize the task with evaluation criteria and offer two datasets, including a complete, manually-annotated list of all characters in 58 literary works. Second, we propose a new technique for character detection based on inducing character prototypes, and in comparisons with three state-of-the-art methods, demonstrate superior performance, achieving significant improvements in F1 over the next-best method. Third, as practical applications, we analyze literary trends in character density over 20 decades and revisit the character-based literary hypothesis tested by Elson et al. (2010).

2 Related Work

Character detection has primarily been performed in the context of mining literary social networks. Elson et al. (2010) extract character mentions from conversational segments, using the Stanford CoreNLP NER system to discover character names (Manning et al., 2014). To account for variability in character naming, alternate forms of a name are generated using the method of Davis et al. (2003) and merged together as a single character. Furthermore, the set of aliases for a character is expanded by creating coreference chains originating from these proper names and merging all coreferent expressions. Agarwal et al. (2013) also rely on the CoreNLP NER and coreference resolution systems for character detection; however for literary analysis, they use gold character mentions that have been marked and resolved by a team of trained annotators, highlighting the difficulty of the task.

He et al. (2013) propose an alternate approach for identifying speaker references in novels, using a probabilistic model to identify which character is speaking. However, to account for the multiple aliases used to refer to a character, the authors first manually constructed a list of characters and their aliases, which is the task proposed in this work and underscores the need for automated methods.

Two approaches mined social interaction net-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 769–774,
Lisbon, Portugal, 17-21 September 2015.

works without relying on dialogue, unlike the methods of Elson et al. (2010) and He et al. (2013). Lee and Yeung (2012) build social networks by recognizing characters from explicit markers (e.g., kinship) and implicit markers (e.g., physical collocation). Similarly, Agarwal and Rambow (2010) build character networks using tree kernels on parse trees to identify interacting agents.

In the two most-related works, Bamman et al. (2014) and Ardanuy and Sporleder (2014), character names are extracted and clustered under a set of constraints. In the BookNLP system developed by Bamman et al. (2014), NER-identified names are retained and merged based on animacy, determined through dependencies with "sentient" lemmas from a small dictionary (including for example, *say* and *smile*), and gender, assigned through pronomial resolution and a dictionary of gender-specific honorifics. Ardanuy and Sporleder (2014) similarly use NER to identify character name mentions. These names are grouped through the application of a series of deterministic rules, beginning with recognizing gender constraints, where gender assignments are based off of gender-specific honorifics and names. If a gender can't be assigned, then one is derived from the majority count of gender-specific pronouns (e.g. he, herself) appearing in the immediate context of the name mentions. The extracted names are then clustered, while respecting the gender impositions, based on a sieve of name variant heuristics. In the final step, any remaining ambiguous referents , i.e., those that can be matched to multiple characters, are assigned to the more prominent character in the story. The authors achieve F1-scores > 0.9 for extracting the 10 most relevant characters in a small collection of novels, but the performance on all characters is unknown.

3 Detecting Characters

We propose an eight stage pipeline for detecting characters, which builds a graph where nodes are names and edges connect names belonging to the same character. The vertices in the graph are initially populated by running NER over the corpus and also incorporating names following an honorific. Second, coreference resolution is run to identify names that occur together in a coreference chain and edges are added where two nodes' names co-occur in a chain. Stanford CoreNLP is used for both NER and co-reference. Third, we apply a series of name variation rules to link

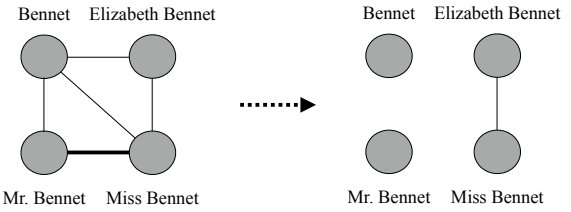

Figure 1: Resolving names in a character graph. The circles represent individual names and the thin and thick lines denote edges and anti-edges, respectively.

names potentially referring to the same character (e.g., by removing an honorific). Fourth, a gazetteer of 1859 hypocorisms for 560 names is used to link variations (e.g., Tim and Timmy).

Stages 2–4 potentially introduce edges connecting names of different characters. Therefore, in the fifth stage, three heuristics are applied to add prohibitions on merging two names into the same character. Two vertices cannot be merged if (1) the inferred genders of both names differ, (2) both names share a common surname but different first names, or (3) the honorific of both names differ, e.g., "Miss" and "Mrs." Similarly, the sixth stage inserts prohibitions by extracting pairs of names from the novel where (1) both names appear connected by a conjunction, (2) one name appears as the speaker mentioning the other name in direct speech, and (3) both names appear together in a quotation.

Together, Stage 1–6 are applied by first linking all nodes by edges and following, identifying pairs prohibited from being connected and remove the edges along the shortest path between those two nodes, effectively creating two new disconnected components in the name graph. Figure 1 illustrates this transformation on a simple character graph.

Next, the seventh step attempts to identify characters whose names may not be recognized by NER. For example, many minor characters do not appear as named entities and instead have general role-based referents such as "the governor" or "the archbishop." However, despite the lack of proper names, such characters behave and interact in similar ways as major characters, including having dialogue. Therefore, to discover such characters, we adopt a bootstrapping technique aimed at uncovering prototypical character behaviors from the novels themselves, inspired by the semantic predicate work of Flati and Navigli (2013). The Project Gutenberg fiction corpus was dependency parsed to identify all verbs in a dependency relation with nouns, where each noun was categorized as (a) a

named entity (b) having its first sense in WordNet refer to an animate entity (Fellbaum, 1998), or (c) neither of the above. All verbs associated with these were then ranked according to their ratio of types (a) and (c) to identify verbs strongly associated with character-like behaviors, which avoids including the behavior of nouns in (b) which may refer to minor characters. Ultimately, 2,073 verbs-and-dependency pairs with a ratio of $\geq$0.25 were retained as predicates selecting for character-like entities, after limited experimental testing showed this threshold extracted sensible verbs such as "rejoice," "accost," and "frown." Using this set of predicates, nouns appearing with the verb in the appropriate dependency relation are added as characters. We prohibit adding names contained in a small stop list of 22 generic nouns (e.g., "man").

Finally, the eighth and last stage removes nodes that are disconnected from the rest of the graph and represent a name that is a portion of one or more names for other nodes. These nodes are typically ambiguous first or last names. Thus, the remaining set of nodes are merged to create sets of names, each associated with a different character.

4 Experiments

Given a literary novel, our objective is to produce a list of characters, where each character may be associated with one or more names.

Datasets Two datasets are used. The first is a manually-annotated collection of 58 works with complete lists of all characters and their possible referents in texts. Of these works, 56 were generated as a part of an on-going longitudinal study of author style for all *Sherlock Holmes* stories written by Sir Arthur Conan Doyle. The remaining two works are the full length novels *Pride and Prejudice* by Jane Austen and *The Moonstone* by Wilkie Collins. Characters and their alias were manually coded by expert annotators, with multiple passes to ensure completeness. *The Moonstone* was treated as truly held-out test data and results were only generated once prior to submission.

The second dataset consists of 30 novels listed on Sparknotes (`sparknotes.com`) and their corresponding lists of characters, with supplemental naming variations of these characters provided by our annotators. These character lists often contain only the major characters in a novel; for example, their list for Pride and Prejudice contains only 17 characters, where as our manually-annotated list identifies 73 characters. Nevertheless, the Sparknotes data serves as a baseline of those characters any method should be able to detect.

Evaluation Character recognition systems produce a list of sets, each containing the names associated with one character, denoted $E = \{E_1, \ldots, E_n\}$ where E_i is a set of names for a character. These lists are evaluated against a gold standard list, denoted G, containing all naming variations for each character. To evaluate, we formalize the problem as finding a maximum bipartite matching where the sets of names in E and those in G constitute the two node types. For precision, matching is measured in the purity of an extracted set of names, E_i, with respect to the gold-standard names, G_j: $1 - \frac{|E^i - G^j|}{|E^i|}$; simply, a match is maximal when the set of extracted names is a subset of the gold standard names, with penalties for including wrong names. Recall uses a looser definition of matching with the aim of measuring whether a character G_j was found at all; matching is measured as a binary function that is 1 if $E_i \cap G_j \neq \emptyset$ and 0 otherwise.

Comparison Systems The task of character recognition has largely been subsumed into the task of extracting the social network of novels. Therefore, three state-of-the-art systems for social network extraction were selected: the method described in Elson et al. (2010), BookNLP (Bamman et al., 2014), and the method described in Ardanuy and Sporleder (2014). For each method, we follow their procedures for identifying the characters in the social network, which produces sets of one or more aliases associated with each identified character. As a baseline, we use the output of Stanford NER, where every name is considered a separate character; this baseline represents the upper-bound in recall from any system using only NER to identify character names.

Experiment 1: Accuracy Table 1 shows the results for the manually-annotated and SparkNotes corpora. The Sherlock Holmes corpus presents a notable challenge due to the presence of many minor characters, which are not detected by NER. An error analysis for our approach revealed that while many characters were extracted, the coreference resolution did not link a characters' different referents together and hence, each name was reported as a separate character, which caused a drop in performance. Nevertheless, our system provided the highest performance for character recognition.

The Pride and Prejudice novel presents a dif-

	Sherlock Holmes Stories			Pride and Prejudice			The Moonstone			SparkNotes

The Moonstone	0.3943	0.4613	0.4294

Table 2: Accuracy of proposed system without stage 7.

ferent set of challenges due to multiple characters sharing the same last name or the same first name. Here, coreference resolution frequently creates incorrect links between the similar names of different characters, creating a drop in precision for most systems. Our precision value particularly benefited from the heuristics for distinguishing characters by gender and stringent name-merging constraints. BookNLP and the approach of Ardanuy and Sporleder (2014) performed quite similarly in identifying characters, which is expected given the overlap in rules applied by both systems.

Moonstone contains a unique novel structure with multiple first-person narrators, group-based characters (e.g., "the jugglers") that present a challenge to co-reference systems, and 419 different names for the 78 unique characters. An error analysis of our system revealed that majority of mistakes were due to the multiple names for a character not being merged into a single identity. Nevertheless, our system performs best of those tested.

For the SparkNotes data, the NER baseline achieves the highest recall, indicating that many of the major character names listed in SparkNotes' data can be directly found by NER. Nevertheless, in reality, the baseline's performance is offset by its significantly lower precision, as shown in its performance on the other novels; indeed the baseline grossly overestimates the number of characters for the SparkNotes novels, reporting 339 characters per novel on average.

Table 2 shows our system's performance without stage 7, which involved the extraction of minor characters. Stage 7 overall improves recall with a slight hindrance to precision. For the Sherlock Holmes corpus, stage 7 is slightly detrimental to overall performance, which as we stipulated earlier is caused by missing co-referent links.

Finally, returning to the initially-posed question of how many characters are present, we find that despite the detection error in our method, the overall predicted number of characters is quite close to the actual: for Sherlock Holmes stories, the number of characters was estimated within 2.4 on average, for *Pride and Prejudice* our method predicted 72 compared with 73 actual characters, and for *The Moonstone* our method predicted 87 compared with 78. Thus, we argue that our procedure can provide a reasonable estimate for the total number of characters. (For comparison, BookNLP, the next best system, extracted 69 and 72 characters for Pride and Prejudice and The Moonstone, respectively, and within 1.2, on average, on the Sherlock Holmes set.)

Experiment 2: Literary Theories Elson et al. (2010) analyze 60 novels to computationally test literary theories for novels in urban and rural settings (Williams, 1975; Moretti, 1999). Recently, Jayannavar et al. (2015) challenged this analysis, showing their improved method for social network extraction did not support the same conclusions. While our work focuses only on character detection, we are nevertheless able to test the related hypothesis of whether the number of characters in novels with urban settings is more than those in rural. Character detection was run on the same novels from Elson et al. (2010) and we found no statistically-significant difference in the mean number of characters in urban and rural settings, even when accounting for text size. Thus, our work raises questions about how these character interact and whether the setting influences the structure of the social network, despite similar numbers of characters.

Experiment 3: Historical Trends As a second application of our technique, we examine historical trends in how many characters appear in a novel. All fiction novels listed on Project Gutenberg were compiled and publication dates were automatically extracted for 1066 and manually entered for an additional 637. This set was combined with a corpus of 6333 novels, including works such as *To The Lighthouse* by Virginia Woolf, not available on Project Gutenberg. Books were then partitioned into the decade in which they were au-

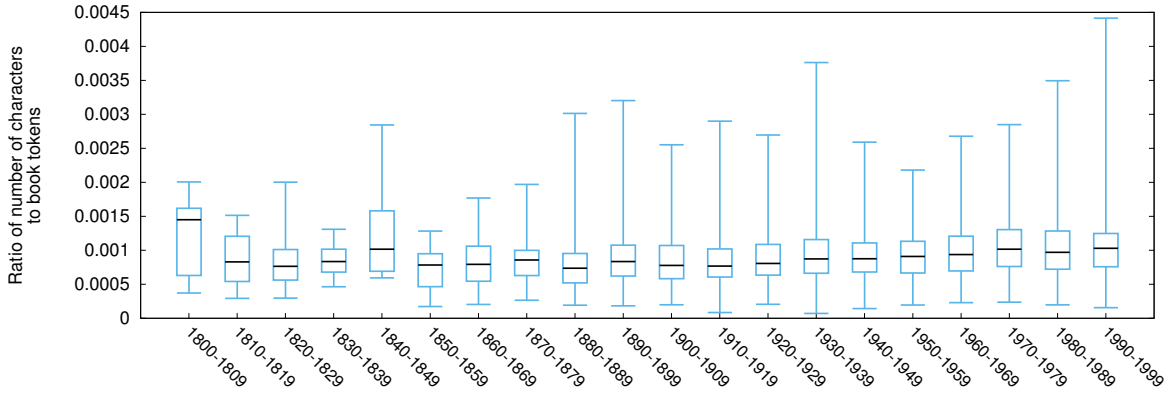

Figure 2: Distributions of the size-normalized number of characters per novel per decade.

thored. We limit our focus to trends starting in 1800 to 1990, when at least 11 books are available for each decade.

To account for variability in novel length, we normalize the novel's number of characters by its number of tokens. Figure 2 shows the box-and-whisker plot of the normalized number of characters per novel, where the box denotes the first and third quartile and the bar denotes the median. Surprisingly, we did not observe any significant change in the relative number of characters per novel, despite the underlying socio-economic changes that accompanied this time period. While novels written before 1850 had slightly more characters on average, this effect may be due to the smaller number of works available from this period. However, our finding raises many questions about whether the social networks for these characters obey similar trends in their size and density.

5 Conclusion

Although a fundamental task to character analysis, identifying the number of characters in a literary novel presents a significant challenge to current state of the art. To lay the foundation towards solving the task, we provide three contributions: (1) an annotated corpus of 58 books, (2) an evaluation framework for measuring performance on the task, (3) a new state-of-the-art method for character extraction. Furthermore, to promote future work we make all software and data available upon request.

6 Acknowledgements

We would like to thank the three annotators for their diligent reading and coding of novels.

Convolutional Sentence Kernel from Word Embeddings for Short Text Categorization

Jonghoon Kim **François Rousseau** **Michalis Vazirgiannis**

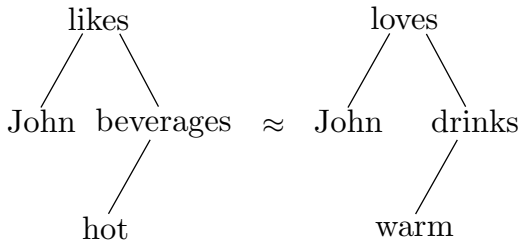
john.jonghoon.kim@gmail.com

Abstract

This paper introduces a convolutional sentence kernel based on word embeddings. Our kernel overcomes the sparsity issue that arises when classifying short documents or in case of little training data. Experiments on six sentence datasets showed statistically significant higher accuracy over the standard linear kernel with n-gram features and other proposed models.



(a) 'John likes hot beverages' (b) 'John loves warm drinks'

Figure 1: Dependency tree representations of semantically related sentences yet with little overlap.

1 Introduction

With the proliferation of text data available online, text categorization emerged as a prominent research topic. Traditionally, words (unigrams) and phrases (n-grams) have been considered as document features and subsequently fed to a classifier such as an SVM (Joachims, 1998). In the SVM dual formulation that relies on kernels, i. e. similarity measures between documents, a linear kernel can be interpreted as the number of exact matching n-grams between two documents. Consequently, for short documents or when little training data is available, sparsity issues due to word synonymy arise, e. g., the sentences 'John likes hot beverages' and 'John loves warm drinks' have little overlap and therefore low linear kernel value (only 1) in the n-gram feature space, even with dependency tree representations and downward paths for n-grams as illustrated in Figure 1.

We propose to relax the exact matching between words by capitalizing on distances in word embeddings. We smooth the implicit delta word kernel, i. e. a Dirac similarity function between unigrams, behind the traditional linear document kernel to capture the similarity between words that are different, yet semantically close. We then aggregate these word and phrase kernels into sentence and documents kernels through convolution resulting in higher kernel values between semantically related sentences (e. g., close to 7 compared to 1 with bigram downward paths in Figure 1). Experiments on six standard datasets for sentiment analysis, subjectivity detection and topic spotting showed statistically significant higher accuracy for our proposed kernel over the bigram approaches. Our main goal is to demonstrate empirically that word distances from a given word vector space can easily be incorporated in the standard kernel between documents for higher effectiveness and little additional cost in efficiency.

The rest of this paper is structured as follows. Section 2 reviews the related work. Section 3 gives the detailed formulation of our kernel. Section 4 describes the experimental settings and the results we obtained on several datasets. Finally, Section 5 concludes our paper and mentions future work.

2 Related work

Siolas and d'Alché Buc (2000) pioneered the idea of *semantic kernels* for text categorization, capitalizing on WordNet (Miller, 1995) to propose continuous word kernels based on the inverse of the path lengths in the tree rather than the common delta word kernel used so far, i. e. exact matching between unigrams. Bloehdorn et al. (2006) extended it later to other tree-based similarity measures from WordNet while Mavroeidis et al. (2005) exploited its hierarchical structure to define a Generalized Vector Space Model kernel.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 775–780,
Lisbon, Portugal, 17-21 September 2015.

In parallel, Collins and Duffy (2001) developed the first *tree kernels* to compare trees based on their topology (e. g., shared subtrees) rather than the similarity between their nodes. Culotta and Sorensen (2004) used them as Dependency Tree Kernels (DTK) to capture *syntactic similarities* while Bloehdorn and Moschitti (2007) and Croce et al. (2011) used them on parse trees with respectively Semantic Syntactic Tree Kernels (SSTK) and Smoothing Partial Tree Kernels (SPTK), adding node similarity based on WordNet to capture *semantic similarities* but limiting to comparisons between words of the same POS tag.

Similarly, Gärtner et al. (2003) developed *graph kernels* based on random walks and Srivastava et al. (2013) used them on dependency trees with Vector Tree Kernels (VTK), adding node similarity based on word embeddings from SENNA (Collobert et al., 2011) and reporting improvements over SSTK. The change from WordNet to SENNA was supported by the recent progress in low-dimension Euclidean vector space representations of words that are better suited for computing distances between words. Actually, in our experiments, word2vec by Mikolov et al. (2013a) led to better results than with SENNA for both VTK and our kernels. Moreover, it possesses an additional additive compositionality property obtained from the Skip-gram training setting (Mikolov et al., 2013b), e. g., the closest word to 'Germany' + 'capital' in the vector space is found to be 'Berlin'.

More recently, for short text similarity, Song and Roth (2015) and Kenter and de Rijke (2015) proposed additional semantic meta-features based on word embeddings to enhance classification.

3 Formulation

We denote the embedding of a word w by $\mathbf{w}$.

3.1 Word Kernel (WK)

We define a kernel between two words as a polynomial kernel over a cosine similarity in the word embedding space:

$$\mathrm{WK}(w_1, w_2) = \left[\frac{1}{2}\left(1 + \frac{\langle \mathbf{w}_1, \mathbf{w}_2 \rangle}{\|\mathbf{w}_1\|\|\mathbf{w}_2\|}\right)\right]^{\alpha} \quad (1)$$

where α is a scaling factor. We also tried Gaussian, Laplacian and sigmoid kernels but they led to poorer results in our experiments. Note that a delta word kernel, i. e. the Dirac function $\mathbb{1}_{w_1=w_2}$, leads to a document kernel corresponding to the standard linear kernel over n-grams.

3.2 Phrase Kernel (PhK)

Next we define a kernel between phrases consisting of several words. In our work, we considered two types of phrases: (1) *co-occurrence phrases* defined as contiguous sequences of words in the text; and (2) *syntactic phrases* defined as downward paths in the dependency tree representation, e. g., respectively 'hot beverages' and 'beverages hot' in Figure 1. With this dependency tree involved, we expect to have phrases that are syntactically more meaningful. Note that VTK considers *random walks* in dependency trees instead of downward paths, i. e. potentially taking into account same nodes multiple times for phrase length greater than two, phenomenon known as tottering.

Once we have phrases to compare, we may construct a kernel between them as the product of word kernels if they are of the same length l. That is, we define the Product Kernel (PK) as:

$$\mathrm{PK}(p_1, p_2) = \prod_{i=1}^{l} \mathrm{WK}(w_i^1, w_i^2) \quad (2)$$

where w_i^j is the i-th word in phrase p_j of length l. Alternatively, in particular for phrases of different lengths, we may embed phrases into the embedding space by taking a composition operation on the constituent word embeddings. We considered two common forms of composition (Blacoe and Lapata, 2012): vector addition ($+$) and element-wise multiplication ($\odot$). Then we define the Composition Kernel (CK) between phrases as:

$$\mathrm{CK}(p_1, p_2) = \mathrm{WK}(\mathbf{p}_1, \mathbf{p}_2) \quad (3)$$

where $\mathbf{p}_j$, the embedding of the phrase p_j, can be obtained either by addition ($\mathbf{p}_j = \sum_{i=1}^{l} \mathbf{w}_i^j$) or by element-wise multiplication ($\mathbf{p}_j = \bigodot_{i=1}^{l} \mathbf{w}_i^j$) of its word embeddings. For CK, we do not require the two phrases to be of the same length so the kernel has a desirable property of being able to compare 'Berlin' with 'capital of Germany' for instance.

3.3 Sentence Kernel (SK)

We can then formulate a sentence kernel in a similar way to Zelenko et al. (2003). It is defined through convolution as the sum of all local phrasal similarities, i. e. kernel values between phrases contained in the sentences:

$$\mathrm{SK}(s_1, s_2) = \sum_{\substack{p_1 \in \phi(s_1),\\ p_2 \in \phi(s_2)}} {\lambda_1}^{\epsilon}\, {\lambda_2}^{\eta}\, \mathrm{PhK}(p_1, p_2) \quad (4)$$

where $\phi(s_k)$ is the set of either statistical or syntactic phrases (or set of random walks for VTK) in sentence s_k, λ_1 is a decaying factor penalizing longer phrases, $\epsilon = \max\{|p_1|, |p_2|\}$ is the maximum length of the two phrases, λ_2 is a distortion parameter controlling the length difference η between the two phrases ($\eta = ||p_1| - |p_2||$) and PhK is a phrase kernel, either PK, CK$^+$ or CK$^\odot$.

Since the composition methods we consider are associative, we employed a dynamic programming approach in a similar fashion to Zelenko et al. (2003) to avoid duplicate computations.

3.4 Document Kernel

Finally, we sum sentence kernel values for all pairs of sentences between two documents to get the document kernel. Once we have obtained all document kernel values K_{ij} between documents i and j, we may normalize them by $\sqrt{K_{ii}K_{jj}}$ as the length of input documents might not be uniform.

4 Experiments

We evaluated our kernel with co-occurrence and syntactic phrases on several standard text categorization tasks.

4.1 Datasets

We considered four tasks: (1) binary *sentiment analysis* with a movie review dataset of 10,662 sentences (PL05) (Pang and Lee, 2005) and a product review dataset (Amazon) of 2,000 multi-line documents for 4 different product groups (Blitzer et al., 2007) (we will report the average effectiveness over the 4 sub-collections); (2) ternary *sentiment analysis* with the SemEval 2013 Task B dataset (Twitter) containing 12,348 tweets classified as positive, neutral or negative (Nakov et al., 2013); (3) binary *subjectivity detection* with a dataset of 10,000 sentences (PL04) (Pang and Lee, 2004) and another of 11,640 sentences (MPQA) (Wiebe et al., 2005); and (4) seven-class *topic spotting* with a news dataset (News) of 32,602 one-line news summaries (Vitale et al., 2012).

4.2 Experimental settings

In all our experiments, we used the FANSE parser (Tratz and Hovy, 2011) to generate dependency trees and the pre-trained version of word2vec[1], a 300 dimensional representation of 3 million English words trained over a Google News dataset of 100 billion words using the Skip-gram model and a context size of 5. While fine-tuning the embeddings to a specific task or on a given dataset may improve the result for that particular task or dataset (Levy et al., 2015), it makes the expected results less generalizable and the method harder to use as an off-the-shelf solution – re-training the neural network to obtain task-specific embeddings requires a certain amount of training data, admittedly unlabeled, but still not optimal under our scenario with short documents and little task-specific training data available. Moreover, tuning the hyperparameters to maximize the classification accuracy needs to be carried out on a validation set and therefore requires additional labeled data. Here, we are more interested in showing that distances in a given word vector space can enhance classification in general. As for the dependency-based word embeddings proposed by Levy and Goldberg (2014), we do not think they are better suited for the problem we are tackling. As we will see in the results, we do benefit from the dependency tree structure in the phrase kernel but we still want the word kernel to be based on topical similarity rather than functional similarity.

To train and test the SVM classifier, we used the LibSVM library (Chang and Lin, 2011) and employed the one-vs-one strategy for multi-class tasks. To prevent overfitting, we tuned the parameters using cross-validation on 80% of PL05 dataset ($\alpha = 5$, $\lambda_1 = 1$ for PK since there is no need for distortion as the phrases are of the same length by definition, and $\lambda_1 = \lambda_2 = 0.5$ for CK) and used the same set of parameters on the remaining datasets. We performed normalization for our kernel and baselines only when it led to performance improvements on the training set (PL05, News, PL04 and MPQA).

We report accuracy on the remaining 20% for PL05, on the standard test split for Twitter (25%) and News (50%) and from 5-fold cross-validation for the other datasets (Amazon, PL04 and MPQA). We only report accuracy as the macro-average F1-scores led to similar conclusions (and except for Twitter and News, the class label distributions are balanced). Results for phrase lengths longer than two were omitted since they were marginally different at best. Statistical significance of improvement over the bigram baseline with the same phrase definition was assessed using the micro sign test ($p < 0.01$) (Yang and Liu, 1999).

[1] https://code.google.com/p/word2vec

Table 1: Accuracy results on the test set for PL05 (20%), standard test split for Twitter (25%) and News (50%) and from 5-fold CV for the other datasets (Amazon, PL04 and MPQA). Bold font marks the best performance in the column. * indicates statistical significance at $p < 0.01$ using micro sign test against the bigram baseline (delta word kernel) of the same column and with the same phrase definition.

4.3 Results

Table 1 presents results from our convolutional sentence kernel and the baseline approaches. Note again that a delta word kernel leads to the typical unigram and bigram baseline approaches (first three rows). The 3rd row corresponds to DTK (Culotta and Sorensen, 2004) and the 4th one to VTK (Srivastava et al., 2013) – the difference with our model on the 9th row lies in the function $\phi(\cdot)$ that enumerates all random walks in the dependency tree representation following Gärtner et al. (2003) whereas we only consider the downward paths.

Overall, we obtained better results than the n-gram baselines, DTK and VTK, especially with syntactic phrases. VTK shows good performance across all datasets but its computation was more than 700% slower than with our kernel. Regarding the phrase kernels, PK generally produced better results than CK, implying that the semantic linearity and ontological relation encoded in the embedding is not sufficient enough and treating them separately is more beneficial. However, we believe CK has more room for improvement with the use of more accurate phrase embeddings such as the ones from Le and Mikolov (2014), Yin and Schütze (2014) and Yu and Dredze (2015).

There was little contribution to the accuracy from non-unigram features, indicating that large part of the performance improvement is credited to the word embedding resolving the sparsity issue.

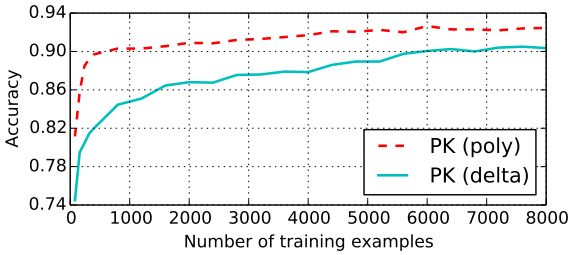

Figure 2: Test accuracy vs. number of training examples for our kernel and the bigram baseline.

This can be well observed with the following experiment on the number of training examples. Figure 2 shows the accuracy on the same test set (20% of the dataset) when the learning was done on 1% to 100% of the training set (80% of the dataset) for the bigram baseline and our bigram PK phrase kernel, both with dependency tree representation, on PL04. We see that our kernel starts to plateau earlier in the learning curve than the baseline and also reaches the maximum baseline accuracy with only about 1,500 training examples.

4.4 Computational complexity

Solving the SVM in the primal for the baselines requires $\mathcal{O}(NnL)$ time where N is the number of training documents, n is the number of words in the document and L is the maximum phrase length considered. The computation of VTK reduces down to power series computation of the

adjacency matrix of the product graph, and since we require kernel values between all documents, it requires $\mathcal{O}(N^2(n^2d + n^4L))$ time where d is the dimension of the word embedding space.

Our kernel is the sum of phrase kernels (PhK) starting from every pair of nodes between two sentences, for all phrase lengths (l) and distortions (λ_2) under consideration. By storing intermediate values of composite vectors, a phrase kernel can be computed in $\mathcal{O}(d)$ time regardless of the phrase length, therefore the whole computation process has $\mathcal{O}(N^2n^2L^2d)$ complexity. Although our kernel has the squared terms of the baseline's complexity, we are tackling the sparsity issue that arises with short text (small n) or when little training data is available (small N). Moreover, we were able to get better results with only bigrams (small L). Hence, the loss in efficiency is acceptable considering significant gains in effectiveness.

5 Conclusion

In this paper, we proposed a novel convolutional sentence kernel based on word embeddings that overcomes the sparsity issue, which arises when classifying short documents or when little training data is available. We described a general framework that can encompass the standard n-gram baseline approach as well as more relaxed versions with smoother word and phrase kernels. It achieved significant improvements over the baselines across all datasets when taking into account the additional information from the latent word similarity (word embeddings) and the syntactic structure (dependency tree).

Future work might involve designing new kernels for syntactic parse trees with appropriate similarity measures between non-terminal nodes as well as exploring recently proposed phrase embeddings for more accurate phrase kernels.

Abstract

Cooking recipes exist in abundance; but due to their unstructured text format, they are hard to study quantitatively beyond treating them as simple bags of words. In this paper, we propose an ingredient-instruction dependency tree data structure to represent recipes. The proposed representation allows for more refined comparison of recipes and recipe-parts, and is a step towards semantic representation of recipes. Furthermore, we build a parser that maps recipes into the proposed representation. The parser's edge prediction accuracy of 93.5% improves over a strong baseline of 85.7% (54.5% error reduction).

1 Introduction

Cooking recipes are a specific genre of how-to instructions which have been gaining interest in recent years as they may allow us to discover insights into culinary and cultural preferences. Most of the work studying recipes relies on simple ingredient bag-of-word representations. While such representations may suffice for many purposes, they fail to capture much of the recipes' internal structure. A smaller number of efforts focus on semantic representations of cooking recipes with an eye toward more complex and deep understanding. Natural language processing (NLP) techniques have been used to interpret cooking instructions; however, the results have not been as successful as other language genres due to the unique aspects of cooking recipes.

This paper makes two contributions. First, we propose an ingredient-instruction dependency tree representation of recipe structure. This representation abstracts textual recipes more expressively than bag-of-word representations; and it allows for more nuanced comparisons of recipes. Second, we present a cooking recipe parser that maps text recipes into our proposed ingredient-instruction tree structures. The overall accuracy of predicting edges of our ingredient-instruction trees is 93.5%, beating a strong baseline of 85.7%, and achieving a relative error reduction of 54.5%.

We present next some related work (Section 2) followed by a discussion of the structure of recipes and our representation (Section 3). Section 4 details the recipe parser design, implementation and evaluation.

2 Related Work

There have been many efforts on the processing of cooking recipes using models that range from bags of words to complex semantic representations.

Among the approaches to studying recipes as ingredient bags of words, Ahn et al. (2011) constructed a data-driven flavor network relating ingredients together. Jain et al. (2015) adopted Ahn et al. (2011)'s framework to further analyze culinary practices of specific cultures. Nedovic (2013) examined underlying ingredient groupings from their recipe co-occurrences, using topic modeling techniques (latent Dirichlet allocation), and further improvised novel ingredient combinations using deep belief networks.

Among the structured representation approaches, Tasse and Smith (2008) proposed MILK (Minimal Instruction Language for the Kitchen), a formal language to describe actions required in directive cooking instructions. They used MILK in developing CURD (Carnegie Mellon University Recipe Database), a corpus of manually annotated recipes. Mori et al. (2014) also manually annotated the procedural flow of Japanese cooking recipes using directed acyclic graphs (DAGs) where graph nodes correspond to food ingredients, cooking instruments, and actions. Tasse and Smith (2008) had limited success in parsing into MILK; and Mori et al. (2014) did not report on parsing experiments.

Other studies explored different machine learning and NLP techniques to processing recipes.

Lisbon, Portugal, 17-21 September 2015.

Text Recipe	
ingredients	
0	6 (2 inch thick) slices French bread
1	1/4 cup ricotta cheese
2	1/4 cup cottage cheese, whipped
3	2 tablespoons lowfat cream cheese
4	2 teaspoons white sugar
5	2 teaspoons vanilla extract
6	3 cups egg substitute
7	1/4 cup evaporated milk
instructions	
0	Cut a pocket in each slice of bread.
1	Open carefully
2	In a large bowl, combine the ricotta, cottage cheese and cream cheese.
3	Add the sugar and flavoring extract and beat until smooth.
4	Spread the mixture evenly into each bread pocket.
5	Beat together the egg substitutes and milk.
6	Dip the slices of bread in the egg mixture.
7	Heat a nonstick pan over medium-high heat.
8	Coat with cooking spray.
9	Cook the toast on each side for about 3 to 4 minutes per side until golden brown.

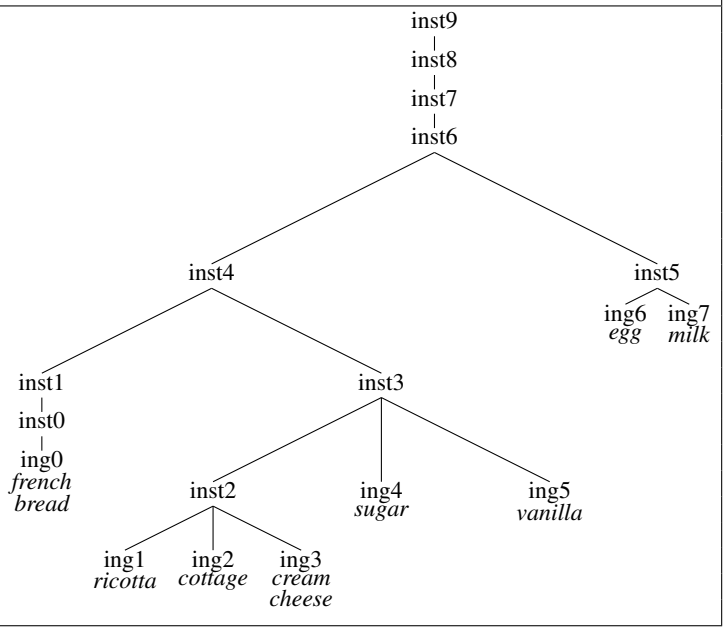

Figure 1: Example of a text recipe for *Surprise-inside French Toast* and its SIMMR representation. **ing**<*index*> and **inst**<*index*> refer to specific ingredients and instructions, respectively.

Mori et al. (2012) applied word segmentation, named entity recognition, and syntactic analysis to extract predicate-argument structures from Japanese recipe instructions as part of an effort to develop complete recipe flow representations. Malmaud et al. (2014) proposed a Markov Decision Process, in which the context of ingredients and tools is propagated along the temporal order of cooking instructions.

Most recently, Abend et al. (2015) proposed an *edge-factored* model to determine the likely temporal order of events based solely on the identity of their predicates and arguments. They demonstrated their approach on recipe text, under the simplifying assumption that such text is also temporally ordered.

In this paper, we present an ingredient-instruction dependency tree representation of recipe structure, which we call SIMMR (Simplified Ingredient Merging Map in Recipes). The SIMMR representation captures the high-level flow of ingredients but without modeling the semantics in each individual instruction unlike other efforts (Tasse and Smith, 2008; Mori et al., 2012; Mori et al., 2014). We create a corpus in our representation by converting the recipes in the CURD corpus (Tasse and Smith, 2008) from MILK to SIMMR. We also develop a parser to generate SIMMR trees from input recipes.

3 Recipe Representation

3.1 Text Recipes

The prototypical text recipe consists of two parts: an ingredient list that declares the food items to process, and a set of instructions that mostly describe the transformations of the ingredients or the actions using the kitchen tools. The instructions relocate, process, combine, and separate ingredients, as well as heat or cool utensils in the recipes. For the most part, the output produced from one instruction feeds as input into another instruction. The list of ingredients can be generalized as special *fetch* instructions whose output feeds as input to one of the cooking instructions.

3.2 SIMMR

Our proposed representation is SIMMR: Simplified Ingredient Merging Map in Recipes. SIMMR represents a recipe as a dependency tree whose leaves (terminal nodes) are the recipe ingredients, and whose internal nodes are the recipe instructions. Figure 1 exemplifies the SIMMR tree of a recipe for *Surprise-inside French Toast*. Indices for all ingredients and instructions are provided here to illustrate mapping between the different parts of the text recipe and its SIMMR tree. The subtree headed by *inst2* indicates that ingredients #1, #2 and #3 (three cheeses) are inputs to instruction #2, whose output is then an input to instruc-

tion #3, together with ingredients #4 and #5 (sugar and vanilla). The SIMMR tree provides additional insights into the structure of recipes, suggesting in the case of this example, that multiple actions can take place in different orders without changing the recipe so long as the order of combinations is not changed. Some instructions simply transforms their input to produce their output, e.g. instructions #1, #7, #8 and #9.

3.3 From MILK to SIMMR

We use MILK commands from the CMU CURD database (Tasse and Smith, 2008) to construct a database of SIMMR trees. The MILK language is a lot more expressive that SIMMR. For example, instruction #2 in Figure 1 translates into create_tool(t0, "large bowl"); combine(ing1, ing2, ing3, ing9, "cheeses", ""); and put(ing9, t0). These details of ingredient processing are abstracted away in SIMMR. To accomplish SIMMR instruction and ingredient linking, we process MILK instructions in order, tracing with MILK id numbers when each ingredient or its transformed or combined form at one instruction node is called for by a subsequent instruction node. The MILK intermediate names for instruction outputs (e.g., "cheeses" above) are not adopted in SIMMR. Additionally, food items that appear in instructions but are not part of the recipe ingredient list text are not included in SIMMR although MILK assigns ingredient ids to them. For example, instruction #8 mentions *cooking spray*, which is not on the ingredient list. As a result *inst8* looks like it has no ingredients coming into it other than the output of *inst7*.

We assume in SIMMR that at most one output is produced from each instruction. One MILK command, *separate*, violates this assumption. For example, the instruction *drain off the fat, and place the mixture into a slow cooker* is MILK-tagged with a *separate* command to dispose fat, and retain the mixture. We ignore the *separate* command which occurs in 3% of all recipes (and 1.3% of the time involves disposing of a separated ingredient, such as *draining off fat*).

Instructions that do not interact with food, such as those calling for preheating the oven or lining the baking sheets, are considered to take the ingredient mixture of the cooking instruction immediately prior and produce the *same* output.

4 Recipe Parser

In this section, we present our SIMMR tree recipe parser. The input and output of the parser correspond to the left hand and right hand sides of Figure 1. We split the parsing process into two phases: first we link ingredients to instructions where the ingredients are first used; then we link instructions to other instructions, where the target instruction uses the source instruction's output. We present the different challenges and solutions employed in each phase below and present evaluation results.

4.1 Experimental Setup

4.1.1 Data

We use a total of 260 recipes downloaded from CMU Recipe Database. MILK tags are used to construct the SIMMR trees as mentioned above. The dataset is randomly split (along recipe boundaries) into training, development, and test sets with ratios of 50%, 20%, and 30%, respectively. The development set is used for tuning parameters. We report here on the test set only. We preprocess the data using standard NLP packages to tokenize, stem, and POS tag the words (De Marneffe et al., 2006; Bird et al., 2009; De Smedt and Daelemans, 2012). We further remove stop words and quantity measures.[1]

4.1.2 Metrics

The evaluation metric is the accuracy of predicting edges in the SIMMR tree. This is comparable to the *attachment score* in dependency parsing. The overall accuracy of the task is computed at the edge level (counting all edges in the data set), and at the recipe level (average accuracy over all recipes).

4.2 Ingredient-Instruction Linking

4.2.1 Challenges

There are several characteristics of recipe text that do not reveal explicit linking of ingredients to instructions that first use them. The ingredients are sometimes referred to by their qualifiers or ontological classes. For example, the ingredient *1 (15 oz) can sliced peaches, drained* may be referred to in the instruction as *canned fruit*. In addition,

[1] Since we start from the MILK representations, the set of ingredients and instructions are clearly identified in each recipe. However, we do not expect this to be the case when starting from raw text recipes, which need to be processed to segment the different ingredients and instructions. We do not attempt this step in this paper and leave it as future work.

	Edge-level Accuracy	Recipe-level Accuracy
Baseline	84.3	84.8
SVMrank	**95.3**	**95.8**

Table 1: Performance of different learning models for ingredient-instruction linking

a number of ingredients are sometimes referred to as a group entity without specific mentions, e.g., *Add the remaining ingredients*, or *mix together the dry ingredients*.

4.2.2 Baseline

For each instruction, in order, we compute all the maximum *stemmed* n-gram chunk matches against all ingredients. For each matching token chunk of the instruction, if it matches only one ingredient, we link the ingredient to the instruction and mark the ingredient as used. Otherwise, we compute the Levenshtein distance between the *unstemmed* surface text of both the ingredient candidate matches and the instruction token chunk, and take the highest matching ingredient. Once an ingredient is used, it is no longer available for linking with subsequent instructions.

4.2.3 Features and Linking

For each ingredient-instruction edge, we provide 1,136 features to classify whether the edge exists or not. The following are some of the most important features we use:

- The baseline decision for the ingredient-instruction edge.
- The number of distinct unigram matches.
- The largest match size.
- The sum of the relative frequency (in the list of instructions) of every word in the largest match (henceforth SRFM).
- The degree of similarity between SRFM and the instruction relative position (InstRP) in the instruction list. The intuition for this feature is that if an ingredient is mentioned more often in the recipe, its first mention is likely to be in an earlier instruction. This feature is computed as $(1 - |SRFM - InstRP|)$.
- The degree of similarity between the ingredient relative position (IngRP) in the ingredient list and the InstRP. This feature captures an observation that earlier listed ingredients are used by earlier instructions. We compute the feature as $(1 - |IngRP - InstRP|)$.
- To model the first word of each instruction (i.e., the directive verb such as *heat* or *mix*), we use a binary term vector whose vocabulary is constructed from all the instruction first words in the training data.
- We model the maximum ingredient-instruction word match using a binary term vector whose vocabulary covers *non-directive recipe words* (NDRW). We construct the NDRW vocabulary by taking the union of the set of words from the compiled food item list of Ahn et al. (2011) and the non-first words of the instructions in the training data.
- If there is a match, we model its surrounding words using a similar binary term vector (NDRW vocabulary). If there is no match, the vector will be empty.
- We use a binary term vector (NDRW vocabulary also) to model the non-first words in the instruction.

We train using Linear SVMrank (Joachims, 2006).[2] The test set results are shown in Table 1. Ranking edges using SVMrank and then picking the best one significantly outperforms the baseline.

4.2.4 Linking Errors

Among the linking errors, three patterns appear. First, stemming reduces the specificity of some of the terms, e.g., one prediction links *baking powder* to an action *bake for 30 minutes*. Second, our approach does not handle negated mentions, e.g. the instruction *mix together the dry ingredients,* **except** *the candies* is incorrectly linked to ingredient *candy*. Finally, the ingredients *flour* and *butter* are specifically part of many erroneous links because they are often used in small quantities to facilitate the cooking process such as board flouring and pan greasing. MILK does not always account for this trivial use of these ingredients and neither does SIMMR.

4.3 Instruction-Instruction Linking

4.3.1 Challenges

Although cooking instructions are written with an implied temporal order, they are not linked in a linear chain. Rather, the instructions describe different cooking *stages*, where the output of apply-

[2] We also experimented Linear SVM and Gaussian Kernel SVM (Pedregosa et al., 2011). We used the distance from the hyperplane to select the best edge among the set of edges connecting an ingredient. However, these techniques underperformed compared to SVMrank.

ing a number of instructions waits until other instructions are finished to be used again, e.g., the output of *instruction #1* in Figure 1 waits until instructions #2 and #3 are done. Sometimes stage switching is explicitly stated as in *Set aside the flour mixture, and combine eggs and oil together*; however, this is not the common case. Furthermore, the waiting output of an earlier stage may be referred to collectively or using the main ingredient which makes linking harder, e.g., referring to the output of an instruction combining *chicken, salt and pepper* as *chicken*.

4.3.2 Baseline

We link the instructions in a linear chain. In the training set, 89% of the instruction-instruction links are to the immediate neighbor.

4.3.3 Features and Linking

For each possible instruction-instruction edge, we provide 1,573 features to classify if the edge exists or not. The features group into three categories.

First are words that suggest cooking stage switching, e.g., ingredient mixture words such as *mixture*, *dough*, and *batter*, or the simple mention of new containers and utensils. They are represented as binary features indicating whether the words appear in either or both instructions along the considered edge, as well as in immediate neighboring instructions. Logic operations (and, or) are further applied to all pairs of these features. Another feature in this group is a binary verb conjugation feature that marks the presence of a past participle verb in the target instruction and a non-past-participle form of the same verb in the source instruction. The intuition here is that an instruction that asks to *chop* an ingredient would be followed later by an instruction containing the word *chopped* when referring to the ingredient.

The second group consists of features that encode whether the n previous or future instructions has m linked ingredients, where n ranges from 1 to 3 and m ranges from 0 to 4.

Finally, the third group deals with term vectors describing the source and target instructions, as well as, the instructions' first words (the directives). The term vector vocabularies used are the same as those discussed above in the ingredient-instruction linking section.

We additionally consider decoupling the features for the case of immediate neighboring instructions from the *further* apart instructions. In the decoupled mode, we effectively double the number of features for each edge with *nil*s used to fill in the gaps. This allows us to learn different models for adjacent and apart instructions. The results are in Table 2 and show that decoupling features in SVMrank is our best setting.

	Edge-level Accuracy	Recipe-level Accuracy
Baseline	87.6	89.5
SVMrank	90.5	92.0
SVMrank - decoupled	**91.3**	**92.4**

Table 2: Performance of different learning models for *instruction*-instruction linking

Examining the weights learned for adjacent and long-distance edge features gives some interesting insights. One example is that the verb conjugation feature has a higher weight for long-distance edges compared to adjacent edges. This is understandable as most adjacent pairs of instructions would not exhibit this feature to express cooking progress: it is redundant to state, *cook the pasta*, and immediately refer to that pasta as the *cooked pasta*.

4.3.4 Linking Errors

As the distance between linked instructions increases, the likelihood of error also increases: while long-distance (i.e., non-adjacent) links constitute 12.3% of the reference, they are 91.7% of the errors. We expect that more training examples of long-distance linking can help address this issue.

4.4 Overall Accuracy

The overall edge-level accuracy of constructing the **full** SIMMR tree is 93.5%, outperforming a baseline of 85.7%, and achieving error reduction of 54.5%.

5 Conclusions and Future Work

We proposed a new ingredient-instruction dependency tree representation to capture the internal structure of cooking recipes, and built a parser for it. Our overall parsing accuracy is 93.5%, outperforming a strong baseline of 85.7%.

We will make our SIMMR database, and our SIMMR parser publicly available. Further, we plan to build on SIMMR to get closer to the MILK representation. We also plan on parsing a large corpus of text recipes to provide structural features on a large scale that will allow us to discover new patterns of similarity across and within cuisines, as well as generate new recipes.

Abstract

Dirichlet process mixture model (DPMM) has great potential for detecting the underlying structure of data. Extensive studies have applied it for text clustering in terms of topics. However, due to the unsupervised nature, the topic clusters are always less satisfactory. Considering that people often have some prior knowledge about which potential topics should exist in given data, we aim to incorporate such knowledge into the DPMM to improve text clustering. We propose a novel model TSDPMM based on a new seeded Pólya urn scheme. Experimental results on document clustering across three datasets demonstrate our proposed TSDPMM significantly outperforms state-of-the-art DPMM model and can be applied in a lifelong learning framework.

1 Introduction

Dirichlet process mixture model (DPMM) (Neal, 2000) has been used in detecting the underlying structure in data. For example, (Vlachos et al., 2008; Vlachos et al., 2009) applied it to lexical-semantic verb clustering. (Wang et al., 2011; Huang et al., 2013; Yin and Wang, 2014) applied it for text clustering in terms of their topics. While DPMM achieved some promising results, it can still sometimes produce unsatisfactory topic clusters due to its unsupervised nature.

On the other hand, people often have prior knowledge about what potential topics should exist in a given text corpus. Take an earthquake event corpus as an example. The topics, such as "*casualties and damages*", "*rescue*" and "*government reaction*", called prior topics, are expected to occur in the corpus according to our common knowledge (e.g., the topics automatically learned from previous events using topic modeling (Ahmed and Xing, 2008)) or external resources (e.g., table of contents at Wikipedia event pages [1]). Similarly, in academic fields, "call for papers (CFP)" of conferences [2] lists main topics that conference organizers would like to focus on. Clearly, these prior topics can be represented as sets of words, which are available in many real-world applications. They can serve as weakly supervised information to enhance the unsupervised DPMM for text clustering.

Standard DPMM (Neal, 2000; Ranganathan, 2006) lacks a mechanism for incorporating prior knowledge. Some existing work (Vlachos et al., 2008; Vlachos et al., 2009) added knowledge of observed *instance*-level constraints (*must-links* and *cannot-links* between documents) to DPMM. (Ahmed and Xing, 2008) proposed recurrent Chinese Restaurant Process to incorporate *previous* documents with known topic clusters. We focus on incorporating *topic*-level knowledge, which is more challenging, as seed/prior topics could be latent rather than observable.

Particularly, we construct our novel TSDPMM (Topic Seeded DPMM) based on a principled seeded Pólya urn (sPU) scheme. Our model inherits the nonparametric property of DPMM and has additional technical merits. Importantly, our model is encouraged but not forced to find evidences of seed topics. Therefore, it has freedom to discover new topics beyond prior topics, as well as to detect which prior topics are not covered by current data. It is thus convenient to observe topic variations between prior topics and newly mined topics. Experimental results on document clustering across three corpora demonstrate that our model effectively incorporates prior topics, and significantly outperforms state-of-the-art DPMM model. Particularly, our TSDPMM can be applied in a lifelong learning framework which enables the prior

topic knowledge to evolve as more and more data are observed.

2 Topic Seeded DPMM

In this section, we first introduce the standard DPMM model for document clustering in terms of topics. Then we describe how to incorporate seed/prior topics into the model using a seeded Pólya urn (sPU) scheme, which gives us our novel TSDPMM model (Topic Seeded DPMM). Finally, we present the model inference.

2.1 DPMM

The DPMM (Antoniak, 1974) as a non-parametric model assumes the given data is governed by an infinite number of components where only a fraction of these components are activated by the data. Figure 1 illustrates the DPMM graphical model and its generative process of a document x_i. First, we sample a topic $\theta_i = \{\theta_{ij}\}_{j=1}^{j=|V|}$ (a multinomial distribution over words belonging to the vocabulary V) for the document x_i according to a Dirichlet Process (DP) $G \sim DP(\alpha, G_0)$, where $\alpha > 0$ is a concentration parameter and the base measure $G_0 = Dir(\vec{\beta})$ can be considered as a prior distribution for θ. Consider the document x_i as a bag of words, given the topic θ_i, the generative distribution F is a given likelihood function parameterized by θ. We define F as $p(x_i|\theta_i) = \prod_{j=1}^{|x_i|} p(x_{ij}|\theta_i)$, where x_{ij} is the j_{th} word in x_i. Note that the DPMM assumes each document can be assigned to one topic cluster only.

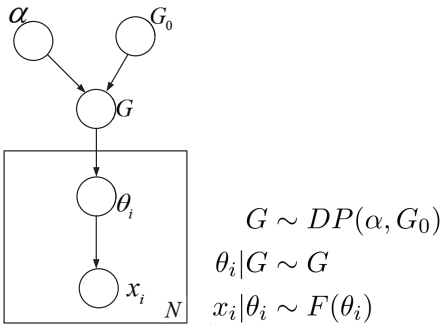

Figure 1: Graphical Representation of DPMM.

The DP process of DPMM, according to which topic θ_i for a document x_i is drawn, can be explained by the popular metaphor of Pólya urn (PU) scheme (Blackwell and MacQueen, 1973), equivalent to the Chinese Restaurant Process (Ahmed and Xing, 2008). The PU scheme works on balls (documents) and colors (topics). It starts with an empty urn. With probability proportional to α, we draw $\theta_i \sim G_0$, and add a ball of this color to the urn. With probability proportional to $i-1$ (i.e., the current number of balls in the urn), we draw a ball at random from the urn, observe its color θ_i and replace the ball with two balls of the same color. In this way, we draw topic θ_i for document x_i. As shown in the process, the prior probability of assigning a document to a topic is proportional to the number of documents already assigned to the topic. As a result, the DPMM exhibits the "rich get richer" property.

2.2 TSDPMM: Incorporating Seed Topics

In this section, we describe our proposed algorithm to incorporate prior seed topics into the DPMM. A prior/seed topic k is represented by a vector $\vec{N}_k^{(0)}$ (word frequencies under the topic). We can obtain the prior topics represented by $\vec{N}_k^{(0)}$ from past learning of topic models or external resources such as Wikipedia and "CFP". Assuming we have $K^{(0)}$ prior topics, we use the parameter $\vec{\alpha}^{(0)} = \{\alpha_k^{(0)}\}_{k=1}^{K^{(0)}}$ to control our confidence about how likely each prior topic exists. Let us go back to Pólya urn (PU) scheme, where a prior topic can be taken as a known color. We extend the PU scheme to incorporate prior topics, which gives the **sPU** (seeded Pólya Urn) scheme. The sPU scheme can be described as follows:

- We start with an urn with $\alpha_k^{(0)}$ balls of each known color $k \in \{1, ..., K^{(0)}\}$.
- With a probability proportional to α, we draw $\theta_i \sim G_0$ and add a ball of this color to the urn.
- With probability proportional to $i - 1 + \sum_{k=1}^{K^{(0)}} \alpha_k^{(0)}$, we draw a random ball from the urn, and replace the ball with two balls of the same color.

As shown in the above process, instead of starting with an empty urn in DPMM, we assume that the urn already has certain balls of known colors. In this way, we incorporate the prior seed topics. The number of initial balls (documents) $\alpha_k^{(0)}$ controls how likely the topic k exists. We can use different values of $\alpha_k^{(0)}$ for prior topics with different confidence levels. This sPU scheme gives our novel model TSDPMM (Topic Seeded DPMM) incorporating prior topics. The TSDPMM has

similar graphical representation as DPMM (Figure 1), except the introduction of hyper-parameter $\vec{\alpha}^{(0)}$. We then present a collapsed gibbs sampling algorithm for model inference as follows.

TSDPMM Inference. The model inference is described in detail in Algorithm 1. It first initializes all documents with random topic clusters. Then it iteratively updates the topic cluster assignments of documents according to the conditional probabilities (Eq.1) until convergence. Eq.1 can be derived as:

$$p(z_i|\vec{Z}_{-i},\vec{X}) \propto p(z_i|\vec{Z}_{-i},\alpha,\vec{\alpha}^{(0)})p(x_i|\vec{X}_{-i},\vec{Z},\vec{\beta}) \quad (1)$$

where z_i is the topic assignment of observation x_i, $\vec{X}$ is the given document corpus, and $\vec{Z}_{-i}$ are $\vec{X}_{-i}$ are the set of topic assignments and the corpus excluding the i_{th} observation x_i, respectively.

Algorithm 1: Collapsed Gibbs Sampling

Input: Document dataset $\vec{X} = \{x_i\}_{i=1}^{m}$, prior topics $\{\vec{N}_k^{(0)}\}_{k=1}^{K^{(0)}}$, parameter $\vec{\alpha}^{(0)}$

Output: Topic assignments $\vec{Z}$ of all documents

Initialize the topic assignments $\vec{Z}$ based on prior topics randomly;

repeat

  Select a document $x_i \in \vec{X}$ randomly

  Fix the other topic assignments $\vec{Z}_{-i}$

  Assign a new value to z_i:$z_i \sim p(z_i|\vec{Z}_{-i},\vec{X})$(Eq. 1)

until *Convergence*;

In Eq.1, the first item $p(z_i{=}k|\vec{Z}_{-i},\alpha,\vec{\alpha}^{(0)})$ denotes a prior probability of $z_i{=}k$, which is proportional to the number of documents already assigned to it. If k is a **prior** topic, it is proportional to $n_{k,-i} + \alpha_k^{(0)}$, where $n_{k,-i}$ is the number of documents of topic k excluding the current document x_i. If k is an **existing** (not prior) topic, it is proportional to $n_{k,-i}$. If k is a **new** topic, the probability is proportional to α. The second item $p(x_i|\vec{X}_{-i},\vec{Z}_{-i},z_i = k,\vec{\beta})$ is the likelihood of x_i given $\vec{X}_{-i}$, $\vec{Z}_{-i}$ and $z_i{=}k$. They can be derived as $p(x_i|\vec{X}_{-i},\vec{Z}_{-i},z_i = k,\vec{\beta}) \propto \frac{p(\vec{X}|\vec{Z},\vec{\beta})}{p(\vec{X}_{-i}|\vec{Z}_{-i},\vec{\beta})}$ where $p(\vec{X}|\vec{Z},\vec{\beta}) = \int p(\vec{X}|\vec{Z},\Theta)p(\Theta|\vec{\beta})d\Theta$. As $p(\Theta|\vec{\beta})$ is a Dirichlet distribution and $p(\vec{X}|\vec{Z},\Theta)$ is a multinomial distribution, we can get $p(\vec{X}|\vec{Z}){=}\prod_{k=1}^{K}\frac{\Delta(\vec{N}_k+\vec{\beta})}{\Delta(\vec{\beta})}$, where $\vec{N}_k = \{N_{k,w}\}_{w=1}^{V}$ and $N_{k,w}$ is the number of occurrences of word w in the k_{th} topic. Here, we adopt the function Δ in (Heinrich, 2009), and we have $\Delta(\vec{\beta}) = \frac{\prod_{w=1}^{V}\Gamma(\beta)}{\Gamma(\sum_{w=1}^{V})\beta}$ and $\Delta(\vec{N}_k+\vec{\beta}) = \frac{\prod_{w=1}^{V}\Gamma(N_{k,w}+\beta)}{\Gamma(\sum_{w=1}^{V}(N_{k,w}+\beta))}$. Finally, we can derive:

$$p(z_i = k|\vec{Z}_{-i},\vec{X}) \propto \begin{cases} (n_{k,-i}+\alpha^{(0)})\cdot\frac{\Delta(\vec{N}_{.,i}+\vec{N}_{k,-i}+\vec{N}_k^{(0)}+\vec{\beta})}{\Delta(\vec{N}_{k,-i}+\vec{N}_k^{(0)}+\vec{\beta})} & \text{prior} \\ n_{k,-i}\cdot\frac{\Delta(\vec{N}_{.,i}+\vec{N}_{k,-i}+\vec{\beta})}{\Delta(\vec{N}_{k,-i}+\vec{\beta})} & \text{existing} \\ \alpha\cdot\frac{\Delta(\vec{N}_{.,i}+\vec{\beta})}{\Delta(\vec{\beta})} & \text{new}, \end{cases}$$

where $\vec{N}_{k,-i}$ is a vector with the word counts for all the documents assigned to topic k excluding x_i, $\vec{N}_{.,i}$ and $\vec{N}_k^{(0)}$ are vectors with word counts in document x_i and in all the documents assigned to k in prior knowledge respectively. According to this equation, documents are likely to go into clusters which are bigger and give higher likelihood of the documents. When the Gibbs sampler converges, we obtain topic cluster assignments of all the documents. Different from DPMM inference process in which topics are removed when no documents is assigned to them, TSDPMM inference can retain prior topics all the time due to the initial number of documents $\vec{\alpha}^{(0)}$, making it able to track prior topics, as well as to detect new topics.

3 Experiments

We evaluate our proposed TSDPMM model for document clustering on 3 datasets where each cluster corresponds to a topic. We implement both DPMM and TSDPMM models — their source codes are available at `https://github.com/newsminer/DPMM_and_TSDPMM`.

3.1 Datasets

We collect machine learning conference NIPS datasets composed of paper titles and abstracts from 2012 to 2014 – each year includes 342, 360 and 411 documents respectively. They are named as NIPS-12, NIPS-13 and NIPS-14.

We also employ the standard *benchmark* news datasets, including 20 Newsgroups [3] and Reuters-21578. As news is often timely reported, we choose three continuous days with the largest number of documents in 20 Newsgroups (i.e. 11, 12 and 13 May) and Reuters-21578 (i.e. 3, 4 and 5 March) for our experiments. These datasets are

[3] http://people.csail.mit.edu/jrennie/20Newsgroups/

denoted as 20N-1, 20N-2, 20N-3 (including 103, 96, 106 documents) and Reu-1, Reu-2, Reu-3 (including 282, 249, 207 documents), respectively.

For all the datasets, we conduct the following preprocessing: (1) Convert letters into lowercase; (2) Remove non-Latin characters and stop words; (3) Remove words with *document frequency* < 2.

3.2 Experimental Setup

We take the standard DPMM as our baseline method and compare it with our proposed TSDPMM model using *different* prior knowledge obtained with different manners.

For NIPS datasets, we use two kinds of prior knowledge: one is the topics learned by DPMM from *previous* year's dataset; the other one is from an *external* resource "CFP" [4] (10 topics, same for each year). We name them as TSDPMM-P and TSDPMM-E respectively. As the topic descriptions in "CFP" are sparse, we repeat each topic description by ten times and then represent a topic with the words with word frequencies in its description text.

For both 20 Newsgroups and Reuters datasets, we use prior knowledge learned by DPMM from the previous day's dataset. Furthermore, to test if we can improve the results *continuously* by applying TSDPMM, every time when we model a new dataset, we incorporate prior topics learned by TSDPMM from previous day's dataset, similar to lifelong learning (Chen and Liu, 2014; Thrun, 1998). We call this model as TSDPMM-L.

Parameter Setting. Following a previous work (Vlachos et al., 2009), we set the hyper-parameters α=1, $\vec{\alpha}^{(0)}$=$\{1.0\}$, $\vec{\beta}$ =$\{1.0\}$. We run Gibbs sampler for 100 iterations and stop the iteration once the log-likelihood of the training data converges.

Evaluation. The widely used NMI (normalized mutual information) measure (Dom, 2002), has been employed to evaluate document clustering results. The higher a value of NMI, the better a clustering result is. However, NMI needs true class labels for documents, and can only be applied to our benchmark news datasets. For NIPS datasets without true labels, we use the measure of *perplexity*, as defined in (Blei et al., 2003), to test per-word likelihood of the datasets. The lower the perplexity, the better a model fits the data.

[4] https://nips.cc/Conferences/2014/CallForPapers

3.3 Results

Table 1 shows the average perplexity values of five runs of 3 models on NIPS datasets. It shows that both TSDPMM-P and TSDPMM-E, leveraging prior topics from previous learning and "CFP" significantly outperform DPMM. In addition, TSDPMM-E achieves lower performance than TSDPMM-P due to its lower quality of prior topics directly obtained from "CFP", compared to higher quality topics from past learning. We may improve "CFP" knowledge by extending it with related texts from search engines or Wikipedia using keywords in "CFP" in future work.

An insight of our clustering results on NIPS-14 dataset suggests that most prior topics in 2013 are covered again in 2014 (consistent topics), except a few missing topics such as "*lasso for Bayesian networks*". Additionally, some newly evolved topics in 2014, e.g. "*monte carlo particle filtering*" and "*nash games*", are successfully discovered by our proposed model.

Models	NIPS-12	NIPS-13	NIPS-14
DPMM	321.7	317.1	362.9
TSDPMM-P	**290.1**	**298.7**	**346.8**
TSDPMM-E	307.5	315.6	360.1

Table 1: Average perplexity of different models on NIPS.

Table 2 illustrates the average NMI values of five runs of DPMM, TSDPMM and TSDPMM-L on news datasets. The results show that TSDPMM using prior topics learnt by DPMM outperforms DPMM (on average **+5.8%**; p <0.025 with *t-test*). Additionally, TSDPMM-L, which continuously uses prior topics learnt by TSDPMM from previous dataset, further outperforms TSDPMM (on average **+3.2%**; p <0.025 with *t-test*). Note TSDPMM-L uses TSDPMM results of 20N-1 and Reu-1 as prior knowledge for the first time, so there are no TSDPMM-L results for the first days in Table 2 for 20N-1 and Reu-1 respectively.

3.4 Discussion

The experimental results across 3 datasets have demonstrated that our proposed models can improve DPMM model by incorporating prior topic knowledge, and the higher-quality knowledge will lead to better results. By applying our TSDPMM in a lifelong continuous learning framework, namely TSDPMM-L, can further improve

Models	20N-1	20N-2	20N-3	Reu-1	Reu-2	Reus-3
DPMM	0.610	0.537	0.590	0.509	0.647	0.653
TSDPMM	0.645	0.610	0.681	0.648	0.654	0.655
TSDPMM-L	—	**0.681**	**0.697**	—	**0.689**	**0.656**

Table 2: Average NMI of different models on news datasets.

text clustering due to the better prior topic knowledge obtained in the evolving environment.

4 Related Work

Our work is related to papers (Vlachos et al., 2008; Vlachos et al., 2009), which added supervision (*instance*-level must-links or cannot-links between documents) to the DPMM. (Ahmed and Xing, 2008) proposed recurrent Chinese Restaurant Process to incorporate previous documents with known topic clusters. However, our work is very different as we focus on how to incorporate latent *topic*-level prior knowledge. We model prior topics as known colors that have a certain probability proportional to $\alpha_k^{(0)}$ to be assigned to a document. In addition, our inference mechanism subsequently takes the prior knowledge into consideration for automatically assigning topics to documents.

Some existing studies such as (Ramage et al., 2009; Andrzejewski et al., 2009; Jagarlamudi et al., 2012; Andrzejewski et al., 2011) worked on incorporating prior lexical or domain knowledge into LDA. Different from all these work, we focus on the nonparametric model DPMM and propose to incorporate the prior topic knowledge obtained in multiple ways.

5 Conclusion

In this paper, we propose a novel problem of incorporating prior topics into DPMM model and address it through a simple yet principled seeded Pólya urn scheme. We show that the topic knowledge can be obtained in multiple ways. Experiments on document clustering across 3 datasets demonstrate our proposed model can effectively incorporate the prior topic knowledge and significantly enhance the standard DPMM for text clustering. In future work, we will study how to discover overlapping clusters, i.e., allowing one document to be grouped into multiple topic clusters. We will also explore how to incorporate prior knowledge about topic relations (such as causation and correlation) into topic modeling.

Abstract

Recently, neural network based sentence modeling methods have achieved great progress. Among these methods, the recursive neural networks (RecNNs) can effectively model the combination of the words in sentence. However, RecNNs need a given external topological structure, like syntactic tree. In this paper, we propose a gated recursive neural network (GRNN) to model sentences, which employs a full binary tree (FBT) structure to control the combinations in recursive structure. By introducing two kinds of gates, our model can better model the complicated combinations of features. Experiments on three text classification datasets show the effectiveness of our model.

1 Introduction

Recently, neural network based sentence modeling approaches have been increasingly focused on for their ability to minimize the efforts in feature engineering, such as Neural Bag-of-Words (NBoW), Recurrent Neural Network (RNN) (Mikolov et al., 2010), Recursive Neural Network (RecNN) (Pollack, 1990; Socher et al., 2013b; Socher et al., 2012) and Convolutional Neural Network (CNN) (Kalchbrenner et al., 2014; Hu et al., 2014).

Among these methods, recursive neural networks (RecNNs) have shown their excellent abilities to model the word combinations in sentence. However, RecNNs require a pre-defined topological structure, like parse tree, to encode sentence, which limits the scope of its application. Cho et al. (2014) proposed the gated recursive convolutional neural network (grConv) by utilizing the directed acyclic graph (DAG) structure instead of parse tree to model sentences. However, DAG structure is relatively complicated. The number of the hidden neurons quadraticly increases with the length of sentences so that grConv cannot effectively deal with long sentences.

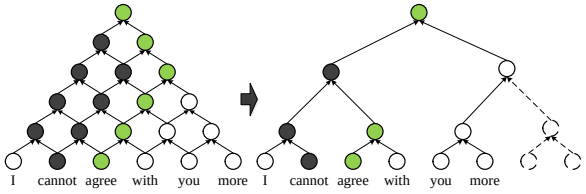

Figure 1: Example of Gated Recursive Neural Networks (GRNNs). Left is a GRNN using a directed acyclic graph (DAG) structure. Right is a GRNN using a full binary tree (FBT) structure. (The green nodes, gray nodes and white nodes illustrate the positive, negative and neutral sentiments respectively.)

Inspired by grConv, we propose a gated recursive neural network (GRNN) for sentence modeling. Different with grConv, we use the full binary tree (FBT) as the topological structure to recursively model the word combinations, as shown in Figure 1. The number of the hidden neurons linearly increases with the length of sentences. Another difference is that we introduce two kinds of gates, reset and update gates (Chung et al., 2014), to control the combinations in recursive structure. With these two gating mechanisms, our model can better model the complicated combinations of features and capture the long dependency interactions.

In our previous works, we have investigated several different topological structures (tree and directed acyclic graph) to recursively model the semantic composition from the bottom layer to the top layer, and applied them on Chinese word segmentation (Chen et al., 2015a) and dependency parsing (Chen et al., 2015b) tasks. However, these structures are not suitable for modeling sentences.

Lisbon, Portugal, 17-21 September 2015.

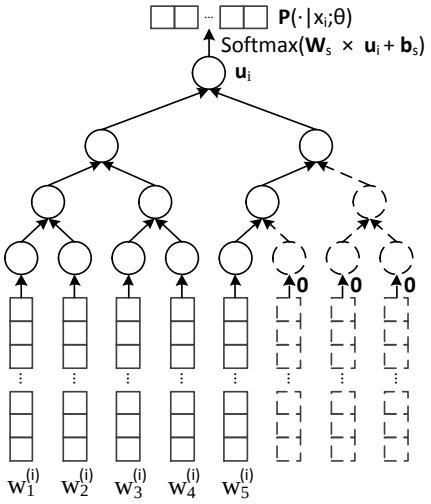

Figure 2: Architecture of Gated Recursive Neural Network (GRNN).

In this paper, we adopt the full binary tree as the topological structure to reduce the model complexity.

Experiments on the Stanford Sentiment Treebank dataset (Socher et al., 2013b) and the TREC questions dataset (Li and Roth, 2002) show the effectiveness of our approach.

2 Gated Recursive Neural Network

2.1 Architecture

The recursive neural network (RecNN) need a topological structure to model a sentence, such as a syntactic tree. In this paper, we use a full binary tree (FBT), as showing in Figure 2, to model the combinations of features for a given sentence.

In fact, the FBT structure can model the combinations of features by continuously mixing the information from the bottom layer to the top layer. Each neuron can be regarded as a complicated feature composition of its governed sub-sentence. When the children nodes combine into their parent node, the combination information of two children nodes is also merged and preserved by their parent node. As shown in Figure 2, we put all-zero padding vectors after the last word of the sentence until the length of $2^{\lceil log_2^n \rceil}$, where n is the length of the given sentence.

Inspired by the success of the gate mechanism of Chung et al. (2014), we further propose a gated recursive neural network (GRNN) by introducing two kinds of gates, namely "reset gate" and "update gate". Specifically, there are two reset gates, $\mathbf{r}_L$ and $\mathbf{r}_R$, partially reading the information from

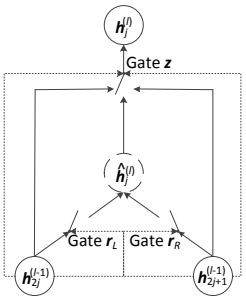

Figure 3: Our proposed gated recursive unit.

left child and right child respectively. And the update gates $\mathbf{z}_N$, $\mathbf{z}_L$ and $\mathbf{z}_R$ decide what to preserve when combining the children's information. Intuitively, these gates seem to decide how to update and exploit the combination information.

In the case of text classification, for each given sentence $x_i = w^{(i)}_{1:N(i)}$ and the corresponding class y_i, we first represent each word $w^{(i)}_j$ into its corresponding embedding $\mathbf{w}_{w^{(i)}_j} \in \mathbb{R}^d$, where $N(i)$ indicates the length of i-th sentence and d is dimensionality of word embeddings. Then, the embeddings are sent to the first layer of GRNN as inputs, whose outputs are recursively applied to upper layers until it outputs a single fixed-length vector. Next, we receive the class distribution $\mathrm{P}(\cdot|x_i;\theta)$ for the given sentence x_i by a softmax transformation of $\mathbf{u}_i$, where $\mathbf{u}_i$ is the top node of the network (a fixed length vectorial representation):

$$\mathrm{P}(\cdot|x_i;\theta) = \mathrm{softmax}(\mathbf{W}_s \times \mathbf{u}_i + \mathbf{b}_s), \qquad (1)$$

where $\mathbf{b}_s \in \mathbb{R}^{|T|}$, $\mathbf{W}_s \in \mathbb{R}^{|T| \times d}$. d is the dimensionality of the top node $\mathbf{u}_i$, which is same with the word embedding size and T represents the set of possible classes. θ represents the parameter set.

2.2 Gated Recursive Unit

GRNN consists of the minimal structures, gated recursive units, as showing in Figure 3.

By assuming that the length of sentence is n, we will have recursion layer $l \in [1, \lceil log_2^n \rceil + 1]$, where symbol $\lceil q \rceil$ indicates the minimal integer $q^* \geq q$. At each recursion layer l, the activation of the j-th ($j \in [0, 2^{\lceil log_2^n \rceil - l}$)) hidden node $\mathbf{h}^{(l)}_j \in \mathbb{R}^d$ is computed as

$$\mathbf{h}^{(l)}_j = \begin{cases} \mathbf{z}_N \odot \hat{\mathbf{h}}^l_j + \mathbf{z}_L \odot \mathbf{h}^{l-1}_{2j} + \mathbf{z}_R \odot \mathbf{h}^{l-1}_{2j+1}, & l > 1, \\ \text{corresponding word embedding}, & l = 1, \end{cases} \qquad (2)$$

where $\mathbf{z}_N$, $\mathbf{z}_L$ and $\mathbf{z}_R \in \mathbb{R}^d$ are update gates for new activation $\hat{\mathbf{h}}_j^l$, left child node $\mathbf{h}_{2j}^{l-1}$ and right child node $\mathbf{h}_{2j+1}^{l-1}$ respectively, and $\odot$ indicates element-wise multiplication.

The update gates can be formalized as:

$$\mathbf{z} = \begin{bmatrix} \mathbf{z}_N \\ \mathbf{z}_L \\ \mathbf{z}_R \end{bmatrix} = \begin{bmatrix} 1/Z \\ 1/Z \\ 1/Z \end{bmatrix} \odot \exp(\mathbf{U} \begin{bmatrix} \hat{\mathbf{h}}_j^l \\ \mathbf{h}_{2j}^{l-1} \\ \mathbf{h}_{2j+1}^{l-1} \end{bmatrix}), \quad (3)$$

where $\mathbf{U} \in \mathbb{R}^{3d \times 3d}$ is the coefficient of update gates, and $Z \in \mathbb{R}^d$ is the vector of the normalization coefficients,

$$Z_k = \sum_{i=1}^{3} [\exp(\mathbf{U} \begin{bmatrix} \hat{\mathbf{h}}_j^l \\ \mathbf{h}_{2j}^{l-1} \\ \mathbf{h}_{2j+1}^{l-1} \end{bmatrix})]_{d \times (i-1)+k}, \quad (4)$$

where $1 \leq k \leq d$.

The new activation $\hat{\mathbf{h}}_j^l$ is computed as:

$$\hat{\mathbf{h}}_j^l = \tanh(\mathbf{W}_{\hat{\mathbf{h}}} \begin{bmatrix} \mathbf{r}_L \odot \mathbf{h}_{2j}^{l-1} \\ \mathbf{r}_R \odot \mathbf{h}_{2j+1}^{l-1} \end{bmatrix}), \quad (5)$$

where $\mathbf{W}_{\hat{\mathbf{h}}} \in \mathbb{R}^{d \times 2d}$, $\mathbf{r}_L \in \mathbb{R}^d$, $\mathbf{r}_R \in \mathbb{R}^d$. $\mathbf{r}_L$ and $\mathbf{r}_R$ are the reset gates for left child node $\mathbf{h}_{2j}^{l-1}$ and right child node $\mathbf{h}_{2j+1}^{l-1}$ respectively, which can be formalized as:

$$\begin{bmatrix} \mathbf{r}_L \\ \mathbf{r}_R \end{bmatrix} = \sigma(\mathbf{G} \begin{bmatrix} \mathbf{h}_{2j}^{l-1} \\ \mathbf{h}_{2j+1}^{l-1} \end{bmatrix}), \quad (6)$$

where $\mathbf{G} \in \mathbb{R}^{2d \times 2d}$ is the coefficient of two reset gates and σ indicates the sigmoid function.

Intuiativly, the reset gates control how to select the output information of the left and right children, which result to the current new activation $\hat{\mathbf{h}}$. By the update gates, the activation of a parent neuron can be regarded as a choice among the the current new activation $\hat{\mathbf{h}}$, the left child, and the right child. This choice allows the overall structure to change adaptively with respect to the inputs.

This gate mechanism is effective to model the combinations of features.

2.3 Training

We use the Maximum Likelihood (ML) criterion to train our model. Given training set (x_i, y_i) and the parameter set of our model θ, the goal is to minimize the loss function:

$$J(\theta) = -\frac{1}{m} \sum_{i=1}^{m} \log \mathrm{P}(y_i|x_i;\theta) + \frac{\lambda}{2m}\|\theta\|_2^2, \quad (7)$$

Initial learning rate	$\alpha = 0.3$
Regularization	$\lambda = 10^{-4}$
Dropout rate on input layer	$p = 20\%$

Table 1: Hyper-parameter settings.

where m is number of training sentences.

Following (Socher et al., 2013a), we use the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatchs to minimize the objective.

For parameter initialization, we use random initialization within (-0.01, 0.01) for all parameters except the word embeddings. We adopt the pre-trained English word embeddings from (Collobert et al., 2011) and fine-tune them during training.

3 Experiments

3.1 Datasets

To evaluate our approach, we test our model on three datasets:

- **SST-1** The movie reviews with five classes in the Stanford Sentiment Treebank[1] (Socher et al., 2013b): negative, somewhat negative, neutral, somewhat positive, positive.

- **SST-2** The movie reviews with binary classes in the Stanford Sentiment Treebank[1] (Socher et al., 2013b): negative, positive.

- **QC** The TREC questions dataset[2] (Li and Roth, 2002) involves six different question types.

3.2 Hyper-parameters

Table 1 lists the hyper-parameters of our model. In this paper, we also exploit dropout strategy (Srivastava et al., 2014) to avoid overfitting. In addition, we set the batch size to 20. We set word embedding size $d = 50$ on the TREC dataset and $d = 100$ on the Stanford Sentiment Treebank dataset.

3.3 Experiment Results

Table 2: Performances of the different models. The result of PV is from our own implementation based on Gensim.

Competitor Models Neural Bag-of-Words (NBOW) model is a simple and intuitive method which ignores the word order. Paragraph Vector (PV) (Le and Mikolov, 2014) learns continuous distributed vector representations for pieces of texts, which can be regarded as a long term memory of sentences as opposed to short memory in recurrent neural network. Here, we use the popular open source implementation of PV in Gensim[1]. Methods in the third block are CNN based models. Kim (2014) reports 4 different CNN models using max-over-time pooling, where CNN-non-static and CNN-multichannel are more sophisticated. MaxTDNN sentence model is based on the architecture of the Time-Delay Neural Network (TDNN) (Waibel et al., 1989; Collobert and Weston, 2008). Dynamic convolutional neural network (DCNN) (Kalchbrenner et al., 2014) uses the dynamic k-max pooling operator as a non-linear sub-sampling function, in which the choice of k depends on the length of given sentence. Methods in the fourth block are RecNN based models. Recursive Neural Tensor Network (RecNTN) (Socher et al., 2013b) is an extension of plain RecNN, which also depends on a external syntactic structure. Recursive Autoencoder (RAE) (Socher et al., 2011) learns the representations of sentences by minimizing the reconstruction error. Matrix-Vector Recursive Neural Network (MV-RecNN) (Socher et al., 2012) is a extension of RecNN by assigning a vector and a matrix to every node in the parse tree. AdaSent (Zhao et al., 2015) adopts recursive neural network using DAG structure.

[1] https://github.com/piskvorky/gensim/

Moreover, the plain GRNN which does not incorporate the gate mechanism cannot outperform the GRNN model. Theoretically, the plain GRNN can be regarded as a special case of GRNN, whose parameters are constrained or truncated. As a result, GRNN is a more powerful model which outperforms the plain GRNN. Thus, we mainly focus on the GRNN model in this paper.

Result Discussion Generally, our model is better than the previous recursive neural network based models (RecNTN, RAE, MV-RecNN and AdaSent), which indicates our model can better model the combinations of features with the FBT and our gating mechanism, even without an external syntactic tree.

Although we just use the top layer outputs as the feature for classification, our model still outperforms AdaSent.

Compared with the CNN based methods (MaxTDNN, DCNN and CNNs), our model achieves the comparable performances with much fewer parameters. Although CNN based methods outperform our model on SST-1 and SST-2, the number of parameters[2] of GRNN ranges from 40K to 160K while the number of parameters is about 400K in CNN.

4 Related Work

Cho et al. (2014) proposed grConv to model sentences for machine translation. Unlike our model, grConv uses the DAG structure as the topological structure to model sentences. The number of the

[2] We only take parameters of network into account, leaving out word embeddings.

internal nodes is $n^2/2$, where n is the length of the sentence. Zhao et al. (2015) uses the same structure to model sentences (called AdaSent), and utilizes the information of internal nodes to model sentences for text classification. Unlike grConv and AdaSent, our model uses full binary tree as the topological structure. The number of the internal nodes is $2n$ in our model. Therefore, our model is more efficient for long sentences. In addition, we just use the top layer neurons for text classification.

Moreover, grConv and AdaSent only exploit one gating mechanism (update gate), which cannot sufficiently model the complicated feature combinations. Unlike them, our model incorporates two kind of gates and can better model the feature combinations.

Hu et al. (2014) also proposed a similar architecture for matching problems, but they employed the convolutional neural network which might be coarse in modeling the feature combinations.

5 Conclusion

In this paper, we propose a gated recursive neural network (GRNN) to recursively summarize the meaning of sentence. GRNN uses full binary tree as the recursive topological structure instead of an external syntactic tree. In addition, we introduce two kinds of gates to model the complicated combinations of features. In future work, we would like to investigate the other gating mechanisms for better modeling the feature combinations.

Abstract

This paper addresses text categorization problem that training data may derive from a different time period from the test data. We present a learning framework which extends a boosting technique to learn accurate model for timeline adaptation. The results showed that the method was comparable to the current state-of-the-art biased-SVM method, especially the method is effective when the creation time period of the test data differs greatly from the training data.

1 Introduction

Text categorization supports and improves several tasks such as creating digital libraries, information retrieval, and even helping users to interact with search engines (Mourao et al., 2008). A growing number of machine learning (ML) techniques have been applied to the text categorization task (Xue et al., 2008; Gopal and Yang, 2010). Each document is represented using a vector of features/terms (Yang and Pedersen, 1997; Hassan et al., 2007). Then, the documents with category label are used to train classifiers. Once category models are trained, each test document is classified by using these models. A basic assumption in the categorization task is that the distributions of terms between training and test documents are identical. When the assumption does not hold, the classification accuracy is worse. However, it is often the case that the term distribution in the training data is different from that of the test data when the training data may drive from a different time period from the test data. Manual annotation of tagged new data is very expensive and time-consuming. The methodology for accurate classification of the new test data by making the maximum use of tagged old data is needed in learning techniques.

In this paper, we present a method for text categorization that minimizes the impact of temporal effects. Our approach extends a boosting technique to learn accurate model for timeline adaptation. We used two types of labeled training data: One is the same creation time period with the test data. Another is different creation time period with the test data. We call the former *same-period* training, and the latter *diff-period* training data. For the same-period training data, the learner shows the same behavior as the boosting. In contrast, for diff-period training data, once they are wrongly predicted by the learned model, these data would be useless to classify test data. We decreased the weights of these data by applying Gaussian function in order to weaken their impacts.

2 Related Work

The analysis of temporal aspects is a practical problem as well as the process of large-scale heterogeneous data since the World-Wide Web (WWW) is widely used by various sorts of people. It is widely studied in many text processing tasks. One attempt is concept or topic drift dealing with temporal effects (Klinkenberg and Joachims, 2000; Kleinberg, 2002; Lazarescu et al., 2004; Folino et al., 2007; Song et al., 2014). Wang *et al*. developed the continuous time dynamic topic model (cDTM) (Wang et al., 2008). He *et al*. proposed a method to find bursts, periods of elevated occurrence of events as a dynamic phenomenon instead of focusing on arrival rates (He and Parker, 2010). They used Moving Average Convergence/Divergence (MACD) histogram which was used in technical stock market analysis (Murphy, 1999) to detect bursts.

Another attempt is domain adaptation. The goal of this attempt is to develop learning algorithms that can be easily ported from one domain to another (Daumé III, 2007; Sparinnapakorn and Ku-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 799–804,
Lisbon, Portugal, 17-21 September 2015.

bat, 2007; Glorot et al., 2011; Siao and Guo, 2013). Domain adaptation is particularly interesting in Natural Language Processing (NLP) because it is often the case that we have a collection of labeled data in one domain but truly desire a model that can work well for another domain. Lots of studies addressed domain adaptation in NLP tasks such as part-of-speech tagging (Siao and Guo, 2013), named-entity (Daumé III, 2007), and sentiment classification (Glorot et al., 2011) are presented. One approach to domain adaptation is to use transfer learning. The transfer learning is a learning technique that retains and applies the knowledge learned in one or more tasks to efficiently develop an effective hypothesis for a new task. The earliest discussion is done by ML community in a NIPS-95 workshop[1], and more recently, transfer learning techniques have been successfully applied in many applications. Blitzer *et al*. proposed a method for sentiment classification using structural correspondence learning that makes use of the unlabeled data from the target domain to extract some relevant features that may reduce the difference between the domains (Blitzer et al., 2006). Several authors have attempted to learn classifiers across domains using transfer learning in the text classification task (Raina et al., 2006; Dai et al., 2007; Sparinnapakorn and Kubat, 2007). Raina *et al*. proposed a transfer learning algorithm that constructs an informative Bayesian prior for a given text classification task (Raina et al., 2006). They reported that a 20 to 40% test error reduction over a commonly used prior in the binary text classification task. Dai *et al*. presented a method called TrAdaBoost which extends boosting-based learning algorithms (Dai et al., 2007). Their experimental results show that TrAdaBoost allows knowledge to be effectively transferred from the old data to the new one. All of these approaches aimed at utilizing a small amount of newly labeled data to leverage the old data to construct a high-quality classification model for the new data. However, the temporal effects are not explicitly incorporated into their models.

To our knowledge, there have been only a few previous work on temporal-based text categorization. Mourao *et al*. investigated the impact of temporal evolution of document collections on the document classification (Mourao et al., 2008). Salles *et al*. presented an approach to classify documents in scenarios where the method uses information about both the past and the future, and this information may change over time (Salles et al., 2010). They address the drawbacks of which instances to select by approximating the Temporal Weighting Function (TWF) using a mixture of two Gaussians. However, their method needs tagged training data across full temporal range of training documents to construct TWF.

There are three novel aspects in our method. Firstly, we propose a method for text categorization that minimizes the impact of temporal effects in a learning technique. Secondly, from manual annotation of data perspective, the method allows users to annotate only a limited number of newly training data. Finally, from the perspective of robustness, the method is automated, and can be applied easily to a new domain, or different languages, given sufficient old labeled documents.

3 Learning Timeline Difference

Our learning model, Timeline Adaptation by Boosting (TABoost) is based on AdaBoost (Freund and Schapire, 1997). AdaBoost aims to boost the accuracy of a weak learner by adjusting the weights of training instances and learn a classifier accordingly. The TABoost uses two types of training data, same-period and diff-period training data. The assumption is that the quantity of the same-period data is limited, while diff-period training data is abundant. The TABoost aims at utilizing the diff-period training data to make up the deficit of a small amount of the same-period to construct a high-quality classification model for the test data. Similar to the TrAdaBoost presented by (Dai et al., 2007), TABoost is the same behavior as boosting for the same-period training data. In contrast, once diff-period training instances are wrongly predicted, we assume that these instances do not contribute to the accurate test data classification, and the weights of these instances decrease in order to weaken their impacts. The difference between TrAdaBoost and TABoost is a weighting manner, *i.e.* TABoost is a continuous timeline model, and it weights these instances by applying Gaussian function in order to weaken their impacts. TABoost is illustrated in Figure 1.

The training data set Tr is partitioned into two labeled sets Tr_{dp}, and Tr_{sp}. Tr_{dp} in Figure 1

[1] http://socrates.acadiau.ca/courses/comp/dsilver/NIPS95_LTL/transfer.workshop.1995.html.

Input {
The diff-period data Tr_{dp}, the same-period data Tr_{sp}, and the maximum number of iterations N.
}

Output {
$h_f(x) = \sum_{t=1}^{N} \alpha_t h_t(x_i)$.
}

Initialization {
$\mathbf{w^1} = (w_1^1, \cdots, w_{n+m}^1)$.
}

TABoost {
For $t = 1, \cdots, N$
1. Set $\mathbf{P^t} = \mathbf{w^t} / (\sum_{k=1}^{n+m} w_i^t)$.
2. Train a weak learner on the combined training set Tr_{dp} and Tr_{sp} with the distribution $\mathbf{P^t}$, and create weak hypothesis h_t: $X \rightarrow \{-1, +1\}$
3. Calculate the error of h_t on the combined training set Tr_{dp} and Tr_{sp}:
$$\epsilon_t = \sum_{i=1}^{n+m} \frac{w_i^t \cdot |h_t(x_i) - c(x_i)|}{\sum_{i=1}^{n+m} w_i^t}.$$
4. Chose $\alpha_t = \frac{1}{2}\mathrm{ln}(\frac{1-\epsilon_t}{\epsilon_t})$
5. Update the new weight vector:

$$w_i^{t+1} = \begin{cases} w_i^t \exp^{F(\delta)\alpha_t |h_t(x_i) - c(x_i)|}, \\ \qquad 1 \leq i \leq n \\ w_i^t \exp^{-\alpha_t |h_t(x_i) - c(x_i)|}, \\ \qquad n+1 \leq i \leq n+m \end{cases}$$

}

Figure 1: Flow of the algorithm

shows the diff-period training data that $Tr_{dp} = \{(x_i^{dp}, c(x_i^{dp}))\}$, where $x_i^{dp} \in X_{dp}$ ($i = 1, \cdots, n$), and X_{dp} refers to the diff-period instance space. Similarly, Tr_{sp} represents the same-period training data that $Tr_{sp} = \{(x_i^{sp}, c(x_i^{sp}))\}$, where $x_i^{sp} \in X_{sp}$ ($i = 1, \cdots, m$), and X_{sp} refers to the same-period instance space. n and m are the number of documents in Tr_{dp} and Tr_{sp}, respectively. $c(x_i)$ returns a label for the input instance x_i. The combined training set $Tr = \{(x_i, c(x_i))\}$ is given by:

$$x_i = \begin{cases} x_i^{dp} & i = 1, \cdots, n \\ x_i^{sp} & i = n+1, \cdots, n+m \end{cases}$$

In each iteration round shown in Figure 1, if a diff-period training instance is wrongly predicted, the instance may be useless to classify test data correctly. We decrease its training weight to reduce the effect. To do this, we assume a standard lognormal distribution (Crow, 1988), *i.e.* $F(\delta) = \frac{1}{\sqrt{2\pi}}\exp(-\frac{\delta^2}{2})$. δ in $F(\delta)$ represents time difference between diff-period training and test data. For instance, if the training data is 1999, and test data is 2000, δ equals to 1. Similarly, if the training data is 2000, and test data is 1999, δ is -1. The greater the time difference value, the smaller the training weight. We fit the model according to the temporal range of the data. As shown in Figure 1, we decrease its training weight w_i^t to reduce its effect through multiplying its weight by $\exp^{F(\delta)\alpha_t |h_t(x_i) - c(x_i)|}$.

We used the Support Vector Machines (SVM) as a learner. We represented each training and test document as a vector, each dimension of a vector is a noun word appeared in the document, and each element of the dimension is a term frequency. We applied the algorithm shown in Figure 1. After several iterations, a learner model is created by linearly combining weak learners, and a test document is classified by using a learner.

4 Experiments

We evaluated our TABoost by using the Mainichi Japanese newspaper documents.

4.1 Experimental setup

We choose the Mainichi Japanese newspaper corpus from 1991 to 2012. The corpus consists of 2,883,623 documents organized into 16 categories. We selected 8 categories, "International(Int)", "Economy(Eco)", "Home", "Culture", "Reading", "Arts", "Sports", and "Local news(Local)", each of which has sufficient number of documents. All documents were tagged by using a morphological analyzer Chasen (Matsumoto et al., 2000) and selected noun words. The total number of documents assigned to these categories are 787,518. For each category within each year, we divided documents into three folds: 2% of documents are used as the same-period training data, 50% of documents are the diff-period training data, and the remains are used to test our classification method.[2]

[2]When the creation time period of the training data is the same as the test data, we used only the same-period training data.

Table 1: The error rates across categories

Cat	TAB_s	SVM	TrAdaB	b-SVM	TAB
Int	0.409	0.467	0.326	0.253	**0.329**
Eco	0.368	0.429	0.243	0.228	**0.208**

M-Avg	0.411	0.514	0.307	0.334	**0.257**

We used LIBLINEAR (Fan et al., 2008) as a basic learner in the experiments. We compared our method, TABoost with four baselines: (1) TABoost with the same-period training data only (TAB_s), (2) SVM, (3) TrAdaBoost (Dai et al., 2007), and (4) biased-SVM (Liu et al., 2003) by SVM-light (Joachims, 1998). TAB_s is the same behavior as boosting. TrAdaBoost (TrAdaB) is presented by (Dai et al., 2007). Biased-SVM (b-SVM) is known as the state-of-the-art SVMs method, and often used for comparison (Elkan and Noto, 2008). Similar to SVM, for biased-SVM, we used the first two folds as a training data, and classified test documents directly, *i.e.* we used closed data. We empirically selected values of two parameters, "c" (trade-off between training error and margin) and "j", *i.e.* cost (cost-factor, by which training errors on positive instances) that optimized result obtained by classification of test documents. Similar to (Liu et al., 2003), "c" is searched in steps of 0.02 from 0.01 to 0.61. "j" is searched in steps of 5 from 1 to 200. As a result, we set c and j to 0.01 and 10, respectively. To make comparisons fair, all five methods including our method are based on linear kernel. Throughout the experiments, the number of iterations is set to 100. We used error rate as an evaluation measure (Dai et al., 2007).

4.2 Results

Categorization results for 8 categories (48% of the test documents, *i.e.* 378,008 documents) are shown in Table 1. Each value in Table 1 shows macro-averaged error rate across 22 years. "M-Avg" refers to macro-averaged error rate across categories. The results obtained by biased-SVM show minimum error rate obtained by varying the parameters, "c" and "j".

As can be seen clearly from Table 1, the overall

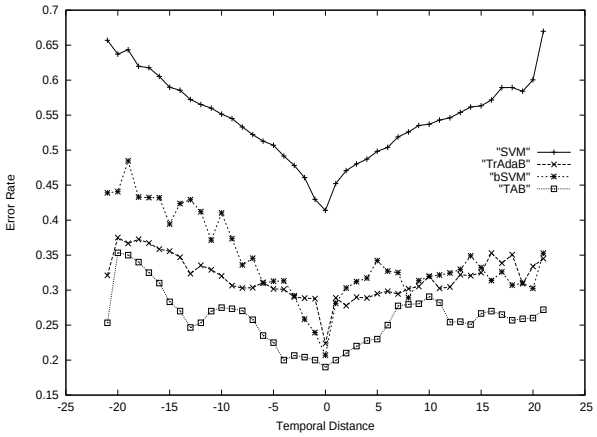

Figure 2: Performance against temporal distance

performance obtained by TAB was the best among the five methods. The macro average error rates with TrAdaB and TAB were lower to those obtained by b-SVM, although b-SVM in Table 1 was the result obtained by using the closed data. In contrast, SVM did not work well. This demonstrates that once the training data drive from a different time period from the test data, the distributions of terms between training and test documents are not identical. The results obtained by TAB_s were worse than those obtained by TrAdaBoost, b-SVM, and TAB. This shows that (i) the same-period training data we used is not sufficient to train a model alone, and (ii) TAB demonstrates a good transfer ability.

Figure 2 illustrates error rate against the temporal difference between diff-period training and test data. Both training and test data are the documents from 1991 to 2012. For instance, "10" of the x-axis in Figure 2 indicates that the test documents are created 10 years later than the training documents. We can see from Figure 2 that the result obtained by TAB was the best in all of the temporal distances. There are no significant differences among three methods, bSVM, TrAdaB, and TAB when the test and training data are the same time period. The performance of these methods including SVM drops when the creation time of the test data differs greatly from the diff-period training data. However, the performance of TAB was still better to those obtained by other methods. This demonstrates that the algorithm with continuous timeline model works well for categorization.

Figure 3 shows the error rate against the number of iterations. Each curve shows averaged error rate under time period between same-period and diff-

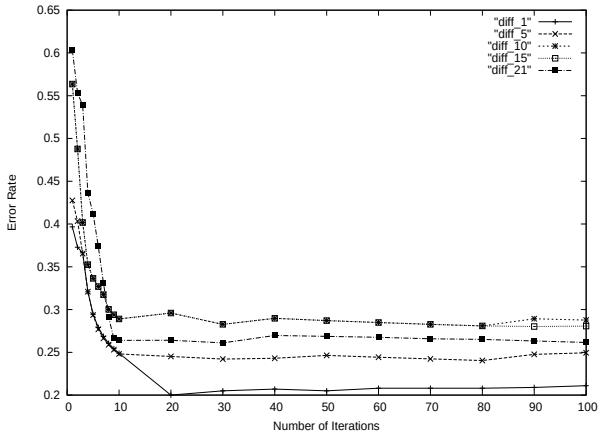

Figure 3: Iteration curves by temporal distance

period training data. For example, "diff_10" indicates that the difference time period between same and diff training data is $\pm$ 10 years. We can see from Figure 3 that all curves except for "diff_20" drop rapidly and converge around 10 iterations. "diff_20" converges around 20 iterations. This was the same behaviour as TrAdaBoost, *i.e.* TrAdaBoost converges around 20 iterations. The fast convergence is not particularly surprising because we used a small number of same-period (2%) and a large number of diff-period (50%) training data. It is necessary to examine how the ratio between same-period and diff-period training data affects overall performance for further quantitative evaluation, although a main contribution of TAB is in situations using by both of a small amount of labeled new data which is not sufficient to train a model alone, and a large amount of old data.

5 Conclusion

We have presented a method for text categorizaiton that minimizes the impact of temporal effects. The results using Japanese Mainichi Newspaper corpus show that it works well for categorization, especially when the creation time of the test data differs greatly from the training data. There are a number of interesting directions for future work. The rate of convergence of TAB ($O(\sqrt{\mathrm{In}n/N})$) is slow which can also be found in (Dai et al., 2007). Here, n is the number of training data, and N is the number of iterations. In the future, we will try to extend the framework to address this issue. We used Japanese newspaper documents in the experiments. For quantitative evaluation, we need to apply our mehtod to other data such as ACM-DL and a large, heterogeneous collection of web content in addition to the experiment to examine the performance agasint the ratio between same-period and diff-period training data.

Abstract

Improving the search and browsing experience in PubMed® is a key component in helping users detect information of interest. In particular, when exploring a novel field, it is important to provide a comprehensive view for a specific subject. One solution for providing this panoramic picture is to find sub-topics from a set of documents. We propose a method that finds sub-topics that we refer to as themes and computes representative titles based on a set of documents in each theme. The method combines a thematic clustering algorithm and the Pool Adjacent Violators algorithm to induce significant themes. Then, for each theme, a title is computed using PubMed document titles and theme-dependent term scores. We tested our system on five disease sets from OMIM® and evaluated the results based on normalized point-wise mutual information and MeSH® terms. For both performance measures, the proposed approach outperformed LDA. The quality of theme titles were also evaluated by comparing them with manually created titles.

1 Introduction

PubMed[1], currently a collection of about 25 million bibliographic records, has grown exponentially in size. With the abundance and diversity of information in PubMed many queries retrieve thousands of documents making it difficult for users to browse the results and identify the information most relevant to their topic of interest. The query 'cystic fibrosis', for example, retrieves papers that discuss different aspects of the disease, including its clinical features, treatment options, diagnosis, etc. A possible solution to this problem is to automatically group the retrieved documents into meaningful thematic clusters or themes (these terms are used interchangeably). However, clustering alone does not solve the problem entirely, as a significant amount of human post-processing is required to infer the topic of the cluster.

There exists a vast collection of probabilistic clustering methods. One common problem among most of them is that different results are obtained depending on the cluster initialization, suggesting that some clusters are unstable or weak. However, there is no obvious way to effectively and efficiently evaluate the quality of clusters. In this paper, we combine EM-based thematic clustering (Kim and Wilbur, 2012) with the Pool Adjacent Violators (PAV) algorithm (Ayer et al., 1955; Wilbur et al., 2005). PAV is an isotonic regression algorithm which we use as a method for converting a score into a probability. Here, we show how PAV can be applied to evaluate the quality of clusters.

Another issue that motivated this research is that most existing algorithms produce clusters that are not self-descriptive. Presenting meaningful titles can significantly improve the user perception of clustering results. To that end, we utilize PubMed document titles and cluster-related term scores to automatically obtain a title for each theme. The method results in thematic clusters of documents with cluster titles.

Studies similar to our approach are ASI (Adaptive Subspace Iteration) (Li et al., 2004) and SKWIC (Simultaneous Keyword Identification and Clustering of text documents) (Frigui and Nasraoui, 2004). Both perform document clustering and cluster-dependent keyword identification simultaneously. SKWIC can only produce hard clustering, while ASI is computationally very expensive as it heavily depends on matrix operations. A study by Hammouda et al. (2005) sug-

[1] http://pubmed.gov

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 805–810,
Lisbon, Portugal, 17-21 September 2015.

gests automatic keyphrase extraction from a cluster of documents as a surrogate to providing a cluster title, but they treat document clustering and cluster-dependent keyword extraction as separate problems.

Topic modeling (Hofmann, 1999; Blei et al., 2003; Blei and Lafferty, 2005) is the most popular and an alternative approach that has a similar underlying goal of discovering hidden thematic structure of a document collection and organizing the collection according to the discovered topics. Topic models are based upon the idea that documents are mixtures of topics, where a topic is a probability distribution over words (Steyvers and Griffiths, 2007). However, topic modeling is not a document clustering scheme in nature. Although a list of keywords that represent a topic is available, the title of the cluster may not be evident.

2 Methods

We here describe the EM-based clustering algorithm, and show how PAV is incorporated with it to yield the PAV-EM thematic clustering technique. We further present a cluster summarization method to induce theme titles.

2.1 Theme definition

Let D be a document set and let T be the set of terms in D. Let R denote the relation between elements of T and D. tRd means $t \in d$. We define a theme as a subject that is described by non-empty sets $U \subseteq T$ and $V \subseteq D$, where all the elements of U have a high probability of occurring in all the element of V. An EM framework is used to extract subject terms for a theme (Wilbur, 2002). In addition to the observed data R, a theme is defined by the latent indicator variables z_d, $\{z_d\}_{d \in D}$. The parameters are

$$\Theta = U(\|U\| = n_U), \{p_t, q_t\}_{t \in U}, \{r_t\}_{t \in T}, \quad (1)$$

where n_U is the size of the set U. For any $t \in U$, p_t is the probability that for any $d \in V$, tRd. q_t is the probability that for any $d \in D - V$, tRd. For any $t \in T$, r_t is the probability that for any $d \in D$, tRd. Assuming all relations tRd are independent of each other, the goal is to obtain the highest probabilities

$$p(R, \{z_d\}|\Theta) = p(R|\{z_d\}, \Theta)p(\{z_d\}|\Theta). \quad (2)$$

E-step (expectation step) evaluates the expectation of the logarithm of Eqn. 2. M-step (maximization step) maximizes this expectation over the parameters Θ. For each term, t, we define a quantity α_t which is the difference between the contribution coming from t depending on whether $u_t = 1$ or $u_t = 0$. The maximization is completed by choosing the n_U largest α_t's and setting $u_t = 1$ for each of them and $u_t = 0$ for all others. Details of this theme extraction scheme can be found in Wilbur (2002).

Algorithm 1 PAV-EM algorithm

Let D be the dataset, where $d \in D$.
Give a value for the parameter q.

Set $X = \emptyset$.
for $i \leftarrow 1, n$ **do**
  Create q random clusters.
  Run the theme clustering algorithm.
  For each cluster C and d with pz_d^C,
    $X \leftarrow X \cup \{< pz_d^C, 1, 1 >\}$[2] if $d \in C$,
    $X \leftarrow X \cup \{< pz_d^C, 1, 0 >\}$ if $d \notin C$.
Obtain the PAV function, $PAV(pz_d^C)$, over X.

Set $S = \emptyset$, where S is the output cluster set.
repeat
  Create q random clusters for $\{d|d \notin \cup S\}$.
  Run the theme clustering algorithm.
  Select any cluster C, where
    $C' = \{d|d \in C, PAV(pz_d^C) > 0.9\}$
    satisfies $|C'| > 10$.
    $S \leftarrow S \cup \{C'\}$.
until no more changes in S.

2.2 PAV-EM thematic clustering

In thematic clustering, a document is assigned to a theme that has the highest probability to the document (Kim and Wilbur, 2012). Although this approach shows a reasonable performance for theme-based document clustering, the dynamic nature of random initialization and multiple subjects described in a document may create many weak themes. Moreover, there is no clear guideline to distinguish strong and weak themes. Thus, we here propose a method that extracts strong themes more effectively. In the EM-based theme extraction scheme, the log odds score pz_d^C indicates the extent to which a document d is coupled with a specific theme C. If a cluster in-

[2]The second and the third arguments in the bracket are the weight and the probability estimate of the data, respectively.

cludes a reasonable number of documents that have high pz_d^Cs, it indicates that the cluster represents a strong theme. Therefore, we can obtain strong themes by collecting these clusters.

Let the probability $p(score)$ be a monotonically non-decreasing function of $score$. The PAV algorithm (Ayer et al., 1955; Wilbur et al., 2005) is a regression method to derive from the data that monotonically non-decreasing estimate of $p(score)$ which assigns maximal likelihood to the data. For our approach, $score = pz_d^C$.

Algorithm 1 shows the theme clustering process using the PAV algorithm. For the given dateset D and the initial number of clusters q, theme clustering is performed n times, and an isotonic regression function is learned by applying the PAV algorithm. Note that q is an initial guess for the number of clusters and it is not guaranteed to remain the same in the output set. For our experiments, we set $q = 50$ and $n = 100$. After the PAV algorithm is applied, theme clustering is performed. At each iteration, we select any cluster in which there are more than 10 documents with PAV scores higher than 0.9. Unselected documents are re-used for clustering in the next iteration. This procedure is repeated until there are no more changes in the selected cluster set S.

2.3 Theme summarization

After obtaining themes (document clusters and their subject terms), we summarize each theme by choosing a text segment from PubMed document titles. A title should cover as many subject terms as possible, but also it should be well-formed, i.e. be descriptive enough and humanly understandable. To achieve this goal, we first extract all possible candidates from document titles as follows:

(i) Extract all possible candidates as n-grams, where $n = 1, ..., 20$. Noun phrases are treated as units and must be totally inside or outside a candidate.

(ii) Check POS tags for starting and ending words in a candidate. Starting with a conjunction, verb, preposition and symbol is not allowed. Ending with a conjunction, verb, preposition, symbol, determiner, adjective or certain pronouns is not allowed.

(iii) Discard any candidates that start or end with '-' or '.'. The candidates including certain characters such as '/', ';', ':' are also removed.

(iv) Check grammatical dependency relations. We discard candidates for which the head word of a preposition does not appear in the same candidate as the proposition. Also, we validate the case, 'between A and B', so that A and B are not separated.

Next, for each candidate, a score is calculated by

$$score(cand_i) = \log \frac{\prod_{t \in U}(tf_t \alpha_t)}{\prod_{t \notin U} tf_t}, \qquad (3)$$

where tf_t is the term frequency of the term t. However, an ideal title should have enough words to be descriptive, hence we subtract $(len(cand_i) - 5)^2$ from $score(cand_i)$, where $len(cand_i)$ is the number of words in $cand_i$, and choose the top score as a title.

3 Experimental Results

We applied our method to the five disease sets, "cystic fibrosis", "deafness", "DiGeorge syndrome", "autism" and "hypertrophic cardiomyopathy" from OMIM[3]. These sets consist of 3000, 3000, 956, 2917 and 1997 PubMed documents, respectively, and are available at `http://www.ncbi.nlm.nih.gov/CBBresearch/Wilbur/IRET/PAVEM`.

For evaluating PAV-EM and comparing with the topic modeling method, latent Dirichlet allocation (LDA) (Blei et al., 2003), both approaches were performed 10 times for each disease set and scores were averaged over all runs. Mallet[4] was used to run LDA. The same tokenization was applied to LDA and PAV-EM. The number of topics given for LDA was 50 and the recommended optimization parameter was used for producing LDA topics.

Table 1 presents average runtimes[5] for LDA and PAV-EM. LDA and PAV-EM spent 15.2 and 13.3 seconds on average for processing the smallest set, "DiGeorge syndrome". However, in larger sets, e.g. "autism", it took 46.9 and 31.3 seconds for LDA and PAV-EM, respectively. We also ran another implementation[6] of LDA, which was 30 times slower than Mallet. While PAV-EM and

Dataset	LDA	PAV-EM
Set 1	25.7	18.4
Set 2	36.5	24.7
Set 3	15.2	13.3
Set 4	46.9	31.3
Set 5	30.3	19.2

Table 1: Average runtimes for LDA and PAV-EM in seconds. Sets 1, 2, 3, 4 and 5 are "cystic fibrosis", "deafness", "DiGeorge syndrome", "autism" and "hypertrophic cardiomyopathy", respectively.

Method	Topic terms	
	Top 5	Top 10
LDA	2.8906	10.9760
PAV-EM	4.0322	14.6213

Table 2: NMPI scores for LDA and PAV-EM.

LDA can be implemented in parallel computation[7], this indicates that PAV-EM may be more efficient to obtain themes for a larger set of PubMed documents.

The PAV-EM algorithm automatically learns themes from unlabeled PubMed documents, hence the performance measures that are used in supervised learning cannot be applied to our setup. Recent studies have shown more interest in topic coherence measures (Chang et al., 2009; Newman et al., 2010; Mimno et al., 2011), which capture the semantic interpretability of topics based on subject terms. Table 2 shows the topic coherence scores measured by normalized point-wise mutual information (NPMI). For both top 5 and top 10 subject terms, PAV-EM achieves better NMPI scores than LDA. NPMI is known to be strongly correlated with human ratings (Aletras and Stevenson, 2013; Röder et al., 2015) and is defined by

$$\text{NPMI} = \sum_{i=2}^{N} \sum_{j=1}^{i-1} \frac{\log \frac{p(t_i,t_j)+\epsilon}{p(t_i)p(t_j)}}{-\log\left(p(t_i,t_j)+\epsilon\right)}, \qquad (4)$$

where $p(t_i, t_j)$ is the fraction of documents containing both terms t_i and t_j, and N indicates the number of top subject terms. $\epsilon = \frac{1}{D}$ is the smoothing factor, where D is the size of the dataset.

MeSH (Medical Subject Headings) is a controlled vocabulary for indexing and searching biomedical literature (Lowe and Barnett, 1994).

[7]A parallel implementation of LDA appears in Wang et al. (2009)

MeSH	Method	Prec.	Recall	F1
Top 1	LDA	0.4529	0.3827	0.4125
	PAV-EM	0.3842	0.5303	0.4427
Top 3	LDA	0.3935	0.3931	0.3925
	PAV-EM	0.3388	0.5239	0.4086

Table 3: Classification performance based on top significant MeSH terms appearing in themes.

MeSH terms assigned to an article are often used to indicate the topics of the article, thus these terms can be used to identify how well documents are grouped by topics. In each cluster, p-values of MeSH terms are calculated using the hypergeometric distribution (Kim and Wilbur, 2001), and the top N significant MeSH terms are used to calculate precision, recall and F1. Table 3 compares PAV-EM with LDA[8] for the MeSH term-based performance. In the table, PAV-EM provides higher recall and F1 for top 1 and top 3 MeSH terms. Higher recall has an advantage in our task because the theme summarization process uses a consensus among PubMed documents to reach a theme title.

The next experiment was performed to compare machine generated titles with manually labeled titles. Although human judgements are subjective, it is not uncommon to collect human judgements for evaluating topic modeling methods (Mei et al., 2007; Chang et al., 2009; Xie and Xing, 2013). To validate the performance of the theme summarization approach, we first chose 500 documents from each disease set, and produced themes and titles. For each topic, five strongest themes were chosen, and they were shown to three human annotators with extracted subject terms. Table 4 shows an example of the proposed approach and the manual annotation for the "hypertrophic cardiomyopathy" set. Among 25 themes, our approach correctly identified 21 theme titles. We assumed that a machine-generated title was correct if it included any of manually annotated titles.

4 Conclusion

This study was inspired by an EM-based thematic clustering approach. In this probabilistic framework, theme terms are iteratively selected and documents are assigned to a most likely theme. The number of themes is dynamically adjusted

[8]For LDA, each document was assigned to the highest scoring topic.

Proposed approach	Annotator 1	Annotator 2	Annotator 3
cardiac myosin binding protein c	myosin binding protein c	cardiac myosin binding protein c	cardiac myosin binding protein c
ptpn11 mutations in leopard syndrome	ptpn11 mutations in leopard syndrome	ptpn11 mutations in leopard syndrome	ptpn11 mutations in leopard syndrome
cytochrome c oxidase	cytochrome c oxidase	mitochondrial cytochrome-c-oxidase deficiency	mitochondrial cytochrome c oxidase deficiency
friedreich ataxia and diabetes mellitus	friedreich ataxia	friedreich ataxia	friedreich ataxia
hepatitis c virus infection	hepatitis c virus	role of hepatitis c virus in cardiomyopathies	hepatitis c virus infection

Table 4: Comparison of the titles generated from the proposed approach and manual annotation for the "hypertrophic cardiomyopathy" set.

by probabilistic evidence from documents. The PAV algorithm is utilized to measure the quality of themes. After themes are identified, subject term weights and PubMed document titles are used to form humanly understandable titles. The experimental results show that our approach provides a useful overview of a set of documents. In addition, the method may allow for a new way of browsing by semantically clustered documents as well as searching with context-based query suggestions.

Acknowledgments

The authors would like to thank Donald C. Comeau and Rezarta Islamaj Doğan for their contribution to the manual evaluation. This research was supported by the Intramural Research Program of the NIH, National Library of Medicine.

Abstract

Wikipedia is the largest collection of encyclopedic data ever written in the history of humanity. Thanks to its coverage and its availability in machine-readable format, it has become a primary resource for large-scale research in historical and cultural studies. In this work, we focus on the subset of pages describing persons, and we investigate the task of recognizing biographical sections from them: given a person's page, we identify the list of sections where information about her/his life is present. We model this as a sequence classification problem, and propose a supervised setting, in which the training data are acquired automatically. Besides, we show that six simple features extracted only from the section titles are very informative and yield good results well above a strong baseline.

1 Introduction

In the last years, several projects have started to address the mechanisms behind cultural development, borrowing techniques and algorithms from computer science and natural language processing to serve historical investigation. Efforts such as BiographyNet[1], Pantheon[2] or the Austrian Prosopographical Information System[3] prove an increasing interest in automatically extracting biographical descriptions from large amounts of data and combining them in a more general picture, taking advantage of the availability of such descriptions on the web. Wikipedia has been the main source of information for research in this direction despite its many biases, for instance its well-known English, Western and gender bias (Wikipedia Contributors, 2014). In fact, Wikipedia coverage both in terms of pages and in terms of languages, as well as the structured information that can be leveraged through DBpedia, has made it the primary resource for large-scale analyses on biographies. However, the lack of a consistent template for describing persons' lives led to the creation of a plethora of page types, where biographical information is displayed in diverse ways.

Based on a random sample of 100 persons' pages, we noticed that only 20% of them includes a section called *Biography* or *Life*, typically containing a set of subsections describing the main periods in a person's life from birth to death (see for instance `https://en.wikipedia.org/wiki/Leonard_Bernstein`). The other pages in our sample do not follow a pre-defined pattern and present the person's biography in one or several sections at the same level of the other ones (see for instance `https://en.wikipedia.org/wiki/Judy_Holliday`, with the *Filmography* and *Discography* sections at the same level of *Early Life* and *Career*). Given this high variability, it is very difficult to extract all and only those sections that describe a biography, and that build all together in sequence the description of a person's life. This depends also on the different types of non-biographical sections available, which in the case of prominent persons typically include main themes, reception, style, influences, legacy, work titles, etc. (see for instance *Will to power*, *Eternal return*, *Perspectivism*, *Critique on mass culture* in `https://en.wikipedia.org/wiki/Friedrich_Nietzsche`).

In this work, we present a simple methodology that, given a person's page in Wikipedia, recog-

nizes all sections that deal with his/her life even if no *Biography* section is present. The problem is modeled as a classification task using Conditional Random Fields, which are particularly suitable for our study because the biographical sections tend to follow a chronological order and present typical sequential patterns (for instance, the section *Early Life* is often followed by *Early Career*). While a simple token-based baseline is very difficult to beat when the task is performed at section level (i.e. deciding whether a section is biographical or not), our method performs best when the evaluation is performed at *page* level, recognizing *all* sections that describe a person's life. This is crucial if the task under investigation is meant as a preliminary step towards the automatic extraction of all events that compose a person's biography.

2 Related Work

To our knowledge, this is the first attempt to extract biographical sections from Wikipedia. Other past works focused on the recognition of biographical sentences (Biadsy et al., 2008; Zhou et al., 2004; Biryukov et al., 2005). However the two tasks have different goals: in our case, we aim at extracting all biographical sections, so that all events of a person's life from birth to death are present. The other approach, instead, is used to generate biography summaries, which was a task of the DUC2004 evaluation exercise[4]. Besides, while approaches for sentence selection look for textual features such as typical unigrams or bigrams that characterize biographical descriptions (Filatova and Prager, 2005), we adopt a much simpler approach by considering only section titles.

Other works focused on the analysis of typical events in selected articles from Wikipedia biographies by looking for a particular list of predefined events (Bamman and Smith, 2014). Our approach may complement such works by introducing a preprocessing step that extracts all and only the sections describing the biographies, upon which event extraction experiments can be performed. This would increase both the precision and the recall of the extracted information.

3 Experimental Setup

In this section we detail the data used for our experiments and the classification task.

[4] http://duc.nist.gov/duc2004/

3.1 Data set

Since our goal is to distinguish between biographical and non biographical sections, we focus only on Wikipedia pages describing persons. We derive our development, training and test data from the Pantheon data set (Yu et al., 2015), freely available for download.[5] The data set includes a list of 11,340 notable individuals with the link to their Wikipedia page in multiple languages, plus a number of additional information such as date and place of birth, category and language editions, which we do not consider for our study. Only the persons whose Wikipedia page is translated in at least 25 languages are included in Pantheon, as a proxy of prominent world personalities.

For each person in the list, we download the corresponding Wikipedia page in English and preprocess it using TheWikiMachine library[6]. Overall, we collect 11,075 pages, while 265 pages could not be retrieved because of problems with the links (mainly redirection links). We randomly select 100 pages as development set, 500 pages for test and the remaining 10,475 for building the training set.

For each page in the development and test set, we ask an annotator to assign a yes/no label to each section, to mark if it describes part of the person's life or not. We involve also a second annotator to label manually the development set (100 pages containing 834 sections). We compute Cohen's Kappa, which corresponds to 0.88. As a rule of thumb, this is considered an almost perfect agreement, which shows the clear-cut difference between biographical and non-biographical sections. The annotators use the Wikipedia original page to decide whether a section is biographical or not, therefore they can see both title and content of sections.

For the training set, we devise a novel methodology to acquire it completely automatically. We first extract from our collection of 10,475 pages the subset of pages containing a section called *Life* or *Biography*, which amount to 2,547. We consider such pages as a gold standard, since the presence of *Life* or *Biography* shows that their editors paid attention to the structure of the page, distinguishing between what belonged to the person's biography and what not. Therefore, all subsec-

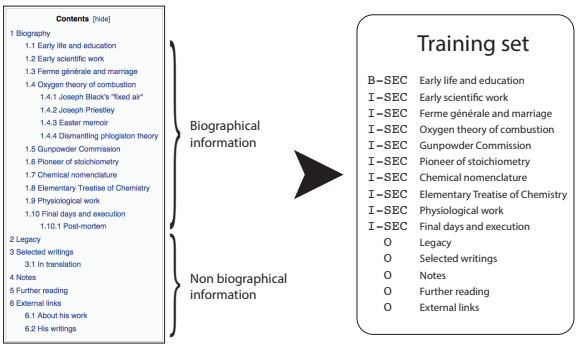

Figure 1: Extraction of training instances, from the Wikipedia page of Antoine Lavoisier (`https://en.wikipedia.org/wiki/Antoine_Lavoisier`). Sections are annotated in IOB2 format.

tions of *Life* or *Biography* are included as positive examples in the training set, because we assume that they all have biographical content. Instead, the remaining sections in the same pages represent our negative examples (see Figure 1). For the negative cases, we do not consider subsections because this level of detail is not needed for the classification, i.e. non-biographical sections contain only non-biographical subsections, and the classification of the first level is enough to propagate the corresponding label to the lower levels. Overall, the training set includes 2,547 sequences of sections (22,499 sections in total: 6,861 positive, 15,638 negative).

3.2 Classification experiment

We cast the problem as a supervised learning classification task, with the goal to label sequences of Wikipedia sections as describing a person's biography or not. As discussed in the introduction, we use Conditional Random Fields, since they are particularly suitable for sequence labelling (Lafferty et al., 2001). We use the implementation provided by CRFsuite[7] (Okazaki, 2007) for both training and classification tasks. The algorithm parameters are tuned on the development set.

In order to compare our approach with a non-sequential one, we perform the classification task also using Support Vector Machines (Vapnik, 1998). We use YAMCHA[8], a tool developed for chunking tasks, in which SVMs are easily combined with different context window sizes and dynamic features (Kudo and Matsumoto, 2001).

Since this work is only a preliminary step towards the automatic identification and extraction of biographical information from Wikipedia, we first experiment with the simplest approach. Therefore, we consider a small set of shallow features extracted *only from section titles*, and we ignore the content of the sections. Our six features are: the whole title, the tokens (lowercased), the bigrams, the first token of the section title, the first bigram, the position of the section with respect to the other sections in the same page (first, last, inside). We also use a sliding window of size 1 (both with CRF and SVM), so that the features extracted from the previous and the next sections are also considered to classify the current one. We experimented with window sizes > 1 on the development set, but they led to worse results.

Other features we implemented include the last word of the section, and a binary feature indicating whether the section title contains a year which is included between the date of birth and date of death of the person of interest. However, both pieces of information led to a performance drop on the development set, so we did not include them in the final feature set.

3.3 Baseline

To assess the performance of our system, we compare it with a baseline approach considering only the most frequent words in section titles. As shown in the evaluation (Section 4), this is indeed a very strong baseline. We identify the four most frequent tokens included in section titles, i.e. "Biography", "Life", "Death" and "Career", and we extract all sections that contain at least one of them (ignoring upper/lowercase). Finally, we consider as a positive example the smallest sequence of consecutive sections containing all of them. For instance, giving the sequence "Early life", "Career", "Presidency", "Death", "Legacy", "Awards", and "References", the first four sections are selected by the baseline as biographical sections: even if the "Presidency" word is not included in the tokens set, it is added as a consequence of its inclusion between "Early life" and "Death", both containing a token from the most frequent set.

[8] `http://chasen.org/~taku/software/yamcha/`

4 Evaluation

We evaluate our system based on two different metrics, accounting for both exact and partial matches.

- In the *Exact* setting, a true positive is scored when *all* and *only* those sections with biographical information in a Wikipedia page are extracted. This measure is useful to understand how often it is possible to extract the *complete* and *exact* biographical text concerning a person.

- The *Intersection* measure, instead, assigns a score between 0 and 1 for every predicted sequence of sections based on how much it overlaps with the gold standard sequence (Johansson and Moschitti, 2013).

Evaluation results are reported in Table 1. The CRF-based approach outperforms the baseline in both configurations, with the highest improvement in the exact setting (+0.111 F1). Compared with the classification performance obtained with SVMs, CRFs yield better results only in the exact setting, while the intersection-based performance does not show substantial differences. In general, CRFs achieves a better precision but a lower recall than SVMs. If we look at the average length (in sections) of the false positive sequences, it is 3.72 for SVMs and 2.71 for CRFs. This difference confirms the behaviour of the SVM-based approach, which tends to overestimate the amount of biographical sections that should be tagged in sequence.

The results in Table 1 show also that a simple baseline relying on the four most frequent tokens in section titles achieves surprisingly good results, especially with the intersection-based metrics. This means that this basic approach tends to recognize correctly at least some of the sections describing a person's biography, because they present some recurrent patterns in their titles. In general, we observe that section titles alone are good indicators of their content, also without the need of more complex features. Although Wikipedia editors are free to name the sections and decide how to arrange them, there are some patterns that can be easily recognized automatically, especially by means of CRF.

5 Discussion

We manually inspected the output of the classifier to identify possible issues. Apart from single classification mistakes, mainly due to unusual section titles that do not appear in the training set (such as "Anathematization" in Pope Honorius I page)[9], we found that some wrong classifications depended on specific types of persons in our data set. In particular, the classifier tends to assign a positive label to sections in the pages of mythological characters, even if they cannot have a biography because they did not exist. For instance, in the page of Apollo[10] there are sections entitled "Birth", "Youth", "Consorts and Children", which led the classifier to label them as biographical. Although mythological characters were included in the original Pantheon data set, we believe that they should be discarded, for instance by filtering them out a priori based on their Wikipedia categories.

Other false positives were found in pages of historical characters whose life was uncertain and was transmitted by others. For instance, the page of the geographer Pytheas[11] reports what the Roman author Pliny told about him, as well as what was said by other sources. These sections are very similar to those found in biographies, and are labelled as such.

We also performed additional experiments in order to investigate the impact of the size of the training data on the classification task. In particular, we extended our training data by creating new training sets based on 25,000, 50,000, 75,000 and 100,000 Wikipedia pages. These were obtained by

[9] https://en.wikipedia.org/wiki/Pope_Honorius_I

[10] https://en.wikipedia.org/wiki/Apollo

[11] https://en.wikipedia.org/wiki/Pytheas

ranking all pages with the PERSONDATA metadata according to the number of languages in which they are available, and then looking for the *Biography* and *Life* sections in the n top-ranked ones. Our evaluation shows that increasing the training size does not lead to a better performance, with an improvement of 0.01 with 100,000 pages over the results in Table 1 at the cost of a significant drop in processing speed.

6 Conclusions and Future Work

In this work we presented a simple yet effective approach to extract sequences of biographical sections from Wikipedia persons' pages. We model this task as a sequence classification problem using CRF and show that the section title alone conveys enough information to achieve a good classification result both in a supervised setting and with a rule-based baseline. Our contribution is threefold: *i)* we introduce the novel task of annotating the sequence of all sections describing a person's biography. This can be used as a preliminary step towards the extraction of all events characterizing a person's life; *ii)* we shed light on the regularities in Wikipedia persons' pages. Although Wikipedia is seen as a resource lacking consistency, with a flawed structure, our results show that at least persons' pages often present recurring patterns that are consistent across different biographies. The fact that only the most prominent figures have been included in the Pantheon data set is only a partial explanation of the good quality of such pages, because the English pages in our data set are often a reduced version of more extensive and edited pages in other languages. Finally, *iii)* we present an original approach to automatically acquire training data, using the pages with a *Biography* or *Life* section as gold data.

In the future, we plan to compare our approach based on section titles with more sophisticated approaches considering also the sections' content, to assess whether the latter improves over our simple methodology. Besides, we will build upon the outcome of this study by extracting the event sequence in a person's life starting from the complete biographies retrieved from Wikipedia.

The ongoing work is available as an open source project on GitHub[12] and is released under the GPLv3 license. In the project wiki one can find the dataset, the gold annotation and all the material needed to replicate the experiments.

Learn to Solve Algebra Word Problems Using Quadratic Programming

Lipu Zhou, Shuaixiang Dai, and Liwei Chen
Baidu Inc., Beijing, China
zhoulipu@outlook.com, {daishuaixiang, chenliwei}@baidu.com

Abstract

This paper presents a new algorithm to automatically solve algebra word problems. Our algorithm solves a word problem via analyzing a hypothesis space containing all possible equation systems generated by assigning the numbers in the word problem into a set of equation system templates extracted from the training data. To obtain a robust decision surface, we train a log-linear model to make the margin between the correct assignments and the false ones as large as possible. This results in a quadratic programming (QP) problem which can be efficiently solved. Experimental results show that our algorithm achieves 79.7% accuracy, about 10% higher than the state-of-the-art baseline (Kushman et al., 2014).

1 Introduction

An algebra word problem describes a mathematical problem which can be typically modeled by an equation system, as demonstrated in Figure 1. Seeking to automatically solve word problems is a classical AI problem (Bobrow, 1964). The word problem solver is traditionally created by the rule-based approach (Lev et al., 2004; Mukherjee and Garain, 2008; Matsuzaki et al., 2013). Recently, using machine learning techniques to construct the solver has become a new trend (Kushman et al., 2014; Hosseini et al., 2014; Amnueypornsakul and Bhat, 2014; Roy et al., 2015). This is based on the fact that word problems derived from the same mathematical problem share some common semantic and syntactic features due to the same underlying logic. Our method follows this trend.[1]

To solve a word problem, our algorithm analyzes all the possible ways to assign the numbers in the word problem to a set of equation system templates. Kushman et al. (2014) also consider filling the equation system templates to generate the candidate equations. But Kushman's template contains number slots (e.g. n_1, n_2, n_3, n_4 in Figure 1) and unknown slots (e.g. u_1^1, u_1^2, u_2^1, u_2^2 in Figure 1). They separately consider assigning nouns into the unknown slots and numbers into the number slots, as demonstrated in Figure 1. As filling the unknown slots is closely related to the number slots assignment, we only consider assigning the number slots, and design effective features to describe the relationship between numbers and unknowns. This scheme significantly reduces the hypothesis space, as illustrated in Figure 1, which benefits the learning and inference processes.

We use a log-linear model to describe the template selection and number assignment. To learn the model parameters of such problem, maximizing the log-likelihood objective is generally adopted (Kwiatkowski et al., 2010; Kushman et al., 2014). The key difficulty of this method is that calculating the gradient of the objective function needs to sum over exponentially many samples. Thus, it is essential to approximate the gradient. For instance, Kushman et al. (2014) use

[1] Our code is available at http://pan.baidu.com/s/1dD336Sx

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 817–822,
Lisbon, Portugal, 17-21 September 2015.

beam search to approximately calculate the gradient. This method can not exploit all the training samples. Thus the resulting model may be suboptimal. Motivated by the work (Taskar et al., 2005; Li, 2014), we adopt the max-margin objective. This results in a QP problem and opens the way toward an efficient learning algorithm (Koller and Friedman, 2009).

We evaluate our algorithm on the benchmark dataset provided by (Kushman et al., 2014). The experimental results show that our algorithm significantly outperforms the state-of-the-art baseline (Kushman et al., 2014).

2 Problem Formulation

Our word problem solver is constructed by training a log-linear model to find the correct mapping from a word problem to an equation.

Notations: Let $\mathcal{X}$ denote the set of training word problems, and $\mathcal{T}$ denote the set of equation system templates abstracted from $\mathcal{X}$ as (Kushman et al., 2014). x_i is the *i*-th word problem in $\mathcal{X}$. Assume T_j is the *j*-th equation system template in $\mathcal{T}$, and $\mathcal{N}_{T_j} = \left\{n^1_{T_j}, n^2_{T_j}, \cdots, n^m_{T_j}\right\}$ is the set of number slots of T_j, where m represents the size of $\mathcal{N}_{T_j}$. Denote the numbers in x_i by $\mathcal{N}_{x_i} = \left\{n^1_{x_i}, n^2_{x_i}, \cdots, n^l_{x_i}\right\}$, where l represents the size of $\mathcal{N}_{x_i}$. Assuming $l \geq m$, we further define π_{ijk} a sequence of m numbers chosen from $\mathcal{N}_{x_i}$ without repetition. Given π_{ijk}, we can map T_j to an equation system e_{ijk} by filling the number slots $\mathcal{N}_{T_j}$ of T_j sequently with the numbers in π_{ijk}. Solving e_{ijk}, we can obtain the corresponding solution s_{ijk}. To simplify the notation, we define $y_{ijk} = (T_j, \pi_{ijk}, e_{ijk}, s_{ijk})$ the k-th derivation give x_i and T_j, and let $\mathcal{Y}_i$ denote the set of all possible y_{ijk} given x_i and $\mathcal{T}$. Therefore, to correctly solve x_i is to find the correct $y_{ijk} \in \mathcal{Y}_i$.

Probabilistic Model: As (Kushman et al., 2014), we use the log-linear model to define the probability of $y_{ijk} \in \mathcal{Y}_i$ given x_i:

$$p(y_{ijk}|x_i;\theta) = \frac{e^{\theta\cdot\phi\left(x_i,y_{ijk}\right)}}{\sum\limits_{y'_{ijk}\in\mathcal{Y}_i} e^{\theta\cdot\phi\left(x_i,y'_{ijk}\right)}} \quad (1)$$

where θ is the parameter vector of the model, and $\phi\left(x_i, y_{ijk}\right)$ denotes the feature function. We adopt the max-margin objective (Vapnik, 2013) to directly learn the decision boundary for the correct derivations and the false ones.

3 Learning and Inference

3.1 Learning

Using (1), we obtain the difference between the log-probability of a correct derivation $y^c_{ijk} \in \mathcal{Y}_i$ and a false one $y^f_{ijl} \in \mathcal{Y}_i$ as:

$$\begin{aligned}&\ln P\left(y^c_{ijk}|x_i;\theta\right) - \ln P\left(y^f_{ijl}|x_i;\theta\right)\\ =&\theta\cdot\left(\phi\left(x_i, y^c_{ijk}\right) - \phi\left(x_i, y^f_{ijl}\right)\right)\end{aligned} \quad (2)$$

Note that the subtraction in (2) cancels the denominator of (1) which contains extensive computation. To decrease the generalization error of the learned model, we would like the minimal gap between the correct derivations and the false ones as large as possible. In practice, we may not find a decision hyperplane to perfectly separate the correct and the false derivations. Generally, this can be solved by introducing a slack variable $\xi_{ijkl} \geq 0$ (Bishop, 2006) for each constraint derived from (2). Define $\varphi\left(x_i, y^c_{ijk}, y^f_{ijl}\right) = \phi\left(x_i, y^c_{ijk}\right) - \phi\left(x_i, y^f_{ijl}\right)$. For $\forall\, x_i \in \mathcal{X}$, the resulting optimization problem is:

$$\begin{aligned}&\arg\min \frac{1}{2}\|\theta\|_2 + C\sum_{i,j,k,l}\xi_{ijkl}\\ &s.t.\ \theta\cdot\varphi\left(x_i, y^c_{ijk}, y^f_{ijl}\right) \geq 1 - \xi_{ijkl},\ \xi_{ijkl} \geq 0\end{aligned} \quad (3)$$

The parameter C is used to balance the slack variable penalty and the margin. This is a QP problem and has been well studied (Platt, 1999; Fan et al., 2008).

According to the Karush-Kuhn-Tucker (KKT) condition, only a part of the constraints is active for the solution of (3) (Bishop, 2006). This leads to an efficient learning algorithm called constraint generation (Koller and Friedman, 2009; Felzenszwalb et al., 2010). Specifically, an initial model is trained by a randomly selected subset of the constraints. Next this model is used to check the constraints and at most N false deviations that are erroneously classified by this model are collected for each word problem. These constraints are then added to train a new model. This process repeats until converges. Our experimental results show that this process converges fast.

3.2 Inference

When we obtain the model parameter θ, the inference can be performed by finding the maximum

Single slot features
Relation between numbers and the question sentence.
Position of a number w.r.t a comparative word.
Context of a number.
Is one or two?
Is a multiplier?
Is between 0 and 1?
Slot pair features
Relation between two numbers.
Context similarity between two numbers.
Does there exist coreference relationship?
Are two numbers both multipliers?
Are two numbers in the same sentence or continuous sentences?
Information of raw path and dependency path between two numbers
One number is larger than another.
Solution features
Is integer solution?
Is positive solution?
Is between 0 and 1?

Table 1: Features used in our algorithm.

value of (1). This can be simplified by computing

$$\arg\max_{y_{ijk} \in \mathcal{Y}_i} \theta \cdot \phi(x_i, y_{ijk}) \quad (4)$$

As we only consider assigning the number slots of the templates in $\mathcal{T}$, generally, the size of the possible assignments per word problem is bearable, as shown in the Table 2. Thus we simply evaluate all the $y_{ijk} \in \mathcal{Y}_i$. The one with the largest score is considered as the solution of x_i.

4 Features

A feature vector $\phi(x_i, y_{ijk})$ is calculated for each word problem x_i and derivation y_{ijk} pair. As Kushman (2014), a feature is associated with a signature related to the template of y_{ijk}. We extract three kinds of features, i.e., single slot features, slot pair features and solution features. Unless otherwise stated, single slot and slot pair features are associated with the slot and slot pair signature of the equation system template, respectively, and solution features are generated for the signature of the equation system template. Table 1 lists the features used in our algorithm. The detailed description is as follows.

4.1 Single Slot Features

To reduce the search space, we only consider the assignment of the number slots of the template. It seems that our algorithm will lose the information about the unknown. But such information can be recovered by the features that include the information of the question sentence. Specifically, we associate a number with all the nouns in the same sentence sorted by the length of the dependence path between them. For instance, [$, tickets, children] is the sorted noun list for 1.5 in Figure 1. Assume the n-th noun of the nouns associated to a given number is the first noun that appears in the question sentence. We quantify the relationship between a number and a queried entity by the reciprocal of n. For instance, in Figure 1, "children" appears in the question sentence, and it is the third noun associated to 1.5. So the value of this feature is $1/3$. A larger value of this feature means a number more likely relates to the queried entity. The maximum value of this feature is 1. Thus we introduce a feature to indicate whether this special case occurs. We also use a feature to indicate whether a number appears in the question sentence.

The comparative meaning is sensitive to both the comparative words and the position of a number relative to them. For example, "one number is 3 less than twice another" is different to "one number is 3 more than twice another", but equal to "twice a number is 3 more than another". To account for this, we use the comparative words coupled with the position of a number relative to them as features.

On the other hand, we use the lemma, part of speech (POS) tag and the dependence type related to the word within a widow [-5, +5] around a number as features. Besides, if the POS tag or the named entity tag of a number is not labeled as a general number, we also import these tags together with the first noun and the dependence type related to the number as features.

Additionally, the numbers 1 and 2 are usually used to indicate the number of variables, such as "the sum of two numbers". To capture such usage, we use a feature to denote whether a number is one or two as (Kushman et al., 2014). Since such usage appears in various kinds of word problems, this feature does not contain the slot signature. We also generate features to indicate whether a number belongs to (0, 1), and whether it is a multiplier, such as twice, triple.

4.2 Slot Pair Features

Assume n_1 and n_2 are two numbers in a word problem. Suppose NP_1 and NP_2 are the lists of nouns associated to n_1 and n_2 (described in section 4.1), respectively. We evaluate the relationship $r(n_1, n_2)$ between n_1 and n_2 by:

$$\max_{\substack{noun_1^i \in NP_1, \\ noun_2^j \in NP_2 \\ s.t.\ noun_1^i = noun_2^j}} \left(\frac{2}{ord\left(noun_1^i\right) + ord\left(noun_2^j\right)} \right)$$

where $ord(\cdot)$ denotes the index of a noun in $NP_i\,(i = 1, 2)$, starting from 1. A larger $r(n_1, n_2)$ means n_1 and n_2 are more related. The maximum value of $r(n_1, n_2)$ is 1, which occurs when the first nouns of NP_1 and NP_2 are equal. We use a feature to indicate whether $r(n_1, n_2)$ is 1. This feature helps to import some basic rules of the arithmetic operation, e.g., the units of summands should be the same.

If two slots are symmetric in a template (e.g., n_2 and n_3 in Figure 1), the contexts around both numbers are generally similar. Assume CT_1 and CT_2 are two sets of certain tags within a window around n_1 and n_2, respectively. Then we calculate the contextual similarity between n_1 and n_2 by:

$$sim(ST_1, ST_2) = \frac{|ST_1 \cap ST_2|}{|ST_1 \cup ST_2|}$$

In this paper, the tags include the lemma, POS tag and dependence type, and the window size is 5.

Besides, we exploit features to denote whether there exists coreference relationship between any elements of the sentences where n_1 and n_2 locate, and whether two numbers are both multipliers. Finally, according to (Kushman et al., 2014), we generate features related to the raw path and dependence path between two numbers, and use the numeric relation between them as a feature to import some basic arithmetic rules, such as the positive summands are smaller than their sum. We also include features to indicate whether two numbers are in the same sentence or continuous sentences.

4.3 Solution Features

Many word problems are math problems about the real life. This background leads the solutions of many word problems have some special numerical properties, such as the positive and integer properties used by (Kushman et al., 2014). To capture such fact, we introduce a set of features to describe the solution properties.

5 Experiments

Dataset: The dataset used in our experiment is provided by (Kushman et al., 2014). Equivalent equation systme templates are automatically merged. The word problems are parsed by (Manning et al., 2014). The version of the parser is the same as (Kushman et al., 2014). The performance of our algorithm is evaluated by comparing each number of the correct answer with the calculated one, regardless of the ordering. We report the average accuracy of 5-fold cross-validation.

Learning: We use liblinear (Fan et al., 2008) to solve the QP problem. The parameter C in (3) is set to 0.01 in all the following experiments. We randomly select 300 false derivations of each word problem to form the initial training set. We add at most 300 false derivations for each word problem during the constraint generation step, and use 5-fold cross-validation to avoid overfitting. We stop iterating when the cross-validation error becomes worse or the training error converges or none new constraints are generated.

Supervision Level: We consider the learning with two different levels of supervision. In the first case, the learning is conducted by providing the equation and the correct answer of every training sample. In the second case, the correct answer is available for every training sample but without the equation. Instead, all the templates are given, but the correspondence between the template and the training sample is not available. During learning, the algorithm should evaluate every derivation of each template to find the true one.

Results: Table 2 lists the learning statistics for our algorithm and (Kushman et al., 2014). We can observe that the number of possible alignments per word problem of our algorithm is much smaller than (Kushman et al., 2014). However, the number of all the false alignments is still 80K. Using the constraint generation algorithm (Koller and Friedman, 2009), only 9K false alignments are used in the quadratic programming. We trained our model on a Intel i5-3210M CUP and 4G RAM laptop. Kushman's algorithm (2014) needs much more memory than our algorithm and can not run on a general laptop. Therefore, we tested their algorithm on a workstation with Intel E5-2620 CPU and 128G memory. As shown in Table 2, their algorithm takes more time than our algorithm.

Table 3 lists the accuracy of our algorithm and Kushman's algorithm (2014). It is clear that our

Mean negative samples	80K
Mean negative samples used in learning	9K
Mean time for feature extraction	22m
Mean training time	7.3m
Mean feature extraction and training time of (Kushman et al., 2014)	83m
# Alignments per problem of (Kushman et al., 2014)	4M
# Alignments per problem of our algorithm	1.9K

Table 2: Learning statistics.

Algorithm	**Accuracy**
Our algorithm fully supervised	**79.7%**
Our algorithm weakly supervised	72.3%
Kushman's algorithm (2014) fully supervised	68.7%

Table 3: Algorithm comparison.

Feature Ablation	**Accuracy**
Without single slot features	70.4%
Without slot pair features	69.3%
Without solution features	71.8%

Table 4: Ablation study for fully supervised data.

algorithm obtains better result. The result of the weakly supervised data is worse than the fully supervised one. But this result is still higher than Kushman's fully supervised result.

Table 4 gives the results of our algorithm with different feature ablations. We can find that all the features are helpful to get the correct solution and none of them dramatically surpasses the others.

Discuss: Although our algorithm gives a better result than (Kushman et al., 2014), there still exist two main problems that need to be further investigated, as demonstrated in Table 5. The first problem is caused by our feature for semantic representation. Our current lexicalized feature can not generalize well for the unseen words. For example, it is hard for our algorithm to relate the word "forfeits" to "minus", if it does not appear in the training corpus. The second problem is caused by the fact that our algorithm only considers the single noun as the entity of a word problem. Thus when the entity is a complicated noun phrase, our algorithm may fail.

Problem	**Example**
Lexicalized features can not generalize well for unseen words.	A woman is paid 20 dollars for each day she works and **forfeits** a 5 dollars for each day she is idle. At the end of 25 days she nets 450 dollars. How many days did she work?
Can not deal with complicated noun phrases.	**The probability that San Francisco plays in the next super bowl** is nine times **the probability that they do not play in the next super bowl**. **The probability that San Francisco plays in the next super bowl** plus **the probability that they do not play** is 1. What is **the probability that San Francisco plays in the next super bowl?**

Table 5: The problems of our algorithm.

6 Conclusion and Future work

In this paper, we present a new algorithm to learn to solve algebra word problems. To reduce the possible derivations, we only consider filling the number slots of the equation system templates, and design effective features to describe the relationship between numbers and unknowns. Additionally, we use the max-margin objective to train the log-linear model. This results in a QP problem that can be efficiently solved via the constraint generation algorithm. Experimental results show that our algorithm significantly outperforms the state-of-the-art baseline (Kushman et al., 2014).

Our future work will focus on studying the performance of applying nonlinear kernel function to the QP problem (3), and using the word embedding vector (Bengio et al., 2003; Mikolov et al., 2013) to replace current lexicalized features. Besides, we would like to compare our algorithm with the algorithms designed for specific word problems, such as (Hosseini et al., 2014).

Abstract

We present an unsupervised method to find lexical variations in Roman Urdu informal text. Our method includes a phonetic algorithm *UrduPhone*, a feature-based similarity function, and a clustering algorithm *Lex-C*. UrduPhone encodes roman Urdu strings to their phonetic equivalent representations. This produces an initial grouping of different spelling variations of a word. The similarity function incorporates word features and their context. Lex-C is a variant of k-medoids clustering algorithm that group lexical variations. It incorporates a similarity threshold to balance the number of clusters and their maximum similarity. We test our system on two datasets of SMS and blogs and show an f-measure gain of up to 12% from baseline systems.

1 Introduction

Urdu is the national language of Pakistan and one of the official languages of India. It is written in Perso-Arabic script. However in social media and short text messages (SMS), a large proportion of Urdu speakers use roman script (i.e., the English alphabet) for writing, called *Roman Urdu*.

Roman Urdu lacks standard lexicon and usually many spelling variations exist for a given word, e.g., the word *zindagi* [life] is also written as *zindagee*, *zindagy*, *zaindagee* and *zndagi*. Specifically, the following normalization issues arise: (1) differently spelled words (see example above), (2) identically spelled words that are lexically different (e.g., *bahar* can be used for both [outside] and [spring], and (3) spellings that match words in English (e.g, *had* [limit] for the English word 'had'). These inconsistencies cause a problem of data sparsity in basic natural language processing tasks such as Urdu word segmentation (Durrani and Hussain, 2010), part of speech tagging (Sajjad and Schmid, 2009), spell checking (Naseem and Hussain, 2007), machine translation (Durrani et al., 2010), etc.

In this paper, we propose an unsupervised feature-based method that tackles above mentioned challenges in discovering lexical variations in Roman Urdu. We exploit phonetic and string similarity based features and incorporate contextual features via top-k previous and next words' features. For phonetic information, we develop an encoding scheme for Roman Urdu, *UrduPhone*, motivated from Soundex. Compared to other available phonetic-based schemes that are mostly limited to English sounds only, UrduPhone maps Roman Urdu homophones effectively. Unlike previous work on short text normalization (see Section 2), we do not have information about standard word forms in the dataset. The problem becomes more challenging as every word in the corpus is a candidate of every other word. We present a variant of the k-medoids clustering algorithm that forms clusters in which every word has at least a specified minimum similarity with the cluster's centroidal word. We conduct experiments on two Roman Urdu datasets: an SMS dataset and a blog dataset and evaluate performance using a gold standard. Our method shows an f-measure gain of up to 12% compared to baseline methods. The dataset and code are made available to the research community.

2 Previous Work

Normalization of short text messages and tweets has been in focus (Sproat et al., 2001; Wei et al., 2011; Clark and Araki, 2011; Roy et al., 2013; Chrupala, 2014; Kaufmann and Kalita, 2010; Sidarenka et al., 2013; Ling et al., 2013; Desai and Narvekar, 2015; Pinto et al., 2012). However, most of the work is limited to English or to other

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 823–828,
Lisbon, Portugal, 17-21 September 2015.

resource-rich languages. In this paper, we focus on Roman Urdu, an under-resourced language, that does not have any gold standard corpus with standard word forms. Therefore, we are restricted to the task of finding lexical variations in informal text. This is a rather more challenging problem since in this case every word is a possible variation of every other word in the corpus.

Researchers have used phonetic, string, and contextual knowledge to find lexical variations in informal text.[1] Pinto et al. (2012; Han et al. (2012; Zhang et al. (2015) used phonetic-based methods to find lexical variations. Han et al. (2012) also used word similarity and word context to enhance performance. Wang and Ng (2013) used normalization operations e.g., missing word recovery and punctuation correction to improve normalization process. Irvine et al. (2012) used manually prepared training data to build an automatic normalization system. Contractor et al. (2010) used string edit distance to find candidate lexical variations. Yang and Eisenstein (2013) used an unsupervised approach with log linear model and sequential Monte Carlo approximation.

We propose an unsupervised method to find lexical variations. It uses string edit distance like Contractor et al. (2010), Sound-based encoding like Pinto et al. (2012) and context like Han et al. (2012) combined in a discriminative framework. However, in contrast, it does not use any corpus of standard word forms to find lexical variations.

3 Our Method

The lexical variations of a lexical entry usually have high phonetic, string-based, and contextual similarity. We integrate a phonetic-based encoding scheme, UrduPhone, a feature-based similarity function, and a clustering algorithm, Lex-C.

3.1 UrduPhone

Several sound-based encoding schemes for words have been proposed in literature such as *Soundex* (Knuth, 1973; Hall and Dowling, 1980), *NYSIIS* (Taft, 1970), *Metaphone* (Philips, 1990), Caverphone (Wang, 2009) and Double Metaphone.[2] These schemes encode words based on their sound which in turn serves as grouping words of similar sounds (lexical variations) to one code. However, most of the schemes are designed for English and European languages and are limited when apply to other family of languages like Urdu.

In this work, we propose a phonetic encoding scheme, *UrduPhone*, tailored for Roman Urdu. The scheme is derived from the Soundex algorithm. It groups consonants on the basis of common homophones in Urdu and English. It is different from Soundex in two particular ways:[3] Firstly, UrduPhone generates encoding of length six compared to length four in Soundex. This enables UrduPhone to avoid mapping different forms of a root word to same code. For example, *muskurana* [smiling] and *mshuraht* [smile] encode to one form *MSKR* in Soundex but in UrduPhone, they have different encoding which are *MSKRN*, *MSKRHT* respectively. Secondly, we introduce consonant groups which are mapped differently in Soundex. We do this by analyzing Urdu alphabets that map to a single roman form e.g. words *samar* [reward], *sabar* [patience] and *saib* [apple], all start with different Urdu alphabets that have identical roman representation: *s*. In UrduPhone, we map all such cases to a single form.[4]

3.2 Similarity Function

The similarity between two words w_i and w_j is computed by the following similarity function:

$$S(w_i, w_j) = \frac{\sum_{f=1}^{F} \alpha^{(f)} \times \sigma_{ij}^{(f)}}{\sum_{f=1}^{F} \alpha^{(f)}}$$

Here, $\alpha^{(f)} > 0$ is the weight given to feature f, $\sigma_{ij}^{(f)} \in [0, 1]$ is the similarity contribution made by feature f, and F is the total number of features. In the absence of additional information, and as used in the experiments in this work, all weights can be taken equal to one. The similarity function returns a value in the interval [0, 1] with larger values signifying higher similarity.

We use two types of features in our method: word features and contextual features. Word features can be based on phonetics and/or string similarity. The phonetic similarity between words w_i and w_j is 1 (i.e., $\sigma_{ij} = 1$) if both words have the same UrduPhone ID or encoding; otherwise, their

[1] Spell correction is also considered as a variant of text normalization (Damerau, 1964; Tahira, 2004; Fossati and Di Eugenio, 2007). Here, we limit ourselves to the previous work on short text normalization.

[2] http://en.wikipedia.org/wiki/Metaphone

[3] Due to limited space, we limit the description of UrduPhone to its comparison with Soundex.

[4] A complete table of UrduPhone mappings is provided in the supplementary material.

similarity is zero. The string similarity between words w_i and w_j is defined as follows:

$$\sigma_{ij} = \frac{lcs(w_i, w_j)}{\min[len(w_i), len(w_j)] \times edist(w_i, w_j)}$$

Here, $lcs(w_i, w_j)$ is the length of the longest common subsequence in words w_i and w_j and $len(w_i)$ is the length of word w_i. $edist(w_i, w_j)$ returns the edit distance between words except when the edit distance is 0, in which case it returns 1.

Contextual features include top-k frequently occurring previous and next words' features. Let $a_1^i, a_2^i, \ldots, a_5^i$ and $a_1^j, a_2^j, \ldots, a_5^j$ be the word IDs for the top-5 frequently occurring words preceding word w_i and w_j, respectively. Then, the similarity between words is given by (Hassan et al., 2009)

$$\sigma_{ij} = \frac{\sum_{k=1}^{5} \rho_k}{\sum_{k=1}^{5} k}$$

Here, ρ_k is zero if a_k^i does not have a match in a_*^j (i.e., in the context of word w_j); otherwise, $\rho_k = 5 - \max[k, l] - 1$ where $a_k^i = a_l^j$ and l is the highest rank (smallest integer) at which a previous match had not occurred. Instead of word IDs in a_i's, UrduPhone IDs or string similarity based cluster IDs can be used to reduce sparsity and improve matches among similar words.

3.3 Lex-C: Clustering Algorithm

We develop a new clustering algorithm, called Lex-C, for discovering lexical variations in informal text. This algorithm is a modified version of the k-medoids algorithm (Han, 2005). It incorporates an assignment similarity threshold, $t > 0$, for controlling the number of clusters and their similarity. In particular, it ensures that all words in a cluster have a similarity greater than or equal to this threshold. It is important to note that the poular k-means algorithm is known to be effective for numeric datasets only which is not true in our case, and it cannot utilize our specialized similarity function for lexical variation discovery.

Specifically, Lex-C starts from an initial clustering based on UrduPhone or string similarity. It finds the centroidal word, w_c^k, for cluster k as the word with which the sum of similarities of all other words in the cluster is a maximum. Then, each non-centroidal word is assigned to the cluster k if $S(w_i, w_c^k)$ is a maximum among all clusters *and* $S(w_i, W_c^k) \geq t$. If the latter condition is not satisfied (i.e., $S(w_i, w_c^k) < t$) then instead of assigning word w_i to cluster k, it starts a new cluster. These two steps are repeated until convergence.

4 Experimental Evaluation

We empirically evaluate UrduPhone and our complete method involving Lex-C separately on two real-world datasets. Performance is reported with B-Cubed precision, recall, and f-measure (Bagga and Baldwin, 1998; Hassan et al., 2015) on a gold standard dataset. These performance measures are based on element-wise comparisons between predicted and actual clusters that are then aggregated over all elements in the clustering. This avoided the issue of 100% precision with low recall (all words belong to separate clusters) and 100% recall with low precision (all words belong to one cluster).

4.1 Dataset and Gold Standard

The first dataset, Web dataset, is scraped from Roman Urdu websites on news[5], poetry[6], SMS[7] and blog[8]. The second dataset, SMS dataset, is obtained from chopaal, an internet based group SMS service[9]. For evaluation, we use a manually annotated database of Roman Urdu variations (Khan and Karim, 2012). Table 1 shows statistics of the datasets in comparison with the gold standard.

Dataset	Web	SMS
Unique words	22,044	28,908
Overlap with Gold Standard	12,600	13,087
UrduPhone IDs	3,952	3,599

Table 1: Datasets and gold standard statistics. Overlap with gold standard = number of words appearing in gold standard; UrduPhone IDs = number of distinct UrduPhone encodings.

4.2 UrduPhone Evaluation

We compare UrduPhone with Soundex and its variants.[10] These algorithms are used to group words based on their encoding and then evaluated against the gold standard. Table 2 shows

[5] http://www.shashca.com,http://stepforwardpak.com/

[6] https://hadi763.wordpress.com/

[7] http://www.replysms.com/

[8] http://roman.urdu.co/

[9] http://chopaal.org

[10] We use NLTK-Trainer's phonetic library `http://bit.ly/1OJGL9Q`

the results on Web dataset. UrduPhone outperforms Soundex, Caverphone, and Metaphone while Nysiis's f-measure is comparable to that of UrduPhone. We observe that Nysiis produces a large number of single word clusters (out of 6,943 clusters produced 5,159 have only one word). This gives high precision but recall is low. UrduPhone produces fewer clusters (and fewer one word clusters) with high recall.

Algorithm	Pre	Rec	Fme
Soundex	0.30	0.97	0.46
Metaphone	0.49	0.80	0.64
Caverphone	0.31	0.92	0.46
Nysiis	0.63	0.69	0.66
UrduPhone	0.51	0.94	**0.67**

Table 2: Comparison of UrduPhone with other algorithms on Web dataset

4.3 Lex-C Evaluation

We compared Lex-C with k-means and EM clustering algorithms. With both of these algorithms we used the same feature set (i.e., word features, phonetic features, and contextual features), However, their performance lagged the performance of our approach. The primary reason for this is that our feature space is not continuous while k-means and EM algorithms work best for continuous feature spaces.

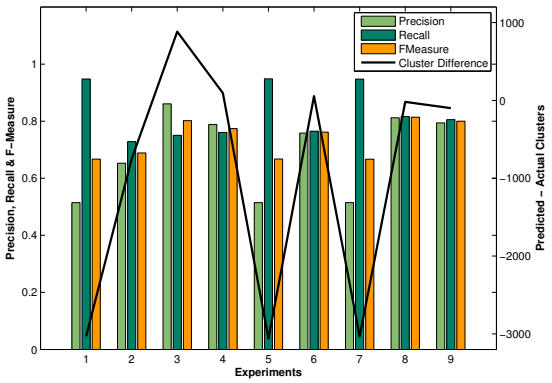

Figure 1: Performance results for Web dataset

4.4 Performance of our Method

We conduct extensive experiments to evaluate the performance of our method. We vary initial clusterings (UrduPhone encoding or string similarity based clustering); evaluate various combinations of phonetic, string, and contextual features; and consider different previous/next top-5 words' features (word ID, cluster ID, and/or UrduPhone ID). Table 3 gives details of each experiment setting.

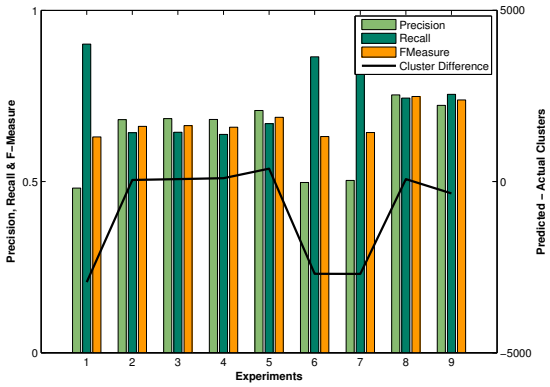

Figure 2: Performance results for SMS dataset

ID	Initial	Word	Context-1	Context-2
1	–	UPhone	–	–
2	–	String	–	–
3	String	String	Word ID	–
4	String	String	Cluster ID	–
5	String	UPhone	Cluster ID	–
6	UPhone	UPhone	Cluster ID	–
7	UPhone	UPhone	Word ID	–
8	UPhone	UPhone	UPhone ID	Word ID
9	UPhone	UPhone	UPhone ID	Cluster ID

Table 3: Details of experiments' settings where Initial is initial clustering based on String or UrduPhone (UPhone)

Figures 1 and 2 show results of selected experiments for Web and SMS datasets respectively. The x-axis shows the experiment (Exp.) IDs while the left y-axis gives the precision, recall, and f-measure and the right y-axis shows the difference between the number of predicted and actual clusters. Exp. 1 and 2 are baselines corresponding to UrduPhone encoding (UPhone ID) and string similarity based word clustering (Cluster ID) respectively. The remaining experiments have different initial clustering, word features, and up to two contextual features. In these results, the similarity threshold t is selected such that the number of discovered clusters is as close as possible to the number of actual clusters in the gold standard for each dataset. This is done to make the results comparable across different settings.

Compared to baselines, our method shows a gain of up to 12% and 8% in Web and SMS datasets respectively. The best performances are obtained when UrduPhone is used as a feature and UrduPhone IDs are used to define the context (Exp. 8 and 9). In particular, when both Urdu-

Phone IDs and word IDs/cluster IDs are used for contextual information (i.e, with two sets of top-5 previous and next words' features) the f-measure is consistently high.

We analyzed the performance of Exp. 8 (best settings for Web dataset) with varying t and showed it in Figure 3. It is observed that the value of t controls the number of clusters smoothly, and precision increases with the number of clusters and f-measure reaches a peak when number of clusters is close to that in the gold standard.

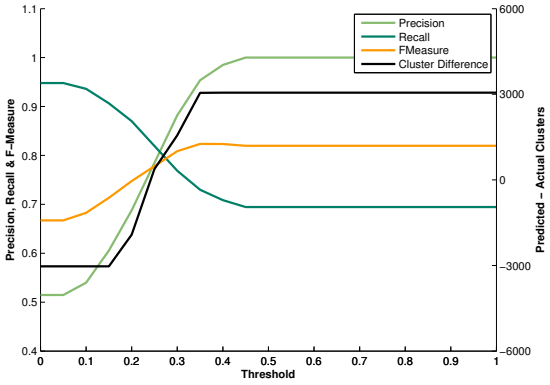

Figure 3: Effect of varying threshold t on Web dataset (experiment 8)

5 Conclusion

We proposed an unsupervised method for finding lexical variations in Roman Urdu. We presented a phonetic encoding scheme UrduPhone for Roman Urdu, and developed a feature-based clustering algorithm Lex-C. Our experiments are evaluated on a manually developed gold standard. The results confirmed that our method outperforms baseline methods. We made the datasets and algorithm code available to the research community.

Abstract

Distributed word representations are very useful for capturing semantic information and have been successfully applied in a variety of NLP tasks, especially on English. In this work, we innovatively develop two component-enhanced Chinese character embedding models and their bigram extensions. Distinguished from English word embeddings, our models explore the compositions of Chinese characters, which often serve as semantic indictors inherently. The evaluations on both word similarity and text classification demonstrate the effectiveness of our models.

1 Introduction

Due to its advantage over traditional one-hot representation, distributed word representation has demonstrated its benefit for semantic representation in various NLP tasks. Among the existing approaches (Huang et al, 2012; Levy and Goldberg, 2014; Yang and Eisenstein, 2015), the continuous bag-of-words model (CBOW) and the continuous skip-gram model (SkipGram) remain the most popular ones that one can use to build word embeddings efficiently (Mikolov et al, 2013a; Mikolov et al, 2013b). These two models learn the distributed representation of a word based on its context. The context defined by the window of surrounding words may unavoidably include certain less semantically-relevant words and/or miss the words with important and relevant meanings (Levy and Goldberg, 2014).

To overcome this shortcoming, a line of research deploys the order information of the words in the contexts by either deriving the contexts using dependency relations where the target word participates (Levy and Goldberg, 2014; Yu and Dredze, 2014; Bansal et al, 2014) or directly keeping the order features (Ling et al, 2015). As to another line, Luong et al (2013) captures morphological composition by using neural networks and Qiu et al (2014) introduces the morphological knowledge as both additional input representation and auxiliary supervision to the neural network framework. While most previous work focuses on English, there is a little work on Chinese. Zhang et al (2013) extracts the syntactical morphemes and Cheng et al (2014) incorporates the POS tags and dependency relations. Basically, the work in Chinese follows the same ideas as in English.

Distinguished from English, Chinese characters are logograms, of which over 80% are phono-semantic compounds, with a semantic component giving a broad category of meaning and a phonetic component suggesting the sound[1]. For example, the semantic component 亻 (*human*) of the Chinese character 他 (*he*) provides the meaning connected with human. In fact, the components of most Chinese characters inherently bring with certain levels of semantics *regardless of* the contexts. Being aware that the components of Chinese characters are finer grained semantic units, then an important question arises before slipping to the applications of word embeddings—would it be better to learn the semantic representations from the character components in Chinese?

We approach this question from both the practical and the cognitive points of view. In practice, we expect the representations to be optimized for good generalization. As analyzed before, the components are more generic unit *inside* Chinese characters that provides semantics. Such *inherent* information somehow alleviates the shortcoming of the *external* contexts. From the cognitive point of view, it has been found that the knowledge of semantic components significantly corre-

[1]http://en.wikipedia.org/wiki/Radical_(Chinese_characters)

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 829–834,
Lisbon, Portugal, 17-21 September 2015.

late to Chinese word reading and sentence comprehension (Ho et al, 2003).

These evidences inspire us to explore novel Chinese character embedding models. Different from word embeddings, character embeddings relate Chinese characters that occur in similar contexts with their component information. Chinese characters convey the meanings from their components, and beyond that, the meanings of most Chinese words also take roots in their composite characters. For example, the meaning of the Chinese word 摇篮 (*cradle*) can be interpreted in terms of its composite characters 摇 (*sway*) and 篮 (*basket*). Considering this, we further extend character embeddings from uni-gram models to bi-gram models.

At the core of our work is the exploration of Chinese semantic representations from a novel character-based perspective. Our proposed Chinese character embeddings incorporate the finer-grained semantics from the components of characters and in turn enrich the representations inherently in addition to utilizing the external contexts. The evaluations on both intrinsic word similarity and extrinsic text classification demonstrate the effectiveness and potentials of the new models.

2 Component-Enhanced Character Embeddings

Chinese characters are often composed of smaller and primitive **components** called radicals or radical-like components, which serve as the most basic units for building character meanings. Dating back to the 2nd century AD, the Han dynasty scholar Shen XU organizes his etymological dictionary *shuō wén jiě zì* (*word and expression*) by selecting 540 recurring graphic components that he called bù (means "categories"). Bù is nearly the same as what we call **radicals** today[2]. Most radicals are common semantic components. Over time, some original radicals evolve into radical-like components. Nowadays, a Chinese character often contains exactly one radical (rarely has two) and several other radical-like components. In what follows, we refer to as components both radicals and radical-like components.

Distinguished from English, these composite components are unique and inherent features inside Chinese characters. A lot of times, they allow us to assumingly understand or infer the meanings of characters without any context. In other words, the component-level features inherently bring with additional information that benefits semantic representations of characters. For example, we know that the characters 你 (*you*), 他 (*he*), 伙 (*companion*), 侣 (*companion*), and 们 (*people*) all have the meanings related to human because of their shared component 亻 (*human*), a variant of the Chinese character 人 (*human*). This kind of component information is intrinsically different from the contexts deriving by dependency relations and POS tags. It motivates us to investigate the component-enhanced Chinese character embedding models. While Sun et al (2014) utilizes radical information in a supervised fashion, we build our models in a holistic unsupervised and bottom-up way.

It is important to note the variation of a radical inside a character. There are two types of variations. The main type is position-related. For example, the radical of the Chinese character 水 (*water*) is itself, but it becomes 氵 as the radical of 池 (*pool*). The original radicals are stretched or squeezed so that they can fit into the general Chinese character shape of a square. The second variation type emerges along with the history of character simplification when traditional characters are converted into simplified characters. For instance, 食 (*eat*) is written as 飠 when it forms as a part of some traditional characters, but is written as 饣 in simplified characters. To cope with these variations and recover the semantics, we match all the radical variants back into their original forms. We extract all the components to build a **component list** for each Chinese character. With the assumption that a character's radical often bring more important semantics than the rest[3], we regard the radical of a character as the first component in its component list.

Let a sequence of characters $D = \{z_1, \ldots, z_N\}$ denotes a corpus of N characters over the character vocabulary V. And $z, c, e, K, T, M, |V|$ denote the Chinese character, the context character, the component list, the corresponding embedding dimension, the context window size, the number of components taken into account for each character, and the vocabulary size, respectively. We develop two component-enhanced character embedding models, namely *char*CBOW

[2] http://en.wikipedia.org/wiki/Radical_(Chinese_characters)

[3] Inside a character, its radical often serves as the semantic-component while its other radical-like components may be phonetics.

and *char*SkipGram.

*char*CBOW follows the original continuous bag-of-words model (CBOW) proposed by (Mikolov et al, 2013a). We predict the central character z_i conditioned on a $2(M+1)TK$-dimensional vector that is the concatenation of the remaining character-level contexts $(c_{i-T}, \ldots, c_{i-1}, c_{i+1}, \ldots, c_{i+T})$ and the components in their component lists. More formally, we wish to maximize the log likelihood of all the characters as follows,

$$L = \sum_{z_i^n \in D} \log p(z_i|h_i),$$

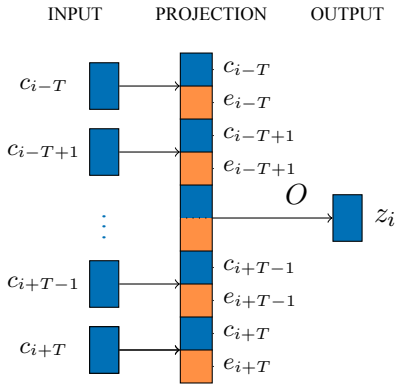
$$h_i = \text{cat}(c_{i-T}, e_{i-T}, \ldots, c_{i+T}, e_{i+T})$$

where h_i denotes the concatenation of the component-enhanced contexts. We make prediction using a $2KT(M+1)|V|$-dimensional matrix $\mathbf{O}$. Different from the original CBOW model, the extra parameter introduced in the matrix $\mathbf{O}$ allows us to maintain the relative order of the components and treat the radical differently from the rest components.

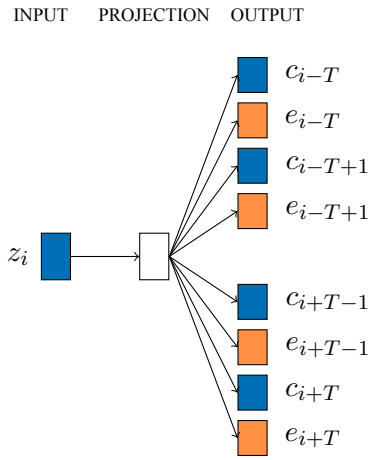
The development of *char*SkipGram is straightforward. We derive the component-enhanced contexts as $(\langle c_{i-T}, e_{i-T}\rangle, \ldots, \langle c_{i+T}, e_{i+T}\rangle)$ based on the central character z_i. The sum of log probabilities given z_i is maximized:

$$L = \sum_{z_i \in D} \sum_{\substack{j=-T \\ j\neq 0}}^{T} \Big(\log p(c_{j+i}|z_i) + \log p(e_{j+i}|z_i)\Big)$$

Figure 1 illustrates the two component-enhanced character embedding models. It is easy to extend *char*CBOW and *char*SkipGram to their corresponding bi-character extensions. Denote the z_i, c_i and e_i in *char*CBOW and *char*SkipGram as uni-character z_{ui}, c_{ui} and e_{ui}, the bi-character extensions are the models fed by bi-character formed z_{bi}, c_{bi} and e_{bi}.



(a) *char*CBOW



(b) *char*SkipGram

Figure 1: Illustrations of two component-enhanced character embedding models.

3 Evaluations

We examine the quality of the proposed two Chinese character embedding models as well as their corresponding extensions on both intrinsic word similarity evaluation and extrinsic text classification evaluation.

Word Similarity. As the widely used public word similarity datasets like WS-353 (Finkelstein et al, 2001), RG-65 (Rubsenstein and Goodenough, 1965) are built for English embeddings, we start from developing appropriate Chinese synonym sets. Two candidate choices are Chinese dictionaries HowNet (Dong and Dong, 2006) and HIT-CIR's Extended Tongyici Cilin (denoted as E-TC)[4]. As HowNet contains less modern words, such as 谷歌 (*Google*), we select E-TC as our benchmark for word similarity evaluation.

Text Classification. We use Tencent news titles as our text classification dataset[5]. A total of 8,826 titles of four categories (*society, entertainment, healthcare*, and *military*) are extracted. The lengths of titles range from 10 to 20 words. We train ℓ_2-regularized logistic regression classifiers using the `LIBLINEAR` package (Fan et al, 2008) with the learned embeddings.

To build the component-enhanced character embeddings, we employ the GB2312 character set

and extract all their component lists. It is easy to obtain the first components (*i.e.*, the radicals), as they are readily available in the *online Xinhua Dictionary*[6]. For the rest radical-like components, we extract them by matching the patterns like "从 (*from*)+X" in the Xinhua dictionary. Such a pattern indicates that a character has a component of X. We also enrich the component lists by matching the pattern "X is only seen" in *Hong Kong Computer Chinese Basic Component Reference*[7] .

It is observed that nearly 65% Chinese characters have only one component (their radicals), and 95% Chinese characters have two components (including their radicals). Thus, we decide to maintain up to two extracted components to build the character embeddings according to the frequency of their occurrences. To cope with the radical variation problem, we transform 24 radical variants to their origins, such as 亻 to 人 (*human*), 扌 to 手 (*hand*), 氵 to 水 (*water*) and 辶 to 足 (*foot*). The complete list of the transformations is provided in Appendix for easy reference.

We adopt Chinese Wikipedia Dump[8] to train our models as well as the original CBOW and SkipGram, implemented in the `Word2Vec` tool[9] for comparison. The corpus in total contains 232,894 articles. In preprocessing, we remove pure digit words and non-Chinese characters, and ignore the words less than 10 occurrences during training. We set the context window size T as 2 and use 5 negative samples experimentally. All the embedding dimensions K are set to 50.

In the word similarity evaluation, we compute the Spearman's rank correlation (Myers and Well, 1995) between the similarity scores based on the learned embedding models and the E-TC similarity scores computed by following Tian and Zhao (2010). The bi-character embeddings are concatenation of the composite character embeddings. For the text classification evaluation, we average the composite single character embeddings for each bi-gram. And each bi-gram overlaps with the previous one. The titles are represented by averaging

[6] `http://xh.5156edu.com/`

[7] `http://www.ogcio.gov.hk/tc/business/tech_promotion/ccli/cliac/glyphs_guidelines.htm`

[8] `http://download.wikipedia.com/zhwiki/`

[9] `https://code.google.com/p/word2vec/`

the embeddings of their composite grams[10].

Table 1 presents the word similarity evaluation results of the eight embedding models mentioned above, where A–L denote the twelve categories in E-TC. The first four rows are the results with the uni-character inputs, and the last four rows correspond to the bi-character embeddings results.

We can see that both CBOW and CBOW-bi perform worse than the corresponding SkipGram and SkipGram-bi. This result is consistent with the finding in the previous work (Pennington et al, 2014; Levy and Goldberg, 2014; Levy et al, 2015). To some extent, CBOW and its extension CBOW-bi are the most different among the eight (the first four models in Table 1 and the first four models in Table 2). They tie together the characters in each context window by representing the context vector as the sum of their characters' vectors. Although they have a potential of deriving better representations (Levy et al, 2015), they lose some particular information from each unit of input in the average operations.

Although the performance on twelve different categories varies, in overall *char*CBOW, *char*SkipGram and their extensions consistently better correlate to E-TC. It provides the evidence that the component information in Chinese characters is of significance. Clearly, the bi-character models achieve higher rank correlations. These results are not surprised. As a matter of fact, a majority of Chinese words are compounds of two characters. Thus, in many cases two characters together is equivalent to a Chinese word. Considering the superiority of the bi-character models, we only apply them in the text classification evaluations.

The results shown in the first four rows of Table 2 are similar to those in the word similarity evaluation. Please notice the significant improvement of *char*CBOW and *char*CBOW-bi. We conjecture this as a hint of the importance of the order information, which is introduced by the extra parameter in the output matrixes. Their better performances verify our assumption that the radicals are more important than non-radicals. This is also attributed to the benefit from the order of the characters in the contexts.

Actually, we also conduct an additional experiment to combine the uni-gram and the bi-gram embeddings for text classification and notice in average about 8.4% of gain over the bi-gram embeddings alone. The detailed results are presented in the last four rows of Table 2.

[10]We do not compare the uni-formed characters with bi-formed compound characters. The word pairs that cannot be found in the vocabulary are removed.

4 Conclusions and Future Work

In this paper, we propose two component-enhanced Chinese character embedding models and their extensions to explore both the internal compositions and the external contexts of Chinese characters. Experimental results demonstrate their benefits in learning rich semantic representations. For the future work, we plan to devise embedding models based together on the composition of component-character and of character-word. The two types of compositions will serve in a coordinate fashion for the distributional representations.

Appendix

As mentioned in Section 3, we present the complete list of transformations of the variant and original forms of 24 radicals. The *meaning* columns provide the corresponding meanings of the components in the left.

transform	meaning	transform	meaning
艹 → 艸	grass	扌 → 手	hand
亻 → 人	human	氵 → 水	water
刂 → 刀	knife	車 → 车	vehicle
犭 → 犬	dog	攵 → 攴	hit
灬 → 火	fire	纟 → 糸	silk
钅 → 金	gold	耂 → 老	old
麥 → 麦	wheat	牜 → 牛	cattle
饣 → 食	eat	飠 → 食	eat
礻 → 示	memory	忄 → 心	heart
罒 → 网	nest	王 → 玉	jade
讠 → 言	speak	衤 → 衣	cloth
月 → 肉	body	辶 → 辵	walk

Abstract

Multi-label text categorization is a type of text categorization, where each document is assigned to one or more categories. Recently, a series of methods have been developed, which train a classifier for each label, organize the classifiers in a partially ordered structure and take predictions produced by the former classifiers as the latter classifiers' features. These predictions-as-features style methods model high order label dependencies and obtain high performance. Nevertheless, the predictions-as-features methods suffer a drawback. When training a classifier for one label, the predictions-as-features methods can model dependencies between former labels and the current label, but they can't model dependencies between the current label and the latter labels. To address this problem, we propose a novel joint learning algorithm that allows the feedbacks to be propagated from the classifiers for latter labels to the classifier for the current label. We conduct experiments using real-world textual data sets, and these experiments illustrate the predictions-as-features models trained by our algorithm outperform the original models.

1 Introduction

The multi-label text categorization is a type of text categorization, where each document is assigned to one or more categories simultaneously. The multi-label setting is common and useful in the real world. For example, in the news categorization task, a newspaper article concerning global warming can be classified into two categories simultaneously, namely environment and science. For another example, in the task of classifying music lyrics into emotions, a song's lyrics can deliver happiness and excitement simultaneously. The research about the multi-label text categorization attracts increasing attention (Srivastava and Zane-Ulman, 2005; Katakis et al., 2008; Rubin et al., 2012; Nam et al., 2013; Li et al., 2014).

Recently, a series of predictions-as-features style methods have been developed, which train a classifier for each label, organize the classifiers in a partially ordered structure and take predictions produced by the former classifiers as the latter classifiers' features. These predictions-as-features style methods model high order label dependencies (Zhang and Zhang, 2010) and obtain high performance. *Classifier chain* (CC) (Read et al., 2011) and *multi-label Learning by Exploiting lAbel Dependency* (Lead) (Zhang and Zhang, 2010) are two famous predictions-as-features methods. CC organizes classifiers along a chain and LEAD organizes classifiers in a Bayesian network. Besides, there are other works on extending the predictions-as-features methods (Zaragoza et al., 2011; Gonçalves et al., 2013; Sucar et al., 2014). In this paper, we focus on the predictions-as-features style methods.

The previous works of the predictions-as-features methods focus on learning the partially ordered structure. They neglect a drawback. When training a classifier for one label, predictions-as-features methods can model dependencies between former labels and the current label, but they can't model dependencies between the current label and the latter labels. Consider the case of three labels. We organize classifiers in a partially ordered structure shown in figure 1. When training the classifier for the second label, the feature (the bold lines in figure) consists of the origin feature and the prediction for the first label. The information about the third label can't be incorporated. It means that we only model the dependencies between the first label and the sec-

Lisbon, Portugal, 17-21 September 2015.

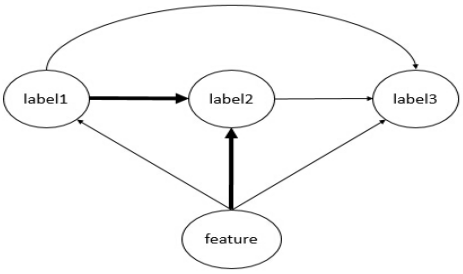

Figure 1: When training the classifier for the second label, the feature (the bold lines) consists of only the origin feature and the prediction for the first label. In this time, it is impossible to model the dependencies between the second label and the third label.

ond label and that the dependencies between the second label and the third label is missing.

To address this problem, we propose a novel joint learning algorithm that allows the feedbacks to be propagated from the classifiers for latter labels to the classifier for the current label, so that the information about the latter labels can be incorporated. It means that the proposed method can model, not only the dependencies between former labels and current label as the usual predictions-as-features methods, but also the dependencies between current label and latter labels. With not missing dependencies. Hence, the proposed method will improve the performance. Our experiments illustrate the models trained by our algorithm outperform the original models. You can find the code of this paper online [1].

The rest of this paper is organized as follows. Section 2 presents the proposed method. We conduct experiments to demonstrate the effectiveness of the proposed method in section 3. Section 4 concludes this paper.

2 Joint Learning Algorithm

2.1 Preliminaries

Let $\mathcal{X}$ denote the document feature space, and $\mathcal{Y} = \{0,1\}^m$ denote label space with m labels. A document instance $\boldsymbol{x} \in \mathcal{X}$ is associated with a label vector $\boldsymbol{y} = (y_1, y_2, ..., y_m)$, where $y_i = 1$ denotes the document has the i-th label and 0 otherwise. The goal of multi-label learning is to learn a function $\mathbf{h} : \mathcal{X} \rightarrow \mathcal{Y}$. In general, $\mathbf{h}$ consists of m functions, one for a label, i.e., $\mathbf{h}(\boldsymbol{x}) = [\mathbf{h}_1(\boldsymbol{x}), \mathbf{h}_2(\boldsymbol{x}), ..., \mathbf{h}_m(\boldsymbol{x})]$.

In the predictions-as-features methods, the classifiers are organized in a partially ordered structure and take predictions produced by the former classifiers as features. We can describe the classifier in the predictions-as-features method as follows.

$$\mathbf{h}_j : \boldsymbol{x}, h_{k\in \boldsymbol{pa_j}}(\boldsymbol{x}) \rightarrow y_j \tag{1}$$

where $\boldsymbol{pa_j}$ denotes the set of parents of the j-th classifiers in the partially ordered structure.

2.2 Architecture and Loss

In this subsection, we introduce architecture and loss function of our joint learning algorithm. As a motivating example, we employ logistic regression as the base classifier in the predictions-as-features methods. The classification function is the sigmoid function, as shown in Eq.(2).

$$\begin{aligned} p_j &= \mathbf{h}_j(\boldsymbol{x}, p_{k\in \boldsymbol{pa_j}}) \\ &= \frac{exp([\boldsymbol{x}, p_{k\in \boldsymbol{pa_j}}]^T \boldsymbol{W_j})}{1 + exp([\boldsymbol{x}, p_{k\in \boldsymbol{pa_j}}]^T \boldsymbol{W_j})} \end{aligned} \tag{2}$$

where p_j denotes the probability the document has the j-th label, $\boldsymbol{W_j}$ denotes the weight vector of the j-th model and $[\boldsymbol{x}, p_{k\in \boldsymbol{pa_j}}]$ denotes the feature vector x extended with predictions $[p_{k\in \boldsymbol{pa_j}}]$ produced by the former classifiers.

The joint algorithm learns classifiers in the partially ordered structure jointly by minimizing a global loss function. We use the sum of negative log likelihood losses of all classifiers as the global loss function.

$$\begin{aligned} \mathcal{L}(\boldsymbol{y}, \boldsymbol{h}(\boldsymbol{x})) &= \sum_{j=1}^{m} \ell(p_j, y_j) \\ &= -\sum_{j=1}^{m} (y_j log(p_j) + (1 - y_j) log(1 - p_j)) \end{aligned} \tag{3}$$

The joint algorithm minimizes this global loss function, as Eq.(4) shows.

$$\boldsymbol{h^*} = \underset{\boldsymbol{h}}{\operatorname{argmin}}\, \mathcal{L}(\boldsymbol{y}, \boldsymbol{h}(\boldsymbol{x})) \tag{4}$$

Minimizing this global loss function is *inequivalent* to minimizing the loss function of each base classifier separately, since minimizing the global

[1] https://github.com/rustle1314/Joint_Learning_Predictions_as_Features_for_Multi_Label_Classification

loss function results in feedbacks from latter classifiers. In the predictions-as-features methods, the weights of the k-th classifier are the factors of not only the k-th classifier but also the latter classifiers. Consequently, when minimizing the global loss function, the weights of the k-th classifier are updated according to not only the loss of the k-th classifier but also the losses of the latter classifiers. In other words, feedbacks are propagated from the latter classifiers to the k-th classifier.

The predictions-as-features models trained by our proposed joint learning algorithm can model the dependencies between former labels and current label, since they take predictions by the former classifiers to extend the latter classifiers' features, as the usual predictions-as-features methods do. Besides, they can also model the dependencies between current label and latter labels due to the feedbacks incorporated by the joint learning algorithm.

Here, we employ logistic regression as the motivating example. If we want to employ other classification models, we use other classification function and other loss function. For example, if we want to employ L2 SVM as base classifiers, we resort to the linear classification function and the L2 hinge loss function.

We employ the Back propagation Through Structure (BTS) (Goller and Kuchler, 1996) to minimize the global loss function. In BTS, parent node is computed with its child nodes at the forward pass stage; child node receives gradient as the sum of derivatives from all its parents.

3 Experiments

3.1 Datasets

We perform experiments on four real world data sets: 1) the first data set is Slashdot (Read et al., 2011). The Slashdot data set is concerned about predicting multiple labels given science and technology news titles and partial blurbs mined from Slashdot.org. 2) the second data set is Medical (Pestian et al., 2007). This data set involves the assignment of ICD-9-CM codes to radiology reports. 3) The third data set is Enron. The enron data set is a subset of the Enron Email Dataset, as labelled by the UC Berkeley Enron Email Analysis Project[2]. It is concerned about classifying emails into some categories. 4) the fourth data set is Tmc2007 (Srivastava and Zane-Ulman, 2005). It is concerned about safety report categorization, which is to label aviation safety reports with respect to what types of problems they describe.

dataset	n	d	m
slashdot	3782	1079	22

enron	1702	1001	53
tmc2007	28596	500	22

Table 2: Multi-label data sets and associated statistics.

Table 2 shows these multi-label data sets and associated statistics. n denotes the size of the entire data set, d denotes the number of the bag-of-words features, m denotes the number of labels. These data sets are available online [3].

3.2 Evaluation Metrics

We use three common used evaluation metrics. The Hamming loss is defined as the percentage of the wrong labels to the total number of labels.

$$Hammingloss = \frac{1}{m}|\mathbf{h}(\boldsymbol{x})\Delta\boldsymbol{y}| \tag{5}$$

where Δ denotes the symmetric difference of two sets, equivalent to XOR operator in Boolean logic.

The multi-label 0/1 loss is the exact match measure as it requires any predicted set of labels $\mathbf{h}(\boldsymbol{x})$ to match the true set of labels S *exactly*. The 0/1 loss is defined as follows:

$$0/1loss = I(\mathbf{h}(\boldsymbol{x}) \neq \boldsymbol{y}) \tag{6}$$

Let p_j and r_j denote the precision and recall for the j-th label. The macro-averaged F score is a harmonic mean between precision and recall, defined as follows:

$$Fscore = \frac{1}{m}\sum_{i=j}^{m}\frac{2 * p_j * r_j}{p_j + r_j} \tag{7}$$

3.3 Method Setup

In this paper, we focus on the predictions-as-features style methods, and use CC and LEAD as the baselines. Our methods are JCC and JLEAD. JCC(JLEAD) is CC(LEAD) trained by our joint algorithm and we compare JCC(JLEAD) to CC(LEAD) respectively. Put it another way, CC/LEAD provide the partial order structure of

classifiers, and train these classifiers one by one. JCC/LEAD train classifiers jointly in the partial order structure provided by CC/LEAD.

For LEAD and JLEAD, we use the Banjo (Bayesian ANalysis with Java Objects) (Smith et al., 2006) package as the Bayesian structure learning tool. Besides, we also perform experiments with Binary Relevance (BR), which is the baseline for the predictions-as-features methods. BR trains a classifier for a label independently, which doesn't model dependencies. The base classifier of all of them is set to logistic regression without regularization. Experiments are performed in ten-fold cross validation with pairwise t-test at 5% significance level.

3.4 Performance

We reports the detailed results in terms of different evaluation metrics on different data sets in table 1. As shown in this figures, CC and LEAD outperform BR, which shows the values of the prediction-as-features methods. JCC and JLEAD wins over CC and LEAD respectively, which shows the values of the proposed joint learning algorithm.

The improvements are much smaller on the Enron data set than other data sets. In fact, BR, the original prediction-as-features methods and our proposed methods share similar performance on the Enron data set. The reason may be that the label dependencies in the Enron dataset is weak. The label dependencies weakness can be validated by the fact that the modeling-correlation CC and LEAD can't obtain much higher performance than the not-modeling-correlation BR. Due to the weak label dependencies, the modeling-correlation-better JCC(JLEAD) can't obtain much higher performance than CC(LEAD).

Criteria	JCC against CC	JLEAD against LEAD
hamming loss	**2/2/0**	**3/1/0**
0/1 loss	**2/2/0**	**2/2/0**
F-score	**3/1/0**	**3/1/0**
Total	**7/5/0**	**8/4/0**

Table 3: The win/tie/loss results for the joint learning algorithm against the original predictions-as-features methods in terms of different evaluation metrics (pairwise t-test at 5% significance level).

We summarize the detailed results into Table 3. JCC is significantly superior to CC in 7/12 cases, tie in 5/12 cases, inferior in zero case. JLEAD is significantly superior to LEAD in 8/12 cases, tie in 4/12 cases, inferior in zero case. The results indicates that our proposed joint algorithm can improve the performance of the predictions-as-features methods.

3.5 Time

The training time (mean) of each approach is showed detailed in table 4. First, we find the training time is related to the number of labels. The training time on the Tmc2007 dataset (28596 instances, 500 features and 22 labels) is less than that on the Enron dataset (1702 instances, 1001 features and 53 labels). This is very easy to understand. We train more classifiers with respect to more labels, which leads to more training time. Second, LEAD/JLEAD have slightly less training time than CC/JCC. The Bayesian network struc-

Dataset	CC	JCC	LEAD	JLEAD
slashdot	63.85	85.63	52.17	73.85
medical	134.11	142.51	115.33	128.78
enron	234.28	257.89	196.87	218.95
tmc2007	153.70	169.52	145.80	158.56

Table 4: The average training time (in seconds) of each approach

ture learning tool limits that a node has five parent nodes at most. Hence, the partially order structure of LEAD/JLEAD is much simpler. Third, the training time of the joint algorithm is slightly more than that of the original methods. Some time is spent on back-propagating feedbacks from latter classifiers.

4 Conclusion

The multi-label text categorization is a common and useful text categorization. Recently, a series of predictions-as-features style methods have been developed, which model high order label dependencies and obtain high performance. The predictions-as-features methods suffer from the drawback that they methods can't model dependencies between current label and the latter labels. To address this problem, we propose a novel joint learning algorithm that allows the feedbacks to be propagated from the latter classifiers to the current classifier. Our experiments illustrate the models trained by our algorithm outperform the original models.

A Framework for Comparing Groups of Documents

Arun S. Maiya
Institute for Defense Analyses — Alexandria, VA, USA
amaiya@ida.org

Abstract

We present a general framework for comparing multiple groups of documents. A bipartite graph model is proposed where document groups are represented as one node set and the comparison criteria are represented as the other node set. Using this model, we present basic algorithms to extract insights into similarities and differences among the document groups. Finally, we demonstrate the versatility of our framework through an analysis of NSF funding programs for basic research.

1 Introduction and Motivation

Given multiple sets (or groups) of documents, it is often necessary to *compare* the groups to identify similarities and differences along different dimensions. In this work, we present a general framework to perform such comparisons for extraction of important insights. Indeed, many real-world tasks can be framed as a problem of comparing two or more *groups* of documents. Here, we provide two motivating examples.

1. Program Reviews. To better direct research efforts, funding organizations such as the National Science Foundation (NSF), the National Institutes of Health (NIH), and the Department of Defense (DoD), are often in the position of reviewing research programs via their artifacts (*e.g.*, grant abstracts, published papers, and other research descriptions). Such reviews might involve identifying overlaps across different programs, which may indicate a duplication of effort. It may also involve the identification of unique, emerging, or diminishing topics. A "document group" here could be defined either as a particular research program that funds many organizations, the totality of funded research conducted by a specific organization, or all research associated with a particular time period (*e.g.*, fiscal year). In all cases, the objective is to draw comparisons *between* groups by comparing the document sets associated with them.

2. Intelligence. In the areas of defense and intelligence, document sets are sometimes obtained from different sources or entities. For instance, the U.S. Armed Forces sometimes seize documents during raids of terrorist strongholds.[1] Similarities between two document sets (each captured from a different source) can potentially be used to infer a non-obvious association between the sources.

Of course, there are numerous additional examples across many domains (*e.g.*, comparing different news sources, comparing the reviews for several products, etc.). Given the abundance of real-world applications as illustrated above, it is surprising, then, that there are no existing general-purpose approaches for drawing such comparisons. While there is some previous work on the comparison of document sets (referred to as *comparative text mining*), these existing approaches lack the generality to be widely applicable across different use case scenarios with different comparison criteria. Moreover, much of the work in the area focuses largely on the summarization of shared or unshared topics among document groups (*e.g.*, Wan et al. (2011), Huang et al. (2011), Campr and Ježek (2013), Wang et al. (2012), Zhai et al. (2004)). That is, the problem of drawing *multi-faceted* comparisons among the groups themselves is not typically addressed. This, then, motivates our development of a *general-purpose* model for comparisons of document sets along arbitrary dimensions. We use this model for the identification of similarities, differences, trends, and anomalies among large *groups* of documents. We begin by

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 840–845,
Lisbon, Portugal, 17-21 September 2015.

formally describing our model.

2 Our Formal Model for Comparing Document Groups

As input, we are given several groups of documents, and our task is to compare them. We now formally define these document groups and the criteria used to compare them. Let $D = \{d_1, d_2, \ldots, d_N\}$ be a document collection comprising the totality of documents under consideration, where N is the size. Let D^P be a partition of D representing the document groups.

Definition 1 *A document group is a subset $D_i^P \in D^P$ (where index $i \in \{1 \ldots |D^P|\}$).*

Each document group in D^P, for instance, might represent articles associated with either a particular organization (*e.g.,* university), a research funding source (*e.g.,* NSF or DARPA program), or a time period (*e.g.,* a fiscal year). Document groups are compared using *comparison criteria*, D^C, a family of subsets of D.

Definition 2 *A comparison criterion is a subset $D_i^C \in D^C$ (where index $i \in \{1 \ldots |D^C|\}$).*

Intuitively, each subset of D^C represents a set of documents sharing some attribute. Our model allows great flexibility in how D^C is defined. For instance, D^C might be defined by the named entities mentioned within documents (*e.g.,* each subset contains documents that mention a particular person or organization of interest). For the present work, we define D^C by topics discovered using latent Dirichlet allocation or LDA (Blei et al., 2003).

LDA Topics as Comparison Criteria. Probabilistic topic modeling algorithms like LDA discover latent themes (*i.e.,* topics) in document collections. By using these discovered topics as the comparison criteria, we can compare arbitrary groups of documents by the themes and subject areas comprising them. Let K be the number of topics or themes in D. Each document in D is composed of a sequence of words: $d_i = \langle s_{i1}, s_{i2}, \ldots, s_{iN_i} \rangle$, where N_i is the number of words in d_i and $i \in \{1 \ldots N\}$. $V = \bigcup_{i=1}^{N} f(d_i)$ is the vocabulary of D, where $f(\cdot)$ takes a sequence of elements and returns a set. LDA takes K and D (including its components such as V) as input and produces two matrices as output, one of which is θ. The matrix $\theta \in \mathbb{R}^{N \times K}$ is the document-topic distribution matrix and shows the distribution of topics within each document. Each row of the matrix represents a probability distribution. D^C is constructed using K subsets of documents, each of which represent a set of documents pertaining largely to the same topic. That is, for $t \in \{1 \ldots K\}$ and $i \in \{1 \ldots N\}$, each subset $D_t^C \in D^C$ is comprised of all documents d_i where $t = \text{argmax}_x \theta_{ix}$.[2] Having defined the document groups D^P and the comparison criteria D^C, we now construct a bipartite graph model used to perform comparisons.

A Bipartite Graph Model. Our objective is to compare the *document groups* in D^P based on D^C. We do so by representing D^P and D^C as a weighted bipartite graph, $G = (P, C, E, w)$, where P and C are disjoint sets of nodes, E is the edge set, and $w : E \rightarrow \mathbb{Z}^+$ are the edge weights. Each subset of D^P is represented as a node in P, and each subset of D^C is represented as a node in C. Let $\alpha : P \rightarrow D^P$ and $\beta : C \rightarrow D^C$ be functions that map nodes to the document subsets that they represent. Then, the edge set E is $\{(u, v) \mid u \in P, v \in C, \alpha(u) \cap \beta(v) \neq \emptyset\}$, and the edge weight for any two nodes $u \in P$ and $v \in C$ is $w((u, v)) = |\alpha(u) \cap \beta(v)|$. Concisely, each weighted edge in G between a document group (in P) and a topic (in C) represents the number of documents shared among the two sets. Figure 1 shows a toy illustration of the model. Each node in P is shown in black and represents a subset of D^P (*i.e.,* a document group). Each node in C is shown in gray and represents a subset of D^C (*i.e.,* a document cluster pertaining primarily to the same topic). Each edge represents the intersection of the two subsets it connects. In the next section, we will describe basic algorithms on such bipartite graphs capable of yielding important insights into the similarities and differences among document groups.

3 Basic Algorithms Using the Model

We focus on three basic operations in this work.

Node Entropy. Let $\vec{w}$ be a vector of weights for all edges incident to some node $v \in E$. The *entropy* H of v is: $\text{H}(v) = -\sum_i p_i \log_{|\vec{w}|}(p_i)$, where $p_i = \frac{w_i}{\sum_j w_j}$ and $i, j \in \{1 \ldots |\vec{w}|\}$. A similar formulation was employed in Eagle et al. (2010). Intuitively, if $v \in P$, $H(v)$ measures the extent to which the document group is concentrated around

[2] D^C is also a partition of D, when defined in this way.

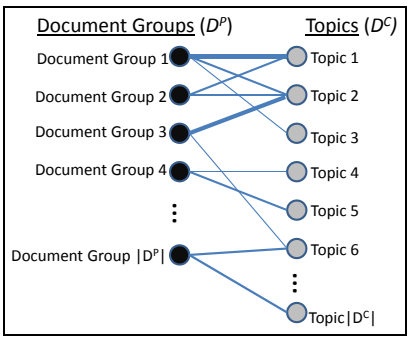

Figure 1: **[Toy Illustration of Bipartite Graph Model.]** Each black node (*i.e.*, node $\in P$) represents a document group. Each gray node (*i.e.*, node $\in C$) represents a cluster of documents pertaining primarily to the same topic.

a small number of topics (lower values of $H(v)$ mean more concentrated). Similarly, if $v \in C$, it is the extent to which a topic is concentrated around a small number of document groups.

Node Similarity. Given a graph G, there are many ways to measure the similarity of two nodes based on their connections. Such measures can be used to infer similarity (and dissimilarity) among document groups. However, existing methods are not well-suited for the task of document group comparison. The well-known SimRank algorithm (Jeh and Widom, 2002) ignores edge weights, and neither SimRank nor its extension, SimRank++ (Antonellis et al., 2008), scale to larger graphs. SimRank++ and ASCOS (Chen and Giles, 2013) do incorporate edge weights but in ways that are not appropriate for document group comparisons. For instance, both SimRank++ and ASCOS incorporate magnitude in the similarity computation. Consider the case where document groups are defined as research labs. ASCOS and SimRank++ will measure large research labs and small research labs as less similar when in fact they may publish nearly identical lines of research. Finally, under these existing methods, document groups sharing zero topics in common could still be considered similar, which is undesirable here. For these reasons, we formulate similarity as follows. Let $N^G(\cdot)$ be a function that returns the neighbors of a given node in G. Given two nodes $u, v \in P$, let $L^{u,v} = N^G(u) \cup N^G(v)$ and let $x : I \rightarrow L^{u,v}$ be the indexing function for $L^{u,v}$.[3] We construct two vectors, $\vec{a}$ and $\vec{b}$, where $a_k = w(u, x(k))$, $b_k = w(v, x(k))$, and $k \in I$. Each vector is essentially a sequence of weights for edges between $u, v \in P$ and each node in $L^{u,v}$. Similarity of two nodes is measured using the cosine similarity of their corresponding sequences, $\frac{\vec{a}\cdot\vec{b}}{\|\vec{a}\|\|\vec{b}\|}$, which we compute using a function $sim(\cdot,\cdot)$. Thus, document groups are considered more similar when they have similar sets of topics in similar proportions. As we will show later, this simple solution, based on item-based collaborative filtering (Sarwar et al., 2001), is surprisingly effective at inferring similarity among document groups in G.

Node Clusters. Identifying clusters of related nodes in the bipartite graph G can show how document groups form larger classes. However, we find that G is typically fairly dense. For these reasons, partitioning of the one-mode projection of G and other standard bipartite graph clustering techniques (*e.g.*, Dhillion (2001) and Sun et al. (2009)) are rendered less effective. We instead employ a different tack and exploit the node similarities computed earlier. We transform G into a new weighted graph $G^P = (P, E^P, w^{sim})$ where $E^P = \{(u, v) \mid u, v \in P, sim(u, v) > \xi\}$, ξ is a pre-defined threshold, and w^{sim} is the edge weight function (*i.e.*, $w^{sim} = sim$). Thus, G^P is the similarity graph of document groups. $\xi = 0.5$ was used as the threshold for our analyses. To find clusters in G^P, we employ the Louvain algorithm, a heuristic method based on modularity optimization (Blondel et al., 2008). Modularity measures the fraction of edges falling within clusters as compared to the expected fraction if edges were distributed evenly in the graph (Newman, 2006). The algorithm initially assigns each node to its own cluster. At each iteration, in a local and greedy fashion, nodes are re-assigned to clusters with which they achieve the highest modularity.

4 Example Analysis: NSF Grants

As a realistic and informative case study, we utilize our model to characterize funding programs of the National Science Foundation (NSF). This corpus consists of 132,372 grant abstracts describing awards for basic research and other support funded by the NSF between the years 1990 and 2002 (Bache and Lichman, 2013).[4] Each award is associated with both a program element (*i.e.*, funding source) and a date. We define *document*

[3] I is the index set of $L^{u,v}$.

[4] Data for years 1989 and 2003 in this publicly available corpus were partially missing and omitted in some analyses.

groups in two ways: by program element and by calendar year. For comparison criteria, we used topics discovered with the MALLET implementation of LDA (McCallum, 2002) using $K = 400$ as the number of topics and 200 as the number of iterations. All other parameters were left as defaults. The NSF corpus possesses unique properties that lend themselves to experimental evaluation. For instance, program elements are not only associated with specific sets of research topics but are named based on the content of the program. This provides a measure of ground truth against which we can validate our model. We structure our analyses around specific questions, which now follow.

Which NSF programs are focused on specific areas and which are not? When defining *document groups* as program elements (*i.e.,* each NSF program is a node in P), node entropy can be used to answer this question. Table 1 shows examples of program elements most and least associated with specific topics, as measured by entropy. For example, the program *1311 Linguistics* (low entropy) is largely focused on a single *linguistics* topic (labeled by LDA with words such as "language," "languages," and "linguistic"). By contrast, the *Australia* program (high entropy) was designed to support US-Australia cooperative research across many fields, as correctly inferred by our model.

Low Entropy Program Elements	
Program	**Primary LDA Topic**
1311 Linguistics	language languages linguistic
4091 Network Infrastructure	network connection internet
High Entropy Program Elements	
Program	**Primary LDA Topic**
5912 Australia	(many topics & disciplines)
9130 Research in Minority Instit.	(many topics & disciplines)

Table 1: **[Examples of High/Low Entropy Programs.]**

Which research areas are growing/emerging? When defining *document groups* as calendar years (instead of program elements), low entropy nodes in C are topics concentrated around certain years. Concentrations in later years indicate growth. The LDA-discovered topic *nanotechnology* is among the lowest entropy topics (*i.e.,* an outlier topic with respect to entropy). As shown in Figure 2, the number of *nanotechnology* grants drastically increased in proportion through 2002. This result is consistent with history, as the National Nanotechnology Initiative was proposed in the late 1990s to promote nanotechnology R&D.[5] One could also measure such trends using budget allocations by incorporating the award amounts into the edge weights of G.

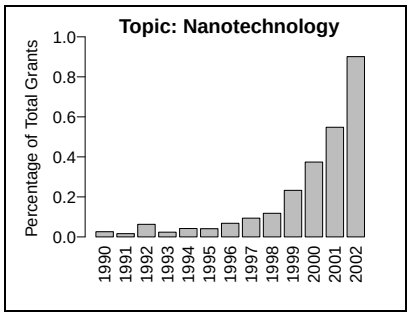

Figure 2: **[Uptrend in Nanotechnology.]** Our model correctly identifies the surge in nanotechnology R&D beginning in the late 1990s.

Given an NSF program, to which other programs is it most similar? As described in Section 3, when each node in P represents an NSF program, our model can easily identify the programs most similar to a given program. For instance, Table 2 shows the top three most similar programs to both the *Theoretical Physics* and *Ecology* programs. Results agree with intuition. For each NSF program, we identified the top n most similar programs ranked by our $sim(\cdot,\cdot)$ function, where $n \in \{3, 6, 9\}$. These programs were manually judged for relatedness, and the Mean Average Precision (MAP), a standard performance metric for ranking tasks in information retrieval, was computed. We were unsuccessful in evaluating alternative weighted similarity measures mentioned in Section 3 due to their aforementioned issues with scalability and the size of the NSF dataset. (For instance, the implementations of ASCOS (Antonellis et al., 2008) and SimRank (Jeh and Widom, 2002) that we considered are available here.[6]) Recall that our $sim(\cdot,\cdot)$ function is based on measuring the cosine similarity between two weight vectors, $\vec{a}$ and $\vec{b}$, generated from our bipartite graph model. As a baseline for comparison, we evaluated two additional similarity implementations using these weight vectors. The first measures the similarity between weight vectors using weighted Jaccard similarity, which is $\frac{\sum_k \min(a_k,b_k)}{\sum_k \max(a_k,b_k)}$ (denoted as *Wtd. Jaccard*). The second measure is implemented by taking the Spearman's rank correlation coefficient of $\vec{a}$ and $\vec{b}$ (de-

[5] http://en.wikipedia.org/wiki/National_Nanotechnology_Initiative

[6] https://github.com/hhchen1105/networkx_addon

noted as *Rank*). Figure 3 shows the Mean Average Precision (MAP) for each method and each value of n. With the exception of the difference between *Cosine* and *Wtd. Jaccard* for MAP@3, all other performance differentials were statistically significant, based on a one-way ANOVA and post-hoc Tukey HSD at a 5% significance level. This, then, provides some validation for our choice.

1245 Theoretical Physics	**1182 Ecology**
1286 Elementary Particle Theory	1128 Ecological Studies
1287 Mathematical Physics	1196 Environmental Biology
1284 Atomic Theory	1195 Ecological Research

Table 2: **[Similarity Queries.]** Three most similar programs to the *Theoretical Physics* and *Ecology* programs.

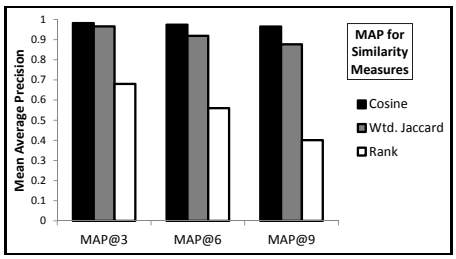

Figure 3: **[Mean Average Precision (MAP).]** Cosine similarity outperforms alternative approaches.

How do NSF programs join together to form larger program categories? As mentioned, by using the similarity graph G^P constructed from G, clusters of related NSF programs can be discovered. Figure 4, for instance, shows a discovered cluster of NSF programs all related to the field of neuroscience. Each NSF program (*i.e.*, node) is composed of many documents.

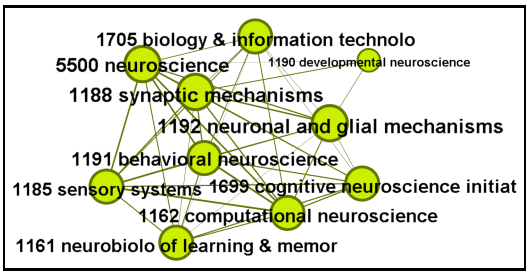

Figure 4: **[Neuroscience Programs.]** A discovered cluster of program elements all related to *neuroscience*.

Which pairs of grants are the most similar in the research they describe? Although the focus of this paper is on drawing comparisons among *groups* of documents, it is often necessary to draw comparisons among *individual* documents, as well. For instance, one may wish to identify pairs of grants from *different* programs describing highly similar lines of research. One common approach to this is to measure the similarity among low-dimensional representations of documents returned by LDA (Blei et al., 2003). We employ the Hellinger distance metric for this. Unfortunately, identifying the set of *most* similar document pairs in this way can be computationally expensive, as the number of pairwise comparisons scales quadratically with the size of the corpus. To address this, our bipartite graph model can be exploited as a *blocking* heuristic using either the document groups or the comparison criteria. In the latter case, one can limit the pairwise comparisons to only those documents that reside in the same subset of D^C. For the former case, *node similarity* can be used. Instead of comparing each document with every other document, we can limit the comparisons to only those document groups of interest that are deemed similar by our model. As an illustrative example, the program *1271 Computational Mathematics* and the program *2865 Numeric, Symbolic, and Geometric Computation* are inferred as being highly similar. Between these groups, the following two grants are easily identified as being the most similar with a Hellinger similarity score of 0.73 (only titles are shown due to space constraints):

- **Grant #1: Analyses of Structured Computational Problems and Parallel Iterative Algorithms**
  (Discusses parallel iterative methods for solutions to large sparse/dense systems of linear equations.)
- **Grant #2: Sparse Matrix Algorithms on Distributed Memory Multiprocessors**

As can be seen, despite some differences in terminology, the two lines of research are related, as matrices (studied in Grant #2) are used to compactly represent and work with systems of linear equations (studied in Grant #1).

5 Conclusion

We have presented a bipartite graph model for drawing comparisons among large *groups* of documents. We showed how basic algorithms using the model can identify trends and anomalies among the document groups. As an example analysis, we demonstrated how our model can be used to better characterize and evaluate NSF research programs. For future work, we plan on employing alternative comparison criteria in our model such as those derived from named entity recognition and paraphrase detection.

$C3EL$: A Joint Model for Cross-Document Co-Reference Resolution and Entity Linking

Abstract

Cross-document co-reference resolution (CCR) computes equivalence classes over textual mentions denoting the same entity in a document corpus. Named-entity linking (NEL) disambiguates mentions onto entities present in a knowledge base (KB) or maps them to $null$ if not present in the KB. Traditionally, CCR and NEL have been addressed separately. However, such approaches miss out on the mutual synergies if CCR and NEL were performed jointly.

This paper proposes $C3EL$, an unsupervised framework combining CCR and NEL for jointly tackling both problems. $C3EL$ incorporates results from the CCR stage into NEL, and vice versa: additional global context obtained from CCR improves the feature space and performance of NEL, while NEL in turn provides distant KB features for already disambiguated mentions to improve CCR. The CCR and NEL steps are interleaved in an iterative algorithm that focuses on the highest-confidence still unresolved mentions in each iteration. Experimental results on two different corpora, news-centric and web-centric, demonstrate significant gains over state-of-the-art baselines for both CCR and NEL.

1 Introduction

With the advent of large knowledge bases (KB) like DBpedia, YAGO, Freebase, and others, entities (people, places, organizations, etc.) along with their attributes and relationships form the basis of smart applications like search, analytics, recommendations, question answering, and more. The major task that arises in both the KB construction process and the entity-centric applications involves precise *recognition*, *resolution*, and *linking* of named entities distributed across web pages, news articles, and social media.

Named Entity Recognition (NER) deals with the identification of entity *mentions* in a text and their classification into coarse-grained semantic types (person, location, etc.) (Finkel et al., 2005; Nadeau & Sekine, 2007; Ratinov & Roth, 2009). This involves segmentation of token sequences to obtain mention boundaries, and mapping relevant token spans to pre-defined entity categories. For example, NER on the text `Einstein won the Nobel Prize` identifies the mentions "Einstein" and "Nobel Prize" and marks them as *person* and *misc* type, respectively.

Named Entity Linking (NEL)[1] involves the *disambiguation* of textual mentions, based on context and semantic information, and their mapping to proper *entities in a KB* (Bunescu & Paşca, 2006; Cucerzan, 2007; Milne & Witten, 2008; Hoffart et al., 2011; Ratinov et al., 2011; Cornolti et al., 2013). For example, in the above text, the mention "Einstein" is linked to the physicist *Albert Einstein*.

Entity *Co-reference Resolution* (CR) (Haghighi & Klein, 2010; Ng, 2010; Lee et al., 2013) is essentially a clustering task to identify mentions (and anaphoras) within a document referring to the same entity, thus computing equivalence classes or *mention groups*. For example, mentions `Albert Einstein` and `Nobel laureate Einstein` both refer to the same entity *German physicist Albert Einstein*, but are different from the mention `Hans Albert Einstein`.

When CR is extended to an entire text corpus, in order to generate equivalence classes of co-referring mentions across documents, the task is known as *Cross-document Co-reference Resolution* (CCR) (Bagga & Baldwin, 1998; Culotta et al., 2007; Singh et al., 2011; Dutta & Weikum, 2015). Note that CCR is not the same as merely concatenating all documents in the corpus and utilizing existing CR methods. The linguistic diversity across documents and high computational cost for huge numbers of mentions in the corpus would typically make such a CR-based simulation perform poorly. Neither CR nor CCR links mention groups to corresponding KB entities. Thus, they represent both in-KB entities and out-of-KB entities (e.g., long-tail or emerging entities that do not have a Wikipedia article) in the same way.

[1] *Named Entity Disambiguation (NED)* and "Wikification" are often used to denote the same task. The latter may be more broadly used, though, to include the disambiguation of common nouns and phrases onto concepts, whereas NED restricts itself to noun phrases that denote individual entities.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 846–856,
Lisbon, Portugal, 17-21 September 2015.

State-of-the-Art and its Limitations: Established CR methods rely on rule-based methods or supervised learning techniques on syntactic paths between mentions, semantic compatibility, and other linguistic features (Haghighi & Klein, 2009), with additional use of distant features from KBs (Lee et al., 2013). Modern cluster-ranking (Rahman & Ng, 2011) and multi-sieve methods (Ratinov & Roth, 2012) involve incremental expansion of mention groups by considering semantic types and Wikipedia categories. CCR methods utilize transitivity-aware clustering techniques (Singh et al., 2011), by considering mention-mention similarities (Bagga & Baldwin, 1998) along with features extracted from external KBs (Dutta & Weikum, 2015).

NEL methods often harness the semantic similarity between mentions and entities and also among candidate entities for different mentions (in Wikipedia or other KBs) for contextualization and coherence disambiguation (Hoffart et al., 2011; Milne & Witten, 2008; Kulkarni et al., 2009; Ratinov et al., 2011). However, in the absence of CR mention groups, NEL has limited context and is bound to miss out on certain kinds of difficult cases.

Although NER, CR, CCR and NEL involve closely related tasks and their tighter integration has been shown to be promising (Chen & Roth, 2013; Zheng et al., 2013), they have mostly been explored in isolation. Recently, several *joint models* have been proposed for `CR-NER` (Haghighi & Klein, 2010; Singh et al., 2013), `CR-NEL` (Hajishirzi et al., 2013), and `NER-CR-NEL` (Durrett & Klein, 2014). However, to the best of our knowledge, no method exists for jointly handling CCR and NEL on large text corpora.

1.1 Approach and Contributions

This paper proposes the novel $C3EL$ *(Cross-doCument Co-reference resolution and Entity Linking)* framework for jointly modeling cross-document co-reference resolution (CCR) and linkage of mention groups to entities in a knowledge base (NEL).

Example: To illustrate the potential synergies between CCR and NEL, consider the 3 documents in Figure 1 containing 9 mentions (on the left) with candidate entities from a KB (on the right). CCR alone would likely miss the co-reference relation between `Logan` (Doc 1) and its alias `Wolverine` (Doc 2), leaving NEL with the difficult task of disambiguating "Logan" in a document with sparse and highly ambiguous context (Doc 1). On the other hand, NEL alone would likely map `Australia` (Doc 3) to the country (not the movie) and could easily choose the wrong link for mention "Hugh". Moreover, the presence of `Ava Eliot` as an out-of-KB mention complicates the task.

However, if we could more freely interleave

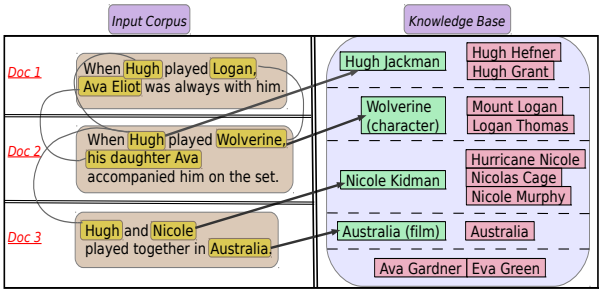

Figure 1: Joint CCR-NEL Example *(Green KB entries connected via arrows denote the correct entity linkage for the mention co-reference groups; while the red ones represent alternative incorrect candidates with similar surface forms)*

CCR and NEL and could iterate them several times, we would be in a much stronger position. An initial NEL step for the easiest mention, namely "Wolverine", maps it to the character of X-Men movies. This indicates that the three "Hugh" mentions could all be the same actor, and are thus easily merged into a co-reference group using CCR. We now have enough cues for NEL to choose the right entity for the "Hugh" mention group, which in turn enables the proper mapping of "Australia" to the movie. Finally, it becomes clear that mentions "Ava Eliot" and "his daughter Ava" should be merged into the same group and represented as an out-of-KB entity mapped to $null$.

The above example clearly demonstrates that interleaving CCR and NEL is highly beneficial. However, appropriate choices for the ordering of CCR and NEL steps are usually not obvious at all. The proposed $C3EL$ algorithm solves this problem: automatically determining an efficient interleaving of CCR and NEL.

Approach: $C3EL$ iteratively aggregates intermediate information obtained from alternating steps of CCR and NEL, thus forming a *feedback loop* for propagating mention features and entity knowledge. Intuitively, co-referring mentions obtained via CCR generate global context for improved NEL performance, while mentions linked to KB entities (by NEL) provide distant semantic features with additional cues for CCR. $C3EL$ couples several building blocks like unsupervised hierarchical clustering, *context summaries* for mentions and distant KB features for entities, drawing inspiration from the CCR-only method of (Dutta & Weikum, 2015). Mention linking to the KB (NEL) is performed using distant knowledge and co-occurring mentions.

In a nutshell, the major contributions of this paper are:

- the $C3EL$ framework for joint computation of cross-document co-reference resolution (CCR) and entity linking to a KB (NEL), based on propagating information across iterative CCR and NEL steps;
- techniques for considering co-occurring mentions in *context summaries* and for harnessing

context-based keywords for *link validation* in NEL, improving accuracy on out-of-KB entities;

- an experimental evaluation with two different corpora, one based on news articles and one based on web pages, demonstrating substantial gains for both CCR and NEL over state-of-the-art methods.

2 $C3EL$: Joint CCR-NEL Framework

Given an input corpus C of n documents, $C = \{D_1, D_2, \cdots, D_n\}$ with entity mentions $EM = \{m_{11}, m_{12}, \cdots, m_{21}, m_{22}, \cdots\}$ ($m_{ij} \in D_i$), $C3EL$ aims to *jointly compute*:

- CCR: an equivalence relation over EM with equivalence classes E_i, such that $E_i \cap_{i \neq j} E_j = \emptyset$ and $\cup_i E_i = EM$, and
- NEL: linking each of the classes E_i to entities present in a KB or map it to $null$ if there is no proper entity in the KB.

To this end, $C3EL$ consists of 3 algorithmic stages: **(i)** Pre-Processing, **(ii)** Interleaved NEL and CCR, and **(iii)** Finalization.

2.1 Pre-Processing Stage

HTML pages in the input corpus C are transformed into plain text using standard tools like `jsoup.org`. Recognition and markup of mentions are performed using the Stanford CoreNLP toolkit (`nlp.stanford.edu`), and a coarse-grained lexical type for each mention (e.g., person, location, organization, etc.) is obtained from the Stanford NER Tagger (Finkel et al., 2005). The multi-pass sieve algorithm for single-document CR (Raghunathan et al., 2010; Lee et al., 2011; Lee et al., 2013) then computes mention co-reference chains per document, and a *head mention* is chosen for each of the mention groups (chains). The head mention is typically represented by the most explicit denotation of the entity (e.g., person's full name with title, location name with country, etc.).

For each of the mention groups M_i, C3EL then constructs a *context summary* using:

- **Sentences** – all sentences in the document that contain mentions of group M_i; and
- **Co-occurrence** – all sentences for other mention groups that contain mentions co-occurring in any of the sentences of M_i (as obtained above).

Formally, for each mention group M_i, let $S(M_i) = \{sentence(m_j) \mid m_j \in M_i\}$ represent the set of extracted sentences, where $sentence(m_j)$ denotes the sentences in which mention m_j occurs. Also, let the co-occurring mention set of M_i be $Co(M_i) = \{m' \mid m' \in S(M_i) \wedge m' \notin M_i\}$. The context summary of M_i is defined as:

$$\mathbb{CS}(M_i) = S(M_i) \cup \left(\bigcup_{m' \in Co(M_i)} S(m') \right)$$

The context summaries intentionally do not include any distant KB features for mentions. The intuition is to minimize potential noise from overly speculative mappings to the KB at this initial stage.

2.2 Interleaved NEL & CCR Approach

After the preliminary CR step on each document and the construction of context summaries, $C3EL$ now performs an initial NEL step for each of the mention groups M_i, using the extracted sentences $S(M_i)$ as inputs to NEL. It obtains the best matching entity, the confidence of the match, and its corresponding Wikipedia page. Off-the-shelf NEL software (like WikipediaMiner or Illinois-Wikifier) is used for mention-entity mapping based on prior popularity of the named-entities (from the KB) and textual similarity between $S(M_i)$ (context of the mention group) and the entity descriptions in KB.

For each M_i, the entity link obtained (from NEL) is then "validated" using a similarity measure between features from the *context summary*, $\mathbb{CS}(M_i)$ (including co-occurring mentions) and distant KB labels – forming the *link validation* procedure of $C3EL$. This explicit use of co-occurring mentions' ($Co(M_i)$) contexts helps to better identify out-of-KB entities compared to direct full-fledged NEL using the entire input text (shown in Section 3). Also the use of NEL on $S(M_i)$ alone, makes $C3EL$ "light-weighted".

The mappings between the mention groups and KB entries are then classified, on the basis of the NEL confidence scores, into *Strong Evidence* (SE), *Weak Evidence* (WE), and *No Evidence* (NE) classes. For mention groups placed in SE, the KB features (obtained previously) are appended to their context summaries, while mentions strongly linked to same KB entities are considered to be co-referring and hence grouped together (performing implicit CCR).

Considering our example (Figure 1), we now outline the iterative steps of $C3EL$ interleaving NEL & CCR.

1. During **Iteration 1**, $C3EL$ performs:

- **NEL:** The initial NEL step maps the unambiguous mentions, `Wolverine` to the X-Men movie character and `Australia` to the country, with high confidence. However, link validation fails for "Australia" as there is very low similarity between the mention context features (e.g., Hugh, Wolverine, etc.) and the distant KB labels extracted from its Wikipedia page (e.g., Commonwealth, population, etc.); thus the link is dropped and the mention is added to NE. So only the mention "Wolverine" is added to the

SE class and enriched with KB features (e.g., alias Logan).

On the other hand, the 3 "Hugh" mentions exhibit low NEL confidence due to the high ambiguity of this first name and are therefore classified into WE. The remaining mentions have extremely low NEL confidence (due to sparse contextual information) and are added to NE.

- **CCR:** The WE and NE classes are fed separately to the CCR procedure. Based on the *context summary* similarities between mentions, $C3EL$ performs hierarchical clustering to group together the "Hugh" mentions (in the WE class) and creates a co-referring mention group with the individual mentions' context summaries concatenated. This merging of summaries grows and strengthens captured contexts, which propagates across documents. This concludes the first iteration of $C3EL$.

2. The above results are provided to the **second Iteration**:

- **NEL:** The *context summary* of the "Hugh" mention group in WE now provides definitive cues to correctly map it to the actor Hugh Jackman with high confidence, thus placing it in the SE class.
- **CCR:** The ensuing CCR step groups together "Ava Eliot" and "Ava" (in NE) using co-occurrence context of the co-referring Hugh mentions.

3. Subsequent NEL iterations (on WE and NE) identify "Ava" as an out-of-KB entity and correctly links "Australia" to the movie using CCR-generated mention-group contexts and link validation. CCR finally groups together "Logan" with "Wolverine" based on context similarity with distant KB features. This process of alternating CCR and NEL is repeated until all mention groups are strongly connected to KB entities (placed in SE), or no changes are made anymore.

The NEL and CCR procedures are performed separately on the different mention types (like PER, LOC, etc.), since different mention types rarely co-refer. We next present the internal working details of the NEL and CCR stages of $C3EL$.

2.2.1 Named-Entity Linking (NEL) Stage

In its NEL procedure, $C3EL$ disambiguates mentions to entities in the YAGO knowledge base (`yago-knowledge.org`). We perform NEL on the sentences ($S(M_i)$) of a mention group, using named-entity popularity statistics and context, to obtain the best matching entity, its confidence score, and the corresponding Wikipedia page (from $sameAs$ link in YAGO). Assume a mention group M_i to be mapped to an entity e_i with a confidence score of $\phi(M_i, e_i)$.

A. Link Validation: For each mention group (e.g., Hugh), we extract *distant KB labels* such as semantic types or categories (e.g., actor), title (e.g., Golden Globe winner), alias (e.g., Wolverine), location, and gender (for person) from the Wikipedia page infoboxes. The similarity of these features to keywords obtained from the context summary $\mathbb{CS}(M_i)$ is computed using IR-style term frequencies within a document (tf) and inverse document frequencies within the corpus (idf). We utilize the bag-of-words model based $tf \times idf$-weighted cosine similarity measure. If the similarity score is above a threshold, τ, the NEL result is accepted, otherwise it is discarded – thus avoiding noisy linkage of sparse mentions to prominent KB entries. This subtle introduction of *controlled distant supervision* within the $C3EL$ framework enables efficient detection of out-of-KB mentions.

B. Classification: To sift out well-known and long-tail entities from new ones, and prevent "noisy" interactions among the contexts of in-KB and out-of-KB mentions (with similar surface forms), mention groups M_i (linked to e_i with score $\phi(M_i, e_i)$) are classified into 3 classes by 2 threshold parameters, δ_s and δ_w, as:

- *Strong Evidence* (SE): For $\phi(M_i, e_i) \geq \delta_s$, mention group M_i exhibits high linkage confidence with e_i and is placed in SE. If two or more mentions in SE are independently mapped to the same KB entity, they co-refer transitively and are hence grouped together with their context summaries merged (implicit CCR). Distant KB features for mentions in SE are extracted and appended to $\mathbb{CS}(M_i)$, providing additional cues for later steps.
- *Weak Evidence* (WE): Mention groups with $\delta_w \leq \phi(M_i, e_i) < \delta_s$ are placed in this class. They mostly represent long-tail in-KB entities (sparsely represented in KB) with limited semantic information (for detection) but might also be new/emerging entities absent from KB.
- *No Evidence* (NE): $\phi(M_i, e_i) < \delta_w$ represents mentions groups that have been mapped to $null$ (or have near-zero match confidence) or have failed link validation during the NEL procedure. These entities are most likely to be out-of-KB and are allocated to this class.

2.2.2 Cross-Document CR (CCR) Stage

The CCR stage of $C3EL$ adopts the sampling-based hierarchical clustering approach of (Dutta & Weikum, 2015), to obtain co-referring mention clusters.

A. Similarity Measure: To infer whether two mention groups represent the same entity, the similarity between the context summaries are computed based on (i) *tf-idf*-weighted bag-of-words cosine distance, and (ii) partial-match scores of multi-word keyphrases in bounded text windows (Taneva et al., 2011). The context summaries (with stopwords removed) are re-interpreted as, (i) bag of words, and (ii) bag of keyphrases, to extract fea-

ture vectors for similarity computation. Finally, the mixture model of *bag-of-words* (BoW) and *keyphrases* (KP) of (Dutta & Weikum, 2015) is used to assign feature weights using *tf-idf* measure.

B. Hierarchical Clustering: s mention groups are uniformly randomly sampled and their similarities to the other groups (using context summary) are computed. A similarity-weighted graph with the mention groups as nodes and edge weights representing mention-mention similarities is constructed. Bisection-based hierarchical *balanced min-edge-cut graph partitioning* (Buluc et al., 2013) is performed, using the $METIS$ software (Karypis & Kumar, 1999)[2], to partition non-coreferent mentions groups. The *Bayesian Information Criterion* (BIC) (Schwarz, 1978; Hourdakis et al., 2010), a Bayesian variant of Minimum Description Length (Grünwald, 2007), is used as the cluster split stopping criterion, and the context summaries within each final cluster are merged.

CCR aims to process heterogeneous corpora that go beyond a single domain and style, such as Web collections.

2.3 Finalization Stage

For the remaining mention groups in WE, we finally perform threshold based disambiguation of mention clusters using the context summaries. For each mention group $M_i \in WE$, we compute (1) its context summary similarities (as in Section 2.2.2) to all other mention groups M_j in SE by also using distance features from the weakly linked KB entities, and (2) textual overlap between the mention group representatives. M_i is concatenated with the best matching entity M_k (in SE) if the similarity score is above a threshold θ; else M_i is marked as an out-of-KB entity (mapped to $null$) and is placed in the NE class. This helps in reducing propagated CR errors like erroneous mention boundary detection (in NER), omissions in co-reference chain, etc. (leading to "phantom" out-of-KB entities).

The obtained mention groups represent the final equivalence classes of co-referring mentions across documents – capturing both in-KB entities (with links to the KB) in the SE class and out-of-KB entities (mapped to $null$) in the NE class.

3 Experimental Evaluation

In this section, we empirically study the performance of $C3EL$ against various state-of-the-art methods. We analyze the individual gains in CCR and NEL due to the joint modeling.

Datasets: We use the following 2 publicly available corpora:

- **EventCorefBank (ECB) corpus**[3] (Bejan & Harabagiu, 2010)**:** contains 482 news and Web articles (classified into 43 topics) with a total of 5447 mentions corresponding to 1068 distinct named-entities. Entity co-reference annotations (across documents within each topic cluster) were provided by (Lee et al., 2012), and we performed manual examination of the annotations for KB linking of the entities to Wikipedia entries, if present; thus providing ground truth for both CCR and NEL.
- **ClueWeb2009 FACC1 dataset**[4] (Gabrilovich et al., 2013)**:** provides machine automated entity-linkage annotations of the *ClueWeb09* corpus (ca. 1 Billion crawled Web pages) with Freebase entries[5]. The corpus contains many topical domains and highly diverse documents from news, movie reviews, people home pages to blogs and other social media posts. We randomly select $500K$ documents containing 4.64 Million mentions associated with 1.29 Million distinct entities to form our corpus. For NEL ground-truth construction, we link the entities to their Wikipedia pages (using Freebase's "on the web" property). Since no explicit annotations of inter-document entity co-references exists, we consider two mentions (in different documents) to co-refer if they are linked with the same Freebase entity.

Evaluation: To assess the output quality of $C3EL$ we use the following established metrics:

- B^3 $F1$ **score** (Bagga & Baldwin, 1998): measures the F1 score as the harmonic mean of average *precision* and *recall* computed over all mention groups in the final equivalence classes. Precision (for a mention group) represents the ratio of the number of correctly reported co-references (or linking) to the actual number; while recall computes the fraction of the gold-standard annotations correctly identified.
- ϕ_3 $-$ $CEAF$ **score** (Luo, 2005): provides an alternate F1 score computed as in the B^3 measure; but calculates precision and recall of mention groups using the best 1-to-1 mapping (i.e., mapping with maximum mention overlap) between the resultant equivalence classes and those in the ground truth. Normalization with the number of mentions for each of the resultant classes yields the ϕ_4-CEAF score.

We consider only the 3 most notable mention types: person (PER), location (LOC), and organization (ORG) – accounting for 99.7% of entities present in the ECB corpus and 96.3% of our ClueWeb09 corpus. All experiments were conducted on a 4 core Intel i5 2.50 GHz processor with 8GB RAM running Ubuntu 12.04 LTS.

3.1 Parameter Tuning & Sensitivity Study

Validation of entity linkage to KB and their subsequent classification into *confidence classes* (as de-

[5] Human analysis of a subset of the annotations generated revealed a precision of $80 - 85\%$ (Gabrilovich et al., 2013)

Approach	P	R	B^3	ϕ_3	ϕ_4
EECR	74.9	55.5	63.7	-	33.7
CROCS	73.11	75.28	74.18	67.35	-
C3EL	79.52	82.91	81.18	73.89	53.3

Table 2: CCR performance (%) comparison on ECB

scribed in Section 2) during the NEL step of $C3EL$ are based on 3 parameters: confidence thresholds (δ_s and δ_w) and validation threshold (τ); the values of which can be tuned based on *cross-validation* approach with *train* and *test* data subsets. Using the "gold annotations" of the train-set (30% of total data), parameter values providing the best precision score are individually learnt using *line search* with small step size.

In our experimental setup, we systematically vary the parameter values and observe its effects on $C3EL$ for the training data. With increase in δ_s, the number of mentions mapped to the *Strong Evidence* (SE) class decreases. This in turn limits the influx of external KB features, thus degrading CCR performance as observed in Table 1(a). While for low values of δ_s, even weak mention links are placed in SE, leading to a decrease in precision due to noisy KB feature inclusion. On the other hand, a high δ_w value increases the number of mentions in the NE class, while low values tends to accumulate mentions in the WE class. This adversely affects the detection of out-of-KB entities due to noise from other co-occurring similar KB mentions (refer Table 1(b)) during clustering in CCR step.

The effect of τ on $C3EL$ has be shown in Table 1(c). Similar to the behavior induced by δ_s, we observe that a high τ limits entity linking and possible KB feature inclusion, while an extremely low value (near to zero) allows for noisy feature incorporation – both situations leading to lowered CCR efficiency. However, since τ prevents gross mis-alignment of mentions to KB entities, a wide range of small value ($0.1 - 0.35$) is seen to provide comparable performance.

Hence, for our remaining experimental study we set $\delta_s = 0.11$ and $\delta_w = 0.06$ (as in (Hoffart et al., 2014)), while τ is set to 0.1, and threshold for the finalization stage $\theta = 2 \times \delta_s = 0.22$.

3.2 CCR Performance Results

We initially benchmark the performance improvement in cross-document co-reference resolution (CCR) procedure by $C3EL$ against two competing approaches:
(1) state-of-the art sampling based hierarchical clustering method, $CROCS$ (Dutta & Weikum, 2015); and
(2) iterative joint entity-event CCR, $EECR$ (Lee et al., 2012).

Table 2 tabulates the results obtained on the ECB dataset. We observe C3EL to decisively outperform both the existing methods, providing a B^3 F1 improvement of around 7% over $CROCS$ and 17% over EECR. We further attain around 6% $\phi_3 - CEAF$ score enhancement over CROCS, and a significant 20% improved $\phi_4 - CEAF$ score compared to EECR.

Approach	P (%)	R (%)	B^3 (%)	ϕ_3 (%)
$CROCS_G$	79.9	83.33	81.58	74.11
$C3EL_G$	84.74	89.9	87.24	80.5

Table 3: CCR results on ECB

Type	Approach	P (%)	R (%)	B^3 (%)
PER	$CROCS_G$	71.8	74.15	72.96
	$C3EL_G$	84.85	82.73	83.78
LOC	$CROCS_G$	78.23	85.41	81.66
	$C3EL_G$	81.41	94.31	87.29
ORG	$CROCS_G$	85.73	87.89	86.8
	$C3EL_G$	88.52	91.82	90.14

Table 4: CCR results on ECB for mention types

A. Gold Results: Errors introduced during the preprocessing stage of C3EL (e.g., mention omission, tag mis-classification, intra-document CR errors, etc., by the Stanford CoreNLP toolkit) propagate to subsequent computing stages and adversely impacts the overall system performance. To provide an unbiased viewpoint of the actual performance of $C3EL$, we manually provided "exact" mentions, mention tags, and intra-document CR mention chains for the ECB corpus; thereby obtaining *gold performance results*. From Table 3 we observe a 6% F1 points improvement (for both B^3 & CEAF-ϕ_3) in $C3EL$ compared to $CROCS$.

B. Mention Categorization: Person mention type (PER) provides the greatest challenge for CCR systems (compared to other types like LOC, ORG, etc.) due to associated nicknames, titles, and varied surface forms (abbreviations, spellings, etc.). We thus evaluate the CCR performance of $C3EL$ (and compare it with CROCS) on the ECB data, with "exact" input mentions, for the different mention categories. Table 4 validates that our joint modeling provides better global information cues, reporting a B^3 F1 score enhancement of around 11% over CROCS for PER mentions; along with improved results for the other mention types as well.

C. Large Data: To study the robustness of $C3EL$ and the effects of large datasets on CCR, we performed evaluations on the ClueWeb09-FACC1 dataset. Similar to the ECB dataset, $C3EL$ exhibits a B^3 F1 score improvement of nearly 10% and a ϕ_3-CEAF F1 improvement of 12% over $CROCS$ (refer Table 5).

The above experimental results showcase that a combined approach helps overcome challenges faced in CCR by entity linkage and corresponding distant KB feature extraction; improving the overall accuracy.

3.3 Named-Entity Linking (NEL) Results

We now benchmark the performance of named-entity linking (NEL) procedure for $C3EL$ against the state-of-the-art open-source AIDA software (`github.com/yago-naga/aida`). We separately inspect the precision of mention linking for *prominent entities* (in-KB) as well as *new/emerging* (out-of-KB) entities, and characterize the links as

Datasets	δ_s (B^3 F1)					δ_w (P)					τ (B^3 F1)				
	0.01	*0.05*	*0.10*	*0.15*	*0.20*	*0.01*	*0.02*	*0.04*	*0.06*	*0.08*	*0.03*	*0.10*	*0.20*	*0.35*	*0.50*
ECB	79.3	82.2	84.2	83.5	81.0	73.1	75.3	77.3	78.7	78.4	76.9	81.2	81.2	81.1	79.2
ClueWeb	70.1	77.2	81.5	81.0	78.7	78.2	81.1	83.6	85.1	85.1	70.3	79.1	78.2	78.8	76.4
	(a)					(b)					(c)

CROCS	68.66	70.96	69.79	62.85
C3EL	75.76	81.42	78.49	74.13

Table 5: CCR results on ClueWeb09-FACC1

Approach	Within-KB			Out-of-KB		Overall
	$\mathbb{C}$	$\mathbb{I}$	$\mathbb{U}$	$\mathbb{C}$	$\mathbb{I}$	**P** (%)
AIDA	86.5	13.5	0.0	63.9	36.1	83.4
C3EL	85.4	14.4	0.2	79.0	21.0	84.9

Table 6: NEL performance (%) comparison on ECB

Correct ($\mathbb{C}$), *Incorrect* ($\mathbb{I}$), or *Unlinked* ($\mathbb{U}$). The results on the ECB corpus are reported in Table 6. $C3EL$ attains comparable performance ($\sim$ 85% precision) to that of AIDA for well-known entity-mentions present in KB; albeit with a few mentions remaining unlinked due to our cautious *link validation* (using τ) approach. However, the use of τ reduces aggressive KB linking to provide a significant 15% improvement (over AIDA) in precise detection of new/emerging entities absent in KB. Overall, an 1.5% precision gain is observed by the joint formulation.

A. Large Data: The diverse nature of the web-scale ClueWeb09 dataset clearly portrays the performance gains in NEL procedure due to CCR generated information integration. For entities present in the KB, we observe an accuracy improvement of 0.5% over AIDA (refer Table 7). Similar to that of the ECB data, $C3EL$ attains a significant $\sim$ 14% improvement in the detection of new/emerging entities not represented in KB. For the 1 million mentions, $C3EL$ provides around 4% overall performance improvements.

Using a bootstrap re-sampling t-test (as in (Durrett & Klein, 2014)), we observed high statistical significance ($p < 0.01$) for Out-of-KB and Overall NEL, whereas the difference for Within-KB NEL is not statistically significant. Coping with Out-of-KB entities is essential for joint CCR+NEL, and an improved NEL performance using propagated information from CCR using semantics along with link validation enables highly efficient detection of new or emerging entities.

3.4 Comparison with Joint Models

Traditional CR methods fail to cope with the heterogeneity of mentions and contexts across multiple documents, and some form of clustering or joint reasoning over all mentions is thus mandatory. These methods have quadratic or cubic (sometimes even exponential) complexity, and hence running CR+NEL on a concatenated super-document works only for small corpora, and would be prohibitively expensive for large corpora, even in offline processing mode (Singh et al., 2011).

However, to study the behavior of existing CR-NEL joint models under "small" CCR environments, we compare $C3EL$ with:
(1) multi-sieve based $NECo$ (Hajishirzi et al., 2013)[6]; and
(2) conditional random field based BER (Durrett & Klein, 2014) [7].

Approach	Within-KB			Out-of-KB		Overall
	$\mathbb{C}$	$\mathbb{I}$	$\mathbb{U}$	$\mathbb{C}$	$\mathbb{I}$	**P** (%)
AIDA	88.5	10.6	1.0	69.6	30.4	84.6
C3EL	89.0	9.8	1.2	83.7	16.3	88.1

Table 7: NEL results (%) on ClueWeb09-FACC1 (statistical significance $p < 0.01$ for Out-of-KB entities)

Three topic clusters from the ECB corpus with 3, 4, and 5 articles respectively were selected, and the documents within each cluster were merged to form 3 "super-articles" (one per topic), forming a simulated CR setting. $NECo$ and BER were then used to perform CR and NEL on these 3 articles, and the results compared with that obtained by $C3EL$ on the original documents. We repeatedly sample 12 articles across 3 topic clusters, and execute the approaches to report the micro-averaged results across 5 independent runs.

From Table 8(a) we observe that the algorithms exhibit comparable co-reference resolution performance; thus validating propagation of global semantics in $C3EL$ due to the joint formulation. However, such CR methods using multi-sieves and CRF do not scale beyond few documents (upon concatenation), and require at least $4\times$ more runtime compared to $C3EL$. Hence, CCR cannot be efficiently tackled by simply employing CR methods on a "super-document".

However, harnessing of non-local mention features (via CCR) and efficient detection of new mentions using link validation enables $C3EL$ to achieve a gain of around 5% in NEL compared to others (see Table 8(b)). For both procedures, we observed statistically significant improvements of C3EL over BER and NECo with $p < 0.05$, using the bootstrap re-sampling t-test.

To further study the effect of larger corpus, we sampled 25 documents (with co-referring mentions) from the ClueWeb09 dataset and performed analysis among the algorithms. As previously, we observed significant computational complexity for traditional CR methods when applied to CCR setting making them far slower ($6-7\times$) than $C3EL$. Table 9 reports the CCR and NEL averaged results obtained across 5 independent runs. We attained comparable performance in CCR with around 3% improvement in NEL. All the algorithms are seen to achieve high NEL results due to the large presence of well-known (in-KB) entities.

3.5 Algorithmic Baseline Study

We explore the performance of variants of $C3EL$ (on both corpora) ablating various system components (see Table 10). Explicitly, we consider:

- **Co-occurring Mentions:** Removal of cooccurrence mentions context from the *context summaries* constructed, reduces semantic information and adversely affects both NEL and CCR procedures. We thus observe a sharp decrease in CCR performance and also a degradation in entity linking.
- **Link Validation:** Filtering of mention linking to KB entities using link validation step (with threshold τ) in $C3EL$ enables corroboration of mention context keywords with the linked entity features. This leads to enhanced detection of new or emerging entities by reducing induction of noise during the CCR phase. Removal of this process permits aggressive entity linking and introduces noise, affecting new/emerging entity detection. We observe (from Table 10) nearly 20% reduction of precision (on both datasets) in identification of out-of-KB entity-mentions compared to $C3EL$.
- **NEL Categorization:** The differentiation of mentions (into classes) confidently mapped to KB entity reduces the collusion of "strong" linked mentions with other "noisy" mention contexts. This reduces incorrect grouping of different mentions with similar surface forms, contexts, etc., thereby improving precision of the CCR process. Use of a single NEL classification approach is observed to degrade CCR results, which in turn increases spurious entity linkage, decreasing NEL efficiency (Table 10).
- **Distant KB features:** As observed in (Baker, 2012; Zheng et al., 2013), extracted external KB features provide global and enhanced information cues promoting CR. We similarly observe CCR to attain the lowest F1 scores (compared to other baselines) when KB features are ignored. This in turn affects the linking of (some) well-known entities due to reduced context, leading to incorrect or low confidence NEL. Since no feature inclusion is performed for out-of-KB mentions, no effect is observed.

We observe that a joint formulation encompassing multiple information sources (along with noise filtering) enables mutually enhanced CCR and NEL within the proposed iterative feedback based framework, $C3EL$.

4 Related Work

Co-reference Resolution (CR): Traditional intra-document CR methods involve syntactic and semantic feature combination for identifying the best antecedent (preceding name or phrase) for a mention. CR methods employ rules or supervised learning techniques based on linguistic features such as syntactic paths and mention distances to assess semantic compatibility (Haghighi & Klein, 2009; Raghunathan et al., 2010; Rahman & Ng, 2011), while syntactic features are derived by deep parsing of sentences and noun group parsing. Semantic features from background knowledge resources like encyclopedia were used in (Daumé & Marcu, 2005; Ponzetto & Strube, 2006; Ng, 2007). The use of Wikipedia and structured knowledge bases (such as YAGO) to obtain mention-type relation and fine-grained mention attributes was explored by (Haghighi & Klein, 2009; Rahman & Ng, 2011). An overview of CR methods is given in (Ng, 2010).

Recent methods involve the use of multi-phase sieve, applying a cascade of rules for narrowing down the antecedent candidates for a mention (Raghunathan et al., 2010). Cluster ranking functions have also been proposed (Rahman & Ng, 2011; Zheng et al., 2013) to extend this paradigm for incrementally expanding and merging mention groups with preceding candidate clusters using relatedness features (Ratinov & Roth, 2012) and distant knowledge inclusion (Durrett & Klein, 2013). Person name disambiguation, a specific variation of CR, dealing with only person names, titles, nicknames, and other surface form variations was introduced in (Chen & Martin, 2007).

Distant Knowledge Labels: For obtaining semantic features, additional knowledge resources such as Wikipedia, YAGO, and FrameNet have been considered (Rahman & Ng, 2011; Baker, 2012). CR methods with confidence-thresholds were proposed in (Ratinov & Roth, 2012; Lee et al., 2013), and (Zheng et al., 2013) generalized these tech-

niques by ranking the matching entities for distant labeling. However, such prior methods utilize distance labels of the current mention and considers all matching mentions making the procedure expensive. On the other hand, we extract distant features for the strongly matching (best) candidate only, reducing the performance overhead.

Cross-Document CR (CCR): Early approaches towards CCR involved the use contextual information from input documents for IR-style similarity measures (e.g., tf×idf score, KL divergence, etc.) over textual features (Bagga & Baldwin, 1998; Gooi & Allan, 2004). Probabilistic graphical models jointly learning the mappings of mentions to equivalent classes (co-referring mentions) using features similar to local CR techniques were studied in (Culotta et al., 2007; Singh et al., 2010; Singh et al., 2011), A clustering approach coupled with statistical learning of parameters was studied in (Baron & Freedman, 2008). However, such methods fail to cope with large corpora, and hence a "light-weight" streaming variant of CCR was introduced by (Rao et al., 2010).

Co-occurring mentions context have been harnessed for disambiguating person names for CR in (Mann & Yarowsky, 2003; Niu et al., 2004; Chen & Martin, 2007; Baron & Freedman, 2008). However, these methods do not use KB and depend on information extraction (IE) methods, witnessing substantial noise due to IE quality variance. A CCR framework combining co-occurring mention context with distant KB features embedded in an active hierarchical clustering procedure (Dutta & Weikum, 2015) was recently shown to perform efficiently, and provides inspiration for parts of our proposed $C3EL$ approach.

Named Entity Linking (NEL): Named entity resolution and linking stems from SemTag (Dill et al., 2003), and similar frameworks like GLOW, WikipediaMiner, AIDA, and others (Milne & Witten, 2008; Ratinov et al., 2011). A collection of entity disambiguation models was presented in (Kulkarni et al., 2009). Other NEL approaches utilize the notion of semantic similarity of entities to corresponding Wikipedia pages (Milne & Witten, 2008), while co-referent mention graph construction modeling mention co-occurrences and context similarity from outgoing hyperlinks in Wikipedia was used by (Hoffart et al., 2011). An integer linear programming (ILP) formulation also based on Wikipedia page similarities was presented in (Ratinov et al., 2011). However, none of these methods involve the incorporation of CR results for NEL. The first study on the benefits of CR for NEL was by (Ratinov & Roth, 2012); but a joint model was not proposed, instead attributes from Wikipedia categories were used as features. An overview and evaluation of different NEL methods has been given by (Hachey et al., 2013).

Joint Models: Jointly solving CR for entities and events utilizing cluster construction based on feature semantic dependencies was devised in (Lee et al., 2012). The use of CR as a pre-processing step for subsequent NEL procedure using an ILP formulation was proposed by (Chen & Roth, 2013). Recently, (Hajishirzi et al., 2013) proposed a joint model for CR and NEL using the Stanford multi-pass cluster update CR system with automatic linking of mentions to Wikipedia. An integrated belief propagation-based framework for CR, NER, and relation extraction was developed in (Singh et al., 2013). Subsequently, the model was enhanced by the use of structured conditional random fields, to solve CR, NER, and NEL in combination (Durrett & Klein, 2014). Other works involving joint formulation of NER and NEL use uncertainty of mention boundaries along with segmentation information extracted from Wikipedia (Sil & Yates, 2013). However, to the best of our knowledge, this work provides the first approach to jointly tackle CCR and NEL across documents in an entire corpus.

5 Conclusions

This paper presented the novel $C3EL$ framework for joint computation of cross-document coreference resolution (CCR) and named-entity linking (NEL). Our approach utilizes: (1) *context summaries* including co-occurring mention groups allowing for global context and feature propagation, and (2) *link validation* for NEL using distant KB features. This is embedded in an interleaved CCR and NEL model allowing for global semantics and feature propagation. The iterative approach enables information feedback between CCR (provides corpus-wide cues) and NEL (providing distant KB features). Experimental results on news and web data demonstrate improved performance of both CCR and NEL compared to prior methods.

Abstract

We present a novel model for the task of joint mention extraction and classification. Unlike existing approaches, our model is able to effectively capture overlapping mentions with unbounded lengths. The model is highly scalable, with a time complexity that is linear in the number of words in the input sentence and linear in the number of possible mention classes. Our model can be extended to additionally capture mention heads explicitly in a joint manner under the same time complexity. We demonstrate the effectiveness of our model through extensive experiments on standard datasets.

1 Introduction

One of the essential goals in natural language processing (NLP) is the development of effective systems that can capture the underlying semantics conveyed by human languages. An important step towards such a goal is the development of practical systems that can efficiently extract useful shallow semantic information such as entities and at the same time identify their semantic classes (*e.g.*, person, organization, etc).

Such a task is often known as named entity recognition and classification (NERC), one of the standard tasks in information extraction (IE). While such a task focuses on the extraction and classification of entities in the texts which are named, recently researchers also showed interest in a closely related task – *mention extraction and classification/typing*. Unlike a named entity, a mention is typically defined as a reference to an entity in natural language text that can be either named, nominal or pronominal (Florian et al., 2004). The task of mention detection and tracking has received substantial attention, largely due to its important role in conducting several downstream tasks, such as *relation extraction* (Mintz et al., 2009), *entity linking* (Guo et al., 2013), and *coreference resolution* (Chang et al., 2013).

While most existing work on named entity recognition and mention extraction and classification have been effective, there remain several key limitations associated with existing models. In fact, one can view these problems as instances of the more general problem of *semantic tagging* – the task of assigning appropriate semantic tags to certain text spans for a given input sentence. Unlike part-of-speech (POS) tagging, which has been extensively studied in the past few decades by the community, such a semantic tagging task presents several additional new challenges. First, a mention can consist of multiple words, so its length can be arbitrarily long. Second, the mentions can overlap with one another. Popular models used for POS tagging, such as linear-chain conditional random fields (Lafferty et al., 2001) or semi-Markov conditional random fields (Sarawagi and Cohen, 2004) have difficulties coping with these issues. While approaches on addressing these issues exist, current algorithms typically suffer from high time complexity (Finkel and Manning, 2009) and are therefore difficult to scale to large datasets. On the other hand, the problem of designing efficient and scalable models for mention extraction and classification from natural language texts becomes increasingly important in this era where a large volume of textual data is becoming available on the Web every day – users need systems which are able to scale to extremely large datasets to support efficient semantic analysis for timely decison-making.

In this paper, we tackle the above-mentioned issue by introducing a novel model for joint mention extraction and classification. We make the following major contributions in this work:

- We propose a model that is able to effectively

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 857–867,
Lisbon, Portugal, 17-21 September 2015.

handle overlapping mentions with unbounded lengths.

- The learning and inference algorithms of our proposed model have a time complexity that is linear in the number of words in the input sentence and also linear in the number of possible semantic classes/types, making our model scalable to extremely large datasets.
- Our model can additionally capture mentions' head information in a joint manner under the same time complexity.

Our system and code are available for download from `http://statnlp.org/research/ie/`.

2 Related Work

Existing work has been largely focused on the task of named entity recognition and classification (NERC). The survey of (Nadeau and Sekine, 2007) is a comprehensive study of this topic.

Most prior work took a supervised learning approach. Zhou and Su (2002) presented a system for recognizing named entities using an HMM-based approach. Florian et al. (2003) presented a system for named entity recognition by combining different classifiers. McDonald and Pereira (2005) used conditional random fields for extracting gene and protein mentions from biomedical texts. Ratinov and Roth (2009) presented a systematic analysis over several issues related to the design of a named entity recognition and classification system where issues such as chunk representations and the choice of inference algorithms were discussed. Researchers also looked into semi-supervised and unsupervised approaches for such a task (Cucchiarelli and Velardi, 2001; Etzioni et al., 2005). Additional efforts on addressing the NERC problem under a multilingual or cross lingual setting also exist (Florian et al., 2004; Che et al., 2013; Wang et al., 2013).

As pointed out by Finkel and Manning (2009), named entities are often nested. This fact was often ignored by the community largely due to technical reasons. They therefore proposed to use a constituency parser with a $O(n^3)$ time complexity (n is the number of words in the input sentence) to handle nested entities, and showed its effectiveness across several datasets. Alex et al. (2007) also presented several approaches by building models on top of linear-chain conditional random fields for recognizing nested entities in biomedical texts. Hoffmann et al. (2011) looked into a separate issue, which is to identify overlapping *relations* amongst entities.

Named entity recognition and classification still remains a popular topic in the field of statistical natural language processing. Ritter et al. (2011) looked into recognizing entities from social media data that involves informal and potentially noisy texts. Pasupat and Liang (2014) looked into the issue of zero-shot entity extraction from Web pages with natural language queries where minimal supervision was used. Neelakantan and Collins (2014) looked into the problem of automatically constructing dictionaries with minimal supervision for improved named entity extraction. Li and Ji (2014) presented an approach to perform the task of extraction of mentions and their relations in a joint and incremental manner.

3 Approach

3.1 Mentions and Their Combinations

Typically, a mention that appears in a natural language sentence consists of a contiguous sequence of natural language words. Consider a sentence that consists of n words where each word is indexed with its position in the sentence. A mention m can be uniquely represented with a tuple $\langle b_m, e_m, \tau \rangle$, where b_m and e_m are the indices of the first and last word of the mention, respectively, and τ is its semantic class (type).

We can see that for a given sentence consisting of n words, there are altogether $tn(n+1)/2$ possible different mention candidates, where t is the total number of possible mention types. Now, for each such candidate in the given sentence, it can be either a mention, or not a mention. This leads to a total number of $2^{tn(n+1)/2}$ possible mention combinations. This number is prohibitively large even for small values of n and t, which prevents us from exhaustively enumerating all of them during learning and inference.

One approach to performing inference over such a large space is to introduce compact representations that are able to encode exponentially many mentions that would enable tractable inference algorithms to be employed. We discuss in the next section our novel mention hypergraph representation proposed for such a purpose.

3.2 Mention Hypergraphs

Central to our approach is the introduction of the novel *mention hypergraphs* that allow us to

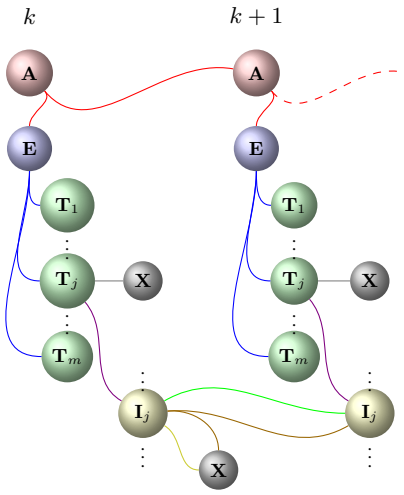

Figure 1: The (partial) hypergraph for representing all possible combinations of mention occurrences. Links that belong to the same hyperedge are highlighted with the same color, and different hyperedges are highlighted with different colors, *e.g.*, the green link that connects two **I** nodes forms a single hyperedge, while the two brown links that connect two **I** nodes and one **X** node form a separate single hyperedge.

compactly represent exponentially many possible combinations of potentially overlapping, length-unbounded mentions of different types.

A *hypergraph* is a generalization of a conventional graph, whose edges (*a.k.a. hyperedges*) can connect two or more nodes. In this work, we consider a special class of hypergraphs, where each hyperedge consists of a designated parent node and an *ordered* list of child nodes. Hypergraphs have also been used in other fields, such as syntactic parsing (Klein and Manning, 2001), semantic parsing (Lu, 2015) and machine translation (Cmejrek et al., 2013).

Our mention hypergraphs consist of five types of nodes which are used to compactly represent many mentions of different semantic types and boundaries, namely, **A** nodes, **E** nodes, **T** nodes, **I** nodes, and **X** nodes. A partial mention hypergraph is depicted in Figure 1. We describe the definition of each type of nodes next.

- **A nodes.** These nodes are used to sequentially arrange mentions with different left boundaries. Specifically, each **A** node at position k (the k-th word), or $\mathbf{A}^k$, is used to compactly represent all such mentions in the sentence whose left boundaries are *exactly at or strictly after* k.
- **E nodes.** The node $\mathbf{E}^k$ is used to compactly represent all possible mentions (possibly of length zero) whose left boundaries are *exactly at* the current position k.
- **T nodes.** The node $\mathbf{T}^k_j$ is used to compactly represent all mentions (possibly of length zero) whose left boundaries are *exactly at* position k, and *have the mention type* j.
- **I nodes.** The node $\mathbf{I}^k_j$ is used to compactly represent all *incomplete* mentions which contain the current word at position k as part of the mention, and have the mention type j.
- **X nodes.** These are the "terminal" nodes indicating the completion of a path. No additional node will be attached to such nodes as a child.

There are also various hyperedges that connect different nodes in the mention hypergraph. We use $\langle \alpha \leftarrow \beta_1, \ldots, \beta_n \rangle$ to denote a hyperedge which connects a parent node α and child nodes $\beta_1, \ldots, \beta_n$. Each hyperedge essentially provides one possible way of re-expressing the semantics conveyed by the parent node using the child nodes. For example, as shown in Figure 1, the hyperedge connecting the parent node $\mathbf{A}^k$ and the child nodes $\mathbf{E}^k, \mathbf{A}^{k+1}$ explains the fact that any mention covered by $\mathbf{A}^k$ either has a left boundary that is "*exactly at* k" ($\mathbf{E}^k$), or "*exactly at* or *strictly after* $k+1$" ($\mathbf{A}^{k+1}$).

Similarly, for each **I** node, there exist 3 hyperedges that connect it to other child nodes. The top hyperedge (in green) encodes the fact that the current word appears in the middle of a mention; the bottom hyperedge (in yellow) encodes the fact that the current word appears in a mention as the last word; the middle hyperedge (in brown) encodes the fact that both cases can occur at the same time (*i.e.*, the current word belongs to multiple overlapping mentions of the same type). We have the following theorem:

Theorem 3.1 *Any combination of mentions in a sentence can be represented with exactly one sub-hypergraph of the complete mention hypergraph.*

Proof For each mention, there exists a unique path in the mention hypergraph to represent it. For any combination of mentions, there exist unique paths in the mention hypergraph to represent such a combination. These paths altogether form a unique sub-hypergraph of the original hypergraph.

For example, consider the following sentence: "*he also talked with the egyptian president* ." This sentence contains three mentions. The first is "*he*" with type `PER`, the second is "*the egyptian president*" with type `PER`, and the third mention is "*egyptian*" with type `GPE`. Figure 2 gives the sub-hypergraph structure showing how these mentions

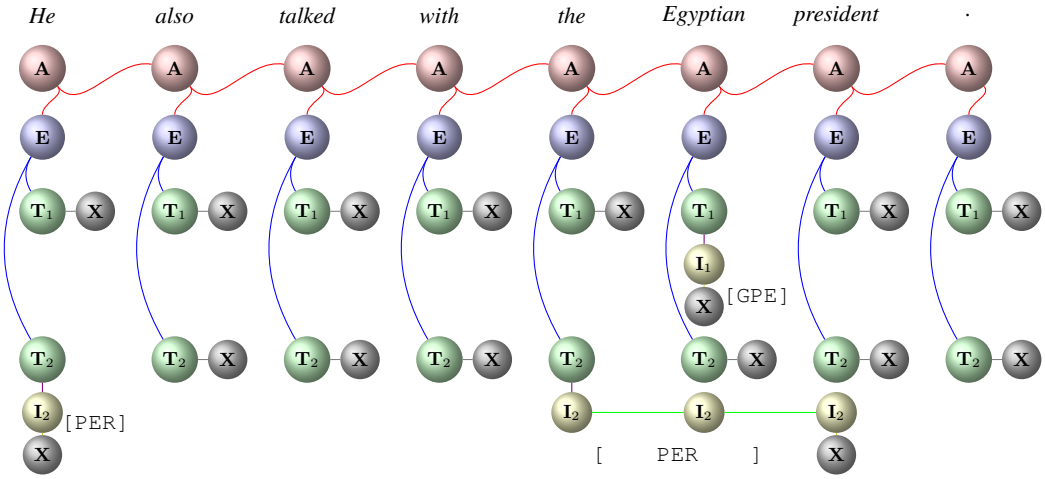

Figure 2: An example sub-hypergraph structure for jointly representing all the three mentions that appear in the sentence "*He also talked with the Egyptian president* ." For simplicity and the ease of illustration, we assume there are only two possible mention types: PER and GPE.

are jointly represented. The mention hypergraph defined over the input sentence contains exponentially many such sub-hypergraph structures.

We note that the converse of Theorem 3.1 is not true. In certain cases, it is possible for two different overlapping mention combinations to share the same mention hypergraph.

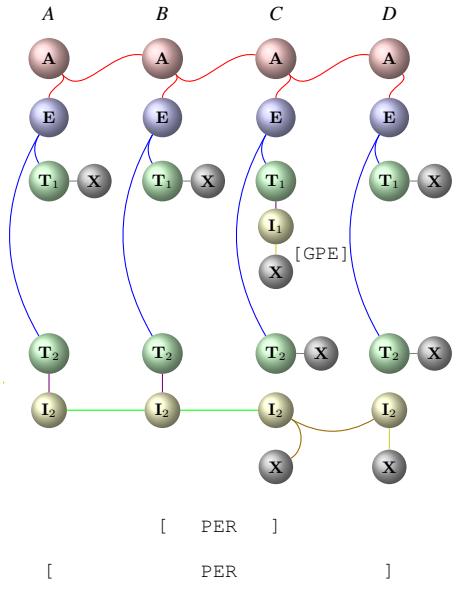

Figure 3: An example illustrating the converse of Theorem 3.1 is not true.

For example, consider a toy example sentence *A B C D* shown in Figure 3, both *B C* and *A B C D* are mentions of the same type PER (*i.e.* one is strictly contained by the other. We call such combinations type-I combinations). The above sub-hypergraph shows how to encode such a combination. However, if both *A B C* and *B C D* are mentions of the same type PER (*i.e.*, two mentions overlap but no one is contained by the other. We call such combinations type-II combinations), such a combination shares the same representation as the above sub-hypergraph. Note that such an ambiguity happens only when two overlapping mentions have the same type, and one mention is strictly contained by the other and their boundaries are all different. In practice, however, we found that in the two datasets that we used for evaluations, if two mentions overlap with one another, they almost always form a type-I combination, and type-II combinations are very rare. Empirically, as we will see later in our experiments, our model is effective in handling overlapping mentions.

3.3 Log-Linear Modeling

Following the conditional random fields (Lafferty et al., 2001), we adopted a log-linear approach for such a joint mention extraction and typing task. Specifically, for a given input sentence $\mathbf{x}$, the probability of predicting a possible output $\mathbf{y}$ (a mention sub-hypergraph that represents a particular combination of mentions) is given as follows:

$$p(\mathbf{y}|\mathbf{x}) = \frac{\exp(\mathbf{w}^T\mathbf{f}(\mathbf{x},\mathbf{y}))}{\sum_{\mathbf{y}'}\exp(\mathbf{w}^T\mathbf{f}(\mathbf{x},\mathbf{y}'))} \quad (1)$$

where $\mathbf{f}(\mathbf{x},\mathbf{y})$ is the feature vector defined over the input-output pair $(\mathbf{x},\mathbf{y})$, and the weight vector $\mathbf{w}$ gives the parameters of the model.

Our objective is to minimize the regularized negative joint log-likelihood of the dataset:

$$\mathcal{L}(\mathbf{w}) = \sum_i \log \sum_{\mathbf{y}'} \exp(\mathbf{w}^T\mathbf{f}(\mathbf{x_i},\mathbf{y}')) - \sum_i \mathbf{w}^T\mathbf{f}(\mathbf{x_i},\mathbf{y_i}) + \lambda\mathbf{w}^T\mathbf{w} \quad (2)$$

where $(\mathbf{x_i}, \mathbf{y_i})$ refers to the i-th training instance, and the last term is a L_2 regularization term with λ being a positive scalar (fixed to 0.01 in this work).

The gradient of the above objective function is:

$$\frac{\partial \mathcal{L}(\mathbf{w})}{\partial w_k} = \sum_i \mathbf{E}_{p(\mathbf{y}'|\mathbf{x_i})}[f_k(\mathbf{x_i}, \mathbf{y}')] - \sum_i f_k(\mathbf{x_i}, \mathbf{y_i}) + 2\lambda w_k \quad (3)$$

where w_k is the weight of the k-th feature f_k.

We note that unlike many recent latent-variable approaches to structured prediction (Petrov and Klein, 2007; Blunsom et al., 2008), we are able to represent each of our outputs $\mathbf{y}$ with a single fully-observed structure. Thus, our objective function essentially defines a standard regularized softmax regression model, and is therefore convex (Boyd and Vandenberghe, 2004), where a global optimum can be found.

The objective function defined in Equation 2 can be optimized with standard gradient-based methods. We used L-BFGS (Liu and Nocedal, 1989) as our optimization method.

3.4 Algorithms

In order to solve the optimization problem described above, one needs to compute the values of the gradient scores in Equation 3. Computation of the second and third terms in this equation is straightforward. The first term in Equation 3 involves the computation of an expectation of feature values over all possible mention combinations for a given input sentence. Following classic dynamic programming algorithms used in graphical models, we develop analogous efficient dynamic programming algorithms that work on hypergraphs and generalize the conventional forward-backward/inside-outside algorithm to efficiently compute such values.

Time Complexity At each time step k, we need to compute scores for m $\mathbf{I}$ nodes, m $\mathbf{T}$ nodes, 1 $\mathbf{E}$ node, and 1 $\mathbf{A}$ node. Hence, the overall time complexity for our algorithm is in $O(mn)$ (assuming computation of the feature scores at each node involves a constant time), where m is the total number of possible mention types, and n is the total number of words in the given sentence. [1]

[1] Note that the time complexity for the linear chain CRF is in $O(m^2 n)$ due to their first-order assumption.

3.5 Features

The features that we use are inspired by the work of (Carreras et al., 2002). Specifically, we consider the following features defined over the inputs:

- Words (and POS tags, if available) that appear around the current word (with position information), with a window of size 3.
- Word n-grams (and POS n-grams, if available) that contain the current word (with position information), for $n = 2, 3, 4$.
- Bag of words around the current word, with a window of size 5.
- Word pattern features [2].

Note that these are the indicator functions defined over the inputs. The final set of features are defined over $(\mathbf{x}, \mathbf{y})$ tuples, which is obtained as a cross-product between the above indicator functions and the following indicator function:

- The type of the node (such as $\mathbf{T}$ or $\mathbf{I}$).

In addition, we also introduce the following feature defined over the output structure only:

- The number of such hyperedges that exactly connect one $\mathbf{T}$ node and one $\mathbf{I}$ node.

We call this feature *mention penalty*. This feature learns a global preference of the number of mentions that should appear in any input sentence.

3.6 Joint Modeling of Mention Heads

One additional assumption for the mention extraction and typing task is that each mention comes with a *head*. A head is strictly a substring of the mention and provides important information about the mention. It is possible to extend our model to support joint modeling of mention heads, while still maintaining the same time complexity.

Due to space limitations, we could only give a relatively brief description of this extension in this section. The idea is to replace the $\mathbf{I}$ nodes with three different types of nodes, namely $\mathbf{I}_j$–$\mathbf{B}$ nodes (used to represent words that appear within a mention of type j and *before* its head), $\mathbf{I}_j$–$\mathbf{W}$ nodes (used to represent words that appear *within* the head of a mention of type j), and $\mathbf{I}_j$–$\mathbf{A}$ nodes (used to represent words that appear within a mention of type j and *after* its head). The hyperedges also need to be established accordingly in order to properly model all possible mention and head

combinations. Since in such a new hypergraph, at each time step, only a constant number (2) of additional nodes are involved, the time complexity for learning and inference with such a model remains the same, which is in $O(mn)$.

3.7 Optimization of F measure

One standard evaluation metric for named entity recognition is the F (F_1) measure. In our task, the F measure is defined as the harmonic mean of the precision (P) and recall (R) scores, where precision is the ratio between the number of correctly predicted mentions and the total number of predicted mentions, and recall is the ratio between the number of correctly predicted mentions and the total number of gold mentions. We will also adopt these metrics in our evaluations later. Unfortunately, the model only optimizes its objective function defined in Equation 2, which is the negative (regularized) joint log-likelihood. Previous work showed it was possible to optimize the F measure in a log-linear model (Suzuki et al., 2006). Culotta and McCallum (2004) also proposed a method for optimizing information extraction performance based on confidence estimation. Their work is based on linear-chain CRF and estimate the confidence of extracted fields based on marginal probabilities. The technique is not directly applicable to our task where a hypergraph representation is used to encode overlapping mentions. In this work, we used a very simple and intuitive technique for optimizing the F measure. The idea is to further tune the weight of a single parameter – *mention penalty* based on the development set, after the training process completes. This is based on the observation that by increasing the value of the mention penalty, we are essentially forcing our model to predict more mentions. Therefore the recall is a monotonic function with respect to the mention penalty. Based on this fact, we use a simple search algorithm with a fixed step size (we set it to 0.01) to determine the optimal value of the modified mention penalty so that the F measure of the development set is optimized.

4 Experiments

In this section, we present empirical evaluations. Our main experiments were conducted on the standard ACE2004 and ACE2005 datasets which contain overlapping mentions. Two additional experiments on the GENIA and CONLL2003 dataset were also conducted .

4.1 Results on ACE

Our primary experiments were conducted based on the English portion of the ACE2004 dataset[3] and the ACE2005 dataset[4]. Following previous work, for ACE2004, we considered all documents from *arabic_treebank, bnews, chinese_treebank*, and *nwire*, and for ACE2005, we considered all documents from *bc, bn, nw*, and *wl* . We randomly split the documents for each dataset into three portions: 80% for training, 10% for development, and the remaining 10% for evaluations. The statistics of the datasets are summarized in Table 1[5]. We

[3]https://catalog.ldc.upenn.edu/LDC2005T09

[4]https://catalog.ldc.upenn.edu/LDC2006T06

[5]Exact train/dev/test splits information can be found on http://statnlp.org/research/ie/.

can observe that overlapping mentions are common – over 30% of the sentences contain overlapping mentions (see row 3 of the table). Mentions can also be very long – over 5% of the mentions consist of more than 6 words, and the longest mention consists of 57 words.

We compared our system's performance with those of several baseline approaches. We first built two simple baseline approaches based on sequence labelling models using the conditional random fields (CRFs). Such approaches can not handle overlapping mentions. To train such models, whenever two mentions overlap with one another in the training set, we remove the mention that is shorter in length. Following (Ratinov and Roth, 2009), we considered the BIO (Begin, Inside, Outside) approach and the BILOU (Begin, Inside, Last, Outside, Unit) approach for designing the output labels. Results show the BILOU approach yields better results. Similar observations were reported in Ratinov and Roth (2009).

In the work of (Alex et al., 2007), the authors proposed several approaches for building models to handle nested named entities in biomedical texts. Their best results were obtained from a *cascaded* approach where they built one model for each named entity class. Outputs from one model can then served as the inputs to the next model for predicting the named entity class of a different type. One fundamental limitation of such an approach is that it being unable to handle overlapping mentions of the same type. Nevertheless, this approach worked very well on both datasets. The results are shown in the row of "CRF (CC)".[6]

Another class of models that is often used in information extraction are the semi-Markov conditional random fields (semi-CRFs) (Sarawagi and Cohen, 2004). Semi-CRF models are able to capture the non-Markovian properties of mentions. However, they are unable to handle nested or overlapping mentions. We thus used the same method as discussed above to exclude certain mentions for training. Such semi-CRF models typically assume there is a length restriction for the mentions – each mention can consist of up to c words – in order to scale linearly. When such a restriction is lifted, the time complexity of such models becomes quadratic in the number of words in the input sentence. We train two models: one with a length restriction, where $c = 6$, and the other without a length restriction ($c = \infty$). For features defined over the inputs, besides the Markovian features described in Sec 3.5, we also used the surface forms of complete mention spans as features. The results of these two models are reported in the fourth and fifth row of Table 2, respectively. Interestingly, imposing the length restriction appears to be helpful for precision, and as a result it makes a positive contribution towards the final F measure.

[6]For all such linear chain CRF-related experiments, we used the CRF++ toolkit (https://code.google.com/p/crfpp/) with L-BFGS, which gives us the most competitive results over several different CRF implementations (see: http://www.chokkan.org/software/crfsuite/benchmark.html).

	7 TYPES		14 TYPES		28 TYPES	
	#f	w/s	#f	w/s	#f	w/s
CRF	3.6M	1219	13.6M	305	51.9M	76
MH	4.2M	**1532**	8.4M	**733**	16.9M	**430**

Table 3: The decoding time and the number of features change as we increase the number of possible types. (#f: number of features created (in millions). w/s: number of words processed per second.) Experiments are conducted on the ACE 2004 dataset.

Our basic model (**MH**: *mention hypergraph*) that optimizes the negative joint log likelihood is able to obtain the best precision across these two datasets. When the model is further augmented with the F measure optimization step described in Sec 3.7 (**MH** (F)) it consistently yields the best results in terms of both recall score and F measure across these two datasets.

4.1.1 Running Time

We also conducted controlled experiments to report the actual execution time of our model and make a comparison with the linear-chain CRF model (BILOU approach). The experiments are all conducted on the ACE2004 dataset on the same machine. To make a proper comparison here, we implemented the linear-chain CRF model using Java (the same language is used when implementing our model), and employed the same data structures for creating features as well as the same learning and inference routines used by our mention hypergraph model.

To understand how the features and speed change as we increase the number of mention types (*i.e.,* semantic types), we also conducted experiments where we increase the number of possible mention types. Specifically, we created subtypes from each original type annotated in the dataset. For example, we randomly replaced the type "GPE" by sub-types "GPE1" or "GPE2" in the dataset. This gave us 14 different mention types. Similarly, we could randomly replace the type "GPE" by sub-types "GPE1" – "GPE4", re-

Table 4: Results on joint mention boundary, type, and head prediction on ACE2004 and ACE2005.

sulting in 28 different mention types in total. Our purpose of doing so is to understand how the models behave when the number of possible mention types becomes large. We found that training on the entire training set of ACE2004 using the linear-chain CRF model with a large number of mention types was very expensive due to the extremely large number of features involved. We instead trained the models on the development set and presented decoding time on the test set.

Table 3 shows the results. We empirically captured the relationship between the speed of each system (average number of words processed per second) and the number of mention types. Specifically, we found that as we linearly increased the number of mention types, for the linear-chain CRF model, the number of features grew quadratically and the speed dropped quadratically, whereas for our model, the number of features grew linearly and the speed dropped linearly. This indicates that our model is more scalable to large, practical datasets with a large number of fine-grained mention types.

4.1.2 Joint Modeling of Heads

We also conducted experiments on these two datasets for the task of joint modeling of mention boundaries, types and heads. We used the same training and tuning methodology for optimizing the F measure. In such experiments, we adopted a very strict evaluation criterion: a predicted mention is regarded as correct iff and only if its boundaries, type and head all exactly match those of the gold standard.

We compared our system's results with those of several baseline approaches based on CRF where the cascaded BILOU approach described above was always used. Specifically, we considered approaches that always regarded the complete span (CC-S), the first word (CC-F), and the last word (CC-L) as the predicted mention's head, respectively. We also considered a cascaded approach (CC-CC) where we first predicted mentions, and then predicted their heads by following a similar approach used for predicting overlapping mentions discussed above. The first four rows of Table 4 give the results of these baseline approaches. We can observe that always predicting the last word as the head gives the best performance. Inspired by this, we performed a simple approach by training a model presented in the previous section without considering head information. When making predictions, we always regarded the last word of each predicted mention as its head. The results for such an approach are given in the fifth row of Table 4. The sixth row shows the results obtained by optimizing our model's objective function. The last row gives the results obtained by tuning the mention penalty based on the development set. As seen, our joint models significantly outperformed all those baseline approaches. We are not aware of any prior work in the literature that performs joint modeling of mention boundaries, types, and heads.

4.2 Additional Experiments

We also additionally evaluated on the GENIA dataset (v3.02) whose focus was on biomedical related named entity recognition and classification, where the entities may overlap with one another. Furthermore, to see how our model works on datasets where mentions do not overlap with one another, we also conducted evaluations on the standard CONLL2003 NER dataset.

4.2.1 Results on GENIA

We followed the description of Finkel and Manning (2009) to set up our experiments on the GENIA dataset. Specifically, we used the first 90% of the sentences as the training data and the remaining 10% as the evaluation data. We also adhered to the paper's prescription of collapsing all *DNA* subtypes into *DNA*; *RNA* subtypes into *RNA*; and all *protein* subtypes into *protein*. We kept *cell line* and *cell type*, and removed all other entities.

To optimize the F measure, we further split the

	P	R	F
Semi-CRF	76.2	61.7	68.2
F & M (2009)	75.4	65.9	70.3
MH (F)	72.5	65.2	68.7

Table 5: Results on the GENIA dataset

training set into two portions. We trained a model using the first 90% of the training data, and used the remaining 10% for development. For features, no POS and no bag-of-words features are used.

We compared our model's performance with that of a model based on a constituency parser proposed by (Finkel and Manning, 2009), as well as the semi-CRF model reported there. The results are shown in Table 5. Our model yields a better F measure than the semi-CRF model, but gives a lower performance than the model of (Finkel and Manning, 2009). We note that, however, these results are not directly comparable. Specifically, both of these two previous models relied on an additional 200 million words from PubMed abstracts to learn word clusters as additional features, which we do not have access to.

One distinctive advantage of our model is the efficiency and scalability. The model of (Finkel and Manning, 2009) had a time complexity that is cubic in the number of words in the input sentence. In contrast, our model scales linearly as the length of the input sentence increases. [7]

4.2.2 Results on CONLL2003

To understand how well our model works on datasets where mentions or entities do not overlap with one another, we conducted additional experiments on the standard dataset used in the CONLL 2003 shared task (Tjong Kim Sang and De Meulder, 2003), where the named entities strictly do not overlap with one another. We compared our system's performance against that of a baseline version of the state-of-the-art Illinois NER system (Ratinov and Roth, 2009). Their system performed sequential prediction over the input words and adopted the BILOU approach. Their full model also incorporates external knowledge resources (*e.g.*, gazetteers and word class).

In order to make a proper comparison with the baseline version of their model, besides the general features we mentioned earlier, we also followed (Ratinov and Roth, 2009) in incorporating word's prefixes and suffixes (of length up to 5) as features, and normalized words referring to months, dates and numbers. Table 6 shows that our system gives an F measure that is comparable to that of the baseline version of their system, where no external resources are used.

	DEV			TEST		
	P	R	F	P	R	F
Illinois (b)	-	-	89.3	-	-	83.7
MH	94.7	83.0	88.5	91.4	76.5	83.3
MH (F)	91.4	86.7	89.2	87.3	80.7	83.8

Table 6: Results on the CONLL2003. Illinois (b): baseline version of (Ratinov and Roth, 2009).

This additional experiment showed that while our model is designed for handling more realistic scenarios where mentions can overlap, it yields a performance competitive to a state-of-the-art system which only handles datasets with non-overlapping mentions.

5 Conclusions

In this work, we have introduced a novel model for the task of joint modeling of mention boundaries, types, as well as their heads. Unlike many previous research efforts for mention extraction and classification, our novel *mention hypergraph* representations for compactly representing exponentially many possible mentions enables a mention's boundaries, type and head information to be jointly learned in a single framework. The model scales linearly with respect to the number of words in the input sentence, and performs exact learning where a unique global optimum can be found. Empirically, we have demonstrated the effectiveness of such a model across several standard datasets.

Future work include explorations of efficient algorithms for other information extraction tasks, such as joint mention and relation extraction (Li and Ji, 2014) and event extraction (Li et al., 2013). Our system and code can be downloaded from `http://statnlp.org/research/ie/`.

This work is supported by Temasek Lab of Singapore University of Technology and Design project IGDSS1403011 and IGDST1403013, and is partly supported by DARPA (under agreement number FA8750-13-2-0008).

[7] In our experiments, for this dataset our model tagged over 5,000 words/second. In (Finkel and Manning, 2009), the authors mentioned that their model tagged about 38 words/second, and the semi-CRF model tagged about 45 words/second. However, we note these numbers are not directly comparable due to the advancement of CPU speed.

FINET: Context-Aware Fine-Grained Named Entity Typing

Luciano Del Corro* **Abdalghani Abujabal*** **Rainer Gemulla†** **Gerhard Weikum***

Abstract

We propose FINET, a system for detecting the types of named entities in short inputs—such as sentences or tweets—with respect to WordNet's super fine-grained type system. FINET generates candidate types using a sequence of multiple extractors, ranging from explicitly mentioned types to implicit types, and subsequently selects the most appropriate using ideas from word-sense disambiguation. FINET combats data scarcity and noise from existing systems: It does not rely on supervision in its extractors and generates training data for type selection from WordNet and other resources. FINET supports the most fine-grained type system so far, including types with no annotated training data. Our experiments indicate that FINET outperforms state-of-the-art methods in terms of recall, precision, and granularity of extracted types.

1 Introduction

Named entity typing (NET) is the task of detecting the type(s) of a named entity in context. For instance, given "John plays guitar on the stage", our goal is to infer that "John" is a *guitarist* or a *musician* and a *person*. We propose FINET, a system for detecting the types of named entities in short inputs—such as sentences or tweets—with respect to WordNet's super fine-grained type system (16k types of organizations, persons and locations).

Named entity typing is a fundamental building block for many natural-language processing tasks. NET is at the heart of information extraction methods for finding types for entities in a knowledge base[1] (KB) (Mitchell et al., 2015). Likewise, NET aids named entity disambiguation by reducing the candidate space for a given entity mention. Entity types are an important resource for entity-based retrieval or aggregation tasks, such as semantic search (Hoffart et al., 2014) or question answering (Yahya et al., 2013). Finally, type information helps to increase the semantic content of syntactic patterns (Nakashole et al., 2012) or in open information extraction (Lin et al., 2012).

The extraction of explicit types has been studied in the literature, most prominently in the context of taxonomy induction (Snow et al., 2006). Explicit types occur, for example, in phrases such as "Steinmeier, the German Foreign Minister, [...]" or "Foreign Minister Steinmeier." These explicit types are often extracted via patterns, such as the well-known Hearst patterns (Hearst, 1992), and subsequently integrated into a taxonomy. Pattern-based methods often have high precision but low recall: Types are usually mentioned when a named entity is introduced or expected to be unknown to readers, but often are not explicitly stated. The NET problem differs from taxonomy induction in that (1) the type system is prespecified, (2) types are disambiguated, and (3) types are associated with each occurrence of named entity in context.

Our FINET system makes use of explicit type extractions whenever possible. But even when types are not explicitly mentioned, sentences may give clues to the correct type. These clues range from almost explicit to highly implicit. For example, in "John plays soccer", the type *soccer player* is almost explicit. The sentence "Pavano never even made it to the mound," however, only implicitly indicates that "Pavano" is a *baseball player*. A

[1] In this paper, we refer to WordNet as a type system and to a collection of entities and their types as a KB.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 868–878,
Lisbon, Portugal, 17-21 September 2015.

key challenge in NET is to extract such implicit, context-aware types to improve recall.

One way to extract implicit types is by training a supervised extractor on labeled data, in which each entity is annotated with appropriate types. The key problem of this approach is that training data is scarce; this scarcity is amplified for fine-grained type systems. To address this problem, many existing systems generate training data by exploiting KBs as a resource (Yosef et al., 2012). A popular approach is to train an extractor on a corpus of sentences (e.g., on Wikipedia), in which each named entity is associated with all its types in a KB. The key problem with such an approach is that the so-obtained type information is oblivious to the context in which the entity was mentioned. For example, in the sentences "Klitschko is known for his powerful punches" and "Klitschko is the Mayor of Kiew," "Klitschko" will be associated with all its types, e.g., *boxer*, *politician* and *mayor*. As a consequence, the labels in the training data can be misleading and negatively affect the extractors. Moreover, such learned extractors are often biased towards prominent types but perform poorly on infrequent types, and they are generally problematic when types are correlated (e.g., most *presidents* are also *graduates* and *authors*).

FINET addresses the above problems by first generating a set of type candidates using multiple extractors and then selecting the most appropriate type(s). To generate candidates, we make use of a sequence of extractors that range from explicit to highly implicit. Implicit extractors are only used when more explicit extractors fail to produce a good type. Our extractors are based on patterns, mention text, and verbal phrases. To additionally extract highly implicit types, we use word vectors (Mikolov et al., 2013) trained on a large unlabeled corpus to determine the types of *similar* entities that appear in *similar* contexts. This extractor is comparable to KB methods discussed above, but is unsupervised, and takes as candidates the types frequent within the related entities and contexts.

After type candidates have been generated, the final step of FINET selects the types that best fit the context. In this step, we leverage previous work on word sense disambiguation (WSD) and resources such as WordNet glosses, and, if available, manually annotated training data.

FINET leverages ideas from existing systems and extends them by (1) handling short inputs (2) supporting a very fine-grained type hierarchy, and (3) producing types that focus on the entity context. Existing systems are unable to extract more than a couple of hundred types. Hyena (Yosef et al., 2012), the system with the most fine-grained type system so far, focuses only on a subset of 505 types from WordNet. Hyena lacks important types such as *president* or *businessman*, and includes *soccer player* but not *tennis player*. Instead of restricting types, FINET operates on the the entire WordNet hierarchy with more than 16k types for persons, organizations, and locations.

We evaluated FINET on a number of real-world datasets. Our results indicate that FINET significantly outperforms previous methods.

Extractor	Stopping Condition
Pattern-based (final)	Always stop
Pattern-based (non-final)	KB-lookup
Mention-based	KB-lookup
Verb-based	KB-lookup
Corpus-based	$\geqslant 50\%$ of score in $\leqslant 10$ types

Table 1: Extractors and their stopping conditions

2 Candidate Generation

In this phase, we collect candidate types for each entity. We first preprocess the input (Sec. 2.1) and then apply a (i) pattern-based extractor (Sec. 2.2), (ii) a mention-based extractor (Sec. 2.4), (iii) a verb-based extractor (Sec. 2.5), and (iv) a corpus-based extractor (Sec. 2.6). The extractors are ordered by decreasing degree of explicitness.

Each extractor has a *stopping condition*, which we check whenever the extractor produced at least one type. When the stopping condition is met, we directly proceed to the type selection phase. The reasoning behind this approach is to bias FINET towards the most explicit types. When the condition is not met, we enrich the set of candidate types of the extractor with their hypernyms; we expect types to be overly specific and want to allow the selection phase to be able to select a more general type. We then also run subsequent extractors. Tab. 1 displays a summary of the extractors and stopping conditions.

All so-found type candidates are passed to the candidate selection phase (Sec. 3).

2.1 Preprocessing

Preprocessing consists of 5 steps: (i) dependency parsing (Socher et al., 2013); (ii) co-reference (Recasens et al., 2013); (iii) named entity recogni-

tion (NER) (Finkel et al., 2005) with the detection of coarse-grained types (i.e., *person*, *organization*, *location*); (iv) clause identification (Del Corro and Gemulla, 2013); (v) word and multi-word expression recognition (Del Corro et al., 2014).

FINET restricts its candidates to the hyponmys of the coarse-grained (CG) type of the NER system. Named entities with the same CG type in a coordinating relation (e.g., "Messi and Ronaldo are soccer players") and identical mentions share the candidate set; the latter is reasonable in short input.

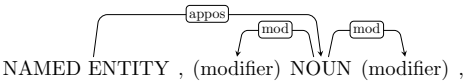
FINET extractors operate either on the sentence or the clause level. A clause is a part of a sentence that expresses a statement and is thus a suitable unit for automatic text processing (Del Corro and Gemulla, 2013). Finally, we identify multi-word explicit type mentions such as *Prime Minister* or *Secretary of Housing and Urban Development* (Del Corro et al., 2014).

2.2 Pattern-based extractor

Our pattern-based extractor targets explicit type mentions. These are commonly used to introduce entities when they first appear ("US President Barack Obama") or when their mention does not refer to the most prominent entity ("Barack Obama, father of the US President"). Following previous work (Hearst, 1992), we use a set of patterns to look for expressions that may refer named entity types. We refer to those expressions as *lexical types* (e.g., "father"). Once lexical types have been identified, we collect as candidate types the WordNet synsets to which they refer (e.g., ⟨*father*-1⟩, ..., ⟨*father*-8⟩, the eight senses of "father").

Our extractor makes use of both syntactic patterns, which operate on the dependency parse, and regular expression patterns, which operate on the text. Syntactic patterns are preferable in that they do not rely on continuous chunks of text and can skip non-relevant information. However, mistakes in the dependency parse may lower recall. To cope with this, we additionally include regular expressions for some syntactic patterns. Fig. 1 shows an example of a syntactic pattern and a related regular-expression pattern. Both produce lexical type "president" from "Barack Obama, president of the US," but only the syntactic pattern applies to "Barack Obama, the current US president."

Tab. 2 gives an overview of our patterns. Most of them also have a symmetric version (e.g., "The president, Barack Obama" and "Barack Obama,



(a) A syntactic pattern

NAMED_ENTITY , NOUN

(b) A regular expression pattern

Figure 1: Patterns capturing appositions

Pattern	Example
Final patterns	
Hearst I	{Presidents} such as [Obama] (and) [Bush]
Hearst II	{Presidents} like [Obama] (and) [Bush]
Hearst III	Obama (and) other {presidents}
Hearst IV	{Presidents} including [Obama] (and) [Bush]
Apposition	[Obama], (the) {president}
Copular	[Obama] is (the) {president}
Noun modifier	{President} [Barack Obama]
Among	[Joe Biden] among (other) {vice presidents}
Enough	[Messi] is enough (of) a {player}
As	[Messi] as {player}
Non-final patterns	
Location	{City} of [London]
Poss. + transf.	[Shakespeare]'s {productions}
by-prep + transf.	{productions} by [Shakespeare]

Table 2: Patterns for explicit type extraction

the president"), which is not displayed. We divide our patterns into final and non-final. Final patterns generally have high precision and extract the lexical type exactly as it occurs. When a final pattern produces a lexical type, we add the corresponding types to the candidate set and go directly to the type selection phase, i.e., we do not consider any other extractor. For non-final patterns, however, we expect erroneous extractions and proceed differently; we perform a KB lookup for all lexical types. The KB lookup (described in the next section) both prunes and expands the candidate set using a KB, and acts as a stopping condition. (FINET can also be run without using KB lookups.)

We treat a pattern as non-final if it may or may not denote a lexical type (e.g. "the president of Argentina" vs. "the city of Buenos Aires") or if a verb-noun transformation is required to obtain the lexical type (e.g. "Shakespeare's productions" to "producer"). To perform the transformations, we use WordNet's *derivationally related forms*, which connect semantically related morphological variations of verbs and nouns. For instance, the noun "production" is connected to the verb "produce," which in turn is connected to the noun "producer". These variations can be exploited to extract explicit types. We treat such transforma-

tions as non-final because we may make mistakes. Moreover, WordNet is highly incomplete in terms of derivational forms. For instance, we may not be able to reach all the possible senses for "producer" from "production," and from "works" in "works by Schumann", we cannot reach "musician" or "artist," but we reach "worker" and there is no synset of "worker" that specifically denotes an artist.

2.3 Exploiting a knowledge base

Most of our extractors (optionally) leverage a knowledge base to (1) prune candidate types, (2) find additional candidates, and (3) decide whether to consider subsequent extractors. To do so, we extract from a KB a repository of (entity mention, type)-pairs.[2] We use the KB conservatively, i.e., we consider KB evidence only if the extracted types match the ones in the KB.

The KB is leveraged via a *KB lookup*. Each KB lookup takes as input an entity mention e and a set T of candidate types found by the extractor (lexical or disambiguated). We first replace each lexical type in T by the set of the corresponding types from WordNet. Afterwards, for each type $t \in T$, we check whether there is one or more matching types (e, t_{KB}) in the KB for the given mention. Type t_{KB} matches t if it is either identical, a hypernym, or a hyponym of t. For each match, the KB lookup outputs t. If t_{KB} is a hyponym of t, we additionally output t_{KB}, that is, a type more specific than the one found by the extractor. We leave the decision of whether t or t_{KB} is a more suitable type to the type selection phase. For example, for e = "Messi" and $t = \langle$*player*-1$\rangle$, we output $\langle$*player*-1$\rangle$ and $\langle$*soccer_player*-1$\rangle$ (a hyponym).

The KB lookup is *successful* if it outputs at least one type. Then we add the resulting types to the candidate set and go directly to the type selection phase. A KB lookup *fails* if no matching type was found. We then proceed differently: if a KB lookup fails, we add the complete set T to the candidate set and continue to the next extractor.

As mentioned above, FINET can also be run without any KB lookups; the corresponding extractors then do not have a stopping condition. In Sec. 4, we experimented with both variants and found that KB lookups generally helped.

[2]We used Yago2 (Hoffart et al., 2013). Our repository contained roughly 9M entity mentions and 20M pairs.

2.4 Mention-based extractor

Our second extractor aims to extract type candidates from the entity mention. This is particularly effective for organizations, which often contain the lexical type in their name (e.g., "Johnson & Wales University" or "Republican House").

Given an entity mention, we check if any of the words or expressions in the name corresponds to a lexical type in WordNet. If so, we consider the corresponding types as potential candidates. For instance, for "Imperial College London", we extract "college" and obtain types $\langle$*college*-1$\rangle$ and $\langle$*college*-2$\rangle$ (both matching the CG type) from WordNet. We then perform a KB lookup.

We extend the above procedure for entities tagged as *location*. Since the set of (named-entity) locations is quite static and known, we assume that the KB contains all locations and their possible types (our experiments strengthened this assumption). If a mention of a location (e.g., "Berlin") occurs in the repository, we add all the corresponding types from the repository to the candidate set (e.g., $\langle$*city*-1$\rangle$) and move to the type selection phase.

2.5 Verb-based extractor

Verbs have been widely exploited to determine the types or roles of its arguments: A verb sense imposes a restriction on the type of its arguments (Quirk et al., 1985; Levin, 1993; Hanks, 1996; Baker et al., 1998; Palmer et al., 2005; Kipper et al., 2008). For instance, from "Ted Kennedy was elected to Congress," we infer that "Ted Kennedy" is a *person* who can be elected. Corresponding types include $\langle$*representative*-1$\rangle$, $\langle$*representative*-2$\rangle$, or $\langle$*politician*-1$\rangle$. Our verb-based extractor leverages this insight to extract types. The extractor operates at the clause level.

A simple way to infer lexical types for entities acting as subjects or objects of a clause is *nominalization*, i.e., the transformation of the verb into *deverbal nouns* (e.g., "play" into "player"). To exploit it, we apply a set of morphological transformations to the verb (Quirk et al., 1985), which depend on the grammatical function of the entity, i.e., subject or object. If the entity mention acts as a subject, we try adding the suffixes "-er,", "-or," and "-ant" to the verb's lemma. If the mention acts as an object, we use suffixes "-ee" and "-ed". To obtain candidate types, we again use derivationally related forms (DER). We consider as potential candidates all types referred to by one of the deverbal nouns and connected to a sense of the

verb via DER. For instance, given "Messi plays in Barcelona," we collect for "Messi" all the senses of "player" that are connected to some sense of "play" (⟨*player*-1⟩, ⟨*musician*-1⟩ and ⟨*actor*-1⟩).

We also explore WordNet in a way that is not restricted to morphological variations of the verb. For instance, in "John committed a crime," "commit" is a synonym of "perpetrate," which in turn can be varied to "perpetrator". We consider the morphological variations of all synonyms of the verb. Moreover, if the named entity is the subject of the clause, and if the clause contains a direct object, we form a new lexical type by adding the direct object as a noun modifier of the deverbal noun (e.g., From "Messi plays soccer", we form "soccer player"). If it exists in WordNet, we consider the respective types as potential candidates as well.

A more indirect way of exploiting the verb-type semantic concordance is via a corpus of frequent (verb, type)-pairs, where the type refers to possible types of the verb's subject or object. As stated above, the set of argument types compatible with a verb is limited. For instance, "treat" is usually followed by ⟨*condition*-1⟩, ⟨*disease*-1⟩, or ⟨*patient*-1⟩. FINET, uses the corpora of Flati and Navigli (2013) and Del Corro et al. (2014). Given a verb and an entity, we search for frequent candidate types (depending on whether the entity acts as a subject or object). For example, from "Messi was treated in the hospital," we obtain ⟨*patient*-1⟩.

Once potential candidates have been collected, we perform a KB lookup to decide how to proceed.

2.6 Corpus-based extractor

Our final extractor leverages a large unlabeled corpus to find entities that co-occur in similar contexts. It is based on the distributional hypothesis (Sahlgren, 2008): similar entities tend to occur in similar contexts. For example, "Messi" and "Cristiano Ronaldo" may both be mentioned in the context of soccer. Thus entity mentions similar to "Messi" in a sport context are likely to include soccer players. Our extractor is related to semi-supervised KB methods in that it propagates types of named entity mentions that may appear in a similar context. It differs in that it is unsupervised, does not require manually or automatically generated training data, and in the way context is modeled and candidates are generated.

Our corpus-based extractor makes use of word vectors (Rumelhart et al., 1988) trained on a large unlabeled corpus. A word vector is a semantic representation of a phrase and represents the semantic context in which the phrase occurs. Phrases that are semantically related, and thus appear in similar contexts, are close to each other in the word vector space. For instance, if "Messi" and "Cristiano Ronaldo" tend to co-occur with a similar sets of words, their word vectors are close. We also may expect "Arnold Schwarzenegger" to be close to both actors and politicians, since it occurs in both contexts. In our work, we use word2vec (Mikolov et al., 2013), which provides a model trained on Google News to predict related words or phrases for a *query* specified as a set of phrases. Given an integer k, word2vec outputs the set of k phrases that are most similar to the query.

Our corpus-based extractor uses (1) the input sentence to construct a set of relevant queries and (2) the word2vec results and a KB. To construct a query for a given entity mention, we focus on the part of the sentence directly related to the entity. This relevant part consists of the clause in which the entity occurs and the subordinate clauses that do not contain another entity. Since word2vec is most effective when queries are short, we construct a set of small queries, each consisting of the named entity mention and some context information. We construct a query for each noun phrase (of length at most 2) and for each other entity mention. If the named entity occurs as subject or object, we also take the corresponding verb and the head of the object or subject. For example, the queries for "Maradona expects to win in South Africa" are {"Maradona", "South Africa"} and {"Maradona", "expect", "win"}.

For each query, we retrieve the 100 most related phrases with their similarity score and union the results. We filter them using our KB and retain only those phrases that correspond to entity mentions (with the correct CG types). We then enrich each mention by the set of their possible types from the KB. Here we exclude widespread but irrelevant implicit types such as ⟨*male*-1⟩, ⟨*female*-1⟩, ⟨*adult*-1⟩, ⟨*commoner*-1⟩, ⟨*friend*-1⟩, or ⟨*alumnus*-1⟩. We also include the types corresponding to the entity mention (with score 1). If there is sufficient evidence that some of the so-obtained types are most prominent, we take these types as candidates. In our example, query {"Maradona" "South Africa"}, all of the top-15 persons (e.g., "Diego Maradona", "Carlos Alberto Parreira", "Dunga", "Beckenbauer") share type ⟨*coach*-1⟩; a strong indication that Maradona may

also be of type ⟨*coach*-1⟩. To select prominent types we traverse the results until we collect 50% of the total score. We take all so-collected types as candidates. If no more than 10 different types were added this way, we directly go to the type selection phase.

3 Type Selection

The type selection phase selects the most appropriate type from the set of candidates of a given named entity. We use techniques from WSD, but adapt them to our setting. WSD aims to disambiguate a word or phrase (e.g., a noun) with respect to a type system as WordNet; e.g., from "player" to ⟨*player*-1⟩. The main difference between WSD and our type selection is that our goal is to decide between a set of types for an entity mention; e.g., from "Messi" to ⟨*soccer_player*-1⟩. Our type selection step can be used as-is; it is not trained on any domain- or corpus-specific data.

3.1 Obtaining context

All WSD systems take a set of candidate types and contextual information as input. The key challenge lies in the construction of candidate types (Sec. 2) as well as context. For each entity, we consider *entity-oblivious context* (from the input sentence) as well as *entity-specific context* (using lexical expansions).

We take all words in the sentence as entity-oblivious context. To construct entity-specific context, we make use of lexical expansions, which have been successfully applied in WSD (Miller et al., 2012). Its goal is to enrich contextual information to boost disambiguation. In our case, it also helps to differentiate between multiple entities in a sentence. We build the entity-specific context using word vectors. As in the corpus-based extractor, we construct a set of queries for the entity but in this case we take as context all so-obtained words that do *not* correspond to a named entity. For instance, the entity-specific context for the entity mention "Maradona" for query "Maradona South_Africa" is: "coach", "cup", "striker", "midfielder", and "captain". The full context for "Maradona" in "Maradona expects to win in South Africa" additionally includes the entity-oblivious context "expects", "win", "South Africa".

3.2 Selecting types

WSD systems fall into two classes: unsupervised, which rely on background knowledge such as WordNet (Ponzetto and Navigli, 2010), and supervised, which require training data (Zhong and Ng, 2010). Here we take a combination, i.e., we leverage WordNet and manually annotated data.

We train a Naive Bayes classifier to select the most appropriate type given its context. We represent context by a bag of lemmatized words. This allows us to automatically generate training data from WordNet (and use manually labeled data). Since WordNet provides information for each of the relevant types, this approach combats the data sparsity that arises with supervised systems. The context for each individual WordNet type consists of all words appearing in the type's gloss and the glosses of its neighbors (Banerjee and Pedersen, 2003). We also include for each type the neighbors from Ponzetto and Navigli (2010) and the corresponding verbs from Del Corro and Gemulla (2013). Finally, we add all words in sentences containing the type in SemCor[3] (Landes et al., 1998) and Ontonotes 5.0 (Hovy et al., 2006).

We trained one classifier per CG type. To train the classifier, we create a single training point for each corresponding WordNet type and use the type's context as features. To map the CG types from our NER system to WordNet, we considered as persons all descendants of ⟨*person*-1⟩, ⟨*imaginary being*-1⟩, ⟨*characterization*-3⟩, and ⟨*operator*-2⟩ (10584 in total); as locations all descendants of ⟨*location*-1⟩, ⟨*way*-1⟩, and ⟨*landmass*-1⟩ (3681 in total); and as organizations all descendants of ⟨*organization*-1⟩ and ⟨*social group*-1⟩ (1968 in total). This approach of handling CG types suffers to some extent from WordNet's incompleteness, esp. with respect to persons and organizations. For instance, phrase "sponsored by Coca-Cola" implies that "Coca-Cola" is a "sponsor," but in WordNet, only persons can be sponsors. Nevertheless, this approach worked well in our experiments.

4 Experiments

We conducted an experimental study on multiple real-word datasets to compare FINET with two state-of-the-art approaches. FINET is used as-is; it does not require training or tuning for any specific dataset. All datasets, detected types, labels, and our source code are publicly available.[4]

4.1 Experimental Setup

Methods. *Hyena (Yosef et al., 2012)* is a representative supervised method that uses a hierarchical classifier. Its features include the words in the named entity mention, in sentence and paragraph, and POS tags. It performs basic co-reference resolution and marks entity mentions connected to a type in the KB using a binary feature. Similar to Ling and Weld (2012), Hyena is trained on Wikipedia entities, each being annotated with its corresponding WordNet types from YAGO. Hyena's type system is restricted to 505 WordNet types with top categories ⟨*artifact*-1⟩, ⟨*event*-1⟩, ⟨*person*-1⟩, ⟨*location*-1⟩, and ⟨*organization*-1⟩. Hyena outperformed a number of previous systems (Fleischman and Hovy, 2002; Rahman and Ng, 2010; Ling and Weld, 2012). We used Hyena via its web service (Yosef et al., 2013).

Pearl (Nakashole et al., 2013) is a semi-supervised system that leverages a repository of 300k relational patterns (Nakashole et al., 2012). Subjects and objects of each pattern carry type information. Pearl types named entity mentions by the most likely type according to its pattern database. Pearl's type system is based on around 200 "interesting" WordNet types. We ran Pearl in its *hard* setting, which performed best.

FINET. We ran FINET in two configurations: (1) with KB lookup, (2) without the KB lookup. This allows us to estimate the extent to which referring to a KB helps. Note that the corpus-based extractor makes use of the KB in both settings.

Datasets. We used three different datasets representing real-world use cases. We created two datasets, New York Times and Twitter, and sampled a subset of the CoNLL data, which provides gold annotations for CG types. We did not consider datasets such as FIGER (Ling and Weld, 2012) or BBN (Weischedel and Brunstein, 2005) because they are not suitable for very fine-grained typing.

New York Times consists of 500 random sentences from the New York Times corpus (Sandhaus, 2008), year 2007; we selected only sentences that contained at least one named entity according to the Stanford CoreNLP 4.4.1 tool.

CoNLL. We sampled 500 sentences from CoNLL (Tjong Kim Sang and De Meulder, 2003), a collection of newswires with manually annotated entities with CG types labels. We directly used the annotations in our evaluation. The sentences tend to be short and sometimes non-verbal (e.g., "Jim Grabb (U.S.) vs. Sandon Stolle (Australia)"). Most entities are prominent and likely to be found in our KB (and the one of existing methods).

Twitter. We collected the first 100 tweets with named entities retrieved by the Twitter API.

Type system. FINET's type system consists of more than 16k types with top categories persons, locations and organizations. We used the mapping between these top categories and WordNet described in Sec. 3.2. Hyena and Pearl use 505 and 200 WordNet types, resp., which is significantly smaller. To compare the performance across different granularities, we classified each type as coarse-grained (CG), fine-grained (FG) or super fine-grained (SFG). The CG types were ⟨*artifact*-1⟩, ⟨*event*-1⟩, ⟨*person*-1⟩, ⟨*location*-1⟩ and ⟨*organization*-1⟩. The FG types were those included in Pearl. All remaining types were considered SFG.

Labeling. All extractions by all systems were independently evaluated by two labelers. We adopted a pessimistic view, i.e., we treat an extraction as correct only if it was labeled correct by both labelers. The Cohen's kappa measure ranged 0.54–0.86, indicating a substantial agreement.

4.2 Results

Description of Tab. 3. Our results are summarized in Tab. 3. When a method did not produce a type of the considered granularity but a more fine-grained type, we selected its closest hypernym. For each configuration, the table shows the number of named entities for which types have been extracted, the total number of extracted types (more than one distinct type per named entity for some methods), the total number of correct types, and the precision (P). The number of named entities for which types have been found and the total number of correct extractions can be seen as a loose measure of recall. It is difficult to estimate recall directly for FG and SFG types since some entities may be associated with either no or multiple such types. To gain more insight, we show the number of correct distinct types, and the average depth (shortest path from ⟨*entity*-1⟩ in WordNet) for both correct FG and correct SFG types. Finally, we list the Cohen's kappa inter-annotator agreement measure for each method.

System	Coarse-Grained (CG)			Fine-Grained (FG)			Super Fine-Grained (SFG)			Distinct	Avg. Depth		Cohen's

Table 3: Summary of results

Discussion. First note that Pearl extracted significantly fewer types than any other system. Pearl does not support SFG. For CG and FG, we conjecture that its database, which was generated from Wikipedia, did not reflect the syntactic structure of the sentences in our datasets. This finding strengthens the case for the use of heterogeneous sources in semi-supervised methods.

Hyena performed better than Pearl and in many cases extracted the largest number of types. Hyena tended to extract multiple types per named entity and mostly at least one FG type. This more recall-oriented approach, and its context-unaware use of supervision, significantly reduced its precision.

FINET had significantly higher precision across all settings, especially for SFG types (almost three times more than Hyena). One reason for this is that FINET is conservative: We provide more than one type per named entity only if the types were explicit. In all other cases, our type selection phase produced only a single type. FINET extracted the largest number of correct SFG types on each dataset. Hyena extracted more FG types, but with a significantly lower precision. The average depth of correct FG and SFG types in FINET was higher than that of Pearl and Hyena. FINET also tended to use more distinct correct types (191 in NYT vs. 127 for Hyena). Again, this more fine-grained typing stemmed from FINET's use of multiple extractors, many of which do not rely on supervision.

Note that FINET also has higher precision for CG. As stated, FINET makes use of the Stanford NER to extract CG types (except in CoNLL, were we used the manual labels), and respects these types for its FG and SFG extractions. Hyena has lower precision for CG types because it sometimes outputs multiple CG types for a single named entity. To ensure a fair comparison, for CoNLL we indirectly used the gold labels for Pearl and Hyena by discarding all types with an incorrect CG type.

FINET's extractors. Tab. 4 shows individual influence of each of FINET's extractors in the NYT dataset with KB lookups. The table shows the number of entities typed by each extractor and the precision of the resulting types after type selection. The mention-based extractor was the most precise and also fired most often, mainly due to locations. The pattern-based extractor also had a good precision and tended to fire often. The first three extractors, the more explicit ones, generated more than half of the extracted types; this indicates that explicit type extractors are important. There were also a substantial fraction of implicit types, covered by the corpus-based extractor. The verb-based extractor had the lowest precision, mostly because of the noisiness and incompleteness of its underlying resources (such as the (verb,type)-repository). We expect overall precision to increase if this extractor is removed. However, this would hinder FINET to infer types from verbs. Instead, we believe a better direction is to improve the underlying resources.

Error analysis. One source of error for FINET were incorrect CG labels. When CG labels were correct (by Stanford NER), the precision of FINET for FG types increased to more than 70% for all datasets. When FG labels were correct, the pre-

Last used extractor	Entities	P
Pattern-based	180	71.11
Mention-based	219	82.65
Verb-based	47	48.94
Corpus-based	205	64.39

Table 4: Per-extractor performance NYT

cision of SFG labels exceeded 90%.

Incompleteness of and noise in our underlying resources also affected precision. For example, some types in WordNet have missing hypernyms, which reduced recall; e.g., sponsor in WordNet is a person but cannot be an organization. WordNet is also biased towards US types (e.g., *supreme court* only refers to the US institution). Our repositories of verbs and their argument types are incomplete and noisy as well. Finally, errors in the KB affected both KB lookups and our corpus-based extractor. One example of such errors are temporal discrepancies; e.g., a person who used to be a $\langle$*player*-1$\rangle$ may now be a $\langle$*coach*-1$\rangle$. The KB types are also noisy, e.g., many soccer players in Yago2 are typed as $\langle$*football_player*-1$\rangle$ and the United Nations is typed as a $\langle$*nation*-1$\rangle$.

Finally, the type selection phase of FINET introduced mistakes (i.e., even when the correct type was a candidate, type selection failed to select it). This is especially visible in the verb-based extractor, which may produce a large number of candidates and thus makes type selection difficult.

Hyena mainly suffered from the general problems of supervised systems. For instance, since $\langle$*graduate*-1$\rangle$ or $\langle$*region*-1$\rangle$ are highly frequent in the KB, many persons (locations) were incorrectly typed as $\langle$*graduate*-1$\rangle$ ($\langle$*region*-1$\rangle$). Errors in the KB also propagate in supervised system, which may lead to "contradictory" types (i.e., an entity being typed as both $\langle$*person*-1$\rangle$ and $\langle$*location*-1$\rangle$).

5 Related Work

The NET problem is related to taxonomy induction (Snow et al., 2006; Wu et al., 2012; Shi et al., 2010; Velardi et al., 2013) and KB construction (Lee et al., 2013; Paulheim and Bizer, 2014; Mitchell et al., 2015), although the goals are different. Taxonomy induction aims to produce or extend a taxonomy of types, whereas KB construction methods aim to find new types for the entities present in a KB. In both cases, this is done by reasoning over a large corpus. In contrast, we are interested in typing each named entity mention individually using an existing type system. FINET draws from ideas used in taxonomy induction or KB construction. Existing systems are either based on patterns or the distributional hypothesis; these two approaches are discussed and compared in (Shi et al., 2010). In FINET, we make use of patterns (such as the ones of Hearst (1992)) in most of our extractors and of the distributional hypothesis in our corpus-based extractor.

Yahya et al. (2014) developed a semi-supervised method to extract facts such as "president"("Barack Obama", "US"), in which the relation acts as a type. FINET differs in that it supports implicit types and produces disambiguated types.

A number of NET systems have been proposed which make use of a predefined type hierarchy. Lin et al. (2012) proposes a semi-supervised system that uses relational patterns to propagate type information from a KB to entity mentions. Similarly, the subsequent Pearl system (Nakashole et al., 2013) is based on a corpus of typed relation patterns. An alternative approach is taken by supervised methods, which train classifiers based on linguistic features (Fleischman and Hovy, 2002; Rahman and Ng, 2010; Ling and Weld, 2012). Both Yosef et al. (2013) and Ling and Weld (2012) use Wikipedia and a KB to generate automatic training data. FINET is less reliant on a KB or training data than the above methods, which improves both precision (no bias against KB types) and recall (more fine-grained types supported).

Our type selection phase is based on WSD (Navigli, 2012), a classification task where words or phrases are disambiguated against senses from some external resource such as WordNet. Supervised WSD systems (Dang and Palmer, 2005; Dligach and Palmer, 2008; Chen and Palmer, 2009; Zhong and Ng, 2010) use a classifier to assign such senses, mostly relying on manually annotated data. KB methods (Agirre and Soroa, 2009; Ponzetto and Navigli, 2010; Miller et al., 2012; Agirre et al., 2014; Del Corro et al., 2014) use of a background KB instead.

6 Conclusion

We presented FINET, a system for fine-grained typing of named entities in context. FINET generates candidates using multiple extractors, ranging from explicitly mentioned to implicit types, and subsequently selects the most appropriate. Our experimental study indicates that FINET has significantly better performance than previous methods.

Abstract

Extracting named entities in text and linking extracted names to a given knowledge base are fundamental tasks in applications for text understanding. Existing systems typically run a named entity recognition (NER) model to extract entity names first, then run an entity linking model to link extracted names to a knowledge base. NER and linking models are usually trained separately, and the mutual dependency between the two tasks is ignored. We propose JERL, Joint Entity Recognition and Linking, to jointly model NER and linking tasks and capture the mutual dependency between them. It allows the information from each task to improve the performance of the other. To the best of our knowledge, JERL is the first model to jointly optimize NER and linking tasks together completely. In experiments on the CoNLL'03/AIDA data set, JERL outperforms state-of-art NER and linking systems, and we find improvements of 0.4% absolute F_1 for NER on CoNLL'03, and 0.36% absolute precision@1 for linking on AIDA.

1 Introduction

In applications of complex Natural Language Processing tasks, such as automatic knowledge base construction, entity summarization, and question answering systems, it is essential to first have high quality systems for lower level tasks, such as part-of-speech (POS) tagging, chunking, named entity recognition (NER), entity linking, and parsing among others. These lower level tasks are usually decoupled and optimized separately to keep the system tractable. The disadvantage of the decoupled approach is that each lower level task is not aware of other tasks and thus not able to leverage information provided by others to improve performance. What is more, there is no guarantee that their outputs will be consistent.

This paper addresses the problem by building a joint model for Entity Recognition and Disambiguation (ERD). The goal of ERD is to extract named entities in text and link extracted names to a knowledge base, usually Wikipedia or Freebase. ERD is closely related to NER and linking tasks. NER aims to identify named entities in text and classify mentions into predefined categories such as persons, organizations, locations, etc. Given a mention and context as input, entity linking connects the mention to a referent entity in a knowledge base.

Existing ERD systems typically run a NER to extract entity mentions first, then run an entity linking model to link mentions to a knowledge base. Such a decoupled approach makes the system tractable, and both NER and linking models can be optimized separately. The disadvantages are also obvious: 1) errors caused by NER will be propagated to linking and are not recoverable 2) NER can not benefit from information available used in entity linking; 3) NER and linking may create inconsistent outputs.

We argue that there is strong mutual dependency between NER and linking tasks. Consider the following two examples:

---

1. The New York Times (NYT) is an American daily newspaper.
2. Clinton plans to have more news conferences in 2nd term. WASHINGTON 1996-12-06

Example 1 is the first sentence from the Wikipedia article about "The New York Times". It is reasonable but incorrect for NER to identify "New York Times" without "The" as a named entity, while entity linking has no trouble connecting "The New York Times" to the correct entity.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 879–888,
Lisbon, Portugal, 17-21 September 2015.

Example 2 is a news title where our NER classifies "WASHINGTON" as a location, since a location followed by a date is a frequent pattern in news articles it learned, while the entity linking prefers linking this mention to the U.S. president "George Washington" since another president's name "Clinton" is mentioned in the context. Both the entity boundaries and entity types predicted by NER are correlated to the knowledge of entities linked by entity linking. Modeling such mutual dependency is helpful in resolving inconsistency and improving performance for both NER and linking.

We propose JERL, Joint Entity Recognition and Linking, to jointly model NER and linking tasks and capture the mutual dependency between them. It allows the information from each task to improve the performance of the other. If NER is highly confident on its outputs of entity boundaries and types, it will encourage entity linking to link an entity which is consistent with NER's outputs, and vice versa. In other words, JERL is able to model how consistent NER and linking's outputs are, and predict coherent outputs. According to our experiments, this approach does improve the end to end performance. To the best of our knowledge, JERL is the first model to jointly optimize NER and linking tasks together completely .

Sil (2013) also proposes jointly conducting NER and linking tasks. They leverage existing NER/chunking systems and Freebase to over generate mention candidates and leave the linking algorithm to make final decisions, which is a reranking model. Their model captures the dependency between entity linking decisions and mention boundary decisions with impressive results. The difference between our model and theirs is that our model jointly models NER and linking tasks from the training phrase, while their model is a combined one which depends on an existing state-of-art NER system. Our model is more powerful in capturing mutual dependency by considering entity type and confidences information, while in their model the confidence of outputs is lost in the linking phrase. Furthermore, in our model NER can naturally benefit from entity linking's decision since both decisions are made together, while in their model, it is not clear how the linking decision can help the NER decision in return.

Joint optimization is costly. It increases the problem complexity, is usually inefficient, and requires the careful consideration of features of multiple tasks and mutual dependency, making proper assumptions and approximations to enable tractable training and inference. However, we believe that joint optimization is a promising direction for improving performance for NLP tasks since it is closer to how human beings process text information. Experiment result indicates that our joint model does a better job at both NER and linking tasks than separate models with the same features, and outperforms state-of-art systems on a widely used data set. We found improvements of 0.4% absolute F_1 for NER on CoNLL'03 and 0.36% absolute precision@1 for linking on AIDA. NER is a widely studied problem, and we believe our improvement is significant.

The contributions of this paper are as follows:
1. We identify the mutual dependency between NER and linking tasks, and argue that NER and linking should be conducted together to improve the end to end performance.
2. We propose the first completely joint NER and linking model, JERL, to train and inference the two tasks together. Efficient training and inference algorithms are also presented.
3. The JERL outperforms the best NER record on the CoNLL'03 data set, which demonstrates how NER could be improved further by leveraging knowledge base and linking techniques.

The remainder of this paper is organized as follows: the next section discusses related works on NER, entity linking, and joint optimization; section 3 presents our Joint Entity Recognition and Linking model in detail; section 4 describes experiments, results, and analysis; and section 5 concludes.

2 Related Work

The NER problem has been widely addressed by symbolic, statistical, as well as hybrid approaches. It has been encouraged by several editions of evaluation campaigns such as MUC (Chinchor and Marsh, 1998), the CoNLL 2003 NER shared task (Tjong Kim Sang and De Meulder, 2003) and ACE (Doddington et al., 2004). Along with the improvement of Machine Learning techniques, statistical approaches have become a major direction for research on NER, especially after Conditional Random Field is proposed by Lafferty et al. (2001). The well known state-of-art NER systems are Stanford NER (Finkel et al., 2005) and UIUC

NER (Ratinov and Roth, 2009). Liang (2005) compares the performance of the 2nd order linear chain CRF and Semi-CRF (Sarawagi and Cohen, 2004) in his thesis. Lin and Wu (2009) cluster tens of millions of phrases and use the resulting clusters as features in NER reporting the best performance on the CoNLL'03 English NER data set. Recent works on NER have started to focus on multi-lingual named entity recognition or NER on short text, e.g. Twitter.

Entity linking was initiated with Wikipedia-based works on entity disambiguation (Bunescu and Pasca, 2006; Cucerzan, 2007). This task is encouraged by the TAC 2009 KB population task[1] first and receives more and more attention from the research community (Hoffart et al., 2011; Ratinov et al., 2011; Han and Sun, 2011). Linking usually takes mentions detected by NER as its input. Stern et al. (2012) and Wang et al. (2012) present joint NER and linking systems and evaluate their systems on French and Chinese data sets. Sil and Yates (2013) take a re-ranking based approach and achieve the best result on the AIDA data set. In 2014, Microsoft and Google jointly hosted "Entity Recognition and Disambiguation Challenge" which focused on the end to end performance of linking system [2].

Joint optimization models have been studied at great length. E.g. Dynamic CRF (McCallum et al., 2003) has been proposed to conduct Part-of-Speech Tagging and Chunking tasks together. Finkel and Manning (2009) show how to model parsing and named entity recognition together. Yu et al. (2011) work on jointly entity identification and relation extraction from Wikipedia. Sil's (2013) work on jointly NER and linking is described in the introduction section of this paper. It is worth noting that joint optimization does not always work. The CoNLL 2008 shared task (Surdeanu et al., 2008) was intended to encourage jointly optimize parsing and semantic role labeling, but the top performing systems decoupled the two tasks.

3 Joint Entity Recognition and Linking

Named entity recognition is usually formalized as a sequence labeling task, in which each word is classified to not-an-entity or entity labels. Conditional Random Fields (CRFs) is one of the popular models used. Most features used in NER are word-level (e.g. a word sequence appears at position i or whether a word contains exactly four digits). It is hard, if not impossible, to encode entity-level features (such as "entity length" and "correlation to known entities") in traditional CRF. Entity linking is typically formalized as a ranking task. Features used for entity linking are at entity-level inherently (such as entity prior probability; whether there are any related entity names or discriminative keywords occurring in the context).

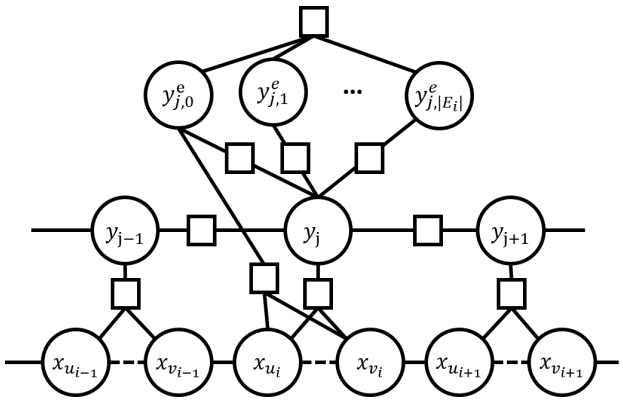

Figure 1: The factor graph of JERL model

The main challenges of joint optimization between NER and linking are: how to combine a sequence labeling model and a ranking model; and how to incorporate word-level and entity-level features. In a linear chain CRF model, each word's label is assumed to depend on the observations and the label of its previous word. Semi-CRF carefully relaxes the Markov assumption between words in CRF, and models the distribution of segmentation boundaries directly. We further extend Semi-CRF to model entity distribution and mutual dependency over segmentations, and name it Joint Entity Recognition and Linking (JERL). The model is described below.

3.1 JERL

Let $\boldsymbol{x} = \{x_i\}$ be a word sequence containing $|\boldsymbol{x}|$ words. Let $\boldsymbol{s} = \{s_j\}$ be a segmentation assignment over $\boldsymbol{x}$, where segment $s_j = (u_j, v_j)$ consist of a start position u_j and an end position v_j. All segments have a positive length and are adjacent to each other, so every (u_j, v_j) always satisfies $1 \leq u_j \leq v_j \leq |\boldsymbol{x}|$ and $u_{j+1} = v_j + 1$. Let $\boldsymbol{y} = \{y_j\}$ be labels in a fixed label alphabet $\mathcal{Y}$ over a segmentation assignment $\boldsymbol{s}$. Here $\mathcal{Y}$ is the set of types NER to predict. $x_{s_j} = (x_{u_j} \dots x_{v_j})$

[1] http://www.nist.gov/tac/2014/KBP/

[2] http://web-ngram.research.microsoft.com/ERD2014/

is the corresponding word sequence to s_j, and $\mathcal{E}_{s_j} = \{e_{j,k}\}$ is a set of entities in the knowledge base (KB), which may be referred by word sequence x_{s_j} in the entity linking task. Each entity $e_{j,k}$ is associated with a label $y^e_{j,k} \in \{0, 1\}$. Label $y^e_{j,k}$ takes 1 iff x_{s_j} referring to entity $e_{j,k}$, and 0 otherwise. If x_{s_j} does not refer to any entity in the KB, $y^e_{j,0}$ takes 1, which is analogous to the NIL[3] identifier in entity linking.

Based on the preliminaries and notations, Figure 1 shows the factor graph (Kschischang et al., 2001) of JERL. There are similar factor nodes for every $(u_j, v_j, y^e_{j,k})$, we only show the first one $(u_j, v_j, y^e_{j,0})$ for clarity.

Given $\boldsymbol{x}$, let $\boldsymbol{a} = (\boldsymbol{s}, \boldsymbol{y}, \boldsymbol{y^e})$ be a joint assignment, and $\boldsymbol{g}(\boldsymbol{x}, j, \boldsymbol{a})$ be local functions for x_{s_j}, namely features, each of which maps an assignment $\boldsymbol{a}$ to a measurement $g^k(x, j, a) \in \Re$. Then $\boldsymbol{G}(\boldsymbol{x}, \boldsymbol{a}) = \sum_{j=1}^{|s|} \boldsymbol{g}(\boldsymbol{x}, j, \boldsymbol{a})$ is the factor graph defining a probability distribution of assignment $\boldsymbol{a}$ conditioned on word sequence $\boldsymbol{x}$.

Then JERL, conditional probability of $\boldsymbol{a}$ over $\boldsymbol{x}$, is defined as:

$$P(\boldsymbol{a}|\boldsymbol{x}, \boldsymbol{w}) = \frac{1}{Z(\boldsymbol{x})} e^{\boldsymbol{w} \cdot \boldsymbol{G}(\boldsymbol{x}, \boldsymbol{a})} \quad (1)$$

where $\boldsymbol{w}$ is the weight vector corresponding to $\boldsymbol{G}$ will be learned later, and $Z(\boldsymbol{x})$ is the normalization factor $Z(\boldsymbol{x}) = \sum_{\boldsymbol{a} \in A} e^{\boldsymbol{w} \cdot \boldsymbol{G}(\boldsymbol{x}, \boldsymbol{a})}$, in which A is the union of all possible assignments over $\boldsymbol{x}$.

JERL is a probabilistic graphical model. More specificly, as shown in Figure 1, there are three groups of local functions and one constrain introduced. Each of them take a different role in JERL, as described below:

Features defined on $\boldsymbol{x}$, s_j, y_j, y_{j-1} are written as $\boldsymbol{g}^{ner}(\boldsymbol{x}, s_j, y_j, y_{j-1})$. These functions model segmentation and entity types' distribution over $\boldsymbol{x}$. Actually, every local features used in NER can be formulated in this way, and thus can be included in JERL. We thus refer to them as "NER features".

Features defined on $\boldsymbol{x}$, s_j, $y^e_{j,k}$ are written as $\boldsymbol{g}^{el}(\boldsymbol{x}, s_j, y^e_{j,k})$ and are called "linking features". These features model joint probabilities of word sequence x_{s_j} and linking decisions $y^k_{j,k} = 1(0 \leq k \leq |\mathcal{E}_{s_j}|)$ given context $\boldsymbol{x}$. JERL incorporates all linking features in this way.

Features defined on y_j, $y^e_{j,k}$ are written as $\boldsymbol{g}^{cr}(y_j, y^e_{j,k})$. These features model "mutual dependency" between NER and linking's outputs. For each entity $e_{j,k}$, there is additional information available in the knowledge base, e.g. categories information, popularity and relationship to other entities. These features encourage predicting coherent outputs for NER and linking.

There is one constrain for each $\boldsymbol{y^e_j}$ that the corresponding x_{s_j} can refer to only one entity $e_{j,k} \in \mathcal{E}_{sj}$ or NIL. This is equivalent to $\sum_{k=0}^{|\mathcal{E}_{s_j}|} y^e_{j,k} = 1$.

Based on the above description, $\boldsymbol{G}(\boldsymbol{x}, \boldsymbol{a})$ in equation 1 is the sum of conjunction $(\boldsymbol{g}^{ner}, \boldsymbol{g}^{el}, \boldsymbol{g}^{cr})$ over $\boldsymbol{s}$, and can be rewritten as,

$$\begin{aligned} \boldsymbol{G}(\boldsymbol{x}, \boldsymbol{a}) = \textstyle\sum_{j=1}^{|\boldsymbol{s}|} (\quad & \boldsymbol{g}^{ner}(\boldsymbol{x}, s_j, y_j, y_{j-1}) \\ & , \textstyle\sum_{k=0}^{|\mathcal{E}_j|} \boldsymbol{g}^{el}(\boldsymbol{x}, s_j, y^e_{j,k}) \\ & , \textstyle\sum_{k=0}^{|\mathcal{E}_j|} \boldsymbol{g}^{cr}(\boldsymbol{x}, y_j, y^e_{j,k}) \ ) \end{aligned}$$

In summary, JERL jointly models the NER and linking, and leverages mutual dependency between them to predict coherent outputs. Previous works (Cucerzan, 2007; Ratinov et al., 2011; Sil and Yates, 2013) on linking argued that entity linking systems often suffer because of errors involved in mention detection phrase, especially false negative errors, and try to mitigate it via overgenerating mention candidates. From the mention generation perspective, JERL actually considers every possible assignment and is able to find the optimal $\boldsymbol{a}$.

3.2 Parameter Estimation

We describe how to conduct parameter estimation for JERL in this section. Given independent and identically distributed (i.i.d.) training data $\boldsymbol{T} = \{(\boldsymbol{x_t}, \boldsymbol{a}_t)\}_{t=1}^N$, the goal of parameter estimation is to find optimal $\boldsymbol{w^*}$ to maximize the joint probability of the assignments $\{\boldsymbol{a_t}\}$ over $\{\boldsymbol{x_t}\}$.

$$\boldsymbol{w}^* = argmax_{\boldsymbol{w} \in \Re^{|\boldsymbol{G}|}} \prod_{t=1}^{N} P(\boldsymbol{a_t}|\boldsymbol{x_t}, \boldsymbol{w})$$

We use conditional log likelihood with ℓ_2 norm as the objective function in training,

$$\mathcal{L}(\boldsymbol{T}, \boldsymbol{w}) = \ \textstyle\sum_t logP(\boldsymbol{a_t}|\boldsymbol{x_t}, \boldsymbol{w}) - \frac{1}{2\sigma^2}||\boldsymbol{w}||_2^2$$

The above function is concave, adding regularization to ensure that it has exactly one global optimum. We adopt a limited-memory quasi-Newton method (Liu and Nocedal, 1989) to solve the optimization problem.

[3] In the entity linking task, if a given mention refers to an entity which is not in the knowledge base, linking system should return a special identifier "NIL".

The gradient of $\mathcal{L}(\boldsymbol{T}, \boldsymbol{w})$ is derived as,

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{w}} = \sum_t (\boldsymbol{G}(\boldsymbol{x_t}, \boldsymbol{a_t}) - \sum_{a'} \boldsymbol{G}(\boldsymbol{x_t}, \boldsymbol{a'}) P(\boldsymbol{a'}|\boldsymbol{x_t}, \boldsymbol{w})) - \frac{\boldsymbol{w}}{\sigma^2} \quad (2)$$

As shown in Figure 1, our model's factor graph is a tree, which means the calculation of the gradient is tractable.

Inspired by the forward backward algorithm (Sha and Pereira, 2003) and Semi-CRF (Sarawagi and Cohen, 2004), we leverage dynamic programming techniques to compute the normalization factor $Z_{\boldsymbol{w}}$ and marginal probability $P(\boldsymbol{a'_j}|\boldsymbol{x_t}, \boldsymbol{w})$ when $\boldsymbol{w}$ is given.(Sutton and McCallum, 2006) The parameter estimation algorithm is abstracted in Algorithm 1.

Algorithm 1: JERL parameter estimation

input : training data $\boldsymbol{T} = \{(\boldsymbol{x}_t, \boldsymbol{a}_t)\}_{t=1}^N$
output: the optimal $\boldsymbol{w}$

$\boldsymbol{w} \leftarrow \boldsymbol{0}$;
while *weight* $\boldsymbol{w}$ *is not converged* **do**
  $Z \leftarrow 0$;
  $\boldsymbol{w'} \leftarrow \boldsymbol{0}$;
  for $t \leftarrow 1$ **to** N **do**
    calculate $\boldsymbol{\alpha_t}, \boldsymbol{\beta_t}$ according to eq.3;
    calculate Z_t according to eq.4
    calculate $\boldsymbol{w'_t}$ according to eq.2, 5;
    $Z \leftarrow Z + Z_t$;
    $\boldsymbol{w'} \leftarrow \boldsymbol{w'} + \boldsymbol{w'_t}$;
  end
  update $\boldsymbol{w}$ to maximize log likelihood $\mathcal{L}(\boldsymbol{T}, \boldsymbol{w})$ under $(Z, \boldsymbol{w'})$ via L-BFGS;
end

Let $\alpha_{i,y}$ $(i \in [0, |x|], y \in \mathcal{Y})$ be the sum of potential functions of all possible assignments over $(x_1 \dots x_i)$ whose last segmentation's labels are y. Then $\alpha_{i,y}$ can be calculated recursively from $i = 0$ to $i = |\boldsymbol{x}|$ as below.

We first define base cases as $\alpha_{0,y} = 1|_{\{y \in \mathcal{Y}\}}$. When $i \in (0, |x|]$:

$$\alpha_{i,y} = \sum_{d=1}^{L} \sum_{y' \in \mathcal{Y}} \alpha_{i-d,y'} \psi^{ner}_{i-d+1,i,y,y'} \left(\sum_{\boldsymbol{y_j^e} \in Y_j^{e*}} \psi^{el.cr}_{i-d+1,i,y,\boldsymbol{y_j^e}} \right) \quad (3)$$

where L is the max segmentation length in Semi-CRF, and Y_j^{e*} is all valid assignments for $\boldsymbol{y_j^e}$ which satisfies $\sum_{k=0}^{|\mathcal{E}_{s_j}|} y^e_{j,k} = 1$. The $\psi^{ner}_{u_j,v_j,y_j,y_{j-1}}$ and $\psi^{el.cr}_{u_j,v_j,y_j,\boldsymbol{y_j^e}}$ are precomputed ahead as below,

$$\psi^{ner}_{u_j,v_j,y_j,y_{j-1}} = e^{\boldsymbol{w}^{ner} \cdot \boldsymbol{g}^{ner}(\boldsymbol{x}, s_j, y_j, y_{j-1})}$$

$$\psi^{el.cr}_{u_j,v_j,y_j,\boldsymbol{y_j^e}} = \prod_{k=0}^{|\mathcal{E}_j|} e^{\boldsymbol{w}^{el} \boldsymbol{g}^{el}(\boldsymbol{x}, s_j, y^e_{j,k}) + \boldsymbol{w}^{cr} \boldsymbol{g}^{cr}(y_j, y^e_{j,k})}$$

where $\boldsymbol{w}^{ner}$, $\boldsymbol{w}^{el}$ and $\boldsymbol{w}^{cr}$ are weights for $\boldsymbol{g}^{ner}$, $\boldsymbol{g}^{el}$ and $\boldsymbol{g}^{cr}$ in $\boldsymbol{w}$ accordingly.

The value of $Z_{\boldsymbol{w}}$ can then be written as

$$Z_{\boldsymbol{w}}(\boldsymbol{x}) = \sum_y \alpha_{|\boldsymbol{x}|,y} \quad (4)$$

Define $\beta_{i,y}$ $(i \in [0, |x|], y \in \mathcal{Y})$ as the sum of potential functions of all possible assignments over $(x_{i+1} \dots x_{|\boldsymbol{x}|})$ whose first segmentation's labels are y. $\beta_{i,y}$ is calculated in a similar way, except they are calculated from $i = |x|$ to left $i = 0$.

Once we get $\{\alpha_{i,j}\}$ and $\{\beta_{i,j}\}$, the marginal probability of arbitrary assignment $a_j = (s_j, y_j, \boldsymbol{y_j^e})$, where $s_j = (u_j, v_j)$, can be calculated as below:

$$P(s_j, y_j|\boldsymbol{x}, \boldsymbol{w}) = \frac{(\sum_{y' \in \mathcal{Y}} \alpha_{u_j - 1, y'} \psi^{ner}_{u_j,v_j,y_j,y'}) \beta_{v_j,y_j}}{Z_{\boldsymbol{w}}(\boldsymbol{x})}$$

and

$$P(a_j|\boldsymbol{x_t}, \boldsymbol{w}) = P(s_j, y_j|\boldsymbol{x}, \boldsymbol{w}) \frac{\psi^{el.cr}_{u_j,v_j,y_j,\boldsymbol{y_j^e}}}{\sum_{\boldsymbol{y_{j'}^e} \in Y_j^{e*}} \psi^{el.cr}_{u_j,v_j,y_j,\boldsymbol{y_{j'}^e}}} \quad (5)$$

3.3 Inference

Given a new word sequence $\boldsymbol{x}$ and model weights $\boldsymbol{w}$ trained on a training set, the goal of inference is to find the best assignment, $\boldsymbol{a^*} = argmax_{\boldsymbol{a}} P(\boldsymbol{a}|\boldsymbol{x}, \boldsymbol{w})$ for $\boldsymbol{x}$. We extend the Viterbi algorithm to exactly infer the best assignment. The inference algorithm is shown in Algorithm 2.

Let $\phi(u_j, v_j, y_j, y_{j-1})$ be the product of potentials depending on (s_j, y_j, y_{j-1}) as,

$$\phi(u_j, v_j, y_j, y_{j-1}) = \psi^{ner}_{u_j,v_j,y_j,y_{j-1}} \left(\sum_{\boldsymbol{y_j^e} \in Y_j^{e*}} \psi^{el.cr}_{u_j,v_j,y_j,\boldsymbol{y_j^e}} \right) \quad (6)$$

Algorithm 2: JERL inference

input : one word sequence $\boldsymbol{x}$ and weights $\boldsymbol{w}$
output: the best assignment $\boldsymbol{a}$ over $\boldsymbol{x}$

// shrink JERL graph to a Semi-CRF graph;
for $u \leftarrow 1$ **to** $|\boldsymbol{x}|$ **do**
  for $v \leftarrow u+1$ **to** $|\boldsymbol{x}|$ **do**
    for $(y, y') \in \mathcal{Y} \times \mathcal{Y}$ **do**
      calculate $\phi_{u,v,y,y'}$ // see eq.6;
    end
  end
end
// infer the best assignment of $(\boldsymbol{s}^*, \boldsymbol{y}^*)$;
for $i \leftarrow 1$ **to** $|\boldsymbol{x}|$ **do**
  for $y \in \mathcal{Y}$ **do**
    calculate $V_{i,y}$ // see eq.7;
  end
end
$(\boldsymbol{s}^*, \boldsymbol{y}^*) \leftarrow argmax(V_{i,y})$;
// infer the best assignment of $\{\boldsymbol{y}_{\boldsymbol{j}}^{\boldsymbol{e}}\}$;
for $j \leftarrow 1$ **to** $|\boldsymbol{s}^*|$ **do**
  $\boldsymbol{y}_{\boldsymbol{j}}^{\boldsymbol{e}} \leftarrow argmax(P(|\boldsymbol{x}, \boldsymbol{w}, \boldsymbol{s}_{\boldsymbol{j}}^*, \boldsymbol{y}_{\boldsymbol{j}}^*))$
end
$\boldsymbol{a}^* \leftarrow (\boldsymbol{s}^*, \boldsymbol{y}^*, \boldsymbol{y}^{\boldsymbol{e}*})$;

and let $V(i, y)$ denotes the largest value of $(\boldsymbol{w} \cdot \boldsymbol{G}(\boldsymbol{x}, \boldsymbol{a'}))$ where $\boldsymbol{a'}$ could be any possible partial assignment starting from x_1 to x_i. The best $(\boldsymbol{s}^*, \boldsymbol{y}^*)$ are derived during the following recursive calculation,

$$V_{i,y} = \begin{cases} max_{y' \in \mathcal{Y}, d \in [1,L]} \\ (V_{i-d,y'} + \phi(i-d+1, i, y, y')) & i > 0 \\ 0 & i = 0 \\ -\infty & i < 0 \end{cases} \quad (7)$$

where L is the maximum segmentation length for Semi-CRF.

Once $(\boldsymbol{s}^*, \boldsymbol{y}^*)$ are found, the corresponding $\boldsymbol{y}_{\boldsymbol{j}}^{\boldsymbol{e}*} = argmax_{\{\boldsymbol{y}_{\boldsymbol{l}}^{\boldsymbol{e}} \in Y_j^{e*}\}}(\psi^{el.cr}_{u_j^*, v_j^*, y_j^*, \boldsymbol{y}_{\boldsymbol{l}}^{\boldsymbol{e}}})$ is also the optimal one. Then $\boldsymbol{a}^* = (\boldsymbol{s}^*, \boldsymbol{y}^*, \boldsymbol{y}^{\boldsymbol{e}*})$ is the best assignment for the given $\boldsymbol{x}$ and $\boldsymbol{w}$.

4 Experiments

In our experiments, we first construct two baseline models JERL$_{ner}$ and JERL$_{el}$, which use exact NER and EL feature sets used in JERL. Then evaluate JERL and the two baseline models against several state-of-art NER and linking systems. After that, we evaluate JERL under different feature settings to analysis the contributions of each features set, and show some examples we find. We also compare the training speed under different settings.

CoNLL'03	Training	Dev set	Test
Articles	946	216	231
Sentences	14,987	3,466	3,684
Tokens	203,621	51,362	46,435
Entities	23,499	5,942	5,648
NIL Entities	4,857	1,129	1,133

Table 1: Overview of CoNLL'03/AIDA data set

4.1 Data set

We take the CoNLL'03/AIDA English data set to evaluate the performance of NER and linking systems. CoNLL'03 is extensively used in prior work on NER evaluation (Tjong Kim Sang and De Meulder, 2003). The English data is taken from Reuters news articles published between August 1966 and August 1997. Four types of entities persons (PER), organizations (ORG), locations (LOC), and miscellaneous names (MISC) are annotated. Hoffart et al. (2011) hand-annotated all proper nouns with corresponding entities wiht YAGO2, Freebase and Wikipedia IDs. This data is referenced as AIDA here. To the best of our knowledge, this data set is the biggest data set which has been labeled for both NER and linking tasks. It becomes a really good starting point for our work. Table 1 contains of an overview of the CoNLL'03/AIDA data set.

For entity linking, we take Wikipedia as the referent knowledge base. We use a Wikipedia snapshot dumped in May 2013, which contains around 4.8 million articles. We also align our Wikipedia dump with additional knowledge bases, Freebase and Satori (a Microsoft internal knowledge base), to enrich the information of these entities.

4.2 Evaluation Metrics

We follow the CoNLL'03 metrics to evaluate NER performance by precision, recall, and F_1 scores, and follow Hoffart's (2011) experiment setting to evaluate linking performance by micro precision@1. Since the linking labels of CONLL'03 were annotated in 2011, it is not completely consistent with the Wikipedia dump we used in the case. We only consider mention entity pairs where the ground truth are known, and ignore around 20% of NIL mentions in the ground truth.

Category	Features
NER	Word unigram / bigram
	Lower cased unigram / bigram
	Word shape unigram / bigram
	Stemmed unigram / bigram
	POS unigram / bigram
	Chunk unigram / bigram
	Words in the 4 left/right window
	Character n-grams, $n \leq 4$
	Brown clusters
	WordNet clusters
	Dictionaries
Linking	Alternative names
	Entity priors
	Entity name priors
	Entity priors over names
	Context scores
	Geo distance
	Related entities
Mutual	Type-category correlation

Table 2: JERL feature list

4.3 JERL Implementation

Table 2 shows features used in our models. JERL uses all features in the three categories, while JERL$_{ner}$ and JERL$_{el}$ use only one corresponding category. All three models are trained on the train and development set, and evaluated on the test set of CoNLL'03/AIDA.

4.3.1 NER

Features in the NER category are relevant to NER. We considered the most commonly used features in literatures (Finkel et al., 2005; Liang, 2005; Ratinov and Roth, 2009). We collect several known name lists, like popular English first/last names for people, organization lists and so on from Wikipedia and Freebase. UIUC NER's lists are also included. In addition, we extract entity name lists from the knowledge base we used for entity linking, and construct 655 more lists. Although those lists are noisy, we find that statistically they do improve the performance of our NER baseline by a significant amount.

4.3.2 Linking

Features in linking category are relevant to entity linking. An entity can be referred by its canonical name, nick names, alias, and first/last names. Those names are defined as alternative names for this entity. We collect all alternative names for all known entities and build a name to entity index. This index is used to select entity candidates for any word sequence, also known as surface form. Following previous work by Han and Sun (2011), we calculate entity priors and entity name priors from Wikipedia. Context scores are calculated based on discriminative keywords. Geo distance and related entities capture the relatedness among entities in the given context.

4.3.3 Mutual

Features in this category capture the mutual dependency between NER and linking's outputs. For each entity in a knowledge base, there is category information available. We aggregate around 1000 distinct categories from multiple sources. One entity can have multiple categories. For example, London is connected to 29 categories. We use all combinations between NER types and categories as features in JERL, and let the model learn the correlation of each combination. This encourages coherent NER and EL decisions, which is one of the key contributions of our work.

4.3.4 Non-local features

Features capturing long distance dependency between hidden labels are classified as non-local features. Those features are very helpful in improving NER system performance but are costly. Since this is not the focus of this paper, we take a simple approach to incorporate non-local features. We cache history results of previous sentences in a 1000 words window, and adopt several heuristic rules for personal names. This approach contributes 0.2 points to the final NER F_1 score. Non-local features are also considered in linking (Ratinov et al., 2011; Han et al., 2011). We try several features, which has been proved to be helpful in TAC data set. However, the gain on CoNLL'03/AIDA data set is not obvious, we do not optimize linking globally.

Lastly, based on preliminary studies and experiments, we set the maximum segmentation length to 6 and max candidate count per segmentation to 5 for efficient training and inference.

4.4 State-of-Art systems

We take three state-of-art NER systems: NereL (Sil and Yates, 2013), UIUC NER (Ratinov and Roth, 2009) and Stanford NER (Finkel et al., 2005). NereL firstly over generates mentions and decomposes them to sets of connected compo-

Dataset	System	Prec.	Recall	F_1
CoNLL'03	Stanford	**95.1**	78.3	85.9
	UIUC	91.2	90.5	90.8
	NereL	86.8	89.5	88.2
	$JERL_{ner}$	90.0	89.9	89.9
	$JERL$	91.5	**91.4**	**91.2**

Table 3: NER evaluation results

Dataset	System	Precision@1
CoNLL'03	Kul09	76.74
	Hof11	81.91
	Nerel	84.22
	JERL_{el}	81.49
	JERL	**84.58**

Table 4: Linking evaluation results

#	Feature set description	NER F_1
0	JERL_{ner} (baseline)	89.9
1	+ candidate	88.7
2	+ candidate + linking	89.9
3	+ candidate + mutual	90.6
4	+ candidate + mutual + linking	91.2

Table 5: JERL features analysis

nents, then trains a maximum-entropy model to re-rank different assignments. UIUC NER uses a regularized averaged perceptron model and external gazetteers to achieve strong performance. In Addition, NereL also uses UIUC NER to generate mentions. Stanford NER uses Conditional Random Fields and Gibbs sampling to incorporate non-local features into its model.

For entity linking systems, NereL, Kul09 (Kulkarni et al., 2009) and Hof11 (Hoffart et al., 2011) are compared with our models. NereL achieves the best precision@1. Kul09 formulates the local compatibility and global coherence in entity linking, and optimizes the overall entity assignment for all entities in a document via a local hill-climbing approach. Hof11 unifies the prior probability of an entity being mentioned, the similarity between context and entity, and the coherence between entity candidates among all mentions in a dense graph.

4.5 Results

Table 3 shows the performance of different NER systems on the CoNLL'03 testb data set. We refer the numbers of state-of-art systems reported by Sil and Yates (2013). Stanford NER achieves the best precision, but its recall is low. UIUC reports the (almost) best recorded F_1. JERL_{ner} considers features only in the NER category, which could be treated as a pure NER system implemented in Semi-CRF. Actually CRF-based implementation with a similar feature set has comparable performance. Our baseline JERL_{ner} is strong enough. We argue that that it is mainly because of the additional dictionaries derived from the knowledge base. JERL further pushes the F_1 to 91.2, which outperforms UIUC by 0.4 points in F_1 score. To the best of our knowledge, it is the best F_1 on CoNLL'03 since 2009. The reason our model can outperform state-of-art systems is that, it has more knowledge about entities via incorporate entity linking techniques. If an entity can be linked to a well known entity via entity linking in high confidence, its mention boundary and entity type are confirmed implicitly.

Table 4 shows the performance of different entity linking systems on the AIDA test set. Kul09 and Hof11 use only the correct mentions detected by the Stanford NER as input, and thus their recall is bound by the recall of NER. NereL uses its overgeneration techniques to generate mention candidates, and outperforms Hoff11 in both precision and recall. Our baseline model JERL_{el} is also evaluated on Stanford NER generated mentions, which has comparable performance with Kul09 and Hof11. JERL achieves precision@1 84.58 which is better than NereL.

We run 15 trials for both NER and linking's experiments and report the average numbers above. The standard deviations are 0.11% and 0.08% for NER and linking separately, which pass the standard t-test with confidence level 5%, demonstrating the significance of our results.

In order to investigate how different features contribute to the overall gain. We compare JERL_{ner} with four different feature sets. Table 5 summaries the results. In the trial "+candidate", JERL expands every possible segmentation with corresponding entity list and builds its factor graph without any linking and mutual features. This version's F_1 drops to 88.7 which indicates the created structure is quite noisy. In the "+candidate +linking" trial, only linking features are enabled and the F_1 is comparable to the baseline. On the other side, in the "+candidate +mutual" trial when mutual features are enabled the F_1 increases to 90.6. If we combine both linking and mutual features,

Category	PER	LOC	ORG	Other
people.person	3.65	0.817	1.260	-1.782
location.city	-0.187	0.712	0.491	-0.188
sports.team	-0.180	2.382	3.595	-2.019

Table 6: Learned mutual dependency

Setting		NER	Linking	Training
MSL	MRC	F_1	prec@1	time (min)
4	5	87.9	76.74	195
5	5	90.8	84.01	234
6	1	90.8	80.13	37
6	3	91.0	83.21	109
6	5	91.2	84.58	280

Table 7: Training time under different settings

JERL achieves the reported performance. The result indicates that mutual features are the determining factor to the performance gain.

Table 6 shows weights of learned mutual dependency of three categories "people.person", "location.city", and "sports.team". The bigger a weight is, the more consistent this combination would be. From the weights, we find several interesting things. If an entity belongs to any of the three categories, it is less likely to be predicted as non-an-entity by NER. If an entity belongs to the category of "people.person", it more likely to be predicted as PER. When an entity belongs to the category "location.city" or "sports.team", NER may predict it as ORG or LOC. This is because in the CoNLL'03/AIDA data set, there are many sports teams mentioned by their city/country names. JERL successfully models such unexpected mutual dependency.

Table 7 compares the performance and training time under different settings of max segmentation length (MSL) and max referent count (MRC). We use machines with Intel Xeon E5620 @ 2.4GHz CPU (8 cores / 16 logical processors) and 48GB memory. We run every setting 10 times and report the averages. As MSL and MRC increasing, the performance is slightly better, but the training time increased a lot. MSL has linear impact on training time, while MRC affects training time more.

5 Conclusion and Future Work

In this paper, we address the problem of joint optimization of named entity recognition and linking. We propose a novel model, JERL, to jointly train and infer for NER and linking tasks. To the best of our knowledge, this is the first model which trains two tasks at the same time. The joint model is able to leverage mutual dependency of the two tasks, and predict coherent outputs. JERL outperforms the state-of-art systems on both NER and linking tasks on the CoNLL'03/AIDA data set.

For future works, we would like to study how to leverage existing partial labeled data, either for NER or for linking only, in joint optimization, and incorporate more NLP tasks together for multi-tasks joint optimization.

Acknowledgments

This work was performed when the first author was working at Microsoft Research. The first author is sponsored by Microsoft Bing Core Relevance team. Thanks Shuming Shi, Bin Gao, and Yohn Cao for their helpful guidance and valuable discussions. Additionally, we would like to thank the three anonymous reviewers for their insightful suggestions and detailed comments.

How Much Information Does a Human Translator Add to the Original?

Abstract

We ask how much information a human translator adds to an original text, and we provide a bound. We address this question in the context of bilingual text compression: given a source text, how many bits of additional information are required to specify the target text produced by a human translator? We develop new compression algorithms and establish a benchmark task.

1 Introduction

Text compression exploits redundancy in human language to store documents compactly, and transmit them quickly. It is natural to think about compressing bilingual texts, which have even more redundancy:

> "From an information theoretic point of view, accurately translated copies of the original text would be expected to contain almost no extra information if the original text is available, so in principle it should be possible to store and transmit these texts with very little extra cost." (Nevill and Bell, 1992)

Of course, if we look at actual translation data (Figure 1), we see that there is quite a bit of unpredictability. But the intuition is sound. If there were a million equally-likely translations of a short sentence, it would only take us $\log_2(1\text{m}) = 20$ bits to specify which one.

By finding and exploiting patterns in bilingual data, we want to provide an upper bound for this question: *How much information does a human translator add to the original?* We do this in the context of building a practical compressor for bilingual text.

上个星期的战斗至少夺取12个人的生命。
At least 12 people were killed in the battle last week.
Last week's fight took at least 12 lives.
The fighting last week killed at least 12.
The battle of last week killed at least 12 persons.
At least 12 people lost their lives in last week's fighting.
At least 12 persons died in the fighting last week.
At least 12 died in the battle last week.
At least 12 people were killed in the fighting last week.
During last week's fighting, at least 12 people died.
Last week at least twelve people died in the fighting.
Last week's fighting took the lives of twelve people.

Figure 1: Eleven human translations of the same source sentence (LDC2002T01).

We adopt the same scheme used in monolingual text compression benchmark evaluations, such as the Hutter Prize (Hutter, 2006), a competition to compress a 100m-word extract of English Wikipedia. A valid entry is an executable, or self-extracting archive, that prints out Wikipedia, byte-for-byte. Decompression code, dictionaries, and/or other resources must be embedded in the executable—we cannot assume that the recipient of the compressed file has access to those resources. This view of compression goes by the name of algorithmic information theory (or Kolmogorov complexity).

Any executable is permitted. For example, if our job were to compress the first million digits of π, then we might submit a very short piece of code that prints those digits. The brevity of that compression would demonstrate our understanding of the sequence. Of course, in our application, we will find it useful to develop generic algorithms that can compress any text.

Our approach will be as follows. Given a bilingual text (`file1` and `file2`), we develop this compression interface:

```
% compress file1 > file1.exe
% bicompress file2 file1 > file2.exe
```

The second command compresses `file2` while looking at `file1`. We take the size of `file1.exe`

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 889–898,
Lisbon, Portugal, 17-21 September 2015.

	Spanish	English
Uncompressed size	324.9 Mb	294.5 Mb

Vocabulary size	73,726	45,423
Distinct word cooc	21,231,874	
Segment pairs	196,573	
Ave. segment length (word tokens)	28.9	27.6
Longest segment (word tokens)	733	682

Figure 3: Small Europarl Spanish/English corpus.

as the amount of information in the original text. We bound how much information the translator adds to the original by:

$|$`file2.exe`$|$ / $|$`file1.exe`$|$

We can say that bilingual compression is more effective that monolingual compression if:

$|$`file2.exe`$| < |$`file3.exe`$|$, where

```
% compress file2 > file3.exe
```

Our decompression interface is:

```
% file1.exe > file1
% file2.exe file1 > file2
```

The second command decompresses `file2` while looking at (uncompressed) `file1`.

The contributions of this paper are:

1. We provide a new quantitative bound for how much information a translator adds to an original text.
2. We present practical software to compress bilingual text with compression rates that exceed the previous state-of-the-art.
3. We set up a public benchmark bilingual text compression challenge to stimulate new researchers to find and exploit patterns in bilingual text. Ultimately, we want to feed those ideas into practical machine translation systems.

2 Data

We propose the widely accessible Spanish/English Europarl corpus v7 (Koehn, 2005) as a benchmark for bilingual text compression (Figure 2). Portions of this large corpus have been used in previous compression work (Sánchez-Martínez et al., 2012). The Spanish side is in UTF-8. For English, we have removed accent marks and further eliminated all but the 95 printable ASCII characters (Brown et al., 1992), plus newline.

Our task is to compress the data "as is": untokenized, but already segment aligned. We also include a tokenized version with 334 manually word-aligned segment pairs (Lambert et al., 2005) distributed throughout the corpus.

For rapid development and testing, we have arranged a smaller corpus that is 10% the size of the full corpus (Figure 3).

3 Monolingual compression

Compression captures patterns in data. Language modeling also captures patterns, but at first blush, these two areas seem distinct. In compression, we seek a small executable that prints out a text, while in language modeling, we seek an executable that assigns low perplexity to held-out test data.[1] Actually, the two areas have much more in common, as a review of compression algorithms reveals.

Huffman coding. A well-known compression technique is to create a binary Huffman tree whose leaves are characters in the text,[2] and whose edges are labeled 0 or 1 (Huffman and others, 1952). The tree is arranged so that frequent characters have short binary codes (edge sequences). It is very important that the Huffman tree for a particular text be included at the beginning of the compressed file, so that decompression knows how to process the compressed bit string.

Adaptive Huffman. Actually, we can avoid shipping the Huffman tree inside the compressed file, by building the tree adaptively, as the compressor processes the input text. If we start with a uniform distribution, the first few characters may not compress very well, but soon we will converge onto a good tree and good compression. It is very

[1] File size has advantages, as perplexity computations are often buggy, and they usually gloss over how probability is apportioned to out-of-vocabulary items.

[2] Or other symbols, such as words, bytes, or unicode sequences.

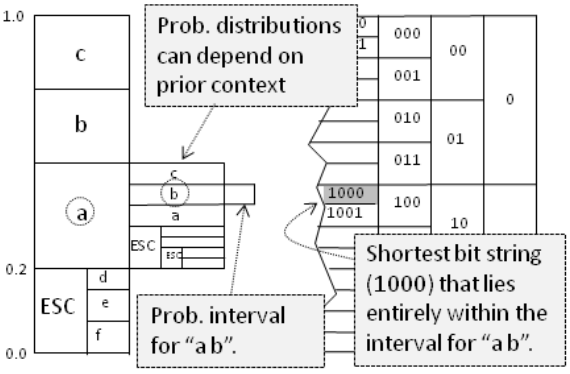

Figure 4: Arithmetic coding.

important that the decompressor exactly recapitulate the same sequence of Huffman trees that the compressor made. It can do this by counting characters as it outputs them, just as the compressor counted characters as it consumed them.

Adaptive compression can also nicely accommodate shifting topics in text, if we give higher counts to recent events. By its single-pass nature, it is also good for streaming data.

Arithmetic coding. Huffman coding exploits a predictive unigram distribution over the next character. If we use more context, we can make sharper distributions. An n-gram table is one way to map contexts onto predictions.

How do we convert good predictions into good compression? The solution is called *arithmetic coding* (Rissanen and Langdon Jr., 1981; Witten et al., 1987). Figure 4 sketches the technique. We produce context-dependent probability intervals, and each time we observe a character, we move to its interval. Our working interval becomes smaller and smaller, but the better our predictions, the wider it stays. A document's compression is the shortest bit string that fits inside the final interval. In practice, we do the bit-coding as we navigate probability intervals.

Arithmetic coding separates modeling and compression, making our job similar to language modeling, where we use try to use context to predict the next symbol.

3.1 PPM

PPM is the most well-known adaptive, predictive compression technique (Cleary and Witten, 1984). PPM updates character n-gram tables (usually n=1..5) as it compresses. In a given context, an n-gram table may predict only a subset of characters, so PPM reserves some probability mass for an escape (ESC), after which it executes a hard backoff to the (n-1)-gram table. In PPMA, P(ESC) is 1/(1+D), where D is the number of times the context has been seen. PPMB uses q/D, where q is the number of distinct character types seen in the context. PPMC uses q/(q+D), aka Witten-Bell. PPMD uses q/2D.

PPM* uses the shortest previously-seen deterministic context, which may be quite long. If there is no deterministic context, PPM* goes to the longest matching context and starts PPMD. Instead of the longest context, PPMZ rates all contexts between lengths 0 and 12 according to each context's most probable character. PPMZ also implements an adaptive P(ESC) that combines context length, number of previous ESC in the context, etc.

We use our own C++ implementation of PPMC for monolingual compression experiments in this paper. When we pass over a set of characters in favor of ESC, we remove those characters from the hard backoff.

3.2 PAQ

PAQ (Mahoney, 2005) is a family of state-of-the-art compression algorithms and a perennial Hutter Prize winner. PAQ combines hundreds of models with a logistic unit when making a prediction. This is most efficient when predictions are at the bit-level instead of the character-level. The unit's model weights are adaptively updated by:

$w_i \leftarrow w_i + \eta x_i(correct - \mathrm{P}(1))$, where
$x_i = ln(\mathrm{P}_i(1)/(1 - \mathrm{P}_i(1))$
η = fixed learning rate
$\mathrm{P}_i(1)$ = ith model's prediction

PAQ models include a character n-gram model that adapts to recent text, a unigram word model (where word is defined as a subsequence of characters with ASCII > 32), a bigram model, and a skip-bigram model.

4 Bilingual Compression: Prior Work

Nevill and Bell (1992) introduce the concept but actually carry out experiments on paraphrase corpora, such as different English versions of the Bible.

Conley and Klein (2008) and Conley and Klein (2013) compress a target text that has been word-aligned to a source text, to which they add a lemmatizer and bilingual glossary. They obtain a 1%-6% improvement over monolingual compression,

without counting the cost of auxiliary files needed for decompression.

Martínez-Prieto et al. (2009), Adiego et al. (2009), Adiego et al. (2010) rewrite bilingual text by first interleaving source words with their translations, then compressing this sequence of biwords. Sánchez-Martínez et al. (2012) improve the interleaving scheme and include offsets to enable decompression to reconstruct the original word order. They also compare several character-based and word-based compression schemes for biword sequences. On Spanish-English Europarl data, they reach an 18.7% compression rate on word-interleaved text, compared to 20.1% for concatenated texts, a 7.2% improvement.

Al-Onaizan et al. (1999) study the perplexity of learned translation models, i.e., the probability assigned to the target corpus given the source corpus. They observed iterative training to improve training-set perplexity (as guaranteed) but degrade test-set perplexity. They hypothesized that an increasingly tight, unsmoothed translation dictionary might exclude word translations needed to explain test-set data. Subsequently, research moved to extrinsic evaluation of translation models, in the context of end-to-end machine translation.

Foster et al. (2002) and others have used prediction to propose auto-completions to speed up human translation. As we have seen, prediction and compression are highly related.

5 Predictive Bilingual Compression

Our algorithm compresses target-language `file2` while looking at source-language `file1`:

```
% bicompress file2 file1 > file2.exe
```

To make use of arithmetic coding, we consider the task of predicting the next target character, given the source sentence and target string so far:[3]

$$\mathrm{P}(e_j | f_1 \ldots f_l, e_1 \ldots e_{j-1})$$

If we are able to accurately predict what a human translator will type next, then we should be able to build a good machine translator. Here is an example of the task:

Spanish:	Pido que hagamos un minuto de silencio.
English so far:	I should like to ob_

[3] We predict e from f in this paper, reversed from Brown et al. (1993), who predict f from e.

	Absolute offsets	Relative offsets
Uncompressed	105.3 Mb	88.9 Mb
Huffman coding	36.6 Mb	24.4 Mb
PPMC	12.4 Mb	13.2 Mb

Figure 5: Compressing a file of (unidirectional) automatic Viterbi word alignments computed from our large Spanish/English corpus (sentences less than 50 words).

5.1 Word alignment

Let us first work at the word level instead of the character level. If we are predicting the jth English word, and we know that it translates f_i ("aligns to f_i"), and if f_i has only a handful of translations, then we may be able to specify e_j with just a few bits. We may therefore suppose that a set of Viterbi word alignments may be useful for compression (Conley and Klein, 2008; Sánchez-Martínez et al., 2012).

We consider unidirectional alignments that link each target position j to a single source position i (including the null word at $i = 0$). Such alignments can be computed automatically using EM (Brown et al., 1993), and stored in one of two formats:

Absolute: 1 2 5 5 7 0 3 6 ...
Relative: +1 +1 +3 0 +2 null -4 +3 ...

In order to interpret the bits produced by the compressor, our decompressor *must also have access to the same Viterbi alignments*. Therefore, we must include those alignments at the beginning of the compressed file. So let's compress them too.

How compressible are alignment sequences? Figure 5 gives results for Viterbi alignments derived from our large parallel Spanish/English corpus. First, some interesting facts:

- Huffman works better on relative offsets, because the common "+1" gets a short bit code.
- PPMC's use of context makes it impressively insensitive to alignment format.
- PPMC beats Huffman on relative offsets. This would not happen if relative offset integers were independent of one another, as assumed by (Brown et al., 1993) and (Vogel et al., 1996). Bigram statistics bear this out:
  P(+1 | -2) = 0.20 P(+1 | +1) = 0.59
  P(+1 | -1) = 0.20 P(+1 | +2) = 0.49
  P(+1 | 0) = 0.52

So this small compression experiment already

suggests that translation aligners might want to model more context than just P(offset).

However, the main point of Figure 5 is that the compressed alignment file requires 12.4 Mb! This is too large for us to prepend to our compressed file, for the sake of enabling decompression.

5.2 Translation dictionary

Another approach is to forget Viterbi alignments and instead exploit a probabilistic translation dictionary table $t(e|f)$. To predict the next target word e_j, we admit the possibility that e_j might be translating *any* of the source tokens. IBM Model 2 (Brown et al., 1993) tells us how to do this:

Given $f_1 \ldots f_l$:

1. Choose English length m $\quad \epsilon(m|l)$
2. For $j = 1..m$, choose alignment a_j $\quad a(a_j|j,l)$
3. For $j = 1..m$, choose translation e_j $\quad t(e_j|f_{a_j})$

which, via the "IBM trick" implies:

$\mathrm{P}(e_1 \ldots e_m|f_1 \ldots f_l) =$
$\epsilon(m|l) \prod_{j=1}^{m} \sum_{i=0}^{l} a(i|j,l)t(e_j|f_i)$

In compression, we must predict English words incrementally, before seeing the whole string. Furthermore, we must predict $\mathrm{P}(STOP)$ to end the English sentence. We can adapt IBM Model 2 to make incremental predictions:

$\mathrm{P}(STOP|f_1 \ldots f_l, e_1 \ldots e_{j-1}) \sim$
$\mathrm{P}(STOP|j,l) =$
$\epsilon(j-1|l) / \sum_{k=j-1}^{max} \epsilon(k|l)$

$\mathrm{P}(e_j|f_1 \ldots f_l, e_1 \ldots e_{j-1}) \sim$
$\mathrm{P}(e_j|f_1 \ldots f_l) =$
$[1 - \mathrm{P}(STOP|j,l)] \sum_{i=0}^{l} a(i|j,l)t(e_j|f_i)$

We can train t, a, and ϵ on our bilingual text using EM (Brown et al., 1993). However, the t-table is still too large to prepend to the compressed English file.

5.3 Adaptive translation modeling

Instead, inspired by PPM, we build up translation tables in RAM, during a single pass of our compressor. Our decompressor then rebuilds these same tables, in the same way, in order to interpret the compressed bit string.

Neal and Hinton (1998) describe *online EM*, which updates probability tables after each training example. Liang and Klein (2009) and Levenberg et al. (2010) apply online EM to a number of language tasks, including word alignment. Here we concentrate on the single-pass case.

We initialize a uniform translation model, use it to collect fractional counts from the first segment pair, normalize those counts to probabilities, use those new probabilities to collect fractional counts from the second segment pair, and so on. Because we pass through the data only once, we hope to converge quickly to high-quality tables for compressing the bulk of the text.

Unlike in batch EM, we need not keep separate count and probability tables. We only need count tables, including summary counts for normalization groups, so memory savings are significant. Whenever we need a probability, we compute it on the fly. To avoid zeroes being immediately locked in, we invoke add-λ smoothing every time we compute a probability from counts:[4]

$t(e|f) = \frac{count(e,f)+\lambda_t}{count(f)+\lambda_t|V_E|}$

$a(i|j,l) = \frac{count(i,j,l)+\lambda_a}{count(j,l)+\lambda_a(l+1)}$

where $|V_E|$ is the size of the English vocabulary. We determine $|V_E|$ via a quick initial pass through the data, then include it at the top of our compressed file.

In batch EM, we usually run IBM Model 1 for a few iterations before Model 2, gripped by an atavistic fear that the a probabilities will enforce rigid alignments before word co-occurrences have a chance to settle in. It turns out this fear is justified in online EM! Because the a table initially learns to align most words to null, we smooth it more heavily ($\lambda_a = 10^2$, $\lambda_t = 10^{-4}$).

We also implement a single-pass HMM alignment model (Vogel et al., 1996). In the IBM models, we can either collect fractional counts after we have compressed a whole sentence, or we can do it word-by-word. In the HMM model, alignment choices are no longer independent of one another:

Given $f_1 \ldots f_l$:

1. Choose English length m w/prob $\epsilon(m|l)$
2. For $j = 1..m$:
   2a. set a_j to null w/prob p_1, *or*
   2b. choose non-null a_j w/prob $(1-p_1)o(a_j - a_k)$
3. For $j = 1..m$, choose translation e_j w/prob $t(e_j|f_{a_j})$

In the expression $o(a_j - a_k)$, k is the maximum English index ($k < j$) such that $a_k \neq 0$. The relative offset o-table learns to encourage adjacent English words to align to adjacent Spanish words.

Batch HMM performs poorly under uniform initialization, with two causes of failure. First, EM training sets $o(0)$ too high, leading to absolute alignments like "1 2 2 2 5 5 5 5 ...". We avoid

[4] In their online EM Model 1 aligner, Liang and Klein (p.c.) skirt the smoothing issue by running an epoch of batch EM to initialize a full set of probabilities before starting.

		Against silver standard (Batch EM)			Against gold standard (Human)		
		IBM1	IBM2	HMM	IBM1	IBM2	HMM
Batch EM		100.0	100.0	100.0	55.4	66.3	70.2
Online EM	Full data	82.2	81.7	89.5	54.9	63.4	70.0
	First 50%	81.4	79.5	88.9	54.9	62.3	70.6
	Last 50%	83.0	83.9	90.0	54.9	64.5	69.4
	Reordered	83.7	83.3	88.1	56.8	65.4	69.5

Figure 6: Word alignment f-scores. Batch EM for IBM 1 is run for 5 iterations; Batch IBM2 adds 5 further iterations of IBM2; Batch HMM adds a further 5 iterations of HMM. Online EM is single-pass. Against the silver standard, alignments are unidirectional; against gold, they are bidirectional and symmetrized with grow-dial-final (Koehn et al., 2003). First and last 50% report on different portions of the corpus. Reordered is on segment pairs ordered short to long. All runs exclude segment pairs with segments longer than 50 words.

this with a standard schedule of 5 IBM1 iterations, 5 IBM2 iterations, then 5 HMM iterations. However, HMM still learns a very high value for p_1, aligning most tokens to null, so we fix $p_1 = 0.1$ for the duration of training.

Single-pass, online HMM suffers the same two problems, both solved when we smooth differentially ($\lambda_o = 10^2, \lambda_t = 10^{-4}$) and fix $p_1 = 0.1$.

Two quick asides before we examine the effectiveness of our online methods:

- Translation researchers often drop long segment pairs that slow down HMM model processing. In compression, we cannot drop any of the text. Therefore, if the source segment contains more than 50 words, we use only monolingual PPMC to compress the target. This affects 26.5% of our word tokens.
- We might assist an online aligner by permuting our n segment pairs to place shorter, less ambiguous ones at the top. However, we would have to communicate the permutation to the decompressor, at a prohibitive cost of $\log_2(n!)/(8 \cdot 10^6)$ = 4.8 Mb.

We next look at alignment accuracy (f-score) on our large Spanish/English corpus (Figure 6). We evaluate against both a silver standard (Batch EM Viterbi alignments[5]) and a gold standard of 334 human-aligned segment pairs distributed throughout the corpus. We see that online methods generate competitive translation dictionaries. Because single-pass alignment is significantly faster than traditional multi-pass, we also investigate its impact on an overall Moses pipeline for phrase-based machine translation (Koehn et al., 2007). Figure 7 shows that we can achieve competitive translation accuracy using fast, single-pass alignment, speeding up the system development cycle. For this use case, we can get an additional +0.3 alignment f-score (just as fast) if we print Viterbi alignments in a second pass instead of during training.

[5]We confirm that our Batch HMM implementation gives f-scores (f=70.2, p=80.4, r=62.3) similar to GIZA++ (f=71.2, p=85.5, r=61.0), and its differently parameterized HMM.

	Alignment speed	Test Set Bleu	
		Europarl	News
Batch HMM	1230.78 min	30.2	26.2
Online HMM	711.87 min	30.0	25.3

Figure 7: Fast, single-pass HMM alignment yields competitive Spanish-English Moses phrase-based translation accuracy, as measured by Bleu (Papineni et al., 2002). In-domain (Europarl) and out-of-domain (SMAT-07 News Commentary) tune/test sets each consist of approximately 1000 sentences, all longer than 50 words to avoid overlap with training.

5.4 Word tokenization

We now want our continuously-improving translation model (TM) to predict target text, and to combine its predictions with PPM's. For that to happen, our TM will need to predict the exact text, including spurious double-spaces, how parentheses combine with quotation marks, and so on.

We devise a tokenization scheme that records spacing information in the word tokens, which allows us to recover the original text uniquely. First, we identify word tokens as subsequences of [a-zA-Z]*, [0-9]*, and [other]*, appending to each token the number of spaces following it (e.g., "...@2"). Next, we remove all "@1", which leaves unique

recoverability intact. Finally, we move any suffix on an alpha-numeric word i to become a prefix on a non-alpha-numeric word $i + 1$. This reduces the vocabulary size for TM learning. An example:

```
"String-theory?" he  asked.
  <=>

5.5 Predicting target words

Under this tokenization scheme, we now ask our TM to give us a probability distribution over possible next words. The TM knows the entire source word sequence $f_1 ... f_l$ and the target words $e_1 ... e_{j-1}$ seen so far. As candidates, we consider target words that can be produced, via the current t-table, from any (non-NULL) source words with probability greater than 10^{-4}.

For HMM, we compute a prediction lattice that gives a distribution over possible *source alignment positions* for the current word we are predicting. Intuitively, the prediction lattice tells us "where we currently are" in translating the source string, and it prefers translations of source words in that vicinity. We efficiently reuse the lattice as we make predictions for each subsequent target word.

To make the TM's prediction more accurate, we weight its prediction for each word with a smoothed, adapted English bigram word language model (LM). This discourages the TM from trying to predict the first character of a word by simply using the most frequent source words. We found that exponentiating the LM's score by 0.2 before weighting keeps it from overpowering the HMM predictions.

5.6 Predicting target characters

To convert word predictions into character predictions, we combine scores for words that share the next character. For example, if the TM predicts "monkey 0.4, car 0.3, cat 0.2, dog 0.1", then we have "P(c) 0.5, P(m) 0.4, P(d) 0.1". Additionally, we restrict ourselves to words prefixed by the portion of e_j already observed. The TM predicts the space character when a predicted word fully matches the observed prefix.

We also adjust PPM to produce a full distribution over the 96 possible next characters. PPM normally computes a distribution over only characters previously seen in the current context (plus ESC). We now back off to the lowest context for every prediction.

We interpolate PPM and TM probabilities:

$$\begin{aligned}&\mathrm{P}(e_k|f_1 \ldots f_l, e_1 \ldots e_{k-1}) = \\ &\quad \mu\, \mathrm{P}_{PPM}(e_k|e_1 \ldots e_{k-1}) + \\ &\quad (1-\mu)\, \mathrm{P}_{TM}(e_k|f_1 \ldots f_l, e_1 \ldots e_{k-1})\end{aligned}$$

We adjust μ dynamically based on the relative confidence of the models:

$$\mu = \frac{max(PPM)^{2.5}}{max(PPM)^{2.5} + max(HMM)^{2.5}}$$

Here, $max(model)$ refers to the highest probability assigned to any character in the current context by the model. This yields better compression rates than simply setting μ to a constant. When the TM is unable to extend a word, we set $\mu = 1$.

	File size	Compression rate	bpb
Uncompressed	324.9 Mb	100.0%	8.00
Huffman coding	172.8 Mb	53.2%	4.26
PPMC	51.4 Mb	15.8%	1.26

Figure 8: Compression of the Spanish side of the bilingual corpus. bpb = bits per byte.

	File size	Compression rate	bpb
Uncompressed	294.5 Mb	100.0%	8.00
Huffman coding	160.7 Mb	54.6%	4.37
PPMC	48.5 Mb	16.5%	1.32
Bilingual (this paper)	35.0 Mb	11.9 %	0.95
Shannon monolingual			1.61
Shannon bilingual			0.51

Figure 9: **Main results.** Compression of the English side of the bilingual corpus. Bilingual compression improves results. For Shannon game studies, bpb are estimated as cross-entropies of n-gram models fitted to human guess sequences.

6 Results

Figure 8 shows that monolingual PPM compresses the Spanish side of our corpus to 15.8% of the original. Figure 9 **(Main results)** shows results for the English side of the corpus. Monolingual PPM compresses to 16.5%, while our HMM-based bilingual compression compresses to 11.9%.[6]

We can say that a human translation is characterized by an additional 0.95 bits per byte on top of the original, rather than the 1.32 bits per byte we

[6]For this result, we divide the English corpus into two pieces and compress them in parallel, and we further increase the sentence length threshold from 50 to 60, incurring a speed penalty. Our fictional Weissman score is 0.676.

	File size	Compression rate	bpb
Uncompressed	619.4 Mb	100.0%	8.00
Huffman coding	336.8 Mb	54.4%	4.35
PPMC	101.6 Mb	16.4%	1.31
Bilingual (this paper)	86.4 Mb	13.9%	1.12
(Sánchez-Martínez et al., 2012) PPMDI	different corpus	20.1%	1.61
(Sánchez-Martínez et al., 2012) bilingual	different corpus	18.7%	1.50

Figure 10: Compression of Spanish plus English. All methods are run on a single file of Spanish concatenated with English, except for "Bilingual (this paper)," which records the sum of (1) Spanish compression and (2) English-given-Spanish compression. Comparative numbers copied from Sánchez-Martínez et al (2012) are for a different subset of Europarl data.

would need if the English were independent text. Assuming our Spanish compression is good, we can also say that the human translator produces at most 68.1% (35.0/51.4) of the information that the original Spanish author produced. Intuitively, we feel this bound is high and should be reduced with better translation modeling.

Figure 9 also reports our Shannon game experiments in which bilingual humans guessed subsequent characters of the English text. As suggested by Shannon, we upper-bound bpb as the cross-entropy of a unigram model over a human *guess sequence* (e.g., 1 1 2 5 17 1 1 ...), which records how many guesses it took to identify each subsequent English character, given context. For a 502-character English sequence, a team of four bilinguals working together gave us an upper-bound bpb of 0.51. This team had access to the original Spanish, plus a Google translation. Monolinguals guessing on the same data (minus the Spanish and Google translation) yielded an upper-bound bpb of 1.61. These human-level models indicate that human translators are actually only adding $\sim 32\%$ more information on top of the original, and that our current translation models are only capturing some fraction of this redundancy.[7]

Figure 10 shows compression of the entire bilingual corpus, allowing us to compare with the previous state-of-the-art (Sánchez-Martínez et al., 2012), which compresses a single, word-interleaved bilingual corpus. It shows how PPMC does on a concatenated Spanish/English file.

Uncompressed English (294.5 Mb) is 90.6% the size of uncompressed Spanish (324.9 Mb). Huffman narrows this gap to 93.0%, and PPM narrows it further to 94.4%, consistent with Behr et al. (2003) and Liberman (2008). Spanish redundancies like adjective-noun agreement and balanced question marks ("¿ ... ?") may remain unexploited.

7 Conclusion

We have created a bilingual text compression challenge web site.[8] This web site contains standard bilingual data, specifies what a valid compression is, and maintains benchmark results.

There are many future directions to pursue. First, we would like to develop and exploit better predictive translation modeling. We have so far adapted machine translation technology circa only 1996. For example, the HMM alignment model cannot "cross off" a source word and stop trying to translate it. Also possible are phrase-based translation, neural nets, or as-yet-unanticipated pattern-finding algorithms. We only require an executable that prints the bilingual text.

Our current method requires segment-aligned input. To work with real-life bilingual corpora, the compressor should take care of segment alignment, in a way that allows decompression back to the original text. Similarly, we are currently restricted to texts written in the Latin alphabet, per our definition of "word."

More broadly, we would also like to import more compression ideas into NLP. Compression has so far appeared sporadically in NLP tasks like native language ID (Bobicev, 2013), text input methods (Powers and Huang, 2004), word segmentation (Teahan et al., 2000; Sornil and Chaiwanarom, 2004; Hutchens and Alder, 1998), alignment (Liu et al., 2014), and text categorization (Caruana & Lang, unpub. 1995).

Translation researchers may also view bilingual compression as an alternate, reference-free evaluation metric for translation models. We anticipate that future ideas from bilingual compression can be brought back into translation. Like Brown et al. (1992), with their *gauntlet thrown down* and *fury of competitive energy*, we hope that cross-fertilizing compression and translation will bring fresh ideas to both areas.

[7] Machine models can also generate guess sequences, and we see that entropy of a 30m-character PPMC guess sequence (1.43) upper-bounds actual PPMC bpb (1.28).

Abstract

This paper proposes a novel hierarchical recurrent neural network language model (HRNNLM) for document modeling. After establishing a RNN to capture the coherence between sentences in a document, HRNNLM integrates it as the sentence history information into the word level RNN to predict the word sequence with cross-sentence contextual information. A two-step training approach is designed, in which sentence-level and word-level language models are approximated for the convergence in a pipeline style. Examined by the standard sentence reordering scenario, HRNNLM is proved for its better accuracy in modeling the sentence coherence. And at the word level, experimental results also indicate a significant lower model perplexity, followed by a practical better translation result when applied to a Chinese-English document translation reranking task.

1 Introduction

Deep Neural Network (DNN), a neural network with multiple layers, has been proven powerful in many different domains, such as visual recognition (Kavukcuoglu et al., 2010) and speech recognition (Dahl et al., 2012), ever since Hinton et al. (2006) formulated an efficient training method for it.

In addition to the applications mentioned above, many neural network based methods have also been applied to natural language processing (NLP) tasks with great success. For example, Collobert et al. (2011) propose a generalized DNN framework for a variety of fundamental NLP tasks, including part-of-speech tagging (postag), chunking, named entity recognition (NER), and semantic role labeling.

DNN is successfully introduced to do word-level language modeling, aka., to predict the next word given the history words. Bengio et al. (2003) propose a feedforward neural network to train a word-level language model with a limited n-gram history. To leverage as much history as possible, Mikolov et al. (2010) apply recurrent neural network to word-level language modeling. The model absorbs one word each time, keeps the information in a history vector, and predicts the next word with all the word history in the vector.

Word-level language model can only learn the relationship between words in one sentence. For sentences in one document which talks about one or several specific topics, the words in the next sentence are chosen partially in accordance with the previous sentences. To model this kind of coherence of sentences, Le and Mikolov (2014) extend word embedding learning network (Mikolov et al., 2013) to learn the paragraph embedding as a fixed-length vector representation for paragraph or sentence. Li and Hovy (2014) propose a neural network coherence model which employs distributed sentence representation and then predict the probability of whether a sequence of sentences is coherent or not.

In contrast to the methods mentioned above which learn the word relationship in or between the sentences separately, we propose a hierarchical recurrent neural network language model (HRNNLM) to capture the word sequence across the sentence boundaries at the document level. HRNNLM is essentially a combination of a word-level language model and a sentence-level language model, both of which are recurrent neural networks. The word-level recurrent neural network follows (Mikolov et al., 2010). The sentence-level language model is another recurrent neural network that takes sentence represen-

*Contribution during internship at Microsoft Research.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 899–907,
Lisbon, Portugal, 17-21 September 2015.

tation as input, and predicts the words in the next sentence. Similar to (Mikolov et al., 2010), the hidden layer in the sentence-level recurrent neural network contains the sentence history information. The hidden layer containing the history information of previous sentences is then linked as an input to the word-level recurrent neural network to predict the next word together with the word-level history vector. This allows the language model to predict the next word probability distribution beyond the words in the current sentence.

We propose a two-step training approach to optimize the parameters of HRNNLM. In the first step, we train the sentence-level language models independently . And then, we connect the hidden layer of the sentence-level language model to the input of word-level RNNLM and train the two models jointly until converged. At sentence level, we evaluate our model with a sentence ordering task and the result shows our method can outperform a maximum entropy based and another state-of-the-art solution. At word level, we compare our method with the conventional recurrent neural network based language model, finding the perplexity is reduced significantly. We also apply our method to rank machine translation output and conduct experiments on a Chinese-English document translation task, yielding a better translation results compared with a state-of-the-art baseline system.

The rest of this paper is organized as follows: Section 2 introduces work related to applying neural network to document modeling and SMT. Section 3 introduces the general framework for document modeling. Our sentence-level language model and its training is described in Section 4, and the overall HRNNLM and its training is presented in Section 5. Section 6 presents our experiments and their results. Finally, we conclude in Section 7.

2 Related work

In this section, we introduce previous efforts on applying neural network to model words coherence across sentence boundaries as well as works on improving machine translation performance at discourse level.

Mikolov and Zweig (2012) propose a RNN-LDA model to implement a context dependent language model. They augment the contextual information into the conventional RNNLM via a real-valued input vector, which is the probability distribution computed by LDA topics for using a block of preceding text. They train a Latent Dirichlet Allocation (LDA) model using documents consisting of about 10 sentences long text from Penn Treebank (PTB) training data. Their approach outperforms RNNLM in perplexity on PTB data with a limited context history over topics instead of complete information of preceding sentences.

Le and Mikolov (2014) extend the Continuous Bag-of-Words Model (CBOW) and Continuous Skip-gram Model (Skip-gram) (Mikolov et al., 2013) by introducing a paragraph vector. In their method, the paragraph vector is learnt in a similar way of word vector model, and there will be $N \times P$ parameters, if there are N paragraphs and each paragraph is mapped to P dimensions. Different from them, the sentence vectors of our model are learnt with nearly unlimited sentence history based on a RNN framework, in which, bag of words in the sentence are used as input. The sentence vector is no longer related with the sentence id, but only based on the words in the sentence. And our sentence vector also integrates nearly all the history information of previous sentences, while their model cannot.

Li and Hovy (2014) implement a neural network model to predict discourse coherence quality in essays. In their work, recurrent (Sutskever et al., 2011) and recursive (Socher et al., 2013) neural networks are both examined to learn distributed sentence representation given pre-trained word embedding. The distributed sentence representation is assigned to capture both syntactic and semantic information. With a slide window of the distributed sentence representation, a neural network classifier is trained to evaluate the coherence of the text. Successful as it is in scoring the coherence for a given sequence of sentences, this method is attempted to discriminate the different word order within a sentence.

An attempt of introducing RNN into convolutional neural network (CNN) is investigated by (Xu and Sarikaya, 2014) for spoken language understanding (SLU). To alleviate more contextual information, they apply a CNN with Jordan-type (Jordan, 1997) recurrent connections. The recurrent connections send the distribution of the last softmax layer's output to the current input layer as additional features. Aimed to improve SLU domain classification, their model is essentially a kind of document representation with certain text

information, neglecting the coherence information between sentences.

Following the thread modeling the word sequence relationship within and across sentences, we propose a hierarchical recurrent neural network language model consist of a sentence-level language model and a word-level language model. This overall network is trained to capture the coherence between sentences and predict words sequence with preceding sentence contexts.

For statistical machine translation (SMT) in which we checked out model as a scenario, DNN has also been revealed for certain good results in several components. Yang et al. (2013) adapt and extend the CD-DNN-HMM (Dahl et al., 2012) model to the HMM-based word alignment model. In their method, they use bilingual word embedding to capture the lexical translation information and modeling the context with surrounding words. Liu et al. (2014) propose a recursive recurrent neural network (R^2NN) for end-to-end decoding to help improve translation quality. And Cho et al. (2014) propose a RNN Encoder-Decoder which is a joint recurrent neural network model at the sentence level as conventional SMT decoder does. However, at the discourse level, there is little report on applying DNN to boost the translation result of a document.

3 Document Language Modeling

Statistical language model assigns a probability to a natural language sequence. Conventional language models only focus on the word sequence within a sentence. For sentences in one document talking about one or several specific topics, the adjacent sentences should be in a coherent order. Therefore, the words in the next sentence are also dependent on the preceding sentences. To model the coherence of sentences in the document D, which contains N sentences S_1, S_2, S_3, ..., S_N, we need to maximize the objective as follow:

$$\begin{aligned} p(D) =& p(S_1, S_2, ..., S_N) \\ =& p(S_1) \cdot p(S_2|S_1) \cdot p(S_3|S_1, S_2) \\ & ...p(S_N|S_1, S_2, ..., S_{N-1}) \end{aligned} \quad (1)$$

For the sentence S_k containing words w_1, w_2, w_3, ..., w_T, $p(S_k|S_1, S_2, ..., S_{k-1})$ is defined as:

$$\begin{aligned} & p(S_k|S_1, S_2, ..., S_{k-1}) \\ & = p(w_1, w_2, ..., w_T|S_1, ..., S_{k-1}) \\ & = p(w_1|S_1, ..., S_{k-1}) \cdot p(w_2|w_1, S_1, ..., S_{k-1}) \\ & ...p(w_T|w_1, w_2, ..., w_{T-1}, S_1, ..., S_{k-1}) \end{aligned} \quad (2)$$

As a special case of approximation to this, classical n-gram language model keep only several words as history, discarding any information across the sentence boundaries. Recurrent neural network language model (Mikolov et al., 2010) uses a hidden layer which employs a real-valued vector recurrently as network's input to keep as many history as possible. This makes RNNLM be able to extend for capturing history beyond a sentence.

To prevent the potential exponential decay of the history, the history length in RNN can not be too long. Here we approximate the history information of previous sentences, $p(S_k|S_1, S_2, ..., S_{k-1})$, by the following:

$$\begin{aligned} & p(S_k|S_1, S_2, ..., S_{k-1}) = \\ & p(BoW_{S_k}|BoW_{S_1}, ..., BoW_{S_{k-1}}) \cdot p(S_k|BoW_{S_k}) \end{aligned} \quad (3)$$

where BoW_{S_k} denotes the bag of words for the sentence S_k. The document is thus generated in two steps.

- Given the previous sentences BoW_{S_1} ,..., $BoW_{S_{k-1}}$ (treating them as bag of words here), first generate the words which will show in the next sentence without considering their order with $p(BoW_{S_k}|BoW_{S_1}, ..., BoW_{S_{k-1}})$
- Generate the words one by one with $p(S_k|BoW_{S_k})$.

The first phase actually completes sentence-level language modeling, and the second addresses the word-level language modeling. Because recurrent neural network has a natural advantage in processing sequential data, we investigate how to model the whole process under a unified framework of recurrent neural network.

4 Sentence-level Language Model

In this section, we describe how to leverage recurrent neural network for sentence-level language modeling. Mikolov et al. (2010) demonstrate a recurrent neural network language model (RNNLM)

for word ordering. It overcomes the limitations of classical language model in capturing only a fixed-length history, yielding a significant performance improvements in terms of perplexity reduction and speech recognition accuracy. Here we adept this framework for a RNN based sentence-level language modeling, i.e. RNNSLM.

4.1 Model

A conventional language model reads a word each time, keeps several words as history and then predict the probability distribution of the next word. Similar to this, our sentence-level language model reads a sentence which is a bag of words representation. And then it stores the sentence history which captures coherence of sentences in a real-valued history vector. With the history vector, our model can predict which words are most likely to appear in the next sentence. All these will be modeled by a recurrent neural network.

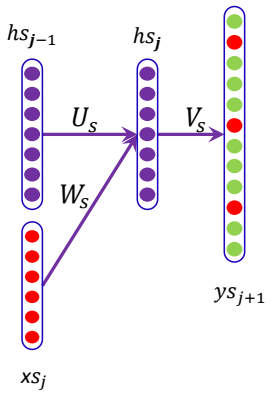

Figure 1: Recurrent Neural Network for Sentence-level Language Modeling

As shown in Figure 1, similar to the conventional recurrent neural network, for the sentence j, our network has two input layers xs_j and hs_{j-1}. xs_j is the current sentence representation, and hs_{j-1} is the history information vector before sentence j. The model has a hidden layer hs_j, which will combine the history information of hs_{j-1} and the current sentence input xs_j, and an output layer ys_{j+1}, which generates the probabilities of the words in the sentence $j+1$. The layers are computed as follows:

$$hs_j = f(U_s \cdot hs_{j-1} + W_s \cdot xs_j) \quad (4)$$

$$ys_{j+1} = g(V_s \cdot hs_j) \quad (5)$$

where W_s, U_s and V_s denote the weight matrix. $f(z)$ is a $HTanh$ function:

$$f(z_j) = \begin{cases} -1 & z_j < -1 \\ z & -1 < z_j < 1 \\ 1 & z_j > 1 \end{cases} \quad (6)$$

and $g(z)$ is a softmax function:

$$g(z_j) = \frac{e^{z_j}}{\sum_k e^{z_k}} \quad (7)$$

The output layer ys_{j+1} is a $1 \times V$ vector that represents probability distribution of words in the next sentence given the current sentence xs_j and previous history hs_{j-1}, where V denotes vocabulary size.

To emphasize coherence between the adjacent sentences, we further add some bigram-like bag of words feature to the output layer. As mentioned in (Mikolov, 2012), this is kind of maximum entropy feature which can be derived by a two-layer neural network. Some experiments show that perplexity significantly decreases after adding these features. Following (Mikolov, 2012), where, the maximum entropy bigram features are added to our RNNSLM by a direct connection between the feature input array and output layer ys_{j+1}. Following (Mahoney, 2000), we map bigram maximum entropy features to a fixed-length array to reduce the memory complexity of direct connections with feature hashing. Then the output layer can be computed as follow:

$$ys_{j+1}(t) = g(V_s(t) \cdot hs_j + \sum_{w \in xs_j} D_{hash(w,t)}) \quad (8)$$

where (t) denotes the t-th row of a vector or a matrix. D denotes that the hash array contains feature weights and $hash(w_i, w_j)$ denotes the hash function for mapping bigram features to a fixed-length array. For a output ys_{j+1}, multiple connections may be activated according to the words in sentence xs_j.

4.2 Training

The training objective of our RNNSLM is to find the best parameters for predicting the words of next sentence. Formally, given the next sentence S_k containing words w_1, w_2, w_3, ..., w_T. The training objective according to (Mikolov et al.,

2013) can be denoted by:

$$log(p(BoW_{S_k}|BoW_{S_1}, ..., BoW_{S_{k-1}})) = \frac{1}{T}\sum_{t=1}^{T} logp(w_t|BoW_{S_1}, ..., BoW_{S_{k-1}}) \quad (9)$$

For weight matrix W_s, U_s, V_s and hash feature weight D, the parameter are trained similar to the conventional recurrent neural network. The learning rate α is set to 0.1 at the start of the training as suggested in (Mikolov et al., 2010). After each epoch, it can be determined by the training loss of network. If the loss decreases significantly, training continues with the same learning rate. Otherwise, if the loss increases, the training will be executed with a new learning rate $\alpha/2$. The training process will be terminated after about 30 epochs.

4.3 Initialization

All elements in weight matrix W_s and U_s are initialized by randomly sampling from a uniform distribution $[-\frac{1}{K_1}, \frac{1}{K_1}]$, where K_1 is the size of the input layer. Elements in weight matrix V_s are initialized by randomly sampling from a uniform distribution $[-\frac{1}{K_2}, \frac{1}{K_2}]$, where K_2 denotes the size of the hidden layer. The hash feature weight array D is initialized as 0.

For the initialization of hs_0, it can be set to a vector of the same values, which is 0.1.

5 Hierarchical Recurrent Neural Network

In the previous section, we propose a RNNSLM which models the coherence between sentences but ignores the word sequence within a sentence. Ideally, a perfect document model should not only capture the information between sentences but also the information with sentence. So we propose a hierarchical recurrent neural network language model (HRNNLM) to fulfill this issue.

5.1 Model

A hierarchical recurrent neural network consists of two independent recurrent neural network. For a conventional word-level language model, it predict the next word only using the word history within the sentence. To capture the longer history, we integrate the sentence history into the word-level language model from sentence-level language model, which forms a hierarchical recurrent neural network.

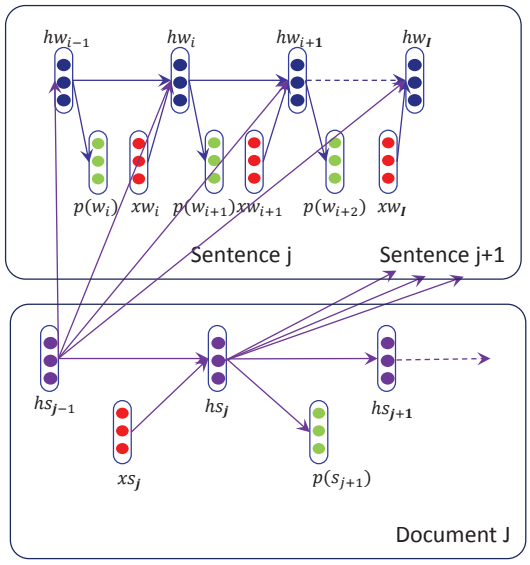

Figure 2: Hierarchical recurrent neural network

As illustrated Figure 2, the upper part is the unfolded illustration of conventional recurrent neural network based language model. It takes one word w_i each time with the previous history information hw_{i-1} together and predicts the probability of the next word $p(w_{i+1})$ with the information kept in the history vector hw_i. The lower part is our RNNSLM, which takes the bag of words representation of a sentence xs_j each time with the history information of previous sentences hs_{j-1} together and predicts the bag of words in the next sentence $p(s_{j+1})$ with the information kept in hs_j.

We integrate these two recurrent neural networks together by adding connections between the sentence-level history vector hs_{j-1} and word level history vector hw_i. So while predicting the next word w_{i+1} of the current sentence, our model will consider the current word w_i, history of previous sentences hs_{j-1} and history of previous words hw_{i-1}. The new word-level history vector hw_i is computed as:

$$hw_i = f(U_w \cdot hw_{i-1} + W_w \cdot xw_i + U_{sw} \cdot hs_{j-1}) \quad (10)$$

where $f(z)$ is a $HTanh$ function. For HRNNLM, we also add a bigram hash feature, similar as we do for RNNSLM.

5.2 Training

The HRNNLM can be trained from scratch following Mikolov et al. (2010) with a dual objective. But this is not without problem. Beginning

of training phase, the sentence history is unstable since the parameters of sentence-level language model are kept updating. Consequently, the training of HRNNLM will be also unstable and hard to converge with unstable sentence history.

In this paper, we approximate the whole training of HRNNLM by a two-step training method. We first train a RNNSLM until it converges. Then we connect the hidden layer of RNNSLM to the hidden layer of RNNWLM. To increase the training speed, all the parameters of RNNSLM are fixed while training HRNNLM. We only update the random initialized parameters in HRNNLM, though ideally the gradient of the sentence history vector could change and the RNNSLM could be updated again. The learning rate α is set to 0.1 and the updating of learning rate is the same as suggested in Section 4.2. All the parameters can be initialize as suggested in Section 4.3.

6 Experiments

We evaluate the sentence-level performance of HRNNLM by the common coherence evaluation of sentence ordering task, its word-level performance by perplexity measure. We also apply our HRNNLM to SMT reranking task in an open Chinese-English translation dataset. The translation performance index is the IBM version of BLEU-4 (Papineni et al., 2002).

6.1 Sentence Ordering

We follow (Barzilay and Lapata, 2008) to evaluate our sentence-level language model via a sentence ordering task with test set 2010 (tst2010), 2011 (tst2011) and 2012 (tst2012) from IWSLT 2014, totaling 37 English documents. 20 random permutations of sentences for each document are generated. Each permutation and its original document are combined as an article pair. Our goal is to find the original one among all the article pairs.

The training data for sentence-level language model is the 1,414 English documents from the parallel corpus also provided by the IWSLT 2014 spoken language translation task. 90% of the documents are for training and the rest are reserved for validation. The size of the hidden layer is set to 30 and hash array size is 10^7.

We define the log probability of a given document as its coherence score. The document with the higher score is regarded as the original document.

We provide two baselines for sentence ordering. One is the state-of-the-art recursive neural network based method proposed by (Li and Hovy, 2014). We implement their model trained and tested with our data. The other is a maximum entropy classifier trained with bag of words features of adjacent sentences which can generate a coherent probability of adjacent sentences. The document with the higher sum of log probability for each adjacency sentences is regarded as the original document. Table 1 shows the accuracy of our system and baseline.

Setting	Accuracy
Recursive	91.39%
ME system	91.89%
Our system	95.68%

Table 1: Accuracy of the sentence ordering task for each system

From Table 1 we can see that the maximum entropy model and the recursive neural network model has almost the same performance. Compared with the baseline systems, the proposed HRNNLM achieves significant improvement with nearly 4.3% improvement in term of accuracy. The experimental result shows that the HRNNLM can model document coherence and capture cross-sentence information.

6.2 Word-level Model Perplexity

We compare the word level performance of HRNNLM with the most popular RNNLM in terms of model perplexity. For a fair comparison, we follow (Mikolov et al., 2010) and train the model also on 90% of the 1.414 English documents form IWSLT 2014, totaling about 3M words. Then we train our model with the same hidden layer size and hash array size as the baseline system. The perplexity of these two models is evaluated on held-out documents, about 370K words. The results are shown in Table 2.

Setting	Perplexity
RNNLM-30	183
HRNNLM-30	174

Table 2: Perplexity of the different language model

According to Table 2, it is reasonable to claim that, by integrating history information of previous

sentences, the model perplexity decreased significantly. Empirically, this confirms the hypothesis that the words selection for the next sentence is dependent on its preceding sentences in the same document.

6.3 Spoken Language Translation

The conventional SMT systems translate sentences independently, without considering the coherence of the sentences in the same document. In order to learn translation coherence between sentences, we apply the HRNNLM to machine translation reranking task.

6.3.1 Data Setting and Baselines

The data comes from the IWSLT 2014 spoken language translation task. The training data consists of 1,414 documents on TED talks, and contains 179k sentence pairs, about 3M Chinese words, and 3.3M English words. The language model for SMT is a 4-gram language model trained with the English documents in the training data. The development set is specified by IWSLT as dev2010, and the test set contains 37 documents from tst2010, tst2011 and tst2012.

The IWSLT 2014 baseline system is built upon the open-source machine translation toolkit Moses at the default configuration, proposed by (Cettolo et al., 2012). We also train a decoder, which is an in-house Bracketing Transduction Grammar (BTG) (Wu, 1997) in a CKY-style decoder with a lexical reordering model trained with maximum entropy (Xiong et al., 2006). The decoder uses commonly used features, such as translation probabilities, lexical weights, a language model, word penalty, and distortion probabilities.

6.3.2 Rerank System

Our reranking system is a linear model with several features, including the SMT system final scores, sentence-level language model scores, and HRNNLM scores. It should be noted all these features are actually employed by the SMT model except for the HRNNLM score. Since Minimum Error Rate Training (MERT) (Och, 2003) is the most general method adopted in SMT systems for tuning, the feature weights are fixed by MERT.

For our reranking system, to score the translation of one sentence we need the translation results of all the previous sentences in the document. Our SMT decoder generates 10-best results of all the sentences of the documents and the reranking system select the best translation result for the first sentence at first. With the translation of first sentence, we score all the translation candidates of the second sentence and select the best one as the result. Following this procedure, we can get the translation results for all the sentences in the document.

6.3.3 Results

The HRNNLM focus on exploiting longer context, esp. cross-sentence word dependencies. Therefor the translation data for IWSLT 2014 is organized as documents instead of sentences for our rerank system. We hope HRNNLM will enable a context-sensitive reranking process, capturing the syntactic and logic relationships between the sentences in the same document.

Setting	tst2010	tst2011	tst2012
IWSLT	11.12	13.34	-
Baseline	12.40	15.09	13.52
SMT + Rerank	12.55	15.23	13.70

Table 3: BLEU scores of SMT systems. The IWSLT is a public baseline which issued by the organizer of IWSLT 2014, as described in (Cettolo et al., 2012).

The translation performance comparison is shown in Table 3. From Table 3, we can find that the rerank system improves SMT performance consistently. For a single sentence without the context information, there are several appropriate translations and it is hard to tell which one is better. When considering the context of a document (previous sentences for our model), some translation candidates may not be coherent with the others which should not be selected. Our model can generate the most coherent translation results by considering previous sentence history.

For example, we have the following two Chinese sentence in one document together with their correct translation:

我 拍摄 过 的 冰山, 有些 冰 是 非常 年轻 - - 几千 年 年龄
Some of the ice in the icebergs that I photograph is very young - - a couple thousand years old.
有些 冰 超过 十万 年
And some of the ice is over 100,000 years old.

Chinese word " 有些" means "some" in English. But when it is used in parallelism sentences, it means "some of" instead of "some". The traditional SMT system translates the italics part without considering the context. The translation result for this kind of system is:

Some ice more than 100,000 years.

For our system, the HRNNLM can take previous sentence as context and learn the parallelism between the two sentences. It can select the best translation "some of" for 有些, and the output of our system is:

Some of the ice more than 100,000 years.

We also calculate the BLEU increase ratio of our system on document level. The ratio is defined as $\frac{1}{N}\#(BleuD_{rerank} > BleuD_{baseline})$, where N denotes the number of documents, and $\#(BleuD_{rerank} > BleuD_{baseline})$ denotes the number of documents for which document level BLEU score of reranking system is higher than the baselines. The results are shown in Table 4.

tst2010	tst2011	tst2012
72.73%	71.43%	75%

Table 4: Experimental results to test BLEU increase ratio after reranking

From Table 4, we can find that, for all the three test data sets, our reranking system can achieve better performance for more than 70% documents.

7 Conclusion and Future Work

In this paper, we propose a hierarchical recurrent neural network language model for document modeling. We first built a RNNSLM to capture the information between sentences. Then we integrate the hidden layer of RNNSLM into the input layer of word-level language model to form a hierarchical recurrent neural network. This enables the model be able to capture both in-sentence and cross-sentence information in a unified RNN. Compared with conventional language models, our model can perceive a longer history than other language models and captures the context patterns in the previous sentences. At sentence level, we examine our model with sentence ordering task. At word level, we test the model perplexity. We also conduct a SMT rerank experiment on IWSLT 2014 data set. All these experimental results show that our hierarchical recurrent neural network has a satisfying performance.

In the future, we will explore better sentence representation such as distributed sentence representation as input for our sentence-level language model to better model document coherence. We can even update the gradient from different RNN to get a better performance.

Auto-Sizing Neural Networks: With Applications to n-gram Language Models

Kenton Murray and **David Chiang**

University of Notre Dame
{kmurray4,dchiang}@nd.edu

Abstract

Neural networks have been shown to improve performance across a range of natural-language tasks. However, designing and training them can be complicated. Frequently, researchers resort to repeated experimentation to pick optimal settings. In this paper, we address the issue of choosing the correct number of units in hidden layers. We introduce a method for automatically adjusting network size by pruning out hidden units through $\ell_{\infty,1}$ and $\ell_{2,1}$ regularization. We apply this method to language modeling and demonstrate its ability to correctly choose the number of hidden units while maintaining perplexity. We also include these models in a machine translation decoder and show that these smaller neural models maintain the significant improvements of their unpruned versions.

1 Introduction

Neural networks have proven to be highly effective at many tasks in natural language. For example, neural language models and joint language/translation models improve machine translation quality significantly (Vaswani et al., 2013; Devlin et al., 2014). However, neural networks can be complicated to design and train well. Many decisions need to be made, and performance can be highly dependent on making them correctly. Yet the optimal settings are non-obvious and can be laborious to find, often requiring an extensive grid search involving numerous experiments.

In this paper, we focus on the choice of the sizes of hidden layers. We introduce a method for automatically pruning out hidden layer units, by adding a sparsity-inducing regularizer that encourages units to deactivate if not needed, so that they can be removed from the network. Thus, after training with more units than necessary, a network is produced that has hidden layers correctly sized, saving both time and memory when actually putting the network to use.

Using a neural n-gram language model (Bengio et al., 2003), we are able to show that our novel auto-sizing method is able to learn models that are smaller than models trained without the method, while maintaining nearly the same perplexity. The method has only a single hyperparameter to adjust (as opposed to adjusting the sizes of each of the hidden layers), and we find that the same setting works consistently well across different training data sizes, vocabulary sizes, and n-gram sizes. In addition, we show that incorporating these models into a machine translation decoder still results in large BLEU point improvements. The result is that fewer experiments are needed to obtain models that perform well and are correctly sized.

2 Background

Language models are often used in natural language processing tasks involving generation of text. For instance, in machine translation, the language model helps to output fluent translations, and in speech recognition, the language model helps to disambiguate among possible utterances.

Current language models are usually n-gram models, which look at the previous $(n-1)$ words to predict the nth word in a sequence, based on (smoothed) counts of n-grams collected from training data. These models are simple but very effective in improving the performance of natural language systems.

However, n-gram models suffer from some limitations, such as data sparsity and memory usage. As an alternative, researchers have begun exploring the use of neural networks for language modeling. For modeling n-grams, the most common approach is the feedforward network of Bengio et

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 908–916,
Lisbon, Portugal, 17-21 September 2015.

al. (2003), shown in Figure 1.

Each node represents a *unit* or "neuron," which has a real valued *activation*. The units are organized into real-vector valued *layers*. The activations at each layer are computed as follows. (We assume $n = 3$; the generalization is easy.) The two preceding words, w_1, w_2, are mapped into lower-dimensional word embeddings,

$$\mathbf{x}^1 = \mathbf{A}_{:w_1}$$
$$\mathbf{x}^2 = \mathbf{A}_{:w_2}$$

then passed through two hidden layers,

$$\mathbf{y} = f(\mathbf{B}^1\mathbf{x}^1 + \mathbf{B}^2\mathbf{x}^2 + \mathbf{b})$$
$$\mathbf{z} = f(\mathbf{C}\mathbf{y} + \mathbf{c})$$

where f is an elementwise nonlinear *activation* (or *transfer*) function. Commonly used activation functions are the hyperbolic tangent, logistic function, and rectified linear units, to name a few. Finally, the result is mapped via a softmax to an output probability distribution,

$$P(w_n \mid w_1 \cdots w_{n-1}) \propto \exp([\mathbf{D}\mathbf{z} + \mathbf{d}]_{w_n}).$$

The parameters of the model are $\mathbf{A}$, $\mathbf{B}^1$, $\mathbf{B}^2$, $\mathbf{b}$, $\mathbf{C}$, $\mathbf{c}$, $\mathbf{D}$, and $\mathbf{d}$, which are learned by minimizing the negative log-likelihood of the the training data using stochastic gradient descent (also known as *backpropagation*) or variants.

Vaswani et al. (2013) showed that this model, with some improvements, can be used effectively during decoding in machine translation. In this paper, we use and extend their implementation.

3 Methods

Our method is focused on the challenge of choosing the number of units in the hidden layers of a feed-forward neural network. The networks used for different tasks require different numbers of units, and the layers in a single network also require different numbers of units. Choosing too few units can impair the performance of the network, and choosing too many units can lead to overfitting. It can also slow down computations with the network, which can be a major concern for many applications such as integrating neural language models into a machine translation decoder.

Our method starts out with a large number of units in each layer and then jointly trains the network while pruning out individual units when possible. The goal is to end up with a trained network

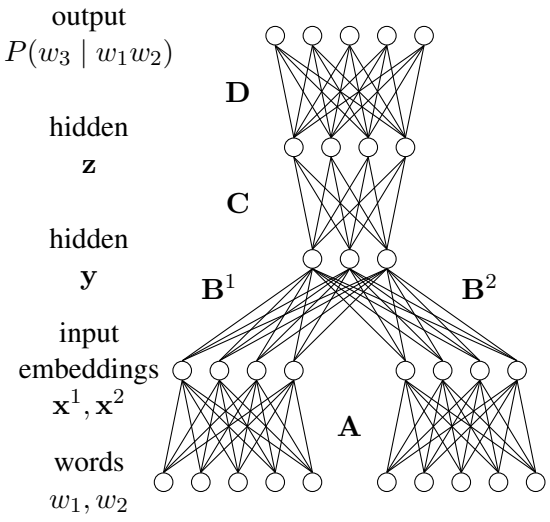

Figure 1: Neural probabilistic language model (Bengio et al., 2003), adapted from Vaswani et al. (2013).

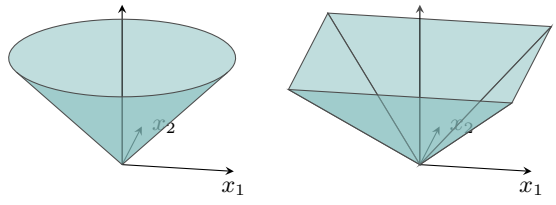
that also has the optimal number of units in each layer.

We do this by adding a regularizer to the objective function. For simplicity, consider a single layer without bias, $\mathbf{y} = f(\mathbf{W}\mathbf{x})$. Let $L(\mathbf{W})$ be the negative log-likelihood of the model. Instead of minimizing $L(\mathbf{W})$ alone, we want to minimize $L(\mathbf{W}) + \lambda R(\mathbf{W})$, where $R(\mathbf{W})$ is a convex regularizer. The ℓ_1 norm, $R(\mathbf{W}) = \|\mathbf{W}\|_1 = \sum_{i,j} |W_{ij}|$, is a common choice for pushing parameters to zero, which can be useful for preventing overfitting and reducing model size. However, we are interested not only in reducing the number of parameters but the number of units. To do this, we need a different regularizer.

We assume activation functions that satisfy $f(0) = 0$, such as the hyperbolic tangent or rectified linear unit ($f(x) = \max\{0, x\}$). Then, if we push the incoming weights of a unit y_i to zero, that is, $W_{ij} = 0$ for all j (as well as the bias, if any: $b_i = 0$), then $y_i = f(0) = 0$ is independent of the previous layers and contributes nothing to subsequent layers. So the unit can be removed without affecting the network at all. Therefore, we need a regularizer that pushes all the incoming connection weights to a unit together towards zero.

Here, we experiment with two, the $\ell_{2,1}$ norm and the $\ell_{\infty,1}$ norm.[1] The $\ell_{2,1}$ norm on a ma-

[1] In the notation $\ell_{p,q}$, the subscript p corresponds to the norm over each group of parameters, and q corresponds to the norm over the group norms. Contrary to more common usage, in this paper, the groups are rows, not columns.



ℓ_2 ℓ_∞

Figure 2: The (unsquared) ℓ_2 norm and ℓ_∞ norm both have sharp tips at the origin that encourage sparsity.

trix $\mathbf{W}$ is

$$R(\mathbf{W}) = \sum_i \|W_{i:}\|_2 = \sum_i \left(\sum_j W_{ij}^2 \right)^{\frac{1}{2}}. \quad (1)$$

(If there are biases b_i, they should be included as well.) This puts equal pressure on each row, but within each row, the larger values contribute more, and therefore there is more pressure on larger values towards zero. The $\ell_{\infty,1}$ norm is

$$R(\mathbf{W}) = \sum_i \|W_{i:}\|_\infty = \sum_i \max_j |W_{ij}|. \quad (2)$$

Again, this puts equal pressure on each row, but within each row, only the maximum value (or values) matter, and therefore the pressure towards zero is entirely on the maximum value(s).

Figure 2 visualizes the sparsity-inducing behavior of the two regularizers on a single row. Both have a sharp tip at the origin that encourages all the parameters in a row to become exactly zero.

4 Optimization

However, this also means that sparsity-inducing regularizers are not differentiable at zero, making gradient-based optimization methods trickier to apply. The methods we use are discussed in detail elsewhere (Duchi et al., 2008; Duchi and Singer, 2009); in this section, we include a short description of these methods for completeness.

4.1 Proximal gradient method

Most work on learning with regularizers, including this work, can be thought of as instances of the *proximal gradient* method (Parikh and Boyd, 2014). Our objective function can be split into two parts, a convex and differentiable part (L) and a convex but non-differentiable part (λR). In proximal gradient descent, we alternate between improving L alone and λR alone. Let $\mathbf{u}$ be the parameter values from the previous iteration. We compute new parameter values $\mathbf{w}$ using:

$$\mathbf{v} \leftarrow \mathbf{u} - \eta \nabla L(\mathbf{u}) \quad (3)$$

$$\mathbf{w} \leftarrow \arg\max_{\mathbf{w}} \left(\frac{1}{2\eta} \|\mathbf{w} - \mathbf{v}\|^2 + \lambda R(\mathbf{w}) \right) \quad (4)$$

and repeat until convergence. The first update is just a standard gradient descent update on L; the second is known as the *proximal operator* for λR and in many cases has a closed-form solution. In the rest of this section, we provide some justification for this method, and in Sections 4.2 and 4.3 we show how to compute the proximal operator for the ℓ_2 and ℓ_∞ norms.

We can think of the gradient descent update (3) on L as follows. Approximate L around $\mathbf{u}$ by the tangent plane,

$$\bar{L}(\mathbf{v}) = L(\mathbf{u}) + \nabla L(\mathbf{u})(\mathbf{v} - \mathbf{u}) \quad (5)$$

and move $\mathbf{v}$ to minimize $\bar{L}$, but don't move it too far from $\mathbf{u}$; that is, minimize

$$F(\mathbf{v}) = \frac{1}{2\eta} \|\mathbf{v} - \mathbf{u}\|^2 + \bar{L}(\mathbf{v}).$$

Setting partial derivatives to zero, we get

$$\frac{\partial F}{\partial \mathbf{v}} = \frac{1}{\eta}(\mathbf{v} - \mathbf{u}) + \nabla L(\mathbf{u}) = 0$$
$$\mathbf{v} = \mathbf{u} - \eta \nabla L(\mathbf{u}).$$

By a similar strategy, we can derive the second step (4). Again we want to move $\mathbf{w}$ to minimize the objective function, but don't want to move it too far from $\mathbf{u}$; that is, we want to minimize:

$$G(\mathbf{w}) = \frac{1}{2\eta} \|\mathbf{w} - \mathbf{u}\|^2 + \bar{L}(\mathbf{w}) + \lambda R(\mathbf{w}).$$

Note that we have *not* approximated R by a tangent plane. We can simplify this by substituting in (3). The first term becomes

$$\frac{1}{2\eta} \|\mathbf{w} - \mathbf{u}\|^2 = \frac{1}{2\eta} \|\mathbf{w} - \mathbf{v} - \eta \nabla L(\mathbf{u})\|^2$$
$$= \frac{1}{2\eta} \|\mathbf{w} - \mathbf{v}\|^2 - \nabla L(\mathbf{u})(\mathbf{w} - \mathbf{v}) + \frac{\eta}{2} \|\nabla L(\mathbf{u})\|^2$$

and the second term becomes

$$\begin{aligned}\bar{L}(\mathbf{w}) &= L(\mathbf{u}) + \nabla L(\mathbf{u})(\mathbf{w} - \mathbf{u}) \\ &= L(\mathbf{u}) + \nabla L(\mathbf{u})(\mathbf{w} - \mathbf{v} - \eta \nabla L(\mathbf{u})).\end{aligned}$$

The $\nabla L(\mathbf{u})(\mathbf{w} - \mathbf{v})$ terms cancel out, and we can ignore terms not involving $\mathbf{w}$, giving

$$G(\mathbf{w}) = \frac{1}{2\eta}\|\mathbf{w} - \mathbf{v}\|^2 + \lambda R(\mathbf{w}) + \text{const.}$$

which is minimized by the update (4). Thus, we have split the optimization step into two easier steps: first, do the update for L (3), then do the update for λR (4). The latter can often be done exactly (without approximating R by a tangent plane). We show next how to do this for the ℓ_2 and ℓ_∞ norms.

4.2 ℓ_2 and $\ell_{2,1}$ regularization

Since the $\ell_{2,1}$ norm on matrices (1) is separable into the ℓ_2 norm of each row, we can treat each row separately. Thus, for simplicity, assume that we have a single row and want to minimize

$$G(\mathbf{w}) = \frac{1}{2\eta}\|\mathbf{w} - \mathbf{v}\|^2 + \lambda\|\mathbf{w}\| + \text{const.}$$

The minimum is either at $\mathbf{w} = 0$ (the tip of the cone) or where the partial derivatives are zero (Figure 3):

$$\frac{\partial G}{\partial \mathbf{w}} = \frac{1}{\eta}(\mathbf{w} - \mathbf{v}) + \lambda\frac{\mathbf{w}}{\|\mathbf{w}\|} = 0.$$

Clearly, $\mathbf{w}$ and $\mathbf{v}$ must have the same direction and differ only in magnitude, that is, $\mathbf{w} = \alpha\frac{\mathbf{v}}{\|\mathbf{v}\|}$. Substituting this into the above equation, we get the solution

$$\alpha = \|\mathbf{v}\| - \eta\lambda.$$

Therefore the update is

$$\begin{aligned}\mathbf{w} &= \alpha\frac{\mathbf{v}}{\|\mathbf{v}\|} \\ \alpha &= \max(0, \|\mathbf{v}\| - \eta\lambda).\end{aligned}$$

4.3 ℓ_∞ and $\ell_{\infty,1}$ regularization

As above, since the $\ell_{\infty,1}$ norm on matrices (2) is separable into the ℓ_∞ norm of each row, we can treat each row separately; thus, we want to minimize

$$G(\mathbf{w}) = \frac{1}{2\eta}\|\mathbf{w} - \mathbf{v}\|^2 + \lambda\max_j |x_j| + \text{const.}$$

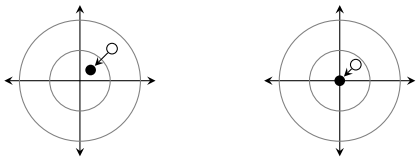


Figure 3: Examples of the two possible cases for the ℓ_2 gradient update. Point $\mathbf{v}$ is drawn with a hollow dot, and point $\mathbf{w}$ is drawn with a solid dot.

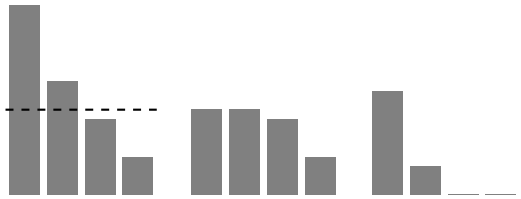

Figure 4: The proximal operator for the ℓ_∞ norm (with strength $\eta\lambda$) decreases the maximal components until the total decrease sums to $\eta\lambda$. Projection onto the ℓ_1-ball (of radius $\eta\lambda$) decreases each component by an equal amount until they sum to $\eta\lambda$.

Intuitively, the solution can be characterized as: Decrease all of the maximal $|x_j|$ until the total decrease reaches $\eta\lambda$ or all the x_j are zero. See Figure 4.

If we pre-sort the $|x_j|$ in nonincreasing order, it's easy to see how to compute this: for $\rho = 1, \ldots, n$, see if there is a value $\xi \leq x_\rho$ such that decreasing all the $x_1, \ldots, x_\rho$ to ξ amounts to a total decrease of $\eta\lambda$. The largest ρ for which this is possible gives the correct solution.

But this situation seems similar to another optimization problem, projection onto the ℓ_1-ball, which Duchi et al. (2008) solve in linear time without pre-sorting. In fact, the two problems can be solved by nearly identical algorithms, because they are convex conjugates of each other (Duchi and Singer, 2009; Bach et al., 2012). Intuitively, the ℓ_1 projection of v is exactly what is cut out by the ℓ_∞ proximal operator, and vice versa (Figure 4).

Duchi et al.'s algorithm modified for the present problem is shown as Algorithm 1. It partitions the x_j about a pivot element (line 6) and tests whether it and the elements to its left can be decreased to a value ξ such that the total decrease is δ (line 8). If so, it recursively searches the right side; if not, the

left side. At the conclusion of the algorithm, ρ is set to the largest value that passes the test (line 13), and finally the new x_j are computed (line 16) – the only difference from Duchi et al.'s algorithm.

This algorithm is asymptotically faster than that of Quattoni et al. (2009). They reformulate $\ell_{\infty,1}$ regularization as a constrained optimization problem (in which the $\ell_{\infty,1}$ norm is bounded by μ) and provide a solution in $\mathcal{O}(n \log n)$ time. The method shown here is simpler and faster because it can work on each row separately.

Algorithm 1 Linear-time algorithm for the proximal operator of the ℓ_∞ norm.

5 Experiments

We evaluate our model using the open-source NPLM toolkit released by Vaswani et al. (2013), extending it to use the additional regularizers as described in this paper.[2] We use a vocabulary size of 100k and word embeddings with 50 dimensions. We use two hidden layers of rectified linear units (Nair and Hinton, 2010).

[2]These extensions have been contributed to the NPLM project.

We train neural language models (LMs) on two natural language corpora, Europarl v7 English and the AFP portion of English Gigaword 5. After tokenization, Europarl has 56M tokens and Gigaword AFP has 870M tokens. For both corpora, we hold out a validation set of 5,000 tokens. We train each model for 10 iterations over the training data.

Our experiments break down into three parts. First, we look at the impact of our pruning method on perplexity of a held-out validation set, across a variety of settings. Second, we take a closer look at how the model evolves through the training process. Finally, we explore the downstream impact of our method on a statistical phrase-based machine translation system.

5.1 Evaluating perplexity and network size

We first look at the impact that the $\ell_{\infty,1}$ regularizer has on the perplexity of our validation set. The main results are shown in Table 1. For $\lambda \leq 0.01$, the regularizer seems to have little impact: no hidden units are pruned, and perplexity is also not affected. For $\lambda = 1$, on the other hand, most hidden units are pruned – apparently too many, since perplexity is worse. But for $\lambda = 0.1$, we see that we are able to prune out many hidden units: up to half of the first layer, with little impact on perplexity. We found this to be consistent across all our experiments, varying n-gram size, initial hidden layer size, and vocabulary size.

Table 2 shows the same information for 5-gram models trained on the larger Gigaword AFP corpus. These numbers look very similar to those on Europarl: again $\lambda = 0.1$ works best, and, counter to expectation, even the final number of units is similar.

Table 3 shows the result of varying the vocabulary size: again $\lambda = 0.1$ works best, and, although it is not shown in the table, we also found that the final number of units did not depend strongly on the vocabulary size.

Table 4 shows results using the $\ell_{2,1}$ norm (Europarl corpus, 5-grams, 100k vocabulary). Since this is a different regularizer, there isn't any reason to expect that λ behaves the same way, and indeed, a smaller value of λ seems to work best.

5.2 A closer look at training

We also studied the evolution of the network over the training process to gain some insights into how the method works. The first question we want to

	2-gram			3-gram			5-gram		
λ	layer 1	layer 2	ppl	layer 1	layer 2	ppl	layer 1	layer 2	ppl
0	1,000	50	103	1,000	50	66	1,000	50	55
0.001	1,000	50	104	1,000	50	66	1,000	50	54
0.01	1,000	50	104	1,000	50	63	1,000	50	55
0.1	499	47	105	652	49	66	784	50	55
1.0	50	24	111	128	32	76	144	29	68

Table 1: Comparison of $\ell_{\infty,1}$ regularization on 2-gram, 3-gram, and 5-gram neural language models. The network initially started with 1,000 units in the first hidden layer and 50 in the second. A regularization strength of $\lambda = 0.1$ consistently is able to prune units while maintaining perplexity, even though the final number of units varies considerably across models. The vocabulary size is 100k.

λ	layer 1	layer 2	perplexity
0	1,000	50	100
0.001	1,000	50	99
0.01	1,000	50	101
0.1	742	50	107
1.0	24	17	173

Table 2: Results from training a 5-gram neural LM on the AFP portion of the Gigaword dataset. As with the smaller Europarl corpus (Table 1), a regularization strength of $\lambda = 0.1$ is able to prune units while maintaining perplexity.

	vocabulary size			
λ	10k	25k	50k	100k
0	47	60	54	55
0.001	47	54	54	54
0.01	47	58	55	55
0.1	48	62	55	55
1.0	61	64	65	68

Table 3: A regularization strength of $\lambda = 0.1$ is best across different vocabulary sizes.

λ	layer 1	layer 2	perplexity
0	1,000	50	100
0.0001	1,000	50	54
0.001	1,000	50	55
0.01	616	50	57
0.1	199	32	65

Table 4: Results using $\ell_{2,1}$ regularization.

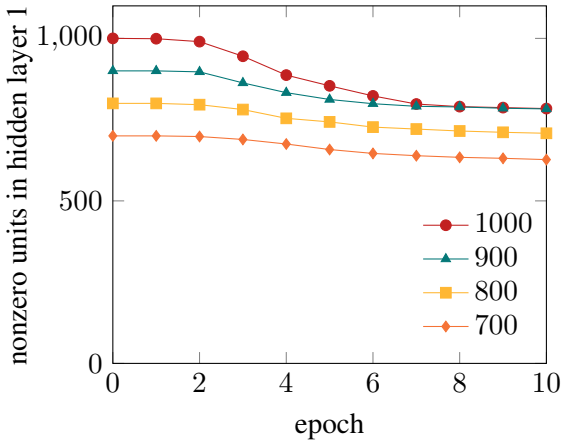

Figure 5: Number of units in first hidden layer over time, with various starting sizes ($\lambda = 0.1$). If we start with too many units, we end up with the same number, although if we start with a smaller number of units, a few are still pruned away.

answer is whether the method is simply removing units, or converging on an optimal number of units. Figure 5 suggests that it is a little of both: if we start with too many units (900 or 1000), the method converges to the same number regardless of how many extra units there were initially. But if we start with a smaller number of units, the method still prunes away about 50 units.

Next, we look at the behavior over time of different regularization strengths λ. We found that not only does $\lambda = 1$ prune out too many units, it does so at the very first iteration (Figure 6, above), perhaps prematurely. By contrast, the $\lambda = 0.1$ run prunes out units gradually. By plotting these curves together with perplexity (Figure 6, below), we can see that the $\lambda = 0.1$ run is fitting the model and pruning it at the same time, which seems preferable to fitting without any pruning ($\lambda =$

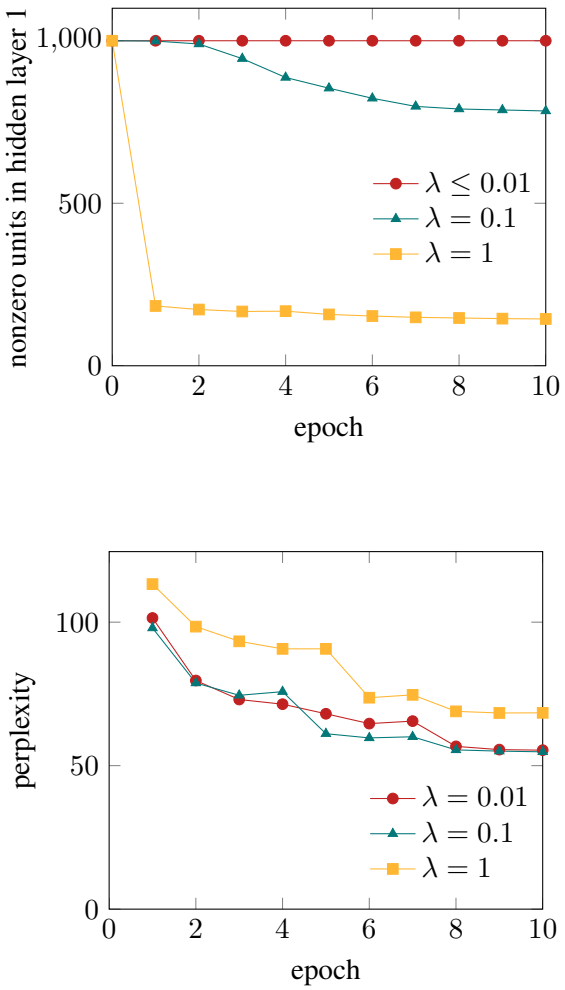

Figure 6: Above: Number of units in first hidden layer over time, for various regularization strengths λ. A regularization strength of ≤ 0.01 does not zero out any rows, while a strength of 1 zeros out rows right away. Below: Perplexity over time. The runs with $\lambda \leq 0.1$ have very similar learning curves, whereas $\lambda = 1$ is worse from the beginning.

	neural LM		
λ	none	Europarl	Gigaword AFP
0 (none)	23.2	24.7 (+1.5)	25.2 (+2.0)
0.1		24.6 (+1.4)	24.9 (+1.7)

Table 5: The improvements in translation accuracy due to the neural LM (shown in parentheses) are affected only slightly by $\ell_{\infty,1}$ regularization. For the Europarl LM, there is no statistically significant difference, and for the Gigaword AFP LM, a statistically significant but small decrease of -0.3.

0.01) or pruning first and then fitting ($\lambda = 1$).

We can also visualize the weight matrix itself over time (Figure 7), for $\lambda = 0.1$. It is striking that although this setting fits the model and prunes it at the same time, as argued above, by the first iteration it already seems to have decided roughly how many units it will eventually prune.

5.3 Evaluating on machine translation

We also looked at the impact of our method on statistical machine translation systems. We used the Moses toolkit (Koehn et al., 2007) to build a phrase based machine translation system with a traditional 5-gram LM trained on the target side of our bitext. We augmented this system with neural LMs trained on the Europarl data and the Gigaword AFP data. Based on the results from the perplexity experiments, we looked at models both built with a $\lambda = 0.1$ regularizer, and without regularization ($\lambda = 0$).

We built our system using the newscommentary dataset v8. We tuned our model using newstest13 and evaluated using newstest14. After standard cleaning and tokenization, there were 155k parallel sentences in the newscommentary dataset, and 3,000 sentences each for the tuning and test sets.

Table 5 shows that the addition of a neural LM helps substantially over the baseline, with improvements of up to 2 BLEU. Using the Europarl model, the BLEU scores obtained without and with regularization were not significantly different ($p \geq 0.05$), consistent with the negligible perplexity difference between these models. On the Gigaword AFP model, regularization did decrease the BLEU score by 0.3, consistent with the small perplexity increase of the regularized model. The decrease is statistically significant, but small compared with the overall benefit of adding a neural LM.

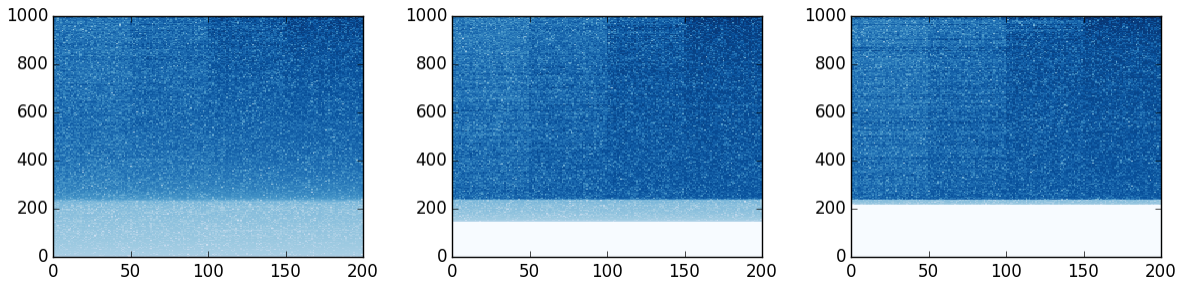

Figure 7: Evolution of the first hidden layer weight matrix after 1, 5, and 10 iterations (with rows sorted by ℓ_∞ norm). A nonlinear color scale is used to show small values more clearly. The four vertical blocks correspond to the four context words. The light bar at the bottom is the rows that are close to zero, and the white bar is the rows that are exactly zero.

6 Related Work

Researchers have been exploring the use of neural networks for language modeling for a long time. Schmidhuber and Heil (1996) proposed a character n-gram model using neural networks which they used for text compression. Xu and Rudnicky (2000) proposed a word-based probability model using a softmax output layer trained using cross-entropy, but only for bigrams. Bengio et al. (2003) defined a probabilistic word n-gram model and demonstrated improvements over conventional smoothed language models. Mnih and Teh (2012) sped up training of log-bilinear language models through the use of noise-contrastive estimation (NCE). Vaswani et al. (2013) also used NCE to train the architecture of Bengio et al. (2003), and were able to integrate a large-vocabulary language model directly into a machine translation decoder. Baltescu et al. (2014) describe a similar model, with extensions like a hierarchical softmax (based on Brown clustering) and direct n-gram features.

Beyond feed-forward neural network language models, researchers have explored using more complicated neural network architectures. RNNLM is an open-source implementation of a language model using recurrent neural networks (RNN) where connections between units can form directed cycles (Mikolov et al., 2011). Sundermeyer et al. (2015) use the long-short term memory (LSTM) neural architecture to show a perplexity improvement over the RNNLM toolkit. In future work, we plan on exploring how our method could improve these more complicated neural models as well.

Automatically limiting the size of neural networks is an old idea. The "Optimal Brain Damage" (OBD) technique (LeCun et al., 1989) computes a *saliency* based on the second derivative of the objective function with respect to each parameter. The parameters are then sorted by saliency, and the lowest-saliency parameters are pruned. The pruning process is separate from the training process, whereas regularization performs training and pruning simultaneously. Regularization in neural networks is also an old idea; for example, Nowland and Hinton (1992) mention both ℓ_2^2 and ℓ_0 regularization. Our method develops on this idea by using a mixed norm to prune units, rather than parameters.

Srivastava et al. introduce a method called *dropout* in which units are directly deactivated at random during training (Srivastava et al., 2014), which induces sparsity in the hidden unit activations. However, at the end of training, all units are reactivated, as the goal of dropout is to reduce overfitting, not to reduce network size. Thus, dropout and our method seem to be complementary.

7 Conclusion

We have presented a method for auto-sizing a neural network during training by removing units using a $\ell_{\infty,1}$ regularizer. This regularizer drives a unit's input weights as a group down to zero, allowing the unit to be pruned. We can thus prune units out of our network during training with minimal impact to held-out perplexity or downstream performance of a machine translation system.

Our results showed empirically that the choice

of a regularization coefficient of 0.1 was robust to initial configuration parameters of initial network size, vocabulary size, n-gram order, and training corpus. Furthermore, imposing a single regularizer on the objective function can tune all of the hidden layers of a network with one setting. This reduces the need to conduct expensive, multi-dimensional grid searches in order to determine optimal sizes.

We have demonstrated the power and efficacy of this method on a feed-forward neural network for language modeling though experiments on perplexity and machine translation. However, this method is general enough that it should be applicable to other domains, both inside natural language processing and outside. As neural models become more pervasive in natural language processing, the ability to auto-size networks for fast experimentation and quick exploration will become increasingly important.

Dual Decomposition Inference for Graphical Models over Strings*

Nanyun Peng and **Ryan Cotterell** and **Jason Eisner**
Department of Computer Science, Johns Hopkins University
{npeng1,ryan.cotterell,eisner}@jhu.edu

Abstract

We investigate dual decomposition for joint MAP inference of many strings. Given an arbitrary graphical model, we decompose it into small acyclic sub-models, whose MAP configurations can be found by finite-state composition and dynamic programming. We force the solutions of these subproblems to agree on overlapping variables, by tuning Lagrange multipliers for an adaptively expanding set of variable-length n-gram count features.

This is the first inference method for arbitrary graphical models over strings that does not require approximations such as random sampling, message simplification, or a bound on string length. *Provided that* the inference method terminates, it gives a certificate of global optimality (though MAP inference in our setting is undecidable in general). On our global phonological inference problems, it always terminates, and achieves more accurate results than max-product and sum-product loopy belief propagation.

1 Introduction

Graphical models allow expert modeling of complex relations and interactions between random variables. Since a graphical model with given parameters defines a probability distribution, it can be used to reconstruct values for unobserved variables. The **marginal inference** problem is to compute the posterior marginal distributions of these variables. The **MAP inference** (or **MPE**) problem is to compute the single highest-probability joint assignment to all the unobserved variables.

Inference in general graphical models is NP-hard even when the variables' values are finite discrete values such as categories, tags or domains. In this paper, we address the more challenging setting where the variables in the graphical models range over strings. Thus, the domain of the variables is an *infinite* space of discrete structures.

In NLP, such graphical models can deal with large, incompletely observed lexicons. They could be used to model diverse relationships among strings that represent spellings or pronunciations; morphemes, words, phrases (such as named entities and URLs), or utterances; standard or variant forms; clean or noisy forms; contemporary or historical forms; underlying or surface forms; source or target language forms. Such relationships arise in domains such as morphology, phonology, historical linguistics, translation between related languages, and social media text analysis.

In this paper, we assume a *given* graphical model, whose factors evaluate the relationships among observed and unobserved strings.[1] We present a dual decomposition algorithm for MAP inference, which returns a certifiably optimal solution when it converges. We demonstrate our method on a graphical model for phonology proposed by Cotterell et al. (2015). We show that the method generally converges and that it achieves better results than alternatives.

The rest of the paper is arranged as follows: We will review graphical models over strings in section 2, and briefly introduce our sample problem in section 3. Section 4 develops dual decomposition inference for graphical models over strings. Then our experimental setup and results are presented in sections 5 and 6, with some discussion.

2 Graphical Models Over Strings

2.1 Factor Graphs and MAP Inference

To perform inference on a graphical model (directed or undirected), one first converts the model to a factor graph representation (Kschischang et al., 2001). A **factor graph** is a finite bipartite

*This material is based upon work supported by the National Science Foundation under Grant No. 1423276.

[1] In some task settings, it is also necessary to discover the model topology along with the model parameters. In this paper we do not treat that structure learning problem. However, both structure learning and parameter learning need to call inference—such as the method presented here—in order to evaluate proposed topologies or improve their parameters.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 917–927,
Lisbon, Portugal, 17-21 September 2015.

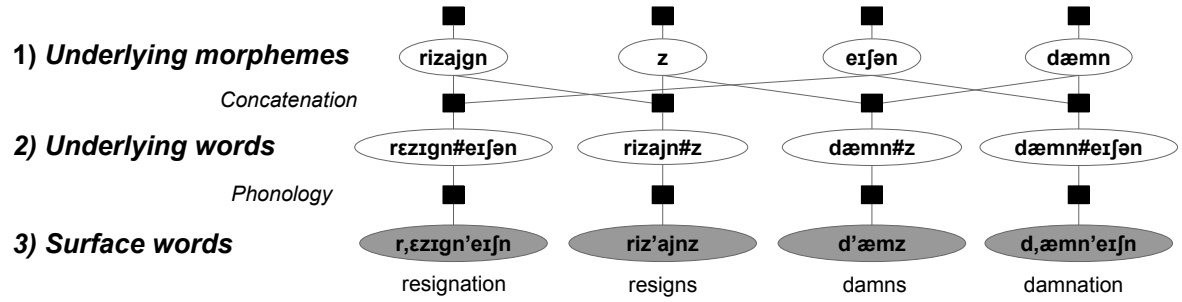

Figure 1: A fragment of the factor graph for the directed graphical model of Cotterell et al. (2015), displaying a possible assignment to the variables (ellipses). The model explains each observed surface word as the result of applying phonology to a concatenation of underlying morphemes. Shaded variables show the observed surface forms for four words: *resignation*, *resigns*, *damns*, and *damnation*. The underlying pronunciations of these words are assumed to be more similar than their surface pronunciations, because the words are known to share latent morphemes. The factor graph encodes what is shared. Each observed word at layer 3 has a latent underlying form at layer 2, which is a deterministic concatenation of latent morphemes at layer 1. The binary factors between layers 2 and 3 score each (underlying,surface) pair for its phonological plausibility. The unary factors at layer 1 score each morpheme for its lexical plausibility. See Cotterell et al. (2015) for discussion of alternatives.

graph over a set $\mathcal{X} = \{X_1, X_2, \ldots\}$ of variables and a set $\mathcal{F}$ of factors. An **assignment** to the variables is a vector of values $\mathbf{x} = (x_1, x_2, \ldots)$. Each factor $F \in \mathcal{F}$ is a real-valued function of $\mathbf{x}$, but it depends on a given x_i *only if* F is connected to X_i in the graph. Thus, a degree d-factor scores some length-d subtuple of $\mathbf{x}$. The score of the whole joint assignment simply sums over all factors:

$$\text{score}(\mathbf{x}) \stackrel{\text{def}}{=} \sum_{F \in \mathcal{F}} F(\mathbf{x}). \quad (1)$$

We seek the $\mathbf{x}$ of maximum score that is consistent with our partial observation of $\mathbf{x}$. This is a generic constraint satisfaction problem with soft constraints. While our algorithm does not depend on a probabilistic interpretation of the factor graph,[2] it can be regarded as peforming maximum *a posteriori* (MAP) inference of the unobserved variables, under the probability distribution $p(\mathbf{x}) \stackrel{\text{def}}{=} (1/Z) \exp \text{score}(\mathbf{x})$.

2.2 The String Case

Graphical models over strings have enjoyed some attention in the NLP community. Tree-shaped graphical models naturally model the evolutionary tree of word forms (Bouchard-Côté et al., 2007; Bouchard-Côté et al., 2008; Hall and Klein, 2010; Hall and Klein, 2011). Cyclic graphical models have been used to model morphological paradigms (Dreyer and Eisner, 2009; Dreyer and Eisner, 2011) and to reconstruct phonological underlying forms of words (Cotterell et al., 2015).

The variables in such a model are strings of unbounded length: each variable X_i is permitted to range over Σ^* where Σ is some fixed, finite alphabet. As in previous work, we assume that a degree-d factor is a d-way rational relation, i.e., a function of d strings that can be computed by a d-tape **weighted finite-state machine (WFSM)** (Mohri et al., 2002; Kempe et al., 2004). Such a machine is called an **acceptor (WFSA)** if $d = 1$ or a **transducer (WFST)** if $d = 2$.[3]

Past work has shown how to approximately *sample* from the distribution over $\mathbf{x}$ defined by such a model (Bouchard-Côté et al., 2007), or approximately compute the distribution's *marginals* using variants of **sum-product belief propagation** (BP) (Dreyer and Eisner, 2009) and expectation propagation (EP) (Cotterell and Eisner, 2015).

2.3 Finite-State Belief Propagation

BP iteratively updates **messages** between factors and variables. Each message is a vector whose elements score the possible values of a variable.

Murphy et al. (1999) discusses BP on cyclic ("loopy") graphs. For pedagogical reasons, suppose momentarily that all factors have degree ≤ 2 (this loses no power). Then BP manipulates only vectors and matrices—whose *dimensionality* depends on the number of possible values of the vari-

[2] E.g., it could be used for exactly computing the separation oracle when training a structural SVM (Tsochantaridis et al., 2005; Finley and Joachims, 2007). Another use is minimum Bayes risk decoding—computing the joint assignment having minimum expected loss—if the loss function does not decompose over the variables, but a factor graph can be constructed that evaluates the expected loss of any assignment.

[3] Finite-state software libraries often support only these cases. Accordingly, Cotterell and Eisner (2015, Appendix B.10) explain how to eliminate factors of degree $d > 2$.

ables. In the string case, they have *infinitely* many rows and columns, indexed by possible strings.

Dreyer and Eisner (2009) represented these infinite vectors and matrices by WFSAs and WFSTs, respectively. They observed that the simple linear-algebra operations used by BP can be implemented by finite-state constructions. The pointwise product of two vectors is the intersection of their WFSAs; the marginalization of a matrix is the projection of its WFST; a vector-matrix product is computed by composing the WFSA with the WFST and then projecting onto the output tape. For degree > 2, BP's rank-d tensors become d-tape WFSMs, and these constructions generalize.

Unfortunately, except in small acyclic models, the BP messages—which are WFSAs—usually become impractically large. Each intersection or composition involves a cross-product construction. For example, when finding the marginal distribution at a degree-d variable, intersecting d WFSA messages having m states each may yield a WFSA with up to m^d states. (Our models in section 6 include variables with d up to 156.) Combining *many* cross products, as BP iteratively passes messages along a path in the factor graph, leads to blowup that is exponential in the length of the path—which in turn is unbounded if the graph has cycles (Dreyer and Eisner, 2009), as ours do.

The usual solution is to prune or otherwise approximate the messages at each step. In particular, Cotterell and Eisner (2015) gave a principled way to approximate the messages using variable-length n-gram models, using an adaptive variant of Expectation Propagation (Minka, 2001).

2.4 Dual Decomposition Inference

In section 4, we will present a dual decomposition (DD) method that decomposes the original complex problem into many small subproblems that are free of cycles and high degree nodes. BP can solve each subproblem without approximation.[4]

The subproblems "communicate" through Lagrange multipliers that guide them towards agreement on a single global solution. This information is encoded in WFSAs that score possible values of a string variable. DD incrementally adjusts the WFSAs so as to encourage values that agree with the variable's average value across subproblems.

Unlike BP messages, the WFSAs in our DD method will be restricted to be variable-length n-gram models, similar to Cotterell and Eisner (2015). They may still grow over time; but DD often halts while the WFSAs are still small. It halts when its strings agree exactly, rather than when it has converged up to a numerical tolerance, like BP.

2.5 Switching Between Semirings

Our factors may be *nondeterministic* WFSMs. So when $F \in \mathcal{F}$ scores a given d-tuple of string values, it may accept that d-tuple along multiple different WFSM paths with different scores, corresponding to different alignments of the strings.

For purposes of MAP inference, we define F to return the *maximum* of these path scores. That is, we take the WFSMs to be defined with weights in the $(\max, +)$ semiring (Mohri et al., 2002). Equivalently, we are seeking the "best global solution" in the sense of choosing not only the strings x_i but also the alignments of the d-tuples.[5]

To do so, we must solve each DD subproblem in the same sense. We use **max-product BP**. This still applies the Dreyer-Eisner method of section 2.3. Since these WFSMs are defined in the $(\max, +)$ semiring, the method's finite-state operations will combine weights using $\max$ and $+$.

MAP inference in our setting is in general computationally undecidable.[6] However, if DD converges (as in our experiments), then *its solution is guaranteed to be the true MAP assignment.*

In section 6, we will compare DD with (loopy) max-product BP and (loopy) sum-product BP. These respectively approximate MAP inference and marginal inference over the entire factor graph. Marginal inference computes marginal string probabilities that sum (rather than maximize) over the choices of other strings *and the choices of paths*. Thus, for sum-product BP, we re-interpret the factor WFSMs as defined over the $(\text{logadd}, +)$ semiring. This means that the exponentiated score assigned by a WFSM is the sum of the exponentiated scores of the accepting paths.

[4] Such small BP problems commonly arise in NLP. In particular, using finite-state methods to decode a composition of several finite-state noisy channels (Pereira and Riley, 1997; Knight and Graehl, 1998) can be regarded as BP on a graphical model over strings that has a linear-chain topology.

[5] This problem is more specifically called **MPE inference**.

[6] The trouble is that we cannot bound the length of the latent strings. If we could, then we could encode them using a finite set of boolean variables, and solve as an ILP problem. But that would allow us to determine whether there exists a MAP assignment with score ≥ 0. That is impossible in general, because it would solve Post's Correspondence Problem as a simple special case (see Dreyer and Eisner (2009)).

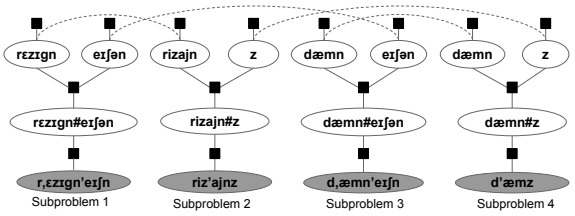

Figure 2: To apply dual decomposition, we choose to decompose 1 into one subproblem per surface word. Dashed lines connect two or more variables from different subproblems that correspond to the same variable in the original graph. The method of Lagrange multipliers is used to force these variables to have identical values. An additional unary factor attached to each subproblem variable (not shown) is used to incorporate its Lagrangian term.

3 A Sample Task: Generative Phonology

Before giving the formal details of our DD method, we give a motivating example: a recently proposed graphical model for morphophonology. Cotterell et al. (2015) defined a Bayesian network to describe the generative process of phonological words. Our Figure 1 shows a conversion of their model to a factor graph and explains what the variables and factors mean.

Inference on this graph performs *unsupervised discovery of latent strings*. Given observed surface representations of words (SRs), inference aims to recover the underlying representations (URs) of the words and their shared constituent morphemes. The latter can then be used to predict held-out SRs.

Notice that the 8 edges in the first layer of Figure 1 form a cycle; such cycles make BP inexact. Moreover, the figure shows only a schematic fragment of the graphical model. In the actual experiments, the graphical models have up to 829 variables, and the variables representing morpheme URs are connected to up to 156 factors (because many words share the same affix).

To handle the above challenges without approximation, we want to decompose the original problem into subproblems where each subproblem can be solved efficiently. In particular, we want the subproblems to be free of cycles and high-degree nodes. In our phonology example, each observed word along with its correspondent latent URs forms an ideal subproblem. This decomposition is shown in Figure 2.

While the subproblems can be solved efficiently in isolation, they may share variables, as shown by the dashed lines in Figure 2. DD repeatedly modifies and re-solves the subproblems until they agree on their shared variables.

4 Dual Decomposition

Dual decomposition is a general technique for solving constrained optimization problems. It has been widely used for MAP inference in graphical models (Komodakis et al., 2007; Komodakis and Paragios, 2009; Koo et al., 2010; Martins et al., 2011; Sontag et al., 2011; Rush and Collins, 2014). However, previous work has focused on variables X_i whose values are in $\mathbb{R}$ or a small finite set; we will consider the infinite set Σ^*.

4.1 Review of Dual Decomposition

To apply dual decomposition, we must partition the original problem into a union of K subproblems, each of which can be solved exactly and efficiently (and in parallel). For example, our experiments partition Figure 1 as shown in Figure 2.

Specifically, we partition the factors into K sets $\mathcal{F}^1, \ldots, \mathcal{F}^K$. Each factor $F \in \mathcal{F}$ appears in exactly one of these sets. This lets us rewrite the score (1) as $\sum_k \sum_{F \in \mathcal{F}^k} F(\mathbf{x})$. Instead of simply seeking its maximizer $\mathbf{x}$, we equivalently seek

$$\operatorname*{argmax}_{\mathbf{x}^1,\ldots,\mathbf{x}^K} \sum_{k=1}^{K} \Big(\sum_{F \in \mathcal{F}^k} F(\mathbf{x}^k) \Big) \text{ s.t. } \mathbf{x}^1 = \cdots = \mathbf{x}^K \tag{2}$$

If we dropped the equality constraint, (2) could be solved by *separately* maximizing $\sum_{F \in \mathcal{F}^k} F(\mathbf{x}^k)$ for each k. This "subproblem" is itself a MAP problem which considers only the factors $\mathcal{F}^k$ and the variables $\mathcal{X}^k$ adjacent to them in the original factor graph. The subproblem objective does not depend on the other variables.

We now attempt to enforce the equality constraint indirectly, by adding Lagrange multipliers that encourage agreement among the subproblems. Assume for the moment that the variables in the factor graph are real-valued (each x_i^k is in $\mathbb{R}$). Then consider the **Lagrangian relaxation** of (2),

$$\max_{\mathbf{x}^1,\ldots,\mathbf{x}^K} \sum_{k=1}^{K} \Big(\sum_{F \in \mathcal{F}^k} F(\mathbf{x}^k) + \sum_i \lambda_i^k \cdot x_i^k \Big) \tag{3}$$

This can still be solved by separate maximizations. For *any* choices of $\lambda_i^k \in \mathbb{R}$ having $(\forall i) \sum_k \lambda_i^k = 0$, it upper-bounds the objective of (2). Why? The solution to (2) achieves the same value in (3), yet (3) may do even better by considering solutions that do not satisfy the constraint. Our goal is to find λ_i^k values that tighten this upper bound as much as possible. *If* we can find λ_i^k values so that

the optimum of (3) satisfies the equality constraint, then we have a tight bound and a solution to (2).

To improve the method, recall that subproblem k considers only variables $\mathcal{X}^k$. It is indifferent to the value of X_i if $X_i \notin \mathcal{X}^k$, so we just leave x_i^k undefined in the subproblem's solution. We treat that as automatically satisfying the equality constraint; thus we do not need any Lagrange multiplier λ_i^k to force equality. Our final solution $\mathbf{x}$ ignores undefined values, and sets x_i to the value agreed on by the subproblems that *did* consider X_i.[7]

4.2 Substring Count Features

But what do we do if the variables are strings? The Lagrangian term $\lambda_i^k \cdot x_i^k$ in (3) is now ill-typed. We replace it with $\boldsymbol{\lambda}_i^k \cdot \boldsymbol{\gamma}(x_i^k)$, where $\boldsymbol{\gamma}(\cdot)$ extracts a real-valued **feature vector** from a string, and $\boldsymbol{\lambda}_i^k$ is a vector of Lagrange multipliers.

This corresponds to changing the constraint in (2). Instead of requiring $x_i^1 = \cdots = x_i^K$ for each i, we are now requiring $\boldsymbol{\gamma}(x_i^1) = \cdots = \boldsymbol{\gamma}(x_i^K)$, i.e., these strings must agree *in their features*.

We want each possible string to have a unique feature vector, so that matching features forces the actual strings to match. We follow Paul and Eisner (2012) and use a **substring count feature** for each $w \in \Sigma^*$. In other words, $\boldsymbol{\gamma}(x)$ is an infinitely long vector, which maps each w to the number of times that w appears in x as a substring.[8]

Computing $\boldsymbol{\lambda}_i^k \cdot \boldsymbol{\gamma}(x_i^k)$ in (3) remains possible because in practice, $\boldsymbol{\lambda}_i^k$ will have only finitely many nonzeros. This is so because our feature vector $\boldsymbol{\gamma}(x)$ has only finitely many nonzeros for any string x, and the subgradient algorithm in section 4.3 below always updates $\boldsymbol{\lambda}_i^k$ by adding multiples of such $\boldsymbol{\gamma}(x)$ vectors.

We will use a further trick below to prevent rapid growth of this finite set of nonzeros. Each variable X_i maintains an **active set** of features, $\mathcal{W}_i$. Only these features may have nonzero Lagrange multipliers. While the active set can grow over time, it will be finite at any given step.

Given the Lagrange multipliers, subproblem k of (3) is simply MAP inference on the factor graph consisting of the variables $\mathcal{X}^k$ and factors $\mathcal{F}^k$ *as well as* an extra unary factor G_i^k at each $X_i \in \mathcal{X}^k$:

$$G_i^k(\mathbf{x}^k) \stackrel{\text{def}}{=} \boldsymbol{\lambda}_i^k \cdot \boldsymbol{\gamma}(x_i^k) \tag{4}$$

These unary factors penalize strings according to the Lagrange multipliers. They can be encoded as WFSAs (Allauzen et al., 2003; Cotterell and Eisner, 2015, Appendices B.1–B.5), allowing us to solve the subproblem by max-product BP as usual. The topology of the WFSA for G_i^k depends only on $\mathcal{W}_i$, while its weights come from $\boldsymbol{\lambda}_i^k$.

4.3 Projected Subgradient Method

We aim to adjust the collection $\boldsymbol{\lambda}$ of Lagrange multipliers to *minimize* the upper bound (3). Following Komodakis et al. (2007), we solve this convex **dual problem** using a projected subgradient method. We initialize $\boldsymbol{\lambda} = \mathbf{0}$ and compute (3) by solving the K subproblems. Then we take a step to adjust $\boldsymbol{\lambda}$, and repeat in hopes of eventually satisfying the equality condition.

The projected subgradient step is

$$\boldsymbol{\lambda}_i^k := \boldsymbol{\lambda}_i^k + \eta \cdot \Big(\mu_i - \boldsymbol{\gamma}(x_i^k)\Big) \tag{5}$$

where $\eta > 0$ is the current step size, and μ_i is the mean of $\boldsymbol{\gamma}(x_i^{k'})$ over all subproblems k' that consider X_i. This update modifies (3) to encourage solutions x^k such that $\gamma(x_i^k)$ comes closer to μ_i.

For each i, we update all $\boldsymbol{\lambda}_i^k$ at once to preserve the property that $(\forall i) \sum_k \lambda_i^k = 0$. However, we are only allowed to update components of the $\boldsymbol{\lambda}_i^k$ that correspond to features in the active set $\mathcal{W}_i$. To ensure that we continue to make progress even after we agree on these features, we first expand $\mathcal{W}_i$ by adding the *minimal* strings (if any) on which the x_i^k do not yet all agree. For example, we will add the `abc` feature only when the x_i^k already agree on their counts of its substrings `ab` and `bc`.[9]

Algorithm 1 summarizes the whole method. Table 1 illustrates how one active set $\mathcal{W}_i$ (section 4.3) evolves, in our experiments, as it tries to enforce agreement on a particular string x_i.

4.4 Past Work: Implicit Intersection

Our DD algorithm is an extension of one that Paul and Eisner (2012) developed for the simpler **implicit intersection** problem. Given many WFSAs $F_1, \ldots, F_K$, they were able to find the string x with maximum total score $\sum_{k=1}^K F_k(x)$. (They applied this to solve instances of the NP-hard **Steiner**

[7] Without this optimization, the Lagrangian term $\lambda_i^k \cdot x_i^k$ would have driven x_i^k to match that value anyway.

[8] More precisely, the number of times that w appears in BOS x EOS, where BOS, EOS are distinguished boundary symbols. We allow w to start with BOS and/or end with EOS, which yields prefix and suffix indicator features.

[9] In principle, we should check that they also (still) agree on `a`, `b`, and `c`, but we skip this check. Our active set heuristic is almost identical to that of Paul and Eisner (2012).

Algorithm 1 DD for graphical models over strings

initialize the active set $\mathcal{W}_i$ for each variable $X_i \in \mathcal{X}$
initialize $\boldsymbol{\lambda}_i^k = \mathbf{0}$ for each X_i and each subproblem k
for t = 1 to T **do** ▷ max number of iterations
  for k = 1 to K **do** ▷ solve all primal subproblems
    if any of the $\boldsymbol{\lambda}_i^k$ have changed **then**
      run max-product BP on the acyclic graph defined by variables $\mathcal{X}^k$ and factors $\mathcal{F}^k$ and G_i^k
      extract MAP strings: $\forall i$ with $X_i \in \mathcal{X}^k$, x_i^k is the label of the max-scoring accepting path in the WFSA that represents the belief at X_i
  for each $X_i \in \mathcal{X}$ **do** ▷ improve dual bound
    if the defined strings x_i^k are not all equal **then**
      Expand active feature set $\mathcal{W}_i$ ▷ section 4.3
      Update each $\boldsymbol{\lambda}_i^k$ ▷ equation (5)
      Update each G_i^k from $\Theta_i, \boldsymbol{\lambda}_i^k$ ▷ see (4)
  if none of the X_i required updates **then**
    return any defined x_i^k (all are equal) for each i
return $\{x_i^1, \ldots, x_i^K\}$ for each i ▷ failed to converge

string problem, i.e., finding the string x of minimum total edit distance to a collection of $K \approx 100$ given strings.) The naive solution to this problem would be to find the highest-weighted path in the intersection $F_1 \cap \cdots \cap F_K$. Unfortunately, the intersection of WFSAs takes the Cartesian product of their state sets. Thus materializing this intersection would have taken time exponential in K.

To put this another way, inference is NP-hard even on a "trivial" factor graph: a *single* variable X_1 attached to K factors. Recall from section 2.3 that BP would solve this via the expensive intersection above. Paul and Eisner (2012) instead applied DD with one subproblem per factor. We generalize their method to handle arbitrary factor graphs, with multiple latent variables and cycles.

4.5 Block Coordinate Update

We also explored a possible speedup for our algorithm. We used a **block coordinate update** variant of the algorithm when performing inference on the phonology problem and observed an empirical speedup. Block coordinate updates are widely used in Lagrangian relaxation and have also been explored specifically for dual decomposition.

In general, block algorithms minimize the objective by holding some variables fixed while updating others. Sontag et al. (2011) proposed a sophisticated block method called MPLP that considers all values of variable X_i instead of the ones obtained from the best assignments for the subproblems. However, it is not clear how to apply their technique to string-valued variables. Instead, the algorithm we propose here is much simpler—it divides the *primal* variables into groups and updates each group's associated *dual* variables in turn, using a single subgradient step (5). Note that this way of partitioning the dual variables has the nice property that we can still use the projected subgradient update we gave in (5) and preserve the property that $(\forall i) \sum_k \lambda_i^k = 0$.

In the graphical model for generative phonology, there are two types of underlying morphemes in the first layer: word stems and word affixes. Our block coordinate update algorithm thus alternates between subgradient updates to the dual variables for the stems and the dual variables for the affixes. Note that when performing block coordinate update on the dual variables, the primal variables are *not* held constant, but rather are chosen by optimizing the corresponding subproblem.

Iter#	x_i^1	x_i^2	x_i^3	x_i^4	$\Delta\mathcal{W}_i$
1	ϵ	ϵ	ϵ	ϵ	∅
3	g	g	g	g	∅
4	gris	griz	griz	griz	{s, z, is, iz, s$ z$ }
5	gris	grizo	griz	griz	{o, zo, o$ }
14	griz	grizo	griz	griz	∅
17	griz	griz	griz	griz	∅
18	griz	griz	grize	griz	{ e, ze, e$ }
19	gris	griz	griz	griz	∅
31	griz	griz	griz	griz	∅

Table 1: One variable's active set as DD runs. This variable is the unobserved stem morpheme shared by the Catalan words gris, grizos, grize, grizes. The second column shows the current set of solutions from the 4 subproblems having copies of this variable. The third column shows the new substrings that are then added to the active set, to try to enforce agreement via their Lagrange multipliers. The table does not show iterations in which these columns have not changed. However, those iterations still update the Lagrange multipliers to more strongly encourage agreement (if needed). Although agreement is achieved at iterations 1, 3, and 17, it is then disrupted—the subproblems' solutions change because of Lagrange-multiplier pressures on their *other* variables (suffixes that do *not* agree yet). At iteration 31, the variable returns to agreement on griz, and never changes again.

5 Experimental Setup

5.1 Datasets

We compare DD to belief propagation, using the graphical model for generative phonology discussed in section 3. Inference in this model aims to reconstruct underlying morphemes. Since our focus is inference, we will evaluate these reconstructions directly (whereas Cotterell et al. (2015) evaluated their ability to predict novel surface forms using the reconstructions).

Our factor graphs have a similar topology to the pedagogical fragment shown in Figure 1. How-

ever, they are actually derived from datasets constructed by Cotterell et al. (2015), which are available with full descriptions at `http://hubal.cs.jhu.edu/tacl2015/`. Briefly:

EXERCISE Small datasets of Catalan, English, Maori, and Tangale, drawn from phonology textbooks. Each dataset contains 55 to 106 surface words, formed from a collection of 16 to 55 morphemes.

CELEX Larger datasets of German, English, and Dutch, drawn from the CELEX database (Baayen et al., 1995). Each dataset contains 1000 surface words, formed from 341 to 381 underlying morphemes.

5.2 Evaluation Scheme

We compared three types of inference:

DD Use DD to perform *exact MAP inference*.

SP Perform *approximate marginal inference* by sum-product loopy BP with pruning (Cotterell et al., 2015).

MP Perform *approximate MAP inference* by max-product loopy BP with pruning. DD and SP improve this baseline in different ways.

DD predicts a string value for each variable. For SP and MP, we deem the prediction at a variable to be the string that is scored most highly by the belief at that variable.

We report the fraction of predicted morpheme URs that exactly match the gold-standard URs proposed by a human (Cotterell et al., 2015). We also compare these predicted URs to one another, to see how well the methods agree.

5.3 Parameterization

The model of Cotterell et al. (2015) has two factor types whose parameters must be chosen.[10] The first is a unary factor M_ϕ. Each underlying-morpheme variable (layer 1 of Figure 1) is connected to a copy of M_ϕ, which gives the prior distribution over its values. The second is a binary factor S_θ. For each surface word (layer 3), a copy of S_θ gives its conditional distribution given the corresponding underlying word (layer 2). M_ϕ and S_θ respectively model the *lexicon* and the *phonology* of the specific language; both are encoded as WFSMs.

M_ϕ is a 0-gram generative model: at each step it emits a character chosen uniformly from the alphabet Σ with probability ϕ, or halts with probability $1-\phi$. It favors shorter strings in general, but ϕ determines how weak this preference is.

S_θ is a sequential edit model that produces a word's SR by stochastically copying, inserting, substituting, and deleting the phonemes of its UR. We explore two ways of parameterizing it.

Model 1 is a simple model in which θ is a scalar, specifying the probability of copying the next character of the underlying word as it is transduced to the surface word. The remaining probability mass $1-\theta$ is apportioned equally among insertion, substitution and deletion operations.[11] This models phonology as "noisy concatenation"—the minimum necessary to account for the fact that surface words cannot quite be obtained as simple concatenations of their shared underlying morphemes.

Model 2 is a replication of the much more complicated parametric model of Cotterell et al. (2015), which can handle linguistic phonology. Here the factor S_θ is a *contextual* edit FST (Cotterell et al., 2014). The probabilities of competing edits in a given context are determined by a log-linear model with weight vector θ and features that are meant to pick up on phonological phenomena.

5.4 Training

When evaluating an inference method from section 5.2, we use the same inference method both for prediction and within training.

We train Model 1 by grid search. Specifically, we choose $\phi \in [0.65, 1)$ and $\theta \in [0.25, 1)$ such that the predicted forms maximize the joint score (1) (always using the $(\max, +)$ semiring).

For Model 2, we compared two methods for training the ϕ and θ parameters (θ is a vector):

Model 2S Supervised training, which *observes* the "true" (hand-constructed) values of the URs. This idealized setting uses the best possible parameters (trained on the test data).

Model 2E Expectation maximization (EM), whose E step *imputes* the unobserved URs.

EM's E step calls for *exact marginal inference*, which is intractable for our model. So we substitute the same inference method that we are test-

[10] The model also has a three-way factor, connecting layers 1 and 2 of Figure 1. This represents deterministic concatenation (appropriate for these languages) and has no parameters.

[11] That is, probability mass of $(1-\theta)/3$ is divided equally among the $|\Sigma|$ possible insertions; another $(1-\theta)/3$ is divided equally among the $|\Sigma|-1$ possible substitutions; and the final $(1-\theta)/3$ is allocated to deletion.

ing. This gives us three approximations to EM, based on DD, SP and MP. Note that DD specifically gives the Viterbi approximation to EM—which sometimes gets better results than true EM (Spitkovsky et al., 2010). For MP (but not SP), we extract only the 1-best predictions for the E step, since we study MP as an approximation to DD.

As initialization, our first E step uses the trained version of Model 1 for the same inference method.

5.5 Inference Details

We run SP and MP for 20 iterations (usually the predictions converge within 10 iterations). We run DD to convergence (usually < 600 iterations). DD iterations are much faster since each variable considers d strings, not d *distributions* over strings. Hence DD does not intersect distributions, and many parts of the graph settle down early because discrete values can converge in finite time.[12]

We follow Paul and Eisner (2012, section 5.1) fairly closely. In particular: Our stepsize in (5) is $\eta = \alpha/(t + 500)$, where t is the iteration number; $\alpha = 1$ for Model 2S and $\alpha = 10$ otherwise. We proactively include all 1-gram and 2-gram substring features in the active sets $\mathcal{W}_i$ at initialization, rather than adding them only as needed. At iterations 200, 400, and 600, we proactively add all 3-, 4-, and 5-gram features (respectively) on which the counts still disagree; this accelerates convergence on the few variables that have not already converged. We handle negative-weight cycles as Paul and Eisner do. If we had ever failed to converge within 2000 iterations, we would have used their heuristic to extract a prediction anyway.

Model 1 suffers from a symmetry-breaking problem. Many edits have identical probability, and when we run inference, many assignments will tie for highest scoring configuration. This can prevent DD from converging and makes performance hard to measure. To break these ties, we add "jitter" separately to each copy of M_ϕ in Figure 1. Specifically, if F_i is the unary factor attached to X_i, we expand our 0-gram model $F_i(x) = \log((p/|\Sigma|)^{|x|} \cdot (1-p))$ to become $F_i(x) = \log(\prod_{c\in\Sigma} p_{c,i}^{|x|_c} \cdot (1-p))$, where $|x|_c$ denotes the count of character c in string x, and $p_{c,i} \propto (p/|\Sigma|) \cdot \exp \varepsilon_{c,i}$ where $\varepsilon_{c,i} \sim N(0, 0.01)$ and we preserve $\sum_{c\in\Sigma} p_{c,i} = p$.

[12] A variable need not update $\boldsymbol{\lambda}$ if its strings agree; a subproblem is not re-solved if none of its variables updated $\boldsymbol{\lambda}$.

6 Experimental Results

6.1 Convergence and Speed of DD

As linguists know, reconstructing an underlying stem or suffix can be difficult. We may face insufficient evidence or linguistic irregularity—or regularity that goes unrecognized because the phonological model is impoverished (Model 1) or poorly trained (early EM iterations on Model 2). DD may then require extensive negotiation to resolve disagreements among subproblems. Furthermore, DD must renegotiate as conditions change elsewhere in the factor graph (Table 1).

DD converged in all of our experiments. Note that DD (section 4.3) has converged when all the equality constraints in (2) are satisfied. In this case, we have found the true MAP configuration.

In section 4.5, we discussed a block coordinate update variation (BCDD) of our DD algorithm. Figure 3 shows the convergence behavior of BCDD against the naive projected subgradient algorithm (NVDD) on the four EXERCISE languages under Model 1. The dual objective (3) always upper-bounds the primal score (i.e., the score (1) of an assignment derived heuristically from the current subproblem solutions). The dual decreases as the algorithm progresses. When the two objectives meet, we have found an optimal solution to the primal problem. We can see in Figure 3 that our DD algorithm converges quickly on the four EXERCISE languages and BCDD converges consistently faster than NVDD. We use BCDD in the remaining experiments.

When DD runs fast, it is competitive with the

	DD	SP	MP	Gold

Table 2: Pairwise agreement (on morpheme URs) of DD, SP, MP and the gold standard, for each group of inference problems. Boldface is highest accuracy (agreement with gold).

other methods. It is typically faster on the EXERCISE data, and a few times slower on the CELEX data. But we stop the other methods after 20 iterations, whereas *DD runs until it gets an exact answer*. We find that this runtime is unpredictable and sometimes quite long. In the grid search for training Model 1, we observed that changes in the parameters (ϕ, θ) could cause the runtime of DD inference to vary by 2 orders of magnitude. Similarly, on the CELEX data, the runtime on Model 1 (over 10 different $N = 600$ subsets of English) varied from about 1 hour to nearly 2 days.[13]

6.2 Comparison of Inference

For each language, we constructed several different unsupervised prediction problems. In each problem, we observe some size-N subset of the words in our dataset, and we attempt to predict the URs of the morphemes in those words. For each CELEX language, we took $N = 600$, and used three of the size-N training sets from (Cotterell et al., 2015). For each EXERCISE language, we took N to be one less than the dataset size, and used all $N + 1$ subsets of size N, again similar to (Cotterell et al., 2015). We report the unweighted macro-average of all these accuracy numbers.

[13]Note that our implementation is not optimized; e.g., it uses Python (not Cython).

We compare DD, SP, and MP inference on each language under different settings. Table 2 shows aggregate results, as an unweighted average over multiple languages and training sets. We present various additional results at `http://cs.jhu.edu/~npeng/emnlp2015/`, including a per-language breakdown of the results, runtime numbers, and significance tests.

The results for Model 1 are shown in Tables 2a and 2b. As we can see, in both datasets, dual decomposition performed the best at recovering the URs, while MP performed the worst. Both DD and MP are doing MAP inference, so the differences reflect the search error in MP. Interestingly, DD agrees more with SP than with MP, even though SP uses marginal inference.

Although the aggregate results on the EXERCISE dataset show a large improvement of DD over both of the BP algorithms, the gain all comes from the English language. SP actually does better than DD on Catalan and Maori, and MP also gets better results than DD on Maori, tying with SP.

For Model 2S, all inference methods achieved 100% accuracy on the EXERCISE dataset, so we do not show a table. The results on the CELEX dataset are shown in Table 2c. Here both DD and MP performed equally well, and outperformed BP—a result like (Spitkovsky et al., 2010). This trend is consistent over all three languages: DD and MP always achieve similar results and both outperform SP. Of course, one advantage of DD in the setting is that it actually finds the true MAP prediction of the model; the errors are known to be due to the model, not the search procedure.

For Model 2E, we show results on the EXERCISE dataset in Table 2d. Here the results resemble the pattern of Model 1.

7 Conclusion and Future Work

We presented a general dual decomposition algorithm for MAP inference on graphical models over strings, and applied it to an unsupervised learning task in phonology. The experiments show that our DD algorithm converges and gets better results than both max-product and sum-product BP.

Techniques should be explored to speed up the DD method. Adapting the MPLP algorithm (Sontag et al., 2011) to the string-valued case would be a nontrivial extension. We could also explore other serial update schemes, which generally speed up message-passing algorithms over parallel update.

Abstract

In this paper we present the first ever, to the best of our knowledge, discourse parser for multi-party chat dialogues. Discourse in multi-party dialogues dramatically differs from monologues since threaded conversations are commonplace rendering prediction of the discourse structure compelling. Moreover, the fact that our data come from chats renders the use of syntactic and lexical information useless since people take great liberties in expressing themselves lexically and syntactically. We use the dependency parsing paradigm as has been done in the past (Muller et al., 2012; Li et al., 2014). We learn local probability distributions and then use MST for decoding. We achieve 0.680 F_1 on unlabelled structures and 0.516 F_1 on fully labeled structures which is better than many state of the art systems for monologues, despite the inherent difficulties that multi-party chat dialogues have.

1 Introduction

Discourse parsing is a difficult, multifaceted problem involving the understanding and modeling of various semantic and pragmatic phenomena as well as understanding the structural properties that a discourse graph can have. Unsurprisingly, most extant theories and computational approaches postulate an extremely simplified version of discourse structure. One of the most widely cited theories, Rhetorical Structure Theory (RST) (Mann and Thompson, 1987; Mann and Thompson, 1988; Taboada and Mann, 2006), requires that only *adjacent* discourse units be connected together with a discourse relation. Another widely cited approach, the Penn Discourse Treebank (PDTB) (Prasad et al., 2008), focuses on decisions about the discourse connectives that label the attachment of potentially arbitrary text spans but does not make any claims as to what the overall discourse structure of the resulting annotation looks like. Further, all computational work on the PDTB takes the attachments as given in discourse parsing tasks. In both cases, the attachment problem, finding which discourse units are attached to which, is vastly simplified, though this has enabled researchers to explore various approaches for discourse parsing (Marcu, 2000; Sagae, 2009; Hernault et al., 2010; Joty et al., 2012).

Our paper's main contribution is to provide a discourse parsing model for multi-party chat dialogue (*i.e.* typed online dialogue), trained on a large corpus we have developed annotated with full discourse structures. We study attachment problem in detail for this genre, without using the simplifying hypotheses mentioned above that we know to be inadequate. In the following section, we describe the *Settlers of Catan* game and our corpus in more detail and discuss some problematic structures for discourse parsing from our corpus. We motivate our choice of a particular discourse theory, the Segmented Discourse Representation Theory (SDRT), as the underlying theoretical model for our annotations. In section 4 we present our parsing approach, which consists of building a local probability distribution model which serves as input to a series of decoder mechanisms. We present and discuss the results we obtain in section 5, while related work and conclusions are presented in sections 6 and 7 respectively.

2 What's so special about multi party dialogue?

Multi-party dialogue or multi-party chat involves multiple interlocutors that may address one or more interlocutors during their turn. For example,

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 928–937,
Lisbon, Portugal, 17-21 September 2015.

a person might pose a question that concerns all the participants; and once everybody has replied, that same person might reply to all of them with a single comment (e.g. thanking them) or with a single acknowledgment. Figure 1 provides an example from our corpus. In turn 234, gotwood4sheep asks a question and makes an underspecified offer to all the players. He then gets back negative responses to his question from inca, CheshireCatGrin and dmm; and then he broadcasts in 239 an acknowledgment of all the negative responses. That is, we have 235, 236 & 238 all attached to 234 as answers to the question in 234; and we have 239 that is attached to 235, 236 & 238 as an acknowledgment of the contents of those turns. A graphical representation is shown on the right of the same picture.

The presence of such structures makes a powerful case that the general framework guiding the annotation of multi-party dialogues should take *non-tree-like* graphs as the basic form of discourse structures. This will require then rethinking the task of discourse parsing when attempting to learn such structures. In particular, the following questions present themselves: 1) how many non-tree-like structures are there? 2) what are the constraints on discourse graphs, if they are not trees? 3) how far can traditional tree-based decoding mechanisms get us in dealing with such data?

Another complicated phenomenon in multi-party chat dialogues is the presence of crossing dependencies. Many theories of discourse structure like RST, given that they allow attachment only of adjacent spans will perforce not allow structures with crossing dependencies. Also theories that postulate a simple *right frontier constraint*, according to which only elements on the right frontier of a discourse structure (whether graph or tree) will in general not generate structures with crossing dependencies. However, crossing dependencies are commonplace in multi-party chat. Several subgroups of interlocutors can and do momentarily form and carry on a discussion amongst themselves, forming thus multiple concurrent discussion threads. Since, though, what is being written is publicly available to all involved parties, it can be the case that participants of one thread might reply or comment to something said to another thread. Figure 2 contains an example from our corpus.

There are at least three threads in this excerpt, and we have given them different fonts to aid the reader. The intuitive attachments in this excerpt involve the following crossing dependencies: (165, 168), (167,170), (176, 178), (177, 179), (175, 181), (177,182), and (180,183). We note also the lack of standard discourse markers such as those found in the PDTB or RST manuals, "personalized" orthography, the lack of elaborate syntactic structure and the frequent presence of sentence fragments, all of which means we cannot rely on sentential syntax to aid with discourse parsing (syntax is very useful in monologue discourse parsing, as witnessed by the dramatically higher scores for intra-sentential discourse parsing (Joty et al., 2015)). Multi-party dialogue presents a discourse parsing problem free of syntactic crutches.

The phenomena we have just described are just some of the complications that appear in the discourse representation of multi-party dialogues, unfortunately rendering discourse theories based on attaching only adjacent units unsuitable for the representation of multi-party dialogues. In order to be able to capture the discourse phenomena present in our chat corpus, we have decided to use the Segmented Discourse Representation Theory (SDRT) (Asher and Lascarides, 2003). This theory not only allows long distance attachments, which (Ginzburg, 2012) finds attested in multilogue, but also has semantics capable of dealing with fragments or non sentential utterances (Schlangen, 2003), which are frequent in our corpus. Also, it can model non-tree like structures, like that shown in Figure 1, which account for at least 9% of the links in our corpus. Such structures make theories that model discourse structures with rooted trees, like *Rhetorical Structure Theory* (RST) (Mann and Thompson, 1987) or simple dialogue models where attachments are always made to *Last*—cf. (Schegloff, 2007; Poesio and Traum, 1997)—unsuitable.

A final feature of discourse annotations that multi-party dialogue and monologue share is the presence of complex discourse units or CDUs. CDUs are in fact subgraphs of the discourse graph that have a rhetorical function or bear some discourse relation to another constituent. Examples are easy to come by. Consider the following example:

(1) gw: Do you have a sheep?
th: I do, if you give me an ore

234	18:55:02:745	gotwood4sheep	anyone got wheat for a sheep?
235	18:55:10:047	inca	sorry, not me
236	18:55:18:787	CheshireCatGrin	nope. you seem to have lots of sheep!
237	18:55:23:428	gotwood4sheep	yup baaa
238	18:55:32:308	dmm	i think i'd rather hang on to my wheat i'm afraid
239	18:55:47:845	gotwood4sheep	kk I'll take my chances then...

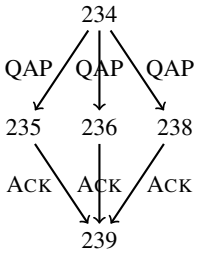

Figure 1: Dialogue excerpt showing the need for general graphs instead of trees.

165	lj	**anyone want sheep for clay?**
166	gw	**got none, sorry :(**
167	gw	so how do people know about the league?
168	wm	**no**
170	lj	i did the trials
174	tk	i know about it from my gf
175	gw	[yeah me too,]$_a$
		[*are you an Informatics student then, lj?*]$_b$
176	tk	did not do the trials
177	wm	**has anyone got wood for me?**
178	gw	[I did them]$_a$ [because a friend did]$_b$
179	gw	**lol william, you cad**
180	gw	**afraid not :(**
181	lj	*no, I'm about to start math*
182	tk	**sry no**
183	gw	**my single wood is precious**
184	wm	**what's a cad?**

Figure 2: Example of interleaved threads

th: or a wood.

Clearly, th's two turns combine to form a CDU that is then related by a conditional discourse relation to *I do*. That is *you give me an ore* and *or a wood* form together the antecedent to the conditional that he expresses. In order to reflect this semantic dependency, SDRT creates collections of Elementary Discourse Units (EDUs) forming a coherent discourse unit (called Complex Discourse Unit, CDU) and link it to any other discourse unit. The end result of this process is the creation of a hypergraph or, equivalently, a graph with two types of edges. Thus, our general conception of a discourse structure for a discourse $D = \{e_1, \ldots, e_n\}$, where e_i are the EDUs of D, is a tuple (V, E_1, E_2, ℓ), where V is a set of nodes or discourse units including $\{e_1, \ldots, e_n\}$, $E_1 \subseteq V \times V$ a set of edges representing discourse relations and $E_2 \subseteq V \times V$ a set of edges that represents parthood in the sense that if $(x, y) \in E_2$, then x is a discourse unit that is an element of the CDU y. ℓ: $E_1 \rightarrow$ *Relations* is a function that assigns each arc a discourse relation type. Our corpus contains many instances of CDUs, some of which are quite large, encompassing an entire question answering session like that seen in Figure 1.

3 The STAC corpus

The corpus that we use was collected from an online version of the game *The Settlers of Catan*. *Settlers* is a multi-party, win-lose game in which players use resources such as wood and sheep to build roads and settlements. In the standard online version, players interact solely through the game interface, making trades and building roads, etc., without saying a word. In our online version, players were asked to discuss and negotiate their trades via a chat interface before finalizing them non-linguistically via the game interface. As a result, players frequently chatted not only to negotiate trades, but to discuss numerous topics, some unrelated to the task at hand.

The *Settlers* corpus is ideal for studying multilogue. First, while the chats maintain the advantage of written text (no need for transcription), they approximate spoken communication. We have to deal with many sentence fragments, non-standard orthography and sometimes lack of syntax. Second, they manifest phenomena particular to multilogue, such as multiple conversation threads and non-tree-like structures.

The corpus consists of 59 games out of which 36 games have so far been annotated for discourse structure in the style of SDRT. Each game consists of several dialogues representing a single turn of the game. Each dialogue is treated as a separate document. About 10% of our corpus was held out for evaluation purposes while the rest was kept for training. Detailed statistics on the number of dialogues, EDUs and relations contained in each subcorpus can be found in table 1.

The dialogues in our corpus have an average size of 10 EDUs with 8 speaker turns, though the longest has 156 EDUs and 119 turns. The vast majority of our discourse connections thus lie between turns. All dialogues also have a dialogue act

	Total	Training	Testing
Dialogues	1091	968	123
EDUs	10677	9545	1132
Relations	11348	10158	1190

Table 1: Dataset overview

style annotation in which each EDU is assigned a particular type (it can be an offer or counter-offer, an acceptance or refusal, or other) (Sidner, 1994a; Sidner, 1994b). The dialogue act annotations have been used to train an automatic classifier for EDUs (Cadilhac et al., 2013). This large annotation effort was carried out by 4 annotators who had no special knowledge of linguistics, but who received training over 22 negotiation dialogues with 560 turns. Because annotating full discourse structures is a very complex task (using an exact match criterion of success, the inter annotator agreement score was a Kappa of 0.72 attachment on structures, 0.58 on labelling (Afantenos et al., 2012a)), experts made several passes over the annotations from the naive annotators, improving the data and debugging it.

The discourse graphs in our development corpus exhibited several interesting properties. First of all they are DAGs with a unique root, one unit that has no incoming edges. Secondly, the graphs are weakly connected in almost all cases: i.e., every discourse unit in it is connected to some other discourse unit. Thirdly, our graphs are *reactive* in the sense that speakers' contributions are reactions and attach anaphorically to prior contributions of other speakers. This means that edges between the contributions of different speakers are always oriented in one direction. This is a general feature of dialogue, as we explain in the next section.

4 Model

4.1 Dependency Structures

For a given discourse graph for SDRT of the form (V, E_1, E_2, ℓ), we have as yet no general and reliable method to calculate edges in E_2; and no such method has been presented in the literature. In order to perform constrained decoding over local probability distributions, we have opted for a strategy first presented in Muller et al. (2012) for SDRT. The strategy involves transforming hypergraphs into dependency graphs. We transform our full graphs (V, E_1, E_2, ℓ) into dependency structures (V', E_1, ℓ), with $V' \subset V$ the set of EDUs in V by replacing any attachment to a CDU with an attachment to the CDU's head—the textually first EDU within the CDU which has no incoming links. Our transformation in effect sets E_2 in our general definition of a graph to $\emptyset$. In the case that we have a discourse relation between two EDUs, this relation is kept intact since it already represents a dependency arc. In case a discourse relation has one or two CDUs as arguments, the CDUs need to be replaced with their *recursive head*. In order to calculate the recursive head we identify all the DUs with no incoming links; if they are CDUs we recursively apply the algorithm until we get an EDU. If there is more than one EDU with no incoming links we pick the leftmost, i.e. the one firstly introduced in the text.

Hirao et al. (2013) and Li et al. (2014) later followed a similar strategy for the creation of dependency structures for RST. Every single nucleus-satellite relation was transformed into a dependency relation with the governor being the EDU representing the nucleus and the dependent being the satellite. For relations between non-EDU higher spans, the recursive head was used. It is unclear how Li et al. (2014) deal with binary multinucleus relations like CONTRAST for example; it is not clear how to calculate the recursive head of the span.[1] In such cases an arbitrary decision—like always taking as the nucleus the leftmost or the rightmost span—has to be taken. In the SDRT annotations, however, every edge in the graph is already directed and so such arbitrary decisions can be avoided.

Ideally, what one then wants is to learn a function

$$h : \mathcal{X}_{E^n} \mapsto \mathcal{Y}_{\mathcal{G}}$$

where $\mathcal{X}_{E^n}$ is the domain of instances representing a collection of EDUs for each dialogue and $\mathcal{Y}_{\mathcal{G}}$ is the set of all possible SDRT graphs. However, given the complexity of this task and the fact that it would require an amount of training data that we currently lack in the community, we aim at the more modest goal of learning a function

$$h : \mathcal{X}_{E^2} \mapsto \mathcal{Y}_R$$

where the domain of instances $\mathcal{X}_{E^2}$ represents features for a pair of EDUs and $\mathcal{Y}_R$ represents the

[1] Although Li et al. (2014) do explain how to treat n-ary multinuclear relations, following others (Hernault et al., 2010, for example).

set of SDRT relations. The upshot of this is that we are building a local sort of model that learns relations between individual EDUs with a certain probability but that it does not learn a local or even global structure.

One of the drawbacks of this approach, however, is that it does not guarantee an object that is well formed. Learning a probability distribution over EDUs and then choosing the most probable relation or attachment for each pair of EDUs potentially leads to structures that contain cycles. To avoid this, we can't blindly choose the most probable relation or attachment decision for each pair of EDUs. Instead, we should use this probability distribution as an input to a decoding mechanism.

4.2 Local probability distributions

We used a regularized maximum entropy (shortened as MaxEnt) model (Berger et al., 1996). In MaxEnt, we estimate the parameters of an exponential model of the following form:

$$P(r|p) = \frac{1}{Z(c)} \exp\left(\sum_{i=1}^{m} w_i f_i(p, r)\right)$$

where p represents the current pair of EDUs and r the learnt label (i.e. the type of relation, or a binary attachment value between the two EDUs). Each pair of EDUs p is encoded as a vector of m indicator features f_i (see table 2 for more details). There is one weight/parameter w_i for each feature f_i that predicts its classification behavior. Finally, $Z(c)$ is a normalization factor over the different class labels, which guarantees that the model outputs probabilities. In MaxEnt, the values for the different parameters $\hat{w}$ are obtained by maximizing the log-likelihood of the training data T with respect to the model (Berger et al., 1996):

$$\hat{w} = \operatorname*{argmax}_{w} \sum_{i}^{T} \log P(r^{(i)}|p^{(i)})$$

4.3 The turn constraint

Given our observations about the structure of dialogues in our corpus, we hypothesize that a dialogue is fundamentally sequential: first one person talks and then others react to them or ignore them, but the discourse links that do occur between speaker turns are *reactive*. In other words, a turn can't be anaphorically and rhetorically dependent on a turn that comes after it. Thus, the nature of dialogue imposes an essential and important constraint on the attachment process that is not present for monologue or single-authored text, where an EDU may be dependent upon any EDU, later in the ordering or not: in dialogue there are no "backwards" rhetorical links such that an EDU in turn n by speaker a is rhetorically and anaphorically dependent upon an EDU in turn $n + m$ of speaker b with $a \neq b$. We call this the *Turn Constraint*. Within a turn, however, just as in monologue (as is evident from a study of most styles of discourse annotations of text), backwards links are allowed.

Given this observation, we decided to split our local model into two different ones. The first one concerns the learning of a model for intra-turn utterances,[2] while the second models inter-turn utterances. The intra-turn model considers as input during learning all pairs of EDUs (i, j) with $i \neq j$. The inter-turn model on the other hand does not contain any backward links during learning. In other words it takes as input all pairs of EDUs (i, j) with $i < j$. We apply the turn constraint not only during learning of the local models, but also during decoding. This practice is also followed—at the sentence level—for monologues (Wellner and Pustejovsky, 2007; Joty et al., 2012; Joty et al., 2013), though our turn constraint, we believe, is firmly supported not only by our data but also by a good theoretical model of dialogue.

4.4 Decoders

The local probability distributions obtained are used as decoder inputs. We have experimented with several decoders. As a baseline measure we have included what we call a LOCAL decoder which creates a simple classifier out of the raw local probability distribution. In the case of MaxEnt, for example, this decoder selects

$$\hat{r} = \operatorname*{argmax}_{r} \left(\frac{1}{Z(c)} \exp\left(\sum_{i=1}^{m} w_i f_i(p, r)\right)\right)$$

with r representing a relation type or a binary attachment value. We also used the baseline LAST, where each EDU is attached to the immediately preceding EDU in the linear, textual order.

[2] EDUs are considered as belonging to the same turn if they are by the same speaker without any interjection from an other speaker. In other words any consecutive EDU by the same speaker is considered as belonging to the same turn.

Maximum Spanning Trees To answer our questions, "how many non-tree-like structures are there?" and "how far can tree decoding algorithms get us in multi-party dialogue?", our first decoder is the classic Maximum Spanning Trees (MST) algorithm— used by McDonald et al. (2005) for syntactic dependency parsing as well as by Muller et al. (2012) and Li et al. (2014) for discourse parsing—tweaking it in order to produce structures that are closer to the ones specific to multi-party dialogue. We are looking for:

$$T^* = \underset{T \text{ a spanning tree of } G}{\operatorname{argmax}} \sum_{e \in E(T)} w(e)$$

$$w(e) = \log\left(\frac{p(e)}{1 - p(e)}\right)$$

G being the complete graph of possible edges returned by the classifiers ; $E(D)$ representing the edges of D. The weight function w computes the log-odds of the probability returned by the model.

We used Chu-Liu-Edmonds version of the MST algorithm (Chu and Liu, 1965; Edmonds, 1967), which requires a specific node to be the root, i.e. a node without any incoming edges, of the initial complete graph. For each dialogue, we made an artificial node as the root with special dummy features. At the end of the procedure, this node points the real root of the discourse graph.

Combining intra- and inter-turn models with the turn constraint As described above, we learn a separate local model for intra- and inter-turn EDUs. We also use the turn constraint during decoding. For the intra-turn decoding, we have experimented with various options. One concerns the creation of a classifier out of the local probability distribution. Another intra-turn decoder is Last, which always takes the last EDU for attachment. Finally we also used MST.

We used the exact same decoding approaches for inter-turn decoding. With the structure for the inter-turn EDUs produced separately, we replace those structures with their heads. The detection of a structure's head, be it intra- or inter-turn, uses the same trick as McDonald et al. (2005) did for syntactic parsing: inserting a dummy node as a fake head which contains only outgoing links enabling us essentially to learn the real head of our structures. Our best overall model used Last to link EDUs inside the turn together with MST and the turn constraint for predicting the global structure.

Category	Description
Positional	Speaker initiated the dialogue
-	First utterance of the speaker in the dialogue
-	Position in dialogue
-	*Distance between EDUs*
-	*EDUs have the same speaker*
Lexical	Ends with exclamation mark
-	Ends with interrogation mark
-	Contains possessive pronouns
-	Contains modal modifiers
-	Contains words in lexicons
-	Contains question words
-	Contains a player's name
-	Contains emoticons
-	First and last words
Parsing	Subject lemmas given by syntactic dependency parsing
-	Dialogue act according to predicting model

Table 2: Feature set description. Pair features are italicized.

5 Experiments and Results

To train our local models, we extracted features for every pair of EDUs in a given dialogue. Our features concern the pair of EDUs as well as features related to each EDU specifically. The feature set, detailed in Table 2, can be summarized as follows:

- Positional features: (related to) the non-linguistic context of the pair;
- Lexical features: single words[3] and punctuation present in the EDUs;
- Parsing features: dependency[4] and dialogue act[5] tagging.

Table 3 shows our results on our unseen test corpus, which contains a randomly selected 10% of dialogues in our corpus. The best configuration was selected after performing ten-fold cross validation on the training corpus. The reported results implement the turn-constraint during training

[3]We use a number of lexicons (opinion markers, quantifiers, etc.), each corresponding to a feature

[4]Provided by the Stanford CoreNLP pipeline (Manning et al., 2014).

[5]The prediction model of Cadilhac et al. (2013) generates EDU tags such as *Offer*, *Refusal*, etc.

for the local models. In other words, training instances for the local models include only forward links.

We used two baselines. The first one, Last, simply attaches every EDU to its previous one. This is a very strong baseline in discourse parsing (Muller et al., 2012, for example). The second baseline is essentially the local classifier without any further decoding; in other words, we simply select the class with the highest probability both for attachment and labeling. Attaching to last gives us an F-score of 0.584 for attachment and 0.391 when we add the relations as well. Using only classification from the local probability distribution without decoding gives 0.541 for attachment and 0.446 for attachments and relations.

The best results for the global parsing problem exploited the turn constraint both during learning the local model and during decoding. Within a turn, our discourse structures are simple and largely linear; the best intra-turn results came from using Last. Most of our interlocutors did not create elaborate discourse structures with long-distance attachments within the same turn. The inter-turn level was a different story, as the figures show. For inter-turn and the global problem, MST using the heads of the intra-turn substructures computed with Last, produced the best results. The F1 score for unlabeled structures is at 0.671 while for labelled structures we have 0.516. To enable a comparison with RST style parsing where exact arguments for discourse relations are not computed, the undirected attachment F1 score = 0.68 for the global parsing problem.

Despite the inherent difficulty of discourse parsing on multi-party chat dialogues (simultaneous, multiple discussion threads, lack of syntax) our results are close to or better than the current state of the art for discourse parsing on monologue. There are two approaches currently that use dependency parsing strategies for discourse, thoroughly described in the next section. Li et al. (2014) report an accuracy of 0.7506 for unlabelled structures and 0.4309 for the full labelled structures. Muller et al. (2012) report 0.662 for unlabelled structure and 0.361 for labelled structures. We outperform both systems for full labelled structures, and despite our non-tree-like structures beat or are close to these on unlabelled attachments. Though comparisons across different corpora are difficult, the numbers suggest that our results are more than competitive. Our results also suggest that one can get quite far with tree-based decoding algorithms, though we know that in principle MST cannot do better than 91% even with a perfect local model (a model in which an arc is giving probability 1 just in case it occurs in the gold standard annotation).

6 Related Work

To date, discourse parsing has almost exclusively been applied to monologue. Multi-party chat dialogues have never been considered before. Baldridge and Lascarides (2005) predicted tree discourse structures for 2 party "directed" dialogues from the Verbmobil corpus by training a PCFG that exploited the structure of the underlying task. Elsner and Charniak (2010), Elsner and Charniak (2011) are presenting a combination of local coherence models initially provided for monologues showing that those models can satisfactorily model local coherence in chat dialogues. Nonetheless they do not present a full-fledged discourse parsing model. Our data required a more open domain approach and a more sophisticated approach to structure.

Our use of dependency parsing for learning discourse structure has a few antecedents in the literature on monologue. One of the first papers to introduce this technique is Muller et al. (2012), working with a small French language corpus, ANNODIS (Afantenos et al., 2012a). They use a similar approach to us, including the classic version of the MST decoder. They also used an A^* search as another decoding mechanism but it gave the same results as MST. As we have said, our results better theirs both on attachment and full labeled structures. In the context of RST, Hirao et al. (2013) and Li et al. (2014) transform RST trees into dependency structures; we have discussed their in section 4.1. Li et al. (2014) use both the Eisner algorithm (Eisner, 1996) as well as the MST algorithm from McDonald et al. (2005). As we mentioned, our labelled scores are higher than theirs, though we are cautious of making comparisons across such different corpora.

Most work on discourse parsing focuses on the task of discourse relation labeling between pairs of discourse units—e.g., Marcu and Echihabi (2002) Sporleder and Lascarides (2005) and Lin et al. (2009). This corresponds to our local model. As we have shown in this paper, this setting makes an unwarranted assumption, as it assumes inde-

Method	Undirected Attachment			Directed Attachment			Full Labelled Structure		
	prec	rec	F1	prec	rec	F1	prec	rec	F1
LAST	0.602	0.566	0.584	0.602	0.566	0.584	0.403	0.379	0.391
LOCAL	0.698	0.488	0.574	0.623	0.478	0.541	0.513	0.394	0.446
INTRA-TURN	0.837	0.955	0.892	0.808	0.922	0.861	0.489	0.558	0.521
INTER-TURN	0.617	0.516	0.562	0.616	0.514	0.561	0.492	0.411	0.448
GLOBAL	0.697	0.663	0.680	0.688	0.655	0.671	0.529	0.503	0.516

Table 3: Evaluation results.

pendence of local attachment decisions. There is also work on discourse structure within a single sentence; e.g., Soricut and Marcu (2003) makes use of dynamic programming along with a standard bottom-up chart parsing, while Sagae (2009) uses shift-reduce algorithm for intra-sentential discourse analysis. Such approaches do not apply to our data, as most of the structure in our dialogues lies beyond the sentence level.

As for document-level discourse parsers, Subba and Di Eugenio (2009) use a transition-based approach, following the paradigm of Sagae (2009). duVerle and Prendinger (2009) and Hernault et al. (2010) both rely on locally greedy methods. Like us, they treat attachment prediction and relation label prediction as independent problems. Feng and Hirst (2012) extend this approach by additional feature engineering but is restricted to sentence-level parsing. Finally, Joty et al. (2012) present a sentence-level discourse parser that uses Conditional Random Fields to capture label interdependencies and chart parsing for decoding. Joty et al. (2013) and Joty et al. (2015) extend this approach on the level of documents and have the best results non-dependency based discourse parsing, with an F1 of 0.689 on unlabelled structures and 0.5587 on labelled structures. Our scores are very close to Joty et al.'s, however, and achieved with much simpler methods than theirs.

7 Conclusions

As far as we know, this is the first paper to deal with discourse parsing in multi-party chat dialogues. We believe that such data will be useful for other discourse parsing tasks like analyzing fora with multi-threads. We have used the STAC corpus (Afantenos et al., 2012b) for our data. To simplify the parsing task, we transformed our SDRT structures into dependency ones. We used two different local probability distribution models as input to several decoding mechanisms, including one based on the Maximum Spanning Tree algorithm, and an enhanced version of it in order to produce structures closer to the ones we observe. We obtain the best results using the enhanced version of the MST algorithm. In future work, we plan to investigate ILP constraints in greater depth to develop a plausible alternative to MST on DAGs.

Abstract

We introduce a new approach to argumentation mining that we applied to a parallel German/English corpus of short texts annotated with argumentation structure. We focus on structure prediction, which we break into a number of subtasks: relation identification, central claim identification, role classification, and function classification. Our new model jointly predicts different aspects of the structure by combining the different subtask predictions in the edge weights of an evidence graph; we then apply a standard MST decoding algorithm. This model not only outperforms two reasonable baselines and two data-driven models of global argument structure for the difficult subtask of relation identification, but also improves the results for central claim identification and function classification and it compares favorably to a complex mstparser pipeline.

1 Introduction

Argumentation mining is a task that has drawn increased interest in the last years. In its full-fledged version, it seeks to automatically recognize the structure of argumentation in a text by identifying and connecting the central claim of the text, supporting premises, possible objections, and counter-objections to these objections.[1]

A variety of applications can profit from access to the argumentative structure of text, including the retrieval of relevant court decisions from legal databases (Palau and Moens, 2011), automatic document summarization systems (Teufel and Moens, 2002), the analysis of scientific papers in biomedical text mining (Teufel, 2010; Liakata et al., 2012), or essay scoring. Importantly, argument analysis can also be an extension of opinion mining applications.

To make argumentation structures available for these applications, their robust automatic recognition is required, a task that is very challenging: argumentative strategies and styles vary across text genres and languages; classifying arguments might require domain knowledge; furthermore, argumentation can often rely on implicitly conveyed messages.

The full-fledged task can be decomposed into several subtasks:

- Segmentation: splitting the text into elementary discourse units (EDUs as used in general kinds of discourse parsing, typically sentences or clauses)
- Identification of argumentative discourse units (ADUs): discarding argumentatively irrelevant EDUs, joining adjacent EDUs to form larger ADUs
- ADU type classification: determining the type of argumentative unit; different schemes have been proposed, involving stance, evidence types, rhetorical status, argumentative function
- Relation identification: building a connected tree- or graph-structure to represent argumentative relations between the ADUs
- Relation type classification: determining the type of argumentative relation (e.g. supporting versus attacking relations or more fine-grained types)

In this paper, we address the last three subtasks: Given a text segmented into relevant ADUs, identify the argumentation structure. We will work with a bilingual corpus of short texts that have been generated in a text production experiment.

[1] A comprehensive overview of the research field is given in (Peldszus and Stede, 2013).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 938–948,
Lisbon, Portugal, 17-21 September 2015.

The next section describes related work. In section 3, we present the dataset used in our experiments. Section 4 gives a more detailed description of the task. The baselines and the models are presented in section 5. We then report the result of our experiments in section 6 and close with some concluding remarks.

2 Related Work

In our discussion of related work, we focus on the three subtasks addressed in this paper:

ADU type classification: One typical classification task concerns the properties of a segment in the argumentation structure: Burstein and Marcu (2003) trained classifiers for identifying thesis and conclusion statements in student essays, using additional automatic discourse parse features and cue words, resulting in an average F-score of 53% for thesis and 80% for conclusion segments. For legal texts, Palau and Moens (2011) demonstrated in their influential work how to classify the segment of a text into premises and conclusions, obtaining an F-score of 68% and 74% for the two classes. More recently, Stab and Gurevych (2014) classified segments in student essays into the classes major claim (of the text), claim (of the paragraph), premise and irrelevant. The macro average F-score for all classes is 73%, the F-score for the claim of the paragraph 54% and for the major claim 63%.

Besides structural segment-wise classification tasks, there is also work on more semantic tasks: The rhetorical status of a segment is classified in the argumentative zoning approaches (Teufel and Moens, 2002; Teufel and Kan, 2011; Liakata et al., 2012), where certain coarse-grained patterns of argumentation in scholarly papers can be captured. Park and Cardie (2014) focus on supporting segments and classify which type of evidence is presented in it. Finally, stance classification (Hasan and Ng, 2013) might be of interest to identify possible objections, although it is typically applied on full comments and not on single segments.

Relation identification: Much less prior work can be found for the process of building argumentation structures. Palau and Moens (2011) used a hand-written context-free grammar to predict argumentation trees on legal documents, achieving an accuracy of 60%. Only recently, data-driven approaches have been applied. Lawrence et al. (2014) construct tree structures on philosophical texts using unsupervised methods based on topical distance between the segments. The relations in the tree are neither labeled not directed. Unfortunately, the method was evaluated on only a few annotated items, which is why we cannot comment on the results. Finally, Stab and Gurevych (2014) present a supervised data-driven approach for relation identification. They predict attachment for support-graphs spanning over paragraphs of English essays and obtain a macro F1 score of 72%, and an F1 score of 52% for positive attachment. No decoding is used to optimize global predictions per text.

Relation type classification: The only study on explicitly classifying argumentative relations we are aware of is (Feng and Hirst, 2011). They classify pairs of premise and conclusion from newswire text into a set of five frequently used argumentation schemes in the sense of Walton et al. (2008). In one-against-others classification, the system yields best average accuracies of over 90% for two schemes, while for the other three schemes the results are between 63% and 70%.

To the best of our knowledge, no data-driven model of argumentation structure has been proposed yet that would optimize argumentation structure globally for the complete input text, as it is done in other discourse parsing tasks, e.g. in (Muller et al., 2012).

3 Dataset

Texts: We use the *arg-microtext* corpus (Peldszus and Stede, to appear), a freely available[2] parallel corpus of 112 short texts with 576 ADUs. The texts are authentic discussions of controversial issues. They were originally written in German and have been professionally translated to English, preserving the segmentation and if possible the usage of discourse markers. The texts have been collected in a controlled text generation experiment, with the result that all of them fulfill the following criteria: (i) The length of each text is about 5 ADUs (henceforth: segments). (ii) One segment explicitly states the central claim. (iii) Each segment is argumentatively relevant. (iv) At least one objection to the central claim is considered.

Scheme: The argumentation structure of every text has been annotated according to a scheme (Peldszus and Stede, 2013) based on Freeman's theory of argumentation structures (Free-

[2]https://github.com/peldszus/arg-microtexts

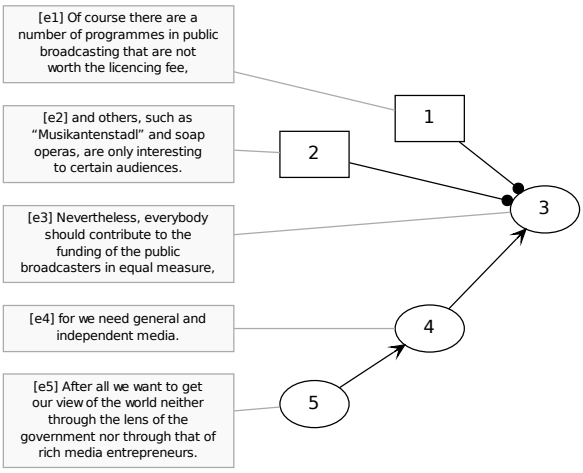

Figure 1: An example text and its reduced argumentation structure: Text segments, proponent (round) and opponent (box) nodes, supporting (arrow-head) and attacking (circle-head) relations.

man, 1991; Freeman, 2011), that has been proven to yield reliable structures in annotation experiments (Peldszus, 2014). The argumentation structure of a text is defined as a graph with the text segments as nodes. Each node is associated with one argumentative *role*: the proponent who presents and defends the central claim, or the opponent who critically questions the proponent's claims. Edges between the nodes represent argumentative relations, and each edge is of one specific argumentative *function*: support or attack. The scheme allows to discriminate between "rebutting" attacks, targeting another node and thereby challenging its acceptability, and "undercutting" attacks, targeting an edge and thereby challenging the acceptability of the inference from the source to the target node. It can also represent linked support, where multiple premises jointly support a claim.

Transformation: The annotated graph structures can be quite complex, especially when they involve undercutting relations and linked support. For the purpose of this study, we thus reduce the graphs to a simpler tree-like representation. All relations pointing to edges are rewritten to point to the source node of the original target edge, which enables the use of standard graph algorithms (like MST). Also, this is a loss-less mapping, given that every segment has only one outgoing arc (as generally done in argumentation models). Furthermore, the set of relation types is reduced to the simple binary distinction between support and attack. We think this is a reasonable simplification that facilitates comparisons with slightly different approaches/datasets (we are not aware of any dataset that makes use of the full granularity proposed in our scheme).

An example text from the corpus in its reduced form is shown in Figure 1. Text boxes are EDUs, each of which constitutes also an ADU. Proponent ADUs are round nodes, opponent ADUs are box nodes. Supporting relations have a normal arrowhead, while attacking relations have a circle arrowhead.

All statistics on the annotated argumentation structures apply equally for the German and the English version of the parallel corpus.

4 Task

Identifying the structure of argumentation according to our scheme involves choosing one segment as the central claim of the text, deciding how the other segments are related to the central claim and to each other, identifying the argumentative role of each segment, and finally the argumentative function of each relation.

Our prior experiments on automating the recognition of argumentation structure approached the problem as a segment-wise classification task (Peldszus, 2014). Formulating the task this way was successful for the recognition of argumentative role and function of a segment. For the automation of the structure building however, the segment-wise classification of attachment with only a small context window around the target segment proved to be a very hard task. This is due to the long-distance dependencies frequently found in argumentation graphs. For example, 46% of the relations marked in the corpus used for this study involve non-adjacent segments. For longer texts this number might increase further: Stab and Gurevych (2014) report a rate of 63% of non-adjacent relations in their corpus.

In this study we therefore frame the task of attachment classification as a binary decision, where the classifier, when given a pair of a source and a target segment, chooses whether or not to establish a relation from the source to the target. Since these relations can hold not only between adjacent but between arbitrary segments of the text, all possible combinations of segments are required to be tested. Consequently, the class distribution is very skewed.

- **attachment (at):** Is there an argumentative

connection between the source and the target segment? In the corpus, a relation has been annotated for 464 segment pairs, no relation has been annotated for the combinatorially remaining 2000 pairs of segments.

In this paper we first address only the task of attachment classification, and then the prediction of the full graph, involving all other levels:

- **central claim (cc):** Is the current segment the central claim of the text? In our data 112 of the 576 segments are central claims.
- **role (ro):** Does the current segment present a claim of the proponent or the opponent? In our data 451 of the 576 segments are proponent segments and 125 are opponent segments.
- **function (fu):** Has the current segment a supporting or an attacking function? In our data, 290 segments are supports, 174 are attacks and 112 are the central claim and thus have no own function.

5 Models

We compare two heuristic baseline models and different data-driven models that we developed, each of them trained and evaluated separately on both language versions of the corpus. All models are evaluated on the basis of 10 iterations of 5x3-fold nested cross validation (CV). The outer 5-fold CV is for evaluation only, i.e. to ensure that the model is trained only on training data and tested only on test data. If a model requires hyperparameters to be tuned or multiple passes, then this is achieved via one (or multiple) inner 3-fold CV over the training data only. The folding is stratified, randomly distributing the texts of the corpus while aiming to reproduce the overall label distribution in both training and test set.

5.1 Baseline: attach to first

In the English-speaking school of essay writing and debating, there is the tendency to state the central claim of a text or a paragraph in the very first sentence, followed by supporting arguments. It is therefore a reasonable baseline to assume that all segments attach to the first segment. In our corpus, the first segment is the central claim in 50 of the 112 texts (44.6%).

This baseline (**BL-first**) will not be able to capture serial argumentation, where one more general argument is supported or attacked by a more specific one. However, it will cover convergent argumentation, where separate arguments are put forward in favor of the central claim (given that it is expressed in the first segment). It will always produce flat trees. In our corpus, 176 of the 464 relations (37.9%) attach to the first segment.

5.2 Baseline: attach to preceding

A typically very strong baseline in discourse parsing is attaching to the immediately preceding segment (Muller et al., 2012). Possibly, this holds more for corpora with relations often or always being adjacent, as in rhetorical structure trees. Since argumentation structures often exhibit non-adjacent relations (see above), this heuristic might be easier to beat in our scenario.

This baseline (**BL-preced.**) will always produce chain trees and thus cover serial argumentation, but not convergent argumentation. In our corpus, 210 of all 464 relations (45.3%) attach to the preceding segment.

5.3 Learned attachment without decoding

We train a linear log-loss model (**simple**) using stochastic gradient descent (SGD) learning, with elastic net regularization, the learning rate set to optimal decrease and class weight adjusted according to class distribution (Pedregosa et al., 2011). The following hyper parameters are tuned in the inner CV: the regularization parameter alpha, the elastic net mixing parameter and the number of iterations. We optimize macro averaged F1-score.

For each text segment, we extract binary features for lemma, pos-tags, lemma- and pos-tag-based dependency-parse triples and the main verb morphology (Bohnet, 2010), and discourse connectives (Stede, 2002), furthermore simple statistics like relative segment position, segment length and punctuation count. For each pair of text segments, we extract relative distance between the segments and their linear order (is the source before or after the target). The feature vector for each pair then contains both the pair features and the segment features for source and target segment and their adjacent segments.[3]

[3] We experimented with several features, some of which were dismissed from the final evaluation runs due to lacking impact: sentiment values and the presence of negation for

5.4 Learned attachment with MST decoding

The simple model just described might be able to learn which segment pairs actually attach, i.e., correspond to some argumentative relation in the corpus. However it is not guaranteed to yield predictions that can be combined to a tree structure again. A more appropriate model would enforce global constraints on its predictions. In the **simple+MST** model, this is achieved by a *minimum spanning tree* (MST) decoding, which has first been applied for syntactic dependency parsing (McDonald et al., 2005a; McDonald et al., 2005b) and later for discourse parsing (Baldridge et al., 2007; Muller et al., 2012). First, we build a fully-connected directed graph, with one node for each text segment. The weight of each edge is the attachment probability predicted by the learned classifier for the corresponding pair of source and target segment. We then apply the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967) to determine the minimum spanning tree, i.e., the subgraph connecting all nodes with minimal total edge cost (in our case highest total edge probability). This resulting tree then represents the best global attachment structure for a text given the predicted probabilities.

5.5 Joint prediction with MST decoding

All models presented in the previous subsections have in common that they do not rely on other features of the argumentation graph. However, it is fair to assume that knowledge about the argumentative role and function of a segment or its likeliness to be the central claim might improve the attachment classification. Consequently, our next model considers not only the predicted probability of attachment for a segment pair, but also the predicted probabilities of argumentative role, function and of being the central claim for each segment. The predictions of all levels are combined in one *evidence graph*.

Additional segment-wise base classifiers: We train base classifiers for the role, function and central claim level using the same learning regime as described in Section 5.3. Contrary to the attachment classification, the items are not segment pairs but single segments. We thus extract all segment-based features as described above for the target segment and its adjacent segments.

segments, and distance measures between pairs of segments in terms of word-overlap, td-idf and LDA distributions.

Combining segment and segment-pair predictions: Our goal in this model is to combine the predicted probabilities of all levels in one edge score, so that the MST decoding can be applied as before. Figure 2 depicts the situation before and after the combination, first with separate prediction for segments and segment pairs and then with the combined edge scores.

The evidence graph is constructed as follows: First, we build a fully connected multigraph over all segments with as many edges per segment-pair as there are edge types. In our scenario there are two edge types, supporting and attacking edges. Then we translate the segment-wise predictions into level-specific edge scores.

The edge-score for the central claim level $\overline{\text{cc}}_{i,j}$ is equal to the probability of the edge's source not being the central claim, which is capturing the intuition that central claims are unlikely to have outgoing edges:

$$\overline{\text{cc}}_{i,j} = \quad p(\text{cc}_i = \text{no}) \tag{1}$$

The edge-score for the argumentative function level $\overline{\text{fu}}_{i,j}$ is equal to the probability of the source being the corresponding segment for the edge type:

$$\overline{\text{fu}}_{i,j} = \begin{cases} p(\text{fu}_i = \text{sup}) & \text{for sup. edges} \\ p(\text{fu}_i = \text{att}) & \text{for att. edges} \end{cases} \tag{2}$$

The edge-score for the argumentative role level $\overline{\text{ro}}_{i,j}$ is also determined by the edge type. Attacking edges involve a role switch (proponent or opponent would not attack their own claims), while supporting edges preserve the role (proponent or opponent will only support their own claims):

$$\overline{\text{ro}}_{i,j} = \begin{cases} p(\text{ro}_i = \text{pro}) \times p(\text{ro}_j = \text{pro}) + \\ p(\text{ro}_i = \text{opp}) \times p(\text{ro}_j = \text{opp}) & \text{for sup. edges} \\ \\ p(\text{ro}_i = \text{pro}) \times p(\text{ro}_j = \text{opp}) + \\ p(\text{ro}_i = \text{opp}) \times p(\text{ro}_j = \text{pro}) & \text{for att. edges} \end{cases} \tag{3}$$

Finally, of course the edge-score for the attachment level $\overline{\text{at}}_{i,j}$ is equal to the probability of attachment between the segment pair:

$$\overline{\text{at}}_{i,j} = \quad p(\text{at}_{i,j} = \text{yes}) \tag{4}$$

The combined score of an edge $w_{i,j}$ is then defined as the weighted sum of the level-specific edge score:
