Abstract

This paper proposes a novel approach to generate abstractive summary for multiple documents by extracting semantic information from texts. The concept of *Basic Semantic Unit* (*BSU*) is defined to describe the semantics of an event or action. A semantic link network on *BSUs* is constructed to capture the semantic information of texts. Summary structure is planned with sentences generated based on the semantic link network. Experiments demonstrate that the approach is effective in generating informative, coherent and compact summary.

1 Introduction

Most automatic summarization approaches are extractive which leverage only literal or syntactic information in documents. Sentences are extracted from the original documents directly by ranking or scoring and only little post-editing is made (Yih et al., 2007; Wan et al., 2007; Wang et al., 2008; Wan and Xiao, 2009). Pure extraction has intrinsic limits compared to abstraction (Carenini and Cheung, 2008).

Abstractive summarization requires semantic analysis and abstract representation of texts, which need knowledge on and beyond the texts (Zhuge, 2015a). There are some abstractive approaches in recent years: sentence compression (Knight and Marcu, 2000; Knight and Marcu, 2002; Cohn and Lapata, 2009), sentence fusion (Barzilay and McKeown, 2005; Filippova and Strube, 2008), and sentence revision (Tanaka et al., 2009). However, these approaches are sentence rewriting techniques based on syntactical analysis without semantic analysis and abstract representation.

Fully abstractive summarization approach requires a separate process for the analysis of texts that serves as an intermediate step before the generation of sentences (Genest and Lapalme, 2011). Statistics of words or phrases and syntactical analysis that have been widely used in existing summarization approaches are all shallow processing of text. It is necessary to explore summarization methods based on deeper semantic analysis.

We define the concept of *Basic Semantic Unit* (*BSU*) to express the semantics of texts. A *BSU* is an action indicator with its obligatory arguments which contain actor and receiver of the action. *BSU* is the most basic element of coherent information in texts, which can describe the semantics of an event or action. The semantic information of texts is represented by extracting *BSUs* and constructing *BSU* semantic link network (Zhuge, 2009). Semantic Link Network consists of semantic nodes, semantic links and reasoning rules (Zhuge, 2010; 2011; 2012; 2015b). The semantic nodes can be any resources. In this work, the semantic nodes are *BSUs* extracted from texts. We use semantic relatedness between *BSUs* as semantic links. Then summary can be generated based on the semantic link network through summary structure planning.

The characteristics of our approaches are as follows:

- Each *BSU* describes the semantics of an event or action. The semantic relatedness between *BSU*s can capture the context semantic relations of texts.
- The *BSU* semantic link network is an abstract representation of texts. Reduction on the network can obtain important information of texts with no redundancy.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1908–1913,
Lisbon, Portugal, 17-21 September 2015.

- Summary is built from sentence to sentence to a coherent body of information based on the *BSU* semantic link network by summary structure planning.

2 Related Work

There are some abstractive summarization approaches in recent years. An approach *TTG* attempts to generate abstractive summary by using text-to-text generation to generate sentence for each subject-verb-object triple (Genest and Lapalme, 2011). A system that attempts to generate abstractive summaries for spoken meetings was proposed (Wang and Cardie, 2013). It identifies relation instances that are represented by a lexical indicator with an argument constituent from texts. Then the relation instances are filled into templates which are extracted by applying multiple sequence alignment. Both of these systems need to select a subset of the large volumes of generated sentences. However, our system generates summary directly by summary structure planning. It can generate well-organized and coherent summary more effectively.

A recent work aims to generate abstractive summary based on Abstract Meaning Representation (AMR) (Liu et al., 2015). It first parses the source text into AMR graphs, and then transforms them into a summary graph and plans to generate text from it. This work only focuses on the graph-to-graph transformation. The module of text generation from AMR has not been developed. The nodes and edges of AMR graph are entities and relations between entities respectively, which are sufficiently different from the *BSUs* semantic link network. Moreover, texts can be generated efficiently from the *BSUs* network. Another recent abstractive summarization method generates new sentences by selecting and merging phrases from the input documents (Bing et al., 2015). It first extracts noun phrases and verb-object phrases from the input documents, and then calculates saliency scores for them. An ILP optimization framework is used to simultaneously select and merge informative phrases to maximize the salience of phrases and meanwhile satisfy the sentence construction constraints. As the results show that the method is difficult to generate new informative sentences really different from the original sentences and may generate some none factual sentences since phrases from different sentences are merged.

Open information extraction has been proposed by (Banko et al., 2007; Etzioni et al., 2011). They extract binary relations from the web, which is different from our approach that extracts events or actions expressed in texts.

3 The Summarization Framework

Our system produces an abstractive summary for a set of topic related documents. It consists of two major components: Information extraction and summary generation.

3.1 Information Extraction

The semantic information of texts is obtained by extracting *BSU*s and constructing *BSU* semantic link network. A *BSU* is represented as an **actor-action-receiver** triple, which can both detects the crucial content and incorporates enough syntactic information to facilitate the downstream sentence generation. Some actions may not have the receiver argument. For example, "*Flight MH370 – disappear*" and "*Flight MH370 - leave - Kuala Lumpur*" are two *BSU*s.

***BSU* Extraction.** *BSU*s are extracted from the sentences of the documents. The texts are preprocessed by name entity recognition (Finkel et al., 2005) and co-reference resolution (Lee et al., 2011). Constituent and dependency parses are obtained by Stanford parser (Klein and Manning, 2003). The eligible action indicator is restricted to be a predicate verb; the eligible actor and receiver arguments are noun phrase. Both the actor and receiver arguments take the form of constituents in the parse tree. A valid *BSU* should have one action indicator and at least one actor argument, and satisfy the following constraints:

- The actor argument is the nominal subject or external subject or the complement of a passive verb which is introduced by the preposition "by" and does the action.
- The receiver argument is the direct object or the passive nominal subject or the object of a preposition following the action verb.

We create some manual rules and syntactic constraints to identify all *BSU*s based on the syntactic structure of sentences in the input texts.

Constructing *BSU* Semantic Link Network. The semantic relatedness between *BSU*s contains three parts: *Arguments Semantic Relatedness* (ASR), *Action-Verbs Semantic Relatedness* (VSR) and *Co-occurrence in the Same Sentence* (CSS). Arguments of *BSU*s include actors and receivers, which both are noun phrases and indicate concepts or entities in the text. When computing ASR, the semantic relatedness between concepts must be measured. We use the explicit

semantic analysis based on Wikipedia to compute semantic relatedness between concepts (Gabrilovich and Markovitch, 2007). When computing VSR, WordNet-based measure is used to calculate the semantic relatedness between action verbs (Mihalcea et al., 2006). CSS is measured whether two different *BSUs* co-occur in the same sentence. Semantic relations between *BSU*s are computed by linearly combining these three parts. Then *BSU*s that are extracted from the texts form a semantic link network.

Semantic Link Network Reduction. A discriminative ranker based on Support Vector Regression (SVR) (Smola and Scholkopf, 2004) is utilized to assign each *BSU* a summary-worthy score. Training data was constructed from the DUC 2005 datasets which contain both the source documents and human generated reference summaries. *BSUs* are extracted from these datasets. For each *BSU* in the source documents, if it has occurred in the corresponding human generated summaries or the semantic relatedness between the *BSU* and one *BSU* in the corresponding human generated summaries is above a threshold δ, then it is considered to be a positive sample and be assigned 1 to its summary-worthy score. Otherwise, the *BSU* is considered to be a negative sample and be assigned 0 to its summary-worthy score. Table 1 displays the features of *BSU* used in the SVR model. Then the saliency score of each *BSU* in the semantic link network is calculated by the following equation:

$$Sal(BSU_i) = SW_i * \sum_j R_{ij} \quad (1)$$

Where SW_i is the summary-worthy score of BSU_i; R_{ij} is the semantic relatedness between BSU_i and BSU_j.

BSUs in the semantic link network are clustered by hierarchical complete-link clustering methods. *BSUs* in each cluster are semantically similar. For example, *Malaysia Airlines plane - vanish* and *Flight MH370 – disappear*. Only the most important one with the largest saliency score is reserved in the network. These less important *BSUs* are eliminated. The remaining *BSU* semantic link network represents the important information of the texts with no redundancy.

3.2 Summary Generation

The summary for the documents is generated directly based on the *BSU* semantic link network. The summary should be well-structured and well-organized. It should not just be a heap of related information, but should build from sentence to sentence to a coherent body of information about a topic.

Basic Features
Number of words in actor/receiver
Number of nouns in actor/receiver
Number of new nouns in actor/receiver
Actor/receiver has capitalized word?
Actor/receiver has stopword?
Action is a phrasal verb?
Content Features
Actor/receiver has name entity?
TF/IDF/TF-IDF of action
TF/IDF/TF-IDF min max average of actor/receiver
Syntax Features
Constituent tag of actor/action/receiver
Dependency relation of action with actor
Dependency relation of action with receiver

Table 1. Features for *BSU* summary-worthy scoring. We use SVM-light with RBF kernel by default parameters (Joachims, 1999).

The summary structure is planned based on the *BSU* semantic link network. An optimal path which covers all the nodes in the network is found. The following two factors are considered when finding the optimal path: (1) **Context Semantic Coherent.** To make the summary semantic coherent, all adjacent sentences should be semantically related. We need to find an optimal path, in which every two adjacent nodes are strong semantically related. The optimal path is denoted as $P=[p_{r_1}, p_{r_2}, ..., p_{r_n}]$ and maximize $1/n\sum_{i=1}^{n-1} R_{r_i r_{i+1}}$. (2) **Clear-cut Theme.** To make the theme of generated summary clear-cut, the important content should be put in prior position. The order of the *i*th node in the path is denoted as u_i and its weight is denoted as $w_i = 1/Sal(BSU_i)$ and maximize $\sum_{i=1}^{n} u_i w_i$.

To combine the above two factors, we need to find an optimal path which covers each node only once and has the longest distance. The biased-sum weight of all nodes in the path should be maximized. The problem can be proved to be NP-hard by reduction to TSP problem. It can be formalized as an integer linear programming (ILP) as follow. x_{ij} is defined to indicate whether the optimal path goes from node i to node j.

$$x_{ij} = \begin{cases} 1 & if\ the\ path\ goes\ from\ node\ i\ to\ node\ j \\ 0 & otherwise \end{cases} \quad (2)$$

Since each node can be traversed only once, the following constraints must be satisfied.

$$\begin{aligned} &\sum_{i=1, j\neq i}^{n} x_{ij} = 1 && j = 1,...n \\ &\sum_{j=1, j\neq i}^{n} x_{ij} = 1 && i = 1,...n \end{aligned} \quad (3)$$

The nodes in the path are sequentially ordered. If the edge between two nodes is in the path, then

System	ROUGE-1	ROUGE-2	ROUGE-SU4
OurSystem	**0.42145**	**0.11016**	**0.15632**
MultiMR	0.41967	0.10302	0.15385
RankBSU	0.39123	0.08742	0.14381
TTG	0.39268	0.09645	0.14553
AveDUC	0.39684	0.09495	0.14671
NIST Baseline	0.33126	0.06425	0.11114

Table 2. Comparison results (F-measure) on DUC 2007 under ROUGE evaluation.

System	OurSystem	MultiMR	RankBSU	TTG
Pyr (Th:0.6)	**0.858**	0.845	0.832	0.834
Pyr (Th:0.65)	**0.743**	0.731	0.718	0.721

Table 3. Comparison results on DUC 2007 under the automated pyramid evaluation with two threshold value 0.6 and 0.65.

the order of the two nodes is sequentially close to each other, which can be formulated as follow:

$$\begin{aligned} & u_i - u_j + nx_{ij} \le n-1 \quad 1 \le i \ne j \le n \\ & 1 \le u_i \le n \qquad\qquad i = 1,...n \\ & u_i \in \mathbb{Z} \qquad\qquad i = 1,...n \end{aligned} \tag{4}$$

At last, we can formulate the objective function as follow:

$$\max \ 1/n \sum_{i=1}^{n} \sum_{j=1, j \ne i}^{n} R_{ij} x_{ij} + \lambda \sum_{i=1}^{n} w_i u_i \tag{5}$$

where parameter λ tunes the effect of the two parts and n is the quantity of *BSU*s in the final *BSU* semantic link network (after reduction).

Sentence Generation. After the summary structure has been planned, sentences are generated for each node in the *BSU* semantic link network. As the *BSU* contains enough semantic and syntactic information, sentence can be generated efficiently according to the following rules:

- Generate a Noun Phrase (NP) based on the actor argument to represent the subject, a NP based on the receiver argument to represent the object if present.
- Generate a Verb Phrase (VP) based on the action verb to link the components above. The tense of the verb is set to the same as in the original sentence, and most modifiers like auxiliaries and negation are conserved.
- Generate complements for the VP when the *BSU* has no receiver. The verb modifiers following the action verb such as prepositional phrases and infinitive phrases can be used as the complement, in case that the verb would have no interesting meaning without a complement.

The process of sentence generation for each node is based on the syntactic structure of the source sentence where the *BSU* is extracted from. The time and location preposition phrases which are important information of new events are kept. The generated sentences are organized according to the summary structure. If some adjacent sentences in the summary have the same subject, the subject of the latter can be substituted by a pronoun (such as it or they) to avoid repetition of noun phrases. One sample summary generated by our system for "Malaysia MH370 Disappear" news is shown in Figure 1.

4 Evaluation Results

4.1 Dataset and Experimental Settings

In order to evaluate the performance of our system, we use two datasets that have been used in recent multi-document summarization shared tasks: DUC2005 and DUC2007. Each task has a gold standard dataset consisting of document clusters and reference summaries. In our experiments, DUC2005 was used for training and parameter tuning, and DUC2007 was used for testing. Based on the tuning set, the parameter λ is set as 10 and δ is set as 0.7 after tuning.

Our system is compared with one state-of-the-art graph-based extractive approach *MultiMR* (Wan and Xiao, 2009) and one abstractive approach *TTG* (Genest and Lapalme, 2011). In addition, we have implemented another baseline *RankBSU* which uses the graph-based ranking methods on the *BSU*s network to rank *BSU*s and select the top ranked *BSU*s to generate sentences.

4.2 Results

ROUGE-1.5.5 toolkit was used to evaluate the quality of summary on DUC 2007 dataset (Lin and Hovy, 2003). The ROUGE scores of the NIST Baseline system (i.e. *NIST Baseline*) and average ROUGE scores of all the participating systems (i.e. *AveDUC*) for DUC 2007 main task were also listed. According to the results in Table 2, our system much outperforms the *NIST Baseline* and *AveDUC*, and achieves higher ROUGE scores than the abstractive approach *TTG*. So the abstract representation of texts and the information extraction process in our system are effective for multi-document summarization. Our system also achieves better performance than the baseline *RankBSU*, which demonstrates that the network reduction method is more efficient than the popular graph-based ranking methods. As compared with the state-of-art graph-based extractive method *MultiMR*, our system also achieves better performance. Furthermore, our system is abstractive with abstract representation and sentence generation. Incorrect

parser and co-reference resolution will lead to wrong extraction of *BSU*. If with more accurate parser and co-reference resolution, our system will be expected to achieve better performance.

Since ROUGE metric evaluates summaries only from word overlapping perspective, we also use the pyramid evaluation metric (Nenkova and Passonneau, 2004) which can measure the summary quality beyond simply string matching. The pyramid evaluation metric involves semantic matching of summary content units (SCUs) so as to recognize alternate realizations of the same meaning, which is a better metric for the abstractive summary evaluation. Since the manual pyramid evaluation is time-consuming and the evaluation results can't be reproducible with different groups of assessors, we use the automated version of pyramid proposed in (Passonneau et al., 2013) and adopt the same setting as in (Bing et al., 2015). Table 3 shows the evaluation results of our system and the three baseline systems on DUC 2007. The results show that the performance of our system is significantly better than the three baseline systems, which demonstrates that the summaries of our system contain more SCUs than summaries of other systems. So our system can generate more informative summary.

In addition, large volumes of news texts for popular news events are crawled from the news websites. Figure 1 and 2 show the summaries for the "Malaysia MH370 Disappear" news event generated by our system and *MultiMR* respectively. The summary by *MultiMR* contains some repetition of facts obviously. And it is just a heap of information about MH370. The summary by our system doesn't contain much repetition of facts, so it can contain more useful information. And it is built from sentence to sentence to a coherent body. Obviously, the summary by our system is more coherent and compact.

Flight MH370 disappeared after leaving Kuala Lumpur. It had been expected to land in Beijing at 06:30. It took off at 00:41 MYT from runway 32R. It ended in the southern Indian Ocean. The aircraft, a Boeing 777-200ER made a sharp turn westwards. It passed into Vietnamese airspace. The captain of another aircraft attempted to reach the crew of Malaysia Airlines flight MH370. Malaysia Airlines flight 386 was requested to attempt to contact Malaysia Airlines flight MH370 on the Lumpur Radar frequency. Malaysia Airlines flight MH17, another Boeing 777-200ER, was surpassed Malaysia Airlines flight MH370. Malaysia Airlines assumes beyond reasonable doubt there are no survivors. They reported the Malaysia Airlines flight MH370 missing. They releases passenger manifest of flight MH370. They will give US$ 5000 to the relatives of each passenger. Malaysia released preliminary report. It set up a Joint Investigation Team. Southeast Asian states have joined forces to search waters between Malaysia and Vietnam. Chinese government criticizes Malaysia for inadequate answers regarding Malaysia Airlines flight MH370. Malaysia will be deploying more ships and equipment to assist in the search. It ends hunt in South China Sea. Continued refinement of analysis of flight MH370's satellite communications identified a wide area search. Australia and Malaysia are working on a Memorandum of Understanding to cover financial and co-operation arrangements for search and recovery activities.

Figure 1. The summary of "Malaysia MH370 Disappear" news event generated by our system.

Malaysia Airlines said in a statement that **flight MH370 had disappeared** at 02:40 local time on Saturday after leaving Kuala Lumpur. Southeast Asian states have joined forces to search waters between Malaysia and Vietnam after **a Malaysia Airlines plane vanished** on a **flight to Beijing**, with 239 people on board. Flight MH370 had been expected to **land in Beijing** at 06:30. If Malaysia Airlines flight MH370 had impacted the ocean hard, resulting underwater sounds could have been detected by hydrophones, given favorable circumstances. Scientists from the CTBTO analyzed their recordings soon after **flight MH370 disappeared**, finding nothing of interest. The CMST researchers believe that the most likely explanation of the hydroacoustic data is that they come from the same event, but unrelated to Malaysia Airlines flight MH370. The lead researcher of the CMST team, Dr.Alec Duncan, believes there's a slim chance that the acoustic event is related to Malaysia Airlines flight MH370. Several IMOS recorders deployed in the Indian Ocean off northwestern Australia by CMST may have recorded data related to Malaysia Airlines flight MH370. Malaysia Airlines released the names and nationalities of the 227 passengers and 12 crew members, based on the flight manifest, later modified to include two Iranian passengers travelling on stolen passports. If the data relates to the same event, related to flight MH370, but the arc derived from analysis of the aircraft's satellite transmission is incorrect, then the most likely place to look for the aircraft would be along a line from HA01.

Figure 2. The summary of "Malaysia MH370 Disappear" news event generated by *MultiMR*.

5 Conclusions and Future Works

The proposed summarization approach is effective in information extraction and achieves good performance on DUC datasets. Through the sample summary, we can find that the approach is very effective for summarizing texts that mainly describe facts and actions of news event. Summaries generated by our system are informative, coherent and compact.

But for texts expressing opinions, the approach can't settle it appropriately. For example, when the verbs of *BSUs* are not meaningful actions, like "be", the semantic relations between them can't be appropriately computed by the methods described in the paper. More efficient methods to computer semantic relations between *BSUs* should be developed in the following work.

The sentence generation process described in the paper is just a preliminary scheme. It should be developed to generate sentence relying less on the original sentence structure and aggregating information from several different *BSUs*.

Abstract

In concept-based summarization, sentence selection is modelled as a budgeted maximum coverage problem. As this problem is NP-hard, pruning low-weight concepts is required for the solver to find optimal solutions efficiently. This work shows that reducing the number of concepts in the model leads to lower ROUGE scores, and more importantly to the presence of multiple optimal solutions. We address these issues by extending the model to provide a single optimal solution, and eliminate the need for concept pruning using an approximation algorithm that achieves comparable performance to exact inference.

1 Introduction

Recent years have witnessed increased interest in global inference methods for extractive summarization. These methods formulate summarization as a combinatorial optimization problem, i.e. selecting a subset of sentences that maximizes an objective function under a length constraint, and use Integer Linear Programming (ILP) to solve it exactly (McDonald, 2007).

In this work, we focus on the concept-based ILP model for summarization introduced by (Gillick and Favre, 2009). In their model, a summary is generated by assembling the subset of sentences that maximizes a function of the unique concepts it covers. Selecting the optimal subset of sentences is then cast as an instance of the budgeted maximum coverage problem[1].

As this problem is NP-hard, pruning low-weight concepts is required for the ILP solver to find optimal solutions efficiently (Gillick and Favre, 2009; Qian and Liu, 2013; Li et al., 2013). However, reducing the number of concepts in the model has two undesirable consequences. First, it forces the model to only use a limited number of concepts to rank summaries, resulting in lower ROUGE scores. Second, by reducing the number of items from which sentence scores are derived, it allows different sentences to have the same score, and ultimately leads to multiple optimal summaries.

To our knowledge, no previous work has mentioned these problems, and only results corresponding to the first optimal solution found by the solver are reported. However, as we will show through experiments, these multiple optimal solutions cause a substantial amount of variation in ROUGE scores, which, if not accounted for, could lead to incorrect conclusions. More specifically, the contributions of this work are as follows:

- We evaluate (Gillick and Favre, 2009)'s summarization model at various concept pruning levels. In doing so, we quantify the impact of pruning on running time, ROUGE scores and the number of optimal solutions.
- We extend the model to address the problem of multiple optimal solutions, and we sidestep the need for concept pruning by developing a fast approximation algorithm that achieves near-optimal performance.

2 Concept-based ILP Summarization

2.1 Model definition

Gillick and Favre (2009) introduce a concept-based ILP model for summarization that casts sentence selection as a maximum coverage problem. The key assumption of their model is that the value of a summary is defined as the sum of the weights of the unique concepts it contains. That way, redundancy within the summary is addressed implicitly at a sub-sentence level: a summary only benefits from including each concept once.

[1] Given a collection S of sets with associated costs and a budget L, find a subset $S' \subseteq S$ such that the total cost of sets in S' does not exceed L, and the total weight of elements covered by S' is maximized (Khuller et al., 1999).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1914–1918,
Lisbon, Portugal, 17-21 September 2015.

Formally, let w_i be the weight of concept i, c_i and s_j two binary variables indicating the presence of concept i and sentence j in the summary, Occ_{ij} an indicator of the occurrence of concept i in sentence j, l_j the length of sentence j and L the length limit for the summary, the concept-based ILP model is described as:

$$\max \quad \sum_i w_i c_i \tag{1}$$

$$s.t. \quad \sum_j l_j s_j \leq L \tag{2}$$

$$s_j Occ_{ij} \leq c_i, \quad \forall i, j \tag{3}$$

$$\sum_j s_j Occ_{ij} \geq c_i, \quad \forall i \tag{4}$$

$$c_i \in \{0, 1\} \, \forall i$$

$$s_j \in \{0, 1\} \, \forall j$$

The constraints formalized in equations 3 and 4 ensure the consistency of the solution: selecting a sentence leads to the selection of all the concepts it contains, and selecting a concept is only possible if it is present in at least one selected sentence.

Choosing a suitable definition for concepts and a method to estimate their weights are the two key factors that affect the performance of this model. Bigrams of words are usually used as a proxy for concepts (Gillick and Favre, 2009; Berg-Kirkpatrick et al., 2011). Concept weights are either estimated by heuristic counting, e.g. document frequency in (Gillick and Favre, 2009), or obtained by supervised learning (Li et al., 2013).

2.2 Pruning to reduce complexity

The concept-level formulation of (Gillick and Favre, 2009) is an instance of the budgeted maximum coverage problem, and solving such a problem is NP-hard (Khuller et al., 1999). Keeping the number of variables and constraints small is then critical to reduce the model complexity.

In previous work, efficient summarization was achieved by pruning concepts. One way to reduce the number of concepts in the model is to remove those concepts that have a weight below a given threshold (Gillick and Favre, 2009). Another way is to consider only the top-n highest weighted concepts (Li et al., 2013). Once low-weight concepts are pruned, sentences that do not contain any remaining concepts are removed, further reducing the number of variables and constraints in the model. As such, this can be regarded as a way to approximate the problem.

Pruning concepts to reduce complexity also cuts down the number of items from which summary scores are derived. As we will see in Section 3.2, this results in a lower ROUGE scores and leads to the production of multiple optimal summaries.

The concept weighting function also plays an important role in the presence of multiple optimal solutions. Limited-range functions, such as frequency-based ones, yield many ties and increase the likelihood that different sentences have the same score. Redundancy within the set of input sentences exacerbate this problem, since highly similar sentences are likely to contain the same concepts.

2.3 Summarization parameters

For comparison purposes, we use the same system pipeline as in (Gillick et al., 2009), which is described below.

Step 1: clean input documents; a set of rules is used to remove bylines and format markup.

Step 2: split the text into sentences; we use splitta[2] (Gillick, 2009) and re-attach multi-sentence quotations.

Step 3: compute parameters needed by the model; we extract and weight the concepts.

Step 4: prune sentences shorter than 10 words, duplicate sentences and those that begin and end with a quotation mark.

Step 5: map to ILP format and solve; we use an off-the-shelf ILP solver[3].

Step 6: order selected sentences for inclusion in the summary, first by source and then by position.

Similar to previous work, we use bigrams of words as concepts. Although bigrams are rough approximations of concepts, they are simple to extract and match, and have been shown to perform well at this task. Bigrams of words consisting of two stop words[4] or containing a punctuation mark are discarded. Stemming[5] is then applied to allow more robust matching.

Concepts are weighted using document frequency, i.e. the number of source documents

[2]We use splitta v1.03, `https://code.google.com/p/splitta/`

Table 1: Average number of optimal solutions, concepts and sentences for different minimum document frequencies. The average time in seconds for finding the first optimal solution is also reported.

where the concept was seen. Document frequency is a simple, yet effective approach to concept weighting (Gillick and Favre, 2009; Woodsend and Lapata, 2012; Qian and Liu, 2013). Reducing the number of concepts in the ILP model is then performed by pruning those concepts that occur in fewer than a given number of documents.

ILP solvers usually provide only one solution. To generate alternate optimal solutions, we iteratively add new constraints to the problem that eliminate already found optimal solutions and rerun the solver. We stop the iterations when the value of the objective function returned by the solver changes.

3 Experiments

3.1 Datasets and evaluation measures

Experiments are conducted on the DUC'04 and TAC'08 datasets. For DUC'04, we use the 50 topics from the generic multi-document summarization task (Task 2). For TAC'08, we focus only on the 48 topics from the non-update summarization task. Each topic contains 10 newswire articles for which the task is to generate a summary no longer than 100 words (whitespace-delimited tokens).

Summaries are evaluated against reference summaries using the ROUGE automatic evaluation measures (Lin, 2004). We set the ROUGE parameters to those[6] that lead to highest agreement with manual evaluation (Owczarzak et al., 2012), that is, with stemming and stopwords not removed.

3.2 Results

Table 1 presents the average number of optimal solutions at different levels of concept pruning. Overall, the average number of optimal solutions increases along with the minimum document frequency, reaching 4.8 for TAC'08 at DF $= 4$. Pruning concepts also greatly reduces the number of variables in the ILP formulation, and consequently improves the run-time for solving the problem.

Interestingly, we note that, even without any pruning, the model produces multiple optimal solutions. The choice of document frequency for weighting concepts is responsible for this as it generates many ties. Finer-grained concept weighting functions such as frequency estimation (Li et al., 2013) should therefore be preferred to limit the number of multiple optimal solutions.

The mean ROUGE recall scores of the multiple optimal solutions for different minimal document frequencies are presented in Table 2. Here, the higher the concept pruning threshold, the higher the variability of the generated summaries as indicated by the standard deviation. Best ROUGE scores are achieved without concept pruning while the best compromise between effectiveness and run-time is given when DF ≥ 3, confirming the findings of (Gillick and Favre, 2009).

To show in a realistic scenario how multiple optimal solutions could lead to different conclusions, we compare in Table 3 the ROUGE-1 scores of the summaries generated from the first optimal solution found by three off-the-shelf ILP solvers against that of the systems[7] that participated at TAC'08. We set the minimum document frequency to 3, which is often used in previous work (Gillick and Favre, 2009; Li et al., 2013), and use a two-sided Wilcoxon signed-rank to compute the number of systems that obtain significantly lower and higher ROUGE-1 recall scores[8].

Despite being comparable (p-value > 0.4), the solutions found by the three solvers support different conclusions. The solution found using GLPK

[6] We use ROUGE-1.5.5 with the parameters: `n 4 -m -a -l 100 -x -c 95 -r 1000 -f A -p 0.5 -t 0`

[7] 71 systems participated at TAC'08 but we removed ICSI1 and ICSI2 systems which are based on the concept-based ILP model.

[8] ROUGE-1 recall is most accurate metric to identify the better summary in a pair (Owczarzak et al., 2012).

Solver	ROUGE-1	↓ / ↑
GLPK	37.33	54 / 0
Gurobi	37.20	52 / 1
CPLEX	37.17	51 / 1

Table 3: ROUGE-1 recall scores for the first optimal solution found by different solvers along with the number of systems that obtain significantly lower (↓) or higher (↑) scores (p-value < 0.05).

indicates that the concept-based model achieves state-of-the-art performance whereas the solutions provided by Gurobi and CPLEX do not do so. The reason for these differences is the use of different solving strategies, involving heuristics for finding feasible solutions more quickly. This example demonstrates that multiple optimal solutions should be considered during evaluation.

3.3 Solving the multiple solution problem

Multiple optimal solutions occur when concepts alone are not sufficient to distinguish between two competing summary candidates. Extending the model so that it provides a single solution can therefore not be done without introducing a second term in the objective function. Following the observation that the frequency of a non-stop word in a document set is a good predictor of a word appearing in a human summary (Nenkova and Vanderwende, 2005), we extend equation 1 as follows:

$$\max \quad \sum_i w_i c_i + \mu \sum_k f_k t_k \qquad (5)$$

where f_k is the frequency of non-stop word k in the document set, and t_k is a binary variable indicating the presence of k in the summary. Here, we want to induce a single solution among the multiple optimal solutions given by concept weighting, and thus set μ to a small value (10^{-6}). We add further constraints, similar to equations 3 and 4, to ensure the consistency of the solution.

This extended model succeeds in giving a single solution that is at least comparable to the mean score of the multiple optimal solutions. However, it requires about twice as much time to solve which makes it impractical for large documents.

3.4 Fast approximation

Instead of pruning concepts to reduce complexity, one may consider using an approximation if results are found satisfactory. Here, similarly to (Takamura and Okumura, 2009; Lin and Bilmes, 2010) we implement the greedy heuristic proposed in (Khuller et al., 1999) that solve the budgeted maximum coverage problem with a performance guarantee $1/2 \cdot (1 - 1/e)$. Table 4 compares the performance of the model that achieves the best trade off between effectiveness and runtime, that is when $DF \geq 3$, with that of the greedy approximation without pruning.

Overall, the approximate solution is over 96% as good as the average optimal solution. Although the ILP solution marks an upper bound on performance, its solving time is exponential in the number of input sentences. The approximate method is then relevant as it marks an upper bound on speed (less than 0.01 seconds to compute) while having performance comparable to the ILP model with concept pruning (p-value > 0.3).

Dataset	ROUGE-1	ROUGE-2
DUC'04	37.14 (−0.7%)	9.37 (+2.3%)
TAC'08	36.90 (−1.3%)	10.27 (−3.3%)

Table 4: ROUGE recall scores of the approximation. The relative difference from the mean score of the multiple optimal solutions is also reported.

4 Conclusion

Multiple optimal solutions are not an issue as long as alternate solutions are equivalent. Unfortunately, summaries generated from different sets of

sentences are likely to differ. We showed through experiments that concept pruning leads to the presence of multiple optimal solutions, and that the latter cause a substantial amount of variation in ROUGE scores. We proposed an extension of the ILP that obtains unique solutions. If speed is a concern, we showed that a near-optimal approximation can be computed without pruning. The implementation of the concept-based summarization model that we use in this study is available at `https://github.com/boudinfl/sume`.

In future work, we intend to extend our study to compressive summarization. We expect that the number of optimal solutions will increase as multiple compression candidates, which are likely to be similar in content, are added to the set of input sentences.

GhostWriter: Using an LSTM for Automatic Rap Lyric Generation

Peter Potash, Alexey Romanov, Anna Rumshisky
Dept. of Computer Science
University of Massachusetts Lowell
Lowell, MA 01854
{ppotash,aromanov,arum}@cs.uml.edu

Abstract

This paper demonstrates the effectiveness of a Long Short-Term Memory language model in our initial efforts to generate unconstrained rap lyrics. The goal of this model is to generate lyrics that are similar in style to that of a given rapper, but not identical to existing lyrics: this is the task of ghostwriting. Unlike previous work, which defines explicit templates for lyric generation, our model defines its own rhyme scheme, line length, and verse length. Our experiments show that a Long Short-Term Memory language model produces better "ghostwritten" lyrics than a baseline model.

1 Introduction

Ghostwriting defines a distinction between the performer/presenter of text, lyrics, etc, and the creator of text/lyrics. The goal is to present something in a style that is believable enough to be credited to the performer. In the domain of rap specifically, rappers sometimes function as ghostwriters early on before embarking on their own public careers, and there are even businesses that provide written lyrics as a service [1]. The goal of GhostWriter is to produce a system that can take a given artist's lyrics and generate *similar* yet *unique* lyrics. To accomplish this, we must create a language model to produce text, while also understanding what 'style' means in a quantitative sense.

The contribution of this paper is three-fold: (1) we present the ghostwriting problem of producing similar yet different lyrics; (2) we present computational, quantitative evaluation methods for these two aspects; (3) we evaluate the performance of a Long Short-Term Memory (LSTM) vs n-gram model for this problem.

2 Related Work

Recent work (Sutskever et al., 2011; Graves, 2013) has shown the effectiveness of Recurrent Neural Networks (RNNs) for text generation. In their works, the authors use an RNN to create a language model at the character level. The results are inspiring, as the models learn various grammatical and punctuation rules, such as opening and closing parentheses, plus learning a large vocabulary of English words at the character level. Graves (2013) uses a variation of an RNN called LSTM architecture which creates a better language model than a regular RNN.

Text generation for artistic purposes, such as poetry and lyrics, has also been explored, often using templates and constraints (Oliveira et al., 2014; Barbieri et al., 2012). In regards to rap lyrics, Wu et al. (2013) present a system for rap lyric generation that produces a single line of lyrics that are meant to be a response to a single line of input. However, the work that is most similar to ours is that of Malmi et al. (2015). The authors create fixed 16-line verses, generating the verse line-by-line using full lines from existing rap songs. The system predicts the best next line based on the previous lines, using a system that records an 81.9% accuracy predicting next lines in already existing verses. The feature that provides the greatest accuracy gain is a neural embedding of the lines, created from the character level.

Hirjee and Brown (2010b) have developed a rhyme detection tool based on a probabilistic model (Hirjee and Brown, 2010a) that analyzes phoneme patterns in words. The model is trained on a set of lyrics that were manually annotated for rhyming words. The statistics generated by the rhyme detection tool will be an important part of

Lisbon, Portugal, 17-21 September 2015.

our evaluation (see Section 5).

3 Generating Lyrics

In a departure from previous work on poetry/lyric generation, our goal is to build a model that does not require templates/constraints to generate lyrics, while also being able to produce full verses, as opposed to single lines. The system must be able to model general human language in order to produce fluent lyrics, but it must also be able to model the style of a target artist, by understanding the artist's vocabulary and rhythmic style, in order to fully execute the ghostwriting task of producing similar yet new lyrics.

3.1 LSTM

Here we will give a very brief overview of RNNs and LSTMs. For a more detailed explanation please refer to (Graves, 2013). The foundation of an RNN (of which an LSTM is specific architecture) is a word embedding E that provides a vector representation for each of the words in our corpus. Given a history of words $w_k, ..., w_0$ we want to determine $P(w_{k+1}|w_k, ..., w_0; E, \Phi)$, where Φ is a set of parameters used by our model. In the context of an RNN we define this probability by:

$$P(w_{k+1}|w_k, ..., w_0; E, \Phi) = f(x, s) \quad (1)$$

At each time-step the RNN computes f given an observation x and a previous state s. The input goes through a transformation where it passes through one or several hidden layers.

The LSTM model uses a specific architecture for the hidden transformation, defined by the LSTM memory cell. The key feature to the LSTM memory cell is the presence of an input gate, output gate, forget gate, and cell/cell memory, which manifest themselves in the model as activation vectors. Each of these gates/cells has its own bias vector, and the hidden layer at each time-step is now a complex nonlinear combination of gate, cell, and hidden vectors.

3.2 Using LSTM for Lyrics Generation

Since previous work has shown the power of RNNs to model language, we hope that it can capture the rhythmic style of an artist by learning rhyme and meter patterns. As noted in Section 2, LSTMs have performed well at sequence forecasting, for example at learning punctuation, such as opening and closing parentheses. We see the task of rhyme detection as something similar in nature. Kaparthy et al. (2015) have also shown that LSTMs could successfully learn where to place the brackets and indentation in C++ code. In their model, certain LSTM cells activated specifically when encountering end of the line. We believe learning rhymes at the end of the line is conceptually similar to such tasks.

3.3 Verse Structure and Rhyme Inference

The goal of our model is to not just generate lyrics, but generate the structure for the lyrics as well. To do this, we have added "<endLine>" and "<endVerse>" tokens to the lyrics. From this, the system will generate its own line breaks, while also defining when a generated verse ends. This allows us to analyze non-rhyming features from (Hirjee and Brown, 2010a), such as number of syllables per line and number of lines per verse. We also desire that, by using the "<endLine>" token, the system has a better chance of understanding rhyme schemes used by an artist. For example, the LSTM can capture the pattern of "came <endLine>" followed shortly by "name <endLine>" to understand that "came" and "name" are a rhyming pair. To do this effectively, the system would need sufficient training data where rhyming pairs occur frequently enough to actually dictate a pattern, similar to (Reddy and Knight, 2011; Addanki and Wu, 2013).

4 Experimental Design

4.1 Dataset

We collected songs from 14 artists from the site *The Original Hip-Hop (Rap) Lyrics Archive - OHHLA.com - Hip-Hop Since 1992*[2]. In the present lyrics generation experiments, we used the lyrics from the rapper Fabolous. For training, we used 219 verses with at least 175 words in each verse. We selected Fabolous because his lyrics produced the highest accuracy in the artist recognition experiments in (Hirjee and Brown, 2010a). We conjecture that because of this, he had the most consistent style, making him a good choice for initial experiments.

[2] http://www.ohhla.com/

4.2 Baseline

To compare with the results of the LSTM model, we followed the work of (Barbieri et al., 2012) and created a Markov model for lyric generation. Since the goal of our work is to make an unsupervised system, we do not use any constraints or templates to produce the lyrics. Thus, our baseline simplifies to a basic n-gram model. Given a history of w_{k+n-1},...,w_k, the system generates a new token t as follows:

$$P(w_{k+n} = t|w_{k+n-1}, ..., w_k) = \frac{|w_k,...,w_{k+n-1},t|}{|w_k,...,w_{k+n-1},\bullet|} \quad (2)$$

where $|w_k...w_{k+n-1}t|$ is the amount of times the the context w_{k+n-1},...,w_1 is followed by t in the training data, and $|w_k...w_{k+n-1}\bullet|$ is the amount of times the context appears followed by any token. There is the possibility that the context has never been encountered in the training data. When this occurs, we back off to a smaller n-gram model:

$$P(w_{k+n} = t|w_{k+n-2}, ..., w_k) = \frac{|w_k,...,w_{k+n-2},\bullet,t|}{|w_k,...,w_{k+n-2},\bullet,\bullet|} \quad (3)$$

The model may have to back-off multiple times before it encounters context it has seen in the training data. Once we back-off to the point where we compute $P(w_{n+k} = t|w_k)$, we are guaranteed to have at least one non-zero probability, because w_k must have appeared in the vocabulary for it to have been generated previously.

Note that rather than backing off to a lower-order n-gram model, we use a skip-gram model which drops the words immediately preceding the predicted word. The main motivation for this is that it allows us to capture long-range dependencies, which makes it into a better baseline comparison for an LSTM.

4.3 Model Initialization

When producing lyrics with either the LSTM or baseline model, we initialize with the "<startVerse>" token. Once the model produces a token, it becomes part of the context for the next step of token generation. Our models are closed in the sense that they only produce tokens that appear in the training vocabulary.

4.4 LSTM Implementation

We used a Python implementation of an LSTM from Jonathan Raiman[3]. The LSTM is built on top of Theano (Bastien et al., 2012; Bergstra et al., 2010). Following (Graves, 2013), we set the amount of LSTM inputs/outputs to be equal to the vocabulary size. Also, to avoid the vanishing gradient problem when training RNNs, we clip the gradients in the range [-1,1]. We train our LSTM model using a Tesla K40 GPU on a single workstation.

5 Evaluation Methods

In this section, we present automated methods for evaluating the quality of generated lyrics. Ideally, judging system output in terms of, e.g. fluency, should be conducted using manual evaluation. However, conducting formal human evaluation is somewhat problematic. For a full *qualitative* evaluation of a given artist that would assess both similarity of style and novelty, the evaluator would need to know that particular artist's body of work very well. Even finding annotators who are well-versed in the general art of rap lyrics can be challenging (Addanki and Wu, 2014). While this may be possible for the present experiments that focus on a single artist, it is hardly feasible for larger-scale studies that will use our full data set that contains the lyrics of 14 different artists. We therefore propose an automated evaluation method which we believe is able to capture two critical aspects of ghostwriting, which are in fact quite tricky to capture together: being similar, yet different.

5.1 Similarity to existing lyrics

In order to evaluate the novelty of generated lyrics, we compare the similarity of the generated lyrics to the lyrics in our training set. We used an algorithm proposed by (Mahedero et al., 2005) for calculating the similarity between produced lyrics and all verses from the same artist. This algorithm is based on the well-known Inverse Document Frequency, using cosine on document vectors to calculate distance. First, we build the Term-Document Matrix with weights for each term in each song:

$$w_{ij} = f_{ij} log(\frac{N}{n_j}) \quad (4)$$

[3] https://github.com/JonathanRaiman/theano_lstm

where N is the total number of documents (verses, in our case), n_j is the number of verses that contains term j and f_{ij} is the frequency of term j in the ith verse. Using this matrix, we can calculate the cosine distance between verses and use it as a measure of similarity. When discussing similarity, we refer to the max similarity: of all verses it is most similar to, exactly *how* similar is it? The lower the max similarity score, the more novel the lyrics.

5.2 Numerical features of the lyrics

We also produced the features from (Hirjee and Brown, 2010a) for our generated verses. The statistics of these features are meant to represent how effective we are in modeling an artist's style. The point of the system is not to produce arbitrary rhymes; it is to produce rhyme types and rhyme frequency that are similar to the target artist. Following (Malmi et al., 2015), the rhyme feature we examine in this work is rhyme density. Rhyme density is defined as the total number of rhymed syllables divided by the total number of syllables.

6 Results

For the lyrics generation experiments reported here, we used the rapper Fabolous as the artist whose style we tried to emulate.

6.1 Example of Generated Lyrics (Warning: Explicit Content)

Below is a sample of lyrics generated by the LSTM model:

> Line 1: i m old enough to know better young enough to not give a fuck
> Line 2: rather hold my head high and die then live and duck
> Line 3: i got ta fuck be up and little niggaz go in
> Line 4: when i m in the feds and scoped by uncle sam
> Line 5: dope and hunn ed grams rope and hunn ed grams
> Line 6: at the same time she jerking and wiggling
> Line 7: smirking and giggling

While the pairs of rhyming end-lines in the generated lyrics are taken from the training data (the max similarity is 0.41), no more than two lines appear from a single verse. Though the generated lyrics aren't novel in a strict sense, the LSTM model is more effective than the n-gram model at using lines from multiple verses (see next Section 6.3). The rhyme density of this verse is 0.35, which is almost equal to Fabolous's average rhyme density (0.34).

6.2 Quantitative Analysis

As previously mentioned, the key to effective ghostwriting is to mirror an artist's style, but also providing original content. While vocabulary and lyrical content are key components for an artist's style, this is inherently satisfied by using words only from the training data. Thus, rhyme style – specifically rhyme density – will be the key performance indicator for imitating an artist's style. In terms of rap lyrics in general, a higher rhyme density is often better. Therefore for our system we would like a high rhyme density, but with a low max similarity score (a higher novelty). Figures 2 and 1 show the graph for rhyme density and max similarity for the LSTM and n-grams models, respectively. For the LSTM model the values are graphed compared to training iteration number – as the model becomes more fit to the data. For the n-gram model they are graphed dependent on n-gram value. For each n-gram value, we generate 10 verses and compute the average value of the two metrics. One expects that a perfectly fit LSTM model without regularization would exactly reproduce lyrics from the training data, and a high n-gram value would would also produce duplicate lyrics. This is evident in the graphs.

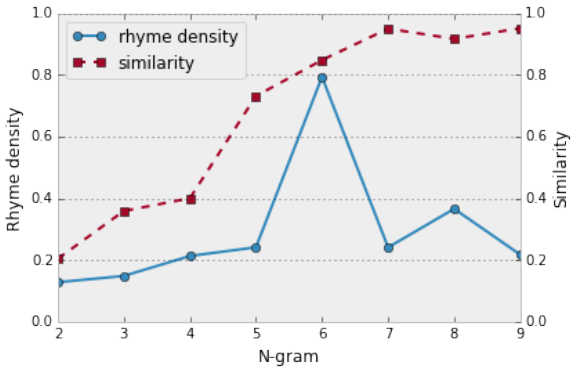

Figure 1: Values of rhyme density and max similarity versus n-gram value for the n-gram model.

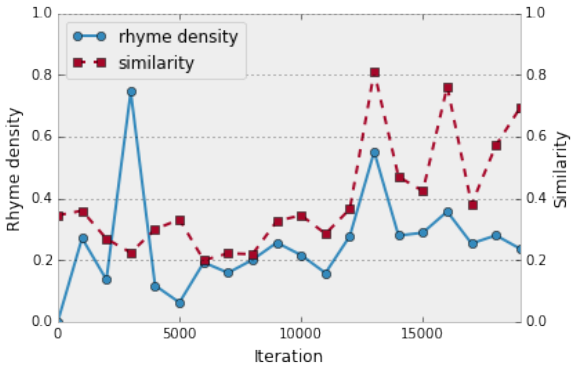

Figure 2: Values of rhyme density and max similarity versus iteration number when training the LSTM model.

6.3 Correlation of Rhyme Density and Max Similarity

Since exact replication would assuredly give a higher rhyme density than randomly produced lyrics, we desire a *low* correlation between rhyme density and max similarity. The correlation between rhyme density and max similarity for the LSTM model is 0.32, and for the n-gram model it is 0.47. When examining Figures 1 and 2 one may notice the anomalous points of high rhyme density (at $n = 6$ on the n-gram graph and 3,000 iterations for the LSTM model). After further inspection of the lyrics at these points, we see the lyrics contain repetitions of the exact same phrase. Since words are repeated frequently, the rhyme density of the lyrics is high (repeated words create rhymed phonemes, according to the rhyme detection tool). These points cause the similarity-density correlations to be artificially lower. After removing these data points, the LSTM model still has a lower correlation than the n-gram model, but the gap is much smaller: 0.71 compared to 0.75. Ultimately however, this shows that the LSTM model is better at generating original, rhyming lyrics.

6.4 Style Matching

Unfortunately, the correlation numbers do not dictate specifically the effectiveness of the LSTM model in the ghostwriting task. Instead, we can look at that max similarity values of both systems when they generate lyrics that produce a rhyme density similar to the average rhyme density of the target rapper. Looking at 100 randomly selected verses, Fabolous has an average rhyme density of 0.34. To do our analysis, first we create four regression lines, one for each metric (max similarity and rhyme density) in each model (we do not include the points of high rhyme density). Next we use the two rhyme density lines to determine at which iteration/n value the systems generate a rhyme density of 0.34. After that we plug these numbers into the two similarity lines to determine what similarity is needed to achieve the target rhyme density. The n-gram model line has a similarity of 1.28 at this point (above the max value of 1 for the metric), while the LSTM model has a value of 0.59. Based on these numbers, the LSTM model clearly outperforms the n-gram model when it comes to making original lyrics that are similar in style to our target rapper.

7 Conclusion

In this work, we have shown the effectiveness of an LSTM model for generating novel lyrics that are similar in style to a target artist. We compare the performance of the LSTM model to a much simpler system: an n-gram model. The results of our experiments show that, as an unsupervised, non-template model, the LSTM model is better able to produce novel lyrics that also reflect the rhyming style of the target artist. In future work, we plan to use more data to train our model, making it easier for our system to actually identify rhyming pairs and use them in new contexts. We also plan to encode phoneme features of words to improve rhyme discovery. Furthermore, we plan to generate lyrics from artists with a varying vocabulary size to see if it is easier to generate lyrics for an artist with a smaller vocabulary. In terms of evaluation, we hope to incorporate some method to evaluate the fluency of generated lyrics (Addanki and Wu, 2014). Lastly, to further avoid over-fitting to the training data and reproducing lyrics with a high similarity, we plan to use weight noise (Jim et al., 1996) to regularize our model.

Better Summarization Evaluation with Word Embeddings for ROUGE

Abstract

ROUGE is a widely adopted, automatic evaluation measure for text summarization. While it has been shown to correlate well with human judgements, it is biased towards surface lexical similarities. This makes it unsuitable for the evaluation of abstractive summarization, or summaries with substantial paraphrasing. We study the effectiveness of word embeddings to overcome this disadvantage of ROUGE. Specifically, instead of measuring lexical overlaps, word embeddings are used to compute the semantic similarity of the words used in summaries instead. Our experimental results show that our proposal is able to achieve better correlations with human judgements when measured with the Spearman and Kendall rank coefficients.

1 Introduction

Automatic text summarization is a rich field of research. For example, shared task evaluation workshops for summarization were held for more than a decade in the Document Understanding Conference (DUC), and subsequently the Text Analysis Conference (TAC). An important element of these shared tasks is the evaluation of participating systems. Initially, manual evaluation was carried out, where human judges were tasked to assess the quality of automatically generated summaries. However in an effort to make evaluation more scaleable, the automatic ROUGE[1] measure (Lin, 2004b) was introduced in DUC-2004. ROUGE determines the quality of an automatic summary through comparing overlapping units such as n-grams, word sequences, and word pairs with human written summaries.

[1]Recall-Oriented Understudy of Gisting Evaluation

ROUGE is not perfect however. Two problems with ROUGE are that 1) it favors lexical similarities between generated summaries and model summaries, which makes it unsuitable to evaluate abstractive summarization, or summaries with a significant amount of paraphrasing, and 2) it does not make any provision to cater for the readability or fluency of the generated summaries.

There has been on-going efforts to improve on automatic summarization evaluation measures, such as the Automatically Evaluating Summaries of Peers (AESOP) task in TAC (Dang and Owczarzak, 2009; Owczarzak, 2010; Owczarzak and Dang, 2011). However, ROUGE remains as one of the most popular metric of choice, as it has repeatedly been shown to correlate very well with human judgements (Lin, 2004a; Over and Yen, 2004; Owczarzak and Dang, 2011).

In this work, we describe our efforts to tackle the first problem of ROUGE that we have identified above — its bias towards lexical similarities. We propose to do this by making use of word embeddings (Bengio et al., 2003). Word embeddings refer to the mapping of words into a multi-dimensional vector space. We can construct the mapping, such that the distance between two word projections in the vector space corresponds to the semantic similarity between the two words. By incorporating these word embeddings into ROUGE, we can overcome its bias towards lexical similarities and instead make comparisons based on the semantics of words sequences. We believe that this will result in better correlations with human assessments, and avoid situations where two word sequences share similar meanings, but get unfairly penalized by ROUGE due to differences in lexicographic representations.

As an example, consider these two phrases: 1) *It is raining heavily*, and 2) *It is pouring*. If we are performing a lexical string match, as ROUGE does, there is nothing in common between the

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1925–1930,
Lisbon, Portugal, 17-21 September 2015.

terms "raining", "heavily", and "pouring". However, these two phrases mean the same thing. If one of the phrases was part of a human written summary, while the other was output by an automatic summarization system, we want to be able to reward the automatic system accordingly.

In our experiments, we show that word embeddings indeed give us better correlations with human judgements when measured with the Spearman and Kendall rank coefficient. This is a significant and exciting result. Beyond just improving the evaluation prowess of ROUGE, it has the potential to expand the applicability of ROUGE to abstractive summmarization as well.

2 Related Work

While ROUGE is widely-used, as we have noted earlier, there is a significant body of work studying the evaluation of automatic text summarization systems. A good survey of many of these measures has been written by Steinberger and Ježek (2012). We will thus not attempt to go through every measure here, but rather highlight the more significant efforts in this area.

Besides ROUGE, Basic Elements (BE) (Hovy et al., 2005) has also been used in the DUC/TAC shared task evaluations. It is an automatic method which evaluates the content completeness of a generated summary by breaking up sentences into smaller, more granular units of information (referred to as "Basic Elements").

The pyramid method originally proposed by Passonneau et al. (2005) is another staple in DUC/TAC. However it is a semi-automated method, where significant human intervention is required to identify units of information, called *Summary Content Units* (SCUs), and then to map content within generated summaries to these SCUs. Recently however, an automated variant of this method has been proposed (Passonneau et al., 2013). In this variant, word embeddings are used, as we are proposing in this paper, to map text content within generated summaries to SCUs. However the SCUs still need to be manually identified, limiting this variant's scalability and applicability.

Many systems have also been proposed in the AESOP task in TAC from 2009 to 2011. For example, the top system reported in Owczarzak and Dang (2011), AutoSummENG (Giannakopoulos and Karkaletsis, 2009), is a graph-based system which scores summaries based on the similarity between the graph structures of the generated summaries and model summaries.

3 Methodology

Let us now describe our proposal to integrate word embeddings into ROUGE in greater detail.

To start off, we will first describe the word embeddings that we intend to adopt. A word embedding is really a function W, where $W : w \rightarrow \mathbb{R}^n$, and w is a word or word sequence. For our purpose, we want W to map two words w_1 and w_2 such that their respective projections are closer to each other if the words are semantically similar, and further apart if they are not. Mikolov et al. (2013b) describe one such variant, called `word2vec`, which gives us this desired property[2]. We will thus be making use of `word2vec`.

We will now explain how word embeddings can be incorporated into ROUGE. There are several variants of ROUGE, of which ROUGE-1, ROUGE-2, and ROUGE-SU4 have often been used. This is because they have been found to correlate well with human judgements (Lin, 2004a; Over and Yen, 2004; Owczarzak and Dang, 2011). ROUGE-1 measures the amount of unigram overlap between model summaries and automatic summaries, and ROUGE-2 measures the amount of bigram overlap. ROUGE-SU4 measures the amount of overlap of skip-bigrams, which are pairs of words in the same order as they appear in a sentence. In each of these variants, overlap is computed by matching the lexical form of the words within the target pieces of text. Formally, we can define this as a similarity function f_R such that:

$$f_R(w_1, w_2) = \begin{cases} 1, & \text{if } w_1 = w_2 \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

where w_1 and w_2 are the words (could be unigrams or n-grams) being compared.

In our proposal[3], which we will refer to as ROUGE-WE, we define a new similarity function f_{WE} such that:

$$f_{WE}(w_1, w_2) = \begin{cases} 0, \text{ if } v_1 \text{or } v_2 \text{ are OOV} \\ v_1 \cdot v_2, \text{ otherwise} \end{cases} \quad (2)$$

where w_1 and w_2 are the words being compared, and $v_x = W(w_x)$. *OOV* here means a situation

[2]The effectiveness of the learnt mapping is such that we can now compute analogies such as *king* $-$ *man* $+$ *woman* $=$ *queen*.

[3]`https://github.com/ng-j-p/rouge-we`

where we encounter a word w that our word embedding function W returns no vector for. For the purpose of this work, we make use of a set of 3 million pre-trained vector mappings[4] trained from part of Google's news dataset (Mikolov et al., 2013a) for W.

Reducing OOV terms for n-grams. With our formulation for f_{WE}, we are able to compute variants of ROUGE-WE that correspond to those of ROUGE, including ROUGE-WE-1, ROUGE-WE-2, and ROUGE-WE-SU4. However, despite the large number of vector mappings that we have, there will still be a large number of OOV terms in the case of ROUGE-WE-2 and ROUGE-WE-SU4, where the basic units of comparison are bigrams.

To solve this problem, we can compose individual word embeddings together. We follow the simple multiplicative approach described by Mitchell and Lapata (2008), where individual vectors of constituent tokens are multiplied together to produce the vector for a n-gram, *i.e.*,

$$W(w) = W(w_1) \times \ldots \times W(w_n) \quad (3)$$

where w is a n-gram composed of individual word tokens, *i.e.*, $w = w_1 w_2 \ldots w_n$. Multiplication between two vectors $W(w_i) = \{v_{i1}, \ldots, v_{ik}\}$ and $W(w_j) = \{v_{j1}, \ldots, v_{jk}\}$ in this case is defined as:

$$\{v_{i1} \times v_{j1}, \ldots, v_{ik} \times v_{jk}\} \quad (4)$$

4 Experiments

4.1 Dataset and Metrics

For our experiments, we make use of the dataset used in AESOP (Owczarzak and Dang, 2011), and the corresponding correlation measures.

For clarity, let us first describe the dataset used in the main TAC summarization task. The main summarization dataset consists of 44 topics, each of which is associated with a set of 10 documents. There are also four human-curated model summaries for each of these topics. Each of the 51 participating systems generated a summary for each of these topics. These automatically generated summaries, together with the human-curated model summaries, then form the basis of the dataset for AESOP.

To assess how effective an automatic evaluation system is, the system is first tasked to assign a score for each of the summaries generated by all of the 51 participating systems. Each of these summaries would also have been assessed by human judges using these three key metrics:

Pyramid. As reviewed in Section 2, this is a semi-automated measure described in Passonneau et al. (2005).

Responsiveness. Human judges are tasked to evaluate how well a summary adheres to the information requested, as well as the linguistic quality of the generated summary.

Readability. Human judges give their judgement on how fluent and readable a summary is.

The evaluation system's scores are then tested to see how well they correlate with the human assessments. The correlation is evaluated with a set of three metrics, including 1) Pearson correlation (P), 2) Spearman rank coefficient (S), and 3) Kendall rank coefficient (K).

4.2 Results

We evaluate three different variants of our proposal, ROUGE-WE-1, ROUGE-WE-2, and ROUGE-WE-SU4, against their corresponding variants of ROUGE (*i.e.*, ROUGE-1, ROUGE-2, ROUGE-SU4). It is worth noting here that in AESOP in 2011, ROUGE-SU4 was shown to correlate very well with human judgements, especially for pyramid and responsiveness, and out-performs most of the participating systems.

Tables 1, 2, and 3 show the correlation of the scores produced by each variant of ROUGE-WE with human assessed scores for pyramid, responsiveness, and readability respectively. The tables also show the correlations achieved by ROUGE-1, ROUGE-2, and ROUGE-SU4. The best result for each column has been bolded for readability.

Measure	P	S	K
ROUGE-WE-1	0.9492	**0.9138**	**0.7534**
ROUGE-WE-2	0.9765	0.8984	0.7439
ROUGE-WE-SU4	0.9783	0.8808	0.7198
ROUGE-1	0.9661	0.9085	0.7466
ROUGE-2	0.9606	0.8943	0.7450
ROUGE-SU4	**0.9806**	0.8935	0.7371

Table 1: Correlation with pyramid scores, measured with Pearson r (P), Spearman ρ (S), and Kendall τ (K) coefficients.

ROUGE-WE-1 is observed to correlate very well with the pyramid, responsiveness, and read-

Measure	P	S	K
ROUGE-WE-1	0.9155	**0.8192**	0.6308
ROUGE-WE-2	0.9534	0.7974	0.6149
ROUGE-WE-SU4	0.9538	0.7872	0.5969
ROUGE-1	0.9349	0.8182	**0.6334**
ROUGE-2	0.9416	0.7897	0.6096
ROUGE-SU4	**0.9545**	0.7902	0.6017

Table 2: Correlation with responsiveness scores, measured with Pearson r (P), Spearman ρ (S), and Kendall τ (K) coefficients.

Measure	P	S	K
ROUGE-WE-1	0.7846	**0.4312**	**0.3216**
ROUGE-WE-2	0.7819	0.4141	0.3042
ROUGE-WE-SU4	**0.7931**	0.4068	0.3020
ROUGE-1	0.7900	0.3914	0.2846
ROUGE-2	0.7524	0.3975	0.2925
ROUGE-SU4	0.7840	0.3953	0.2925

Table 3: Correlation with readability scores, measured with Pearson r (P), Spearman ρ (S), and Kendall τ (K) coefficients.

ability scores when measured with the Spearman and Kendall rank correlation. However, ROUGE-SU4 correlates better with human assessments for the Pearson correlation. The key difference between the Pearson correlation and Spearman/Kendall rank correlation, is that the former assumes that the variables being tested are normally distributed. It also further assumes that the variables are linearly related to each other. The latter two measures are however non-parametric and make no assumptions about the distribution of the variables being tested. We argue that the assumptions made by the Pearson correlation may be too constraining, given that any two independent evaluation systems may not exhibit linearity.

Looking at the two bigram based variants, ROUGE-WE-2 and ROUGE-WE-SU4, we observe that ROUGE-WE-2 improves on ROUGE-2 most of the time, regardless of the correlation metric used. This lends further support to our proposal to use word embeddings with ROUGE.

However ROUGE-WE-SU4 is only better than ROUGE-SU4 when evaluating readability. It does consistently worse than ROUGE-SU4 for pyramid and responsiveness. The reason for this is likely due to how we have chosen to compose unigram word vectors into bigram equivalents. The multiplicative approach that we have taken worked better for ROUGE-WE-2 which looks at contiguous bigrams. These are easier to interpret semantically than skip-bigrams (the target of ROUGE-WE-SU4). The latter, by nature of their construction, loses some of the semantic meaning attached to each word, and thus may not be as amenable to the linear composition of word vectors.

Owczarzak and Dang (2011) reports only the results of the top systems in AESOP in terms of Pearson's correlation. To get a more complete picture of the usefulness of our proposal, it will be instructive to also compare it against the other top systems in AESOP, when measured with the Spearman/Kendall correlations. We show in Table 4 the top three systems which correlate best with the pyramid score when measured with the Spearman rank coefficient. `C_S_IIITH3` (Kumar et al., 2011) is a graph-based system which assess summaries based on differences in word co-locations between generated summaries and model summaries. `BE-HM` (baseline by the organizers of the AESOP task) is the BE system (Hovy et al., 2005), where basic elements are identified using a head-modifier criterion on parse results from Minipar. Lastly, `catolicasc1` (de Oliveira, 2011) is also a graph-based system which frames the summary evaluation problem as a maximum bipartite graph matching problem.

Measure	S	K
ROUGE-WE-1	**0.9138**	0.7534
C_S_IIITH3	0.9033	**0.7582**
BE-HM	0.9030	0.7456
catolicasc1	0.9017	0.7351

Table 4: Correlation with pyramid scores of top systems in AESOP 2011, measured with the Spearman ρ (S), and Kendall τ (K) coefficients.

We see that ROUGE-WE-1 displays better correlations with pyramid scores than the top system in AESOP 2011 (*i.e.*, `C_S_IIITH3`) when measured with the Spearman coefficient. The latter does slightly better however for the Kendall coefficient. This observation further validates that our proposal is an effective enhancement to ROUGE.

5 Conclusion

We proposed an enhancement to the popular ROUGE metric in this work, ROUGE-WE.

ROUGE is biased towards identifying lexical similarity when assessing the quality of a generated summary. We improve on this by incorporating the use of word embeddings. This enhancement allows us to go beyond surface lexicographic matches, and capture instead the semantic similarities between words used in a generated summary and a human-written model summary. Experimenting on the TAC AESOP dataset, we show that this proposal exhibits very good correlations with human assessments, measured with the Spearman and Kendall rank coefficients. In particular, ROUGE-WE-1 outperforms leading state-of-the-art systems consistently.

Looking ahead, we want to continue building on this work. One area to improve on is the use of a more inclusive evaluation dataset. The AESOP summaries that we have used in our experiments are drawn from systems participating in the TAC summarization task, where there is a strong exhibited bias towards extractive summarizers. It will be helpful to enlarge this set of summaries to include output from summarizers which carry out substantial paraphrasing (Li et al., 2013; Ng et al., 2014; Liu et al., 2015).

Another immediate goal is to study the use of better compositional embedding models. The generalization of unigram word embeddings into bigrams (or phrases), is still an open problem (Yin and Schütze, 2014; Yu et al., 2014). A better compositional embedding model than the one that we adopted in this work should help us improve the results achieved by bigram variants of ROUGE-WE, especially ROUGE-WE-SU4. This is important because earlier works have demonstrated the value of using skip-bigrams for summarization evaluation.

An effective and accurate automatic evaluation measure will be a big boon to our quest for better text summarization systems. Word embeddings add a promising dimension to summarization evaluation, and we hope to expand on the work we have shared to further realize its potential.

Abstract

Automated text summarization is aimed at extracting essential information from original text and presenting it in a minimal, often predefined, number of words. In this paper, we introduce a new approach for unsupervised extractive summarization, based on the Minimum Description Length (MDL) principle, using the Krimp dataset compression algorithm (Vreeken et al., 2011). Our approach represents a text as a transactional dataset, with sentences as transactions, and then describes it by itemsets that stand for frequent sequences of words. The summary is then compiled from sentences that compress (and as such, best describe) the document. The problem of summarization is reduced to the maximal coverage, following the assumption that a summary that best describes the original text, should cover most of the word sequences describing the document. We solve it by a greedy algorithm and present the evaluation results.

1 Introduction

Many unsupervised approaches for extractive text summarization follow the maximal coverage principle (Takamura and Okumura, 2009; Gillick and Favre, 2009), where the extract that maximally covers the information contained in the source text, is selected. Since the exhaustive solution demands an exponential number of tests, approximation techniques, such as a greedy approach or a global optimization of a target function, are utilized. It is quite common to measure text informativeness by the frequency of its components– words, phrases, concepts, and so on.

A different approach that received much less attention is based on the Minimum Description Length (MDL) principle, defining the best summary as the one that leads to the *best compression* of the text by providing its *shortest and most concise description*. The MDL principle is widely useful in compression techniques of non-textual data, such as summarization of query results for OLAP applications. (Lakshmanan et al., 2002; Bu et al., 2005) However, only a few works on text summarization using MDL can be found in the literature. Authors of (Nomoto and Matsumoto, 2001) used K-means clustering extended with MDL principle for finding diverse topics in the summarized text. Nomoto in (2004) also extended the C4.5 classifier with MDL for learning rhetorical relations. In (Nguyen et al., 2015) the problem of micro-review summarization is formulated within the MDL framework, where the authors view the tips as being encoded by snippets, and seek to find a collection of snippets that produce the encoding with the minimum number of bits.

This paper introduces a new MDL-based approach for extracting relevant sentences into a summary. The approach represents documents as a sequential transactional dataset and then compresses it by replacing frequent sequences of words by codes. The summary is then compiled from sentences that best compress (or describe) the document content. The intuition behind this approach says that a summary that best describes the original text should cover its most frequent word sequences. As such, the problem of summarization is very naturally reduced to the maximal coverage problem. We solve it by the greedy method which ranks sentences by their coverage of best compressing frequent word sequences and selects the top-ranked sentences to a summary. There are a few works that applied the common data mining techniques for calculating frequent itemsets from transactional data to the text summarization task (Baralis et al., 2012; Agarwal et al., 2011; Dalal and Zaveri, 2013), but none of them followed the MDL principle. The comparative results on three different corpora

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1931–1935,
Lisbon, Portugal, 17-21 September 2015.

show that our approach outperforms other unsupervised state-of-the-art summarizers.

2 Methodology

The proposed summarization methodology, denoted by Gamp[1], is based on the MDL principle that is defined formally as follows (Mitchell, 1997). Given a set of models $\mathcal{M}$, a model $M \in \mathcal{M}$ is considered the *best* if it minimizes $L(M) + L(D|M)$ where $L(M)$ is the bit length of the description of M and $L(D|M)$ is the bit length of the dataset D encoded with M.

In our approach, we first represent an input text as a transactional dataset. Then, using the Krimp dataset compression algorithm (Vreeken et al., 2011), we build the MDL for this dataset using its frequent sequential itemsets (word sequences). The sentences that cover most frequent word sequences are chosen to a summary. The following subsections describe our methodology in detail.

2.1 Problem statement

We are given a single text or a collection of texts about the same topic, composed of a set of sentences $S_1, \ldots, S_n$ over terms $t_1, \ldots, t_m$. The word limit W is defined for the final summary.

We represent a text as a *sequential transactional dataset*. Such a dataset consists of *transactions* (sentences), denoted by $T_1, \ldots, T_n$, and unique items (terms[2]) $I_1, \ldots, I_m$. Items are unique across the entire dataset. The number n of transactions is called the *size* of a dataset. Transaction T_i is a sequence of items from $I_1, \ldots, I_m$, denoted by $T_i = (I_{i_1}, \ldots, I_{i_k})$; the same item may appear in different places within the same transaction. *Support* of an item sequence s in the dataset is the ratio of transactions containing it as a subsequence to the dataset size n, i.e., $supp(s) = \frac{|\{T \in D | s \subseteq T\}|}{n}$. Given a support bound $Supp \in [0, 1]$, a sequence s is called *frequent* if $supp(s) \geq Supp$.

According to the MDL principle, we are interested in the minimal size of a compressed dataset $D|CT$ after frequent sequences in D are encoded with the compressing set–codes from the *Coding Table* CT, where shorter codes are assigned to more frequent sequences. The description length of non-encoded terms is assumed proportional to their length (number of characters). We rank sentences by their coverage of the best compressing set, which is the number of CT members in the sentence. The sentences with the highest coverage score are added to the summary as long as its length does not exceed W.

2.2 Krimping text

The purpose of the Krimp algorithm (Vreeken et al., 2011) is to use frequent sets (or sequences) to compress a transactional database in order to achieve MDL for that database. Let $FreqSeq$ be the set of all frequent sequences in the database. A collection CT of sequences from $FreqSeq$ (called the *Coding Table*) is called *best* when it minimizes $L(CT) + L(D|CT)$. We are interested in both *exact* and *inexact* sequences, allowing a sequence to have gaps inside it as long as the ratio of sequence length to sequence length with gaps does not exceed a pre-set parameter $Gap \in (0, 1]$. Sequences with gaps make sense in text data, as phrasing of the same fact or entity in different sentences may differ. In order to encode the database, every member $s \in CT$ is associated with its binary *prefix code* c (such as Huffman codes for 4 members: 0, 10, 110, 111), so that the most frequent code has the shortest length. We use an upper bound C on the number of encoded sequences in the coding table CT, in order to limit document compression. Krimp-based extractive summarization (see Algorithm 1) is given a document D with n sentences and m unique terms. The algorithm parameters are described in Table 1:

#	*note*	*description*	*affects*
1	**W**	summary words limit	summary length
2	**Supp**	minimal support bound – minimal fraction of sentences containing a frequent sequence	number of frequent word sequences $\|FreqSeq\|$, compression rate
3	**C**	maximal number of codes	as in 2
4	**Gap**	maximal allowed sequence gap ratio	as in 2

Table 1: Parameters of Algorithm 1.

The algorithm consists of the following steps.

1. We find all frequent term sequences in the document using Apriori-TID algorithm (R and R, 1994) for the given $Supp$ and Gap and store them in set $FreqSeq$, which is kept in Standard Candidate Order[3]. The coding table CT is initialized to contain all single normalized terms and their frequencies. CT is always kept in Standard Cover Order[4] (Steps

[1] abbreviation of two words: GAp and kriMP

[2] normalized words following tokenization, stemming, and stop-word removal

[3] first, sorted by increasing support, then by decreasing sequence length, then lexicographically

[4] first, sorted by decreasing sequence length, then by decreasing support, and finally, in lexicographical order

1 and 2 in Algorithm 1).

2. We repeatedly choose frequent sequences from the set $FreqSeq$ so that the size of the encoded dataset is minimal, with every selected sequence replaced by its code. Selection is done by computing the decrease in the size of the encoding when each one of the sequences is considered to be a candidate to be added to CT (Step 3 in Algorithm 1).

3. The summary is constructed by incrementally adding sentences with the highest coverage of encoded term sequences (Step 4 in Algorithm 1) that are not covered by previously selected sentences. The sentences are selected in the greedy manner as long as the word limit W is not exceeded.

Algorithm 1: Gamp: Krimp-based extractive summarization with gaps

Input: (1) A document, containing sentences $S_1, \ldots, S_n$ after tokenization, stemming and stop-word removal;
(2) normalized terms $T_1, \ldots, T_m$;
(3) summary size W
(3) limit C on the number of codes to use;
(4) minimal support bound $Supp$;
(5) maximal gap ratio Gap.
Output: Extractive summary $Summary$
/ STEP 1: Frequent sequence mining */*
$FreqSeq \leftarrow$ inexact frequent sequences of terms from $\{T_1, \ldots, T_m\}$ appearing in at least $Supp$ fraction of sentences and having a gap ratio of at least Gap;
Sort $FreqSeq$ according to Standard Candidate Order;
/ STEP 2: Initialize the coding table */*
Add all terms $T_1, \ldots, T_m$ and their support to CT;
Keep CT always sorted according to Standard Cover Order;
Initialize prefix codes according to the order of sequences in CT; */* STEP 3: Find the best encoding */*
$EncodedData \leftarrow$ *PrefixEncoding*$(\{S_1, \ldots, S_n\}, CT)$;
$CodeCount \leftarrow 0$;
while $CodeCount < B$ *and* $FreqSeq \neq \emptyset$ **do**
  $BestCode \leftarrow c \in FreqSeq$ such that $L(CT \cup \{c\}) + L($*PrefixEncoding*$(\{S_1, \ldots, S_n\}, CT \cup \{c\}))$ is minimal;
  $CT \leftarrow CT \cup \{BestCode\}$;
  $FreqSeq \leftarrow FreqSeq \setminus \{BestCode\}$;
  Remove supersets of $BestCode$ from $FreqSeq$;
  $CodeCount$++;
end
$Summary \leftarrow \emptyset$; */* STEP 4: Build the summary */*
while $\#words(Summary) < W$ **do**
  Find the sentence S_i that covers the largest set $\mathcal{T}$ of terms in CT and add it to $Summary$;
  Remove terms of $\mathcal{T}$ from CT;
end
return $Summary$

Example 2.1 Let dataset D contain following three sentences (taken from the "House of cards" TV show):

S_1 = *A hunter must stalk his prey until the hunter becomes the hunted.*
S_2 = *Then the prey becomes the predator.*
S_3 = *Then the predator and the hunter fight.*

After stemming, tokenization and stop-word removal we obtain unique (stemmed) terms:

t_1 = *hunter*, t_2 = *must*, t_3 = *stalk*, t_4 = *prei*,
t_5 = *becom*, t_6 = *hunt*, t_7 = *predat*, t_8 = *fight*.
$supp(t_1) = supp(t_4) = supp(t_5) = supp(t_7) = \frac{2}{3}$.
$supp(t_2) = supp(t_3) = supp(t_8) = \frac{1}{3}$.

Now we can view sentences as the following sequences of normalized terms.

$S_1 = (t_1, t_2, t_3, t_4, t_1, t_5, t_4)$
$S_2 = (t_4, t_5, t_7)$
$S_3 = (t_7, t_1, t_8)$

Initial coding table CT will contain all frequent single terms in Standard Cover Order: $t_5, t_1, t_7, t_4, t_8, t_2, t_3$. Let the minimal support bound be $\frac{2}{3}$, i.e., to be frequent a sequence must appear in at least 2 sentences, and let the gap ratio be $\frac{1}{2}$. Also, let the limit C be 4, meaning that only the first four entries of the coding table will be used for encoding. There exists a frequent sequence (t_4, t_5) that appears twice in the text, once in S_1 with a gap and once in S_2 without a gap. We add it to the coding table according to the Standard Cover Order, generate prefix codes for the first four entries, and get

$CT =$

seq	*supp*	*code*	*code len*
(**prei**, **becom**)	2/3	0	1
becom	2/3	10	2
hunter	2/3	110	3
predat	2/3	111	3
prei	2/3	–	–
...	...	–	–

Now S_1 covers 3 out of 4 entries in CT, while S_2 and S_3 cover 2 terms each. If our summary is to contain just one sentence, we select S_1.

3 Experimental settings and results

We performed experiments on three corpora from the Document Understanding Conference (DUC): 2002, 2004, and 2007 (duc, 2002 2007), summarized in Table 2. DUC 2002 and 2007 each contains a set of single documents, and DUC 2004 contains 50 sets of 10 related documents. We generated summaries per single documents in the DUC 2002 and 2007 corpora, and per each set of related documents (by considering each set of documents as one meta-document) in DUC 2004, following the corresponding length restrictions. The summarization quality was measured

corpus	# documents	# summaries	summ len	doc size (KB)	type
DUC'02	533	2-3	100	1-20	SD
DUC'04	50	4	100	20-89	MD (50x10)
DUC'07	23	4	250	28-131	SD

Table 2: Corpora statistics.

by the ROUGE-1 and ROUGE-2 (Lin, 2004) recall scores, with the word limit indicated in Table 2, without stemming and stopword removal.

The results of the introduced algorithm (Gamp) may be affected by several input parameters: minimum support ($Supp$), codes limit (C), and the maximal gap allowed between frequent words (Gap). In order to find the best algorithm settings for a general case, we performed experiments that explored the impact of these parameters on the summarization results. First, we experimented with different values of support count in the range of $[2, 10]$. The results show that we get the best summaries using the sequences that occur in at least four document sentences.

A limit on the number of codes is an additional parameter.We explored the impact of this parameter on the quality of generated summaries. As we could conclude from our experiments, the best summarization results are obtained if this parameter is set to the maximal number of words in the summary, W. Consequently, we used 100 codes for summarizing DUC 2002 and DUC 2004 documents and 250 codes for DUC 2007 documents.

The maximal gap ratio defines a pattern for generating the frequent sequences and has a direct effect on their structure and number. Our experiments showed that allowing a small gap between words of a sequence helps to improve slightly the ranking of sentences, but the improvement is not significant. Thus we used $Gap = 0.8$ in comparative experiments for all corpora. The resulting settings for each corpus are shown in Table 3.

Corpus	Supp	Max. codes	Gap
DUC 2002 and 2004	4	100	0.8
DUC 2007	4	250	0.8

Table 3: Best settings.

We compared the Gamp algorithm with the two known unsupervised state-of-the-art summarizers denoted by Gillick (Gillick and Favre, 2009) and McDonald (McDonald, 2007). As a baseline, we used a very simple approach that takes first sentences to a summary (denoted by TopK). Table 4 contains the results of comparative evaluations. The best scores are shown in bold. Gamp outperformed the other methods on all datasets (using ROUGE-1 score). The difference between the scores of Gamp and Gillick (second best system) on DUC 2007 is highly significant according to the Wilcoxon matched pairs test. Based on the same test, the difference of scores obtained on the DUC 2004 is not statistically significant. On the DUC 2002, Gamp is ranked first, with insignificant difference from the second best (McDonald's) scores. Based on this result, we can conclude that MDL-based summarization using frequent sequences works better on long documents or multi-document domain. Intuitively, it is a very logical conclusion, because single short documents do not contain a sufficient number of frequent sequences. It is noteworthy that, in addition to the greedy approach, we also evaluated the global optimization with maximizing coverage and minimizing redundancy using Linear Programming (LP). However, experimental results did not provide any improvement over the greedy approach. Therefore, we report only the results of the greedy solution.

	ROUGE-1 Recall			ROUGE-2 Recall		
Algorithm	DUC'02	DUC'04	DUC'07	DUC'02	DUC'04	DUC'07
Gamp	**0.4421**	**0.3440**	**0.3959**	0.1941	**0.0829**	**0.0942**
Gillick	0.4207	0.3314	0.3518	0.1773	0.0753	0.0650
McDonald	0.4391	0.2955	0.3500	**0.1981**	0.0556	0.0672
TopK	0.4322	0.2973	0.3525	0.1867	0.0606	0.0706

Table 4: Comparative results.

4 Conclusions

In this paper, we introduce a new approach for summarizing text documents based on their Minimal Description Length. We describe documents using frequent sequences of their words. The sentences with the highest coverage of the best compressing set are selected to a summary. The experimental results show that this approach outperforms other unsupervised state-of-the-art methods when summarizing long documents or sets of related documents. We would not recommend using our approach for summarizing single short documents which do not contain enough content for providing a high-quality description. In the future, we intend to apply the MDL method to keyword extraction, headline generation, and other related tasks.

Abstract

Predicting the success of referring expressions (RE) is vital for real-world applications such as navigation systems. Traditionally, research has focused on studying Referring Expression Generation (REG) in virtual, controlled environments. In this paper, we describe a novel study of spatial references from real scenes rather than virtual. First, we investigate how humans describe objects in *open, uncontrolled* scenarios and compare our findings to those reported in virtual environments. We show that REs in real-world scenarios differ significantly to those in virtual worlds. Second, we propose a novel approach to quantifying image complexity when complete annotations are not present (e.g. due to poor object recognition capabitlities), and third, we present a model for success prediction of REs for objects in real scenes. Finally, we discuss implications for Natural Language Generation (NLG) systems and future directions.

1 Introduction

REG has attracted considerable interest in the NLG community over the past 20 years (Krahmer and van Deemter, 2011; Gatt et al., 2014). While initially, the standard evaluation metric for REG was human-likeness, as compared to human corpora similarity as in TUNA (Gatt et al., 2009), the field has moved on to evaluating REG effectiveness by measuring task success in virtual interactive environments (Byron et al., 2009; Gargett et al., 2010; Janarthanam et al., 2012). Virtual environments however eliminate real-world uncertainty, such object recognition errors or cluttered scenes. In this paper, we investigate whether the lessons learnt in virtual environments can be transferred to real-world scenes. We consider the case where we are uncertain about the scene itself, i.e. we assume that the complexity of the scene is hidden and we are interested in identifying a specific object, and thus our work differs from approaches that generate descriptions for images such as (Mitchell et al., 2012; Feng and Lapata, 2013; Yang et al., 2011; Yatskar et al., 2014).

Related work has focused on computer generated objects (van Deemter et al., 2006; Viethen and Dale, 2008), crafts (Mitchell et al., 2010), or small objects in a simple background (Mitchell et al., 2013a; FitzGerald et al., 2013). One notable exception is the recent work by Kazemzadeh et al. (2014), who investigate referring expressions of objects in "complex photographs of real-world cluttered scenes". They report that REs are heavily influenced by the object type. Here, we are interested in studying REs for visual objects in urban scenes. As the success of a RE is heavily dependent on the complexity of the scene as well as its linguistic features, we are interested in modelling and thus predicting the success of a RE.

Initially, this paper presents and analyses a novel, real-world corpus REAL (to be released) – "Referring Expression Anchored Language" (Section 2), and compares the findings to those reported in virtual worlds (Gargett et al., 2010). We then provide a detailed analysis of how syntactic and semantic features contribute to the success of REs (Sections 4.1, 4.2, 4.3), accounting for unobservable latent variables, such as the complexity of the visual scene (as described in Section 3). Finally, we summarise our work and discuss the implications of our work for NLG systems (Section 5). The dataset and models will be released.

2 The REAL Corpus

The REAL corpus contains a collection of images of real-world urban scenes (Fig. 1) together with verbal descriptions of target objects (see Fig. 2)

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1936–1942,
Lisbon, Portugal, 17-21 September 2015.

Figure 1: Original picture.

Figure 2: Target object in yellow box.

Figure 3: The identified object by the validators.

generated by humans, paired with data on how successful other people were able to identify the same object based on these descriptions (Fig. 3). The data was collected through a web-based interface. The images were taken in Edinburgh (Scotland, UK), very early one summer morning. This was necessary to reduce the occlusion of city objects from buses and crowds, and to minimise lighting and weather variations between images.

2.1 Experimental Setup

There were 190 participants recruited (age between 16 to 71). Each participant was presented with an urban image (Fig. 1), where the target object was outlined by a yellow box (Fig. 2), and was asked to describe the target using free text. After completing a (self-specified) number of tasks, participants were then asked to validate descriptions provided by other participants by clicking on the object using previously unseen images (Fig. 3).

# participants	190
# images/ stimuli	32
# descriptions	868
# verifications	2618
– ambiguous	201
– not found	75
– correct	1994
– incorrect	251
– NA	7

Table 1: The REAL corpus

Overall, 868 descriptions across 32 images were collected, averaging around 27 descriptions per image. The balance of generation and validations was adjusted to ensure that all descriptions were identified by at least 3 other participants, generating 2618 image tag verifications. All cases were manually checked to determine if the 'correct' (green) or 'incorrect' (red) target had been identified Fig. 3. Overall, 76.2% of human descriptions provided were successfully identified. For the experiments reported in following sections, we summarised answers categorised as 'incorrect', 'ambitious' and 'not found' as *unsuccessful*.

2.2 Comparison to GIVE-2 Corpus

We now compare this data with human data generated for the GIVE-2 challenge (Gargett et al., 2010). In GIVE-2, the target objects have distinct attributes, such as colour and position. For instance, an effective RE in GIVE-2 could be "*the third button from the second row*". In real-world situations though, object properties are less well defined, making a finite set of pre-defined qualities unfeasible. Consider, for instance, the building highlighted in Figure 2, for which the following descriptions were collected:

1. *The Austrian looking white house with the dark wooden beams at the water side.*
2. *The white building with the x-shape balconies. It seems it's new.*
3. *The white building with the balconies by the river.*
4. *Apartments with balconies.*
5. *The nearest house on right side. It's black and white.*
6. *The white and black building on the far right, it has lots of triangles in its design.*
7. *The rightmost house with white walls and wood finishings.*

It is evident that the REAL users refer to a variety of object qualities. We observe that all participants refer to the colour of the building (*white, black and white, greyish-whitish*) and some mention location (*by the river, at the water side*).

Experimental Factors influencing Task Performance: In REAL, task success is defined as the ability to correctly identify an object, whereas in GIVE-2, task success refers to the successful completion of the navigation task. In contrast to GIVE-2, not all REAL participants were able to correctly identify the referred objects (76.2% task

	GIVE-2		REAL
	German	English	
Overall task success	100%	100%	76.2%
Task success (female)	100%	100%	78.8%
Task success (male)	100%	100%	69.6%
Length of descriptions (no. words)	5.2	4.7	16.01
Length of descriptions (female)	NA	NA	97.36
Length of descriptions (male)	NA	NA	91.38

Table 2: Descriptive statistics for GIVE-2 and REAL

success). We assume that this is because GIVE-2 was an interactive setup, where the participants were able to engage in a clarification dialogue. **Gender:** In REAL, gender was not a significant factor with respect to task success (Mann-Whitney U test, $p = 0.2$). **Length of REs (no. words):** In REAL, females tend to provide lengthier REs than males, however the difference is not statistically significant (Mann-Whitney U test, $p = 0.58$). In GIVE-2, only German females produced significantly longer descriptions than their male counterparts. **Relation between length (no. words) and task success:** The REAL data shows a positive relationship between length and success rate, i.e. for a one word increase in length, the odds of *correct* object identification is significantly increased ($p < 0.05$, Logit), i.e. longer and more complex sentences lead to more successful REs.

3 Quantifying the Image Complexity

We assume that the complexity of the urban scene represented in the image is hidden due to the lack of semantic annotations. Our dataset does not include any quantifiable image descriptions, such as computer vision output as in (Mitchell et al., 2012) or manual annotations as in (Yatskar et al., 2014). In addition, the same RE might not always result in successful identification of an object due to scene complexity. In order to marginalise the effect of the scene complexity, we exploit the multiple available data points per image. This allows us to estimate the average success rate of each referring expression $\overline{SR}_{RE}$ (the proportion of successful validations) and the average success rate of each image $\overline{SR}_i$ (the proportion of the correctly identified objects in the image). We use $\overline{SR}_i$ to marginalise over the (hidden) image complexity, where we assume that some pictures are inherently more complex than others and thus achieve lower success rates. Similar normalisation methods are used for user ratings to account for the fact that some users are more "tolerant" and in general give higher ratings (Jin and Si, 2004). We employ *Gaussian normalisation* (Resnick et al., 1994) to normalise image success rates by considering the following factors:

1. *Shift of average success rate per image:* some images are inherently easier than others and gain higher success rates, independently of the REs used. This factor can be accounted by subtracting average success rates of all images from the average rating of a specific image x.
2. *Different ratings:* there are 27 REs per image on average, some of which are harder to understand than others, thus they gain lower success rates. To account for this, the success rates of each image are divided by the overall SR variance.

The normalised image success rate (NSR_i) per image x is defined by the following equation:

$$NSR_i(x) = \frac{SR_i(x) - \overline{SR_i}}{\sqrt{\sum_n (SR_i(x) - \overline{SR_i})^2}} \quad (1)$$

Using the (NSR_i), we now investigate the REs in terms of their linguistic properties, including automatically annotated syntactic features and manually annotated semantic features.

4 Modelling REG Success

Unlike previous work, we use both successful and unsuccessful REs in order to build a model that is able to predict the success or the failure of a RE.

4.1 Syntactic Analysis of REG Success

We use the Stanford CoreNLP tool (Manning et al., 2014) to syntactically annotate the REs and we investigate which linguistic features contribute to the RE success in relation to the image complexity. Note that these analyses are based on normalised values, as discussed in Section 3).

Predicting RE Success Rate ($\overline{SR}_{RE}$): Initially, we compare successful and unsuccessful REs by taking the upper and lower quartiles and extracting their syntactic features., i.e. the top and bottom 25% of REs with respect to their average success rate, and group them into two groups. We then extract syntactic features of these two groups and compare their frequencies (occurrence per RE), means, and standard deviations (Table 3), and compare them using a t-test ($p < 0.05$). The difference between successful and unsuccessful ex-

	Successful REs			Successful REs		
	Mean	SD	Freq.	Mean	SD	Freq.
NP*	7.35	3.958	100	6.7	3.8	100
VP	1.45	1.673	41.8	1.46	1.923	58
PRN	.02	.181	2.1	.03	.193	2.4
NNP*	.57	1.131	27	.38	.918	19.3
NN*	4.2	2.284	98.8	3.79	2.441	98.1
DT	2.59	1.791	86.7	2.63	1.813	85.4
JJ*	1.92	1.61	80.9	1.66	1.288	81.1
CC	.4	.645	32.8	.31	.588	25
PP	2.52	1.754	92.3	2.54	1.778	85.8
ADJP	.2	.536	16.2	.041	.597	19.3
ADVP	.27	.538	22.8	.25	.539	19.8
RB	.34	.639	26.6	.34	.859	21.2
VBN*	.22	.465	20.3	.31	.445	10.8
NNS	.61	.902	40.7	.72	.782	53.3
CD	.27	.552	22	.25	.478	23.6

Table 3: Statistics regarding the linguistic features in successful vs unsuccessful referring expressions. (* denotes significant difference at $p < 0.05$).

pressions lies in the use of NP (Noun phrases), NNP (Proper noun, singular), NN (Noun, singular or mass), JJ (Adjective) and VBN (Verb, past participle) (Table 3). Successful REs include more NPs, including NNPs and NNs, which indicates that more than one reference is used to describe and distinguish a target object. This could mean that distractors are explicitly mentioned and eliminated or that the object of interest has a complex appearance, as opposed to simply structured objects, such as buttons, in GIVE-2. For example, the following description refers to a complex object:

> *The **large American-style wooden building** with **balcony painted cream and red/brown**. **Ground floor** is a **cafe with tables and parasols** outside.*

In addition, successful REs contain significantly more adjectives and verbs in past participle[1], which indicates that the object was further described and distinguished using its attributes, as for instance the following description:

> *Large modern **glass fronted** building, **butted up** against traditional Victorian terrace, slightly **set back** from road and with facing **bowed** frontage.*

The main difference between successful and unsuccessful REs is the amount of detail provided to describe and distinguish the target object. This is also in-line with our previous results that success is positively correlated to the number of words used (Section 2.2) and it might explain why humans overspecify.

[1]A participle is a form of a verb that is used in a sentence as modifier, and thus plays a role similar to that of an adjective or adverb, such as *built* or *worn*.

Models	R^2
Syntactic: NP+PP+ADVP+CD+length	.15
Semantic model: taxonomic + absolute	.338
Joint model: PP + taxonomic + absolute	.407

Table 4: Models and their fit.

To further verify this hypothesis, we build a predictive model of average success rate, using *multiple step-wise linear regression* with syntactic features as predictors. We find a significant ($p < 0.05$) positive relationship between success rate and NP, PP (Prepositional phrase), ADVP (Adverbial phrase), CD (Cardinal number), and length (Table 4). NPs are used to distinguish and describe the target object. ADVPs and PPs serve a similar function to adjectives in this case, i.e. to describe further attributes, especially spatial ones, like "the one near the river", "next to the yellow building". Cardinal numbers are used to refer to complex structured features of the target object, e.g. *two-story building* or *two large double doors*.

Predicting Image Success Rate ($\overline{NSR}_{image}$): We repeat a similar analysis for estimating how syntactic features relate to image success rate, i.e. how the image complexity, as estimated from the success rate of an image, influences how humans describe the target object, i.e. how human generated descriptions change with respect to the image complexity as estimated from the (normalised) success rate of an image. We find that humans use significantly more PPs and number of words ($p < 0.05$) when describing complex images.

In sum, syntactical features, which further describe and distinguish the target object (such as NPs, ADJ, and ADVPs and PPs) indicate successful REs. However, they cannot fully answer the question of "what makes a RE successful", therefore we enrich our feature set using manually annotated semantic features.

4.2 Semantic Analysis of REG

We extract semantic features by annotating spatial frames of reference as described in (Gargett et al., 2010). We annotate a sample of the corpus (100 instances), which allows us to perform a direct comparison between the two corpora.

Comparison to GIVE-2 Corpus: We observe that in the REAL corpus, the *taxonomic* property, the *relative property* and the *macro-level landmark*

Spatial Frame	REAL	GIVE-2	
		German	English
Taxonomic Property	**92***	53.66	58.51
Absolute Property	**57***	85.37	92.53
Relative Property	**15***	6.83	4.56
Viewer-centred	15	15.61	12.45
Micro-level landmark intrinsic	**9***	13.17	17.84
Distractor Intrinsic	**5***	10.73	14.11
Macro-level landmark intrinsic	**43***	6.83	4.15
Deduction by elimination	1	0.98	3.32

Table 5: Frequency of semantic frames in REAL vs. GIVE-2 (* denotes significant differences at $p < 0.05$, χ^2 test).

intrinsic property of the object in question are used significantly more often than in the GIVE-2 corpus (Table 5)[2].

In contrast, in GIVE-2 the *absolute property* of the object, such as the colour, and references to *distractors* are used significantly more often than in REAL. These results reflect the fact that scenes in REAL were more complex, and as such, relative properties to other objects and landmarks were used more often. In GIVE-2, target objects were mostly buttons, therefore, absolute descriptions (*"the blue button"*) or referring to an intrinsic distractor (*"the red button next to the green"*) are more frequent. In addition, real-world environments are dynamic. Humans choose to refer to immovable objects (*macro-level landmarks*) more often than in closed-world environments. In GIVE-2, immovable objects are limited to walls, ceilings or floors, whereas in REAL there is a wide range of immovable objects /landmarks that a user can refer to, e.g. another building, rivers, parks, shops, etc. Landmark descriptions will play an important role in future navigation systems (Kandangath and Tu, 2015).

Predicting RE Success Rate ($\overline{SR}_{RE}$): Next, we analyse which spatial frames significantly contribute to task success, using *multiple step-wise linear regression*.We find that *taxonomic* and *absolute* properties significantly ($p < 0.05$) contribute to the success of a referring expression (Table 4). Semantic features explain more of the variance observed in $\overline{SR}_{RE}$, than syntactic features.

[2]Note that for GIVE-2 we consider both, the German and the English data.

4.3 Joint Model of REG Success

Both syntactic and semantic features contribute to the success of a RE. Therefore, we construct a joint model for predicting $\overline{SR}_{RE}$ using *step-wise linear regression* over the joint feature space. We find that both syntactic and semantic features significantly ($p < 0.05$) contribute to the success of a RE, see Table 4. This model explains almost half of the variation observed in $\overline{SR}_{RE}$ ($R^2 = .407$). Clarke et al. (2013) reports an influence of visual salience on REG, therefore, in future, we will investigate the influence of visual features.

5 Discussion and Conclusions

From the results presented, the following conclusions can be drawn for real-world NLG systems. Firstly, semantic features have a bigger impact on the success rate of REs than syntactic features, i.e. content selection is more important than surface realisation for REG. Secondly, semantic features such as *taxonomic* and *absolute* properties can significantly contribute to RE success. Taxonomic properties refer to the type of target object, and in general depend on the local knowledge of the information giver. Similarly, the success of the RE will depend on the expertise of the information follower. As such, modelling the user's level of knowledge (Janarthenam et al., 2011) and stylistic differences (Di Fabbrizio et al., 2008) is crucial. Absolute properties refer to object attributes, such as colour. Attribute selection for REG has attracted a considerable amount of attention, therefore it would be interesting to investigate how these automatic attribute selection algorithms perform in real-world, interactive environments. Finally, the more complex scenes seem to justify longer and more complex descriptions. As such, there is an underlying trade-off which needs to be optimised, e.g. following the generation framework described in (Rieser et al., 2014).

In future, we will compare existing REG algorithms on our dataset, in a similar experiment to Mitchell et al. (2013b). Then, we will extend existing algorithms to take into account other properties such as material (e.g. "wooden"), components of the referred object (e.g. "balconies") etc. Finally, we will incorparate such an algorithm in interactive settings to investigate the influence of user dialogue behaviour and the influence of visual features, such as salience (Clarke et al., 2013), in order to improve the fit of our predictive model.

Acknowledgments

This research received funding from the EPSRC GUI project Generation for Uncertain Information (EP/L026775/1). The data has been collected through the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement no. 216594 (SPACEBOOK project).

An Unsupervised Bayesian Modelling Approach to Storyline Detection from News Articles

Abstract

Storyline detection from news articles aims at summarizing events described under a certain news topic and revealing how those events evolve over time. It is a difficult task because it requires first the detection of events from news articles published in different time periods and then the construction of storylines by linking events into coherent news stories. Moreover, each storyline has different hierarchical structures which are dependent across epochs. Existing approaches often ignore the dependency of hierarchical structures in storyline generation. In this paper, we propose an unsupervised Bayesian model, called dynamic storyline detection model, to extract structured representations and evolution patterns of storylines. The proposed model is evaluated on a large scale news corpus. Experimental results show that our proposed model outperforms several baseline approaches.

1 Introduction

The rapid development of online news media sites is accompanied by the generation of tremendous news reports. Facing such massive amount of news articles, it is crucial to develop an automated tool which can provide a temporal summary of events and their evolutions related to a topic from news reports. Therefore, storyline detection, aiming at summarising the development of certain related events, has been studied in order to help readers quickly understand the major events reported in news articles. It has attracted great attention recently. Kawamae (2011) proposed a trend analysis model which used the difference between temporal words and other words in each document to detect topic evolution over time. Ahmed et al. (2011) proposed a unified framework to group temporally and topically related news articles into same storylines in order to reveal the temporal evolution of events. Tang and Yang (2012) developed a topic-user-trend model, which incorporates user interests into the generative process of web contents. Radinsky and Horvitz (2013) built storylines based on text clustering and entity entropy to predict future events. Huang and Huang (2013) developed a mixture-event-aspect model to model sub-events into local and global aspects and utilize an optimization method to generate storylines. Wang et al. (2013) proposed an evolutionary multi-branch tree clustering method for streaming text data in which the tree construction is casted as an online posterior estimation problem by considering both the current tree and the previous tree simultaneously.

With the fast development of social media platforms, newsworthy events are widely scattered not only on traditional news media but also on social media (Zhou et al., 2015). For example, Twitter, one of the most widely adopted social media platforms, appears to cover nearly all newswire events (Petrovic et al., 2013). Therefore, approaches have also been proposed for storyline summarization on social media. Given a user input query of an ongoing event, Lin et al. (2012) extracted the storyline of an event by first obtaining relevant tweets and then generating storylines via graph optimization. In (Li and Li, 2013), an evolutionary hierarchical Dirichlet process was proposed to capture the topic evolution pattern in storyline summarization.

However, most of the aforementioned approaches do not represent events in the form of structured representation. More importantly, they ignore the dependency of the hierarchical structures of events at different epochs in a storyline. In this paper, we propose a dynamic storyline detection model to overcome the above limitations.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1943–1948,
Lisbon, Portugal, 17-21 September 2015.

We assume that each document could belong to one storyline s, which is modelled as a joint distribution over some named entities e and a set of topics z. Furthermore, to link events at different epochs and detect different types of storylines, the weighted sum of storyline distribution of previous epochs is employed as the prior of the current storyline distribution. The proposed model is evaluated on a large scale news corpus. Experimental results show that our proposed model outperforms several baseline approaches.

2 Methodology

To model the generation of a storyline in consecutive time periods for a stream of documents, we propose an unsupervised latent variable model, called dynamic storyline detection model (DSDM), The graphical model of DSDM is shown in Figure 1.

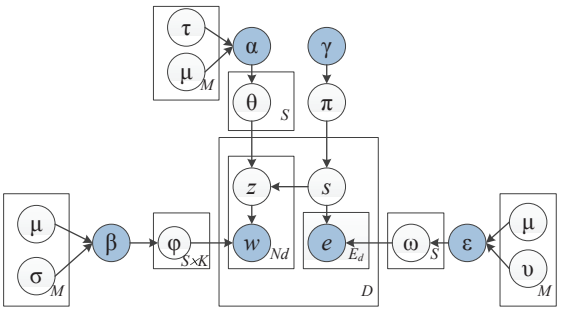

Figure 1: The Dynamic Storyline Detection model.

In this model, we assume that the storyline-topic-word, storyline-topic and storyline-entity probabilities at time t are dependent on the previous storyline-topic-word, storyline-topic and storyline-entity distributions in the last M epochs. For a certain period of time, we assume that each document could belong to one storyline s, which is modelled as a joint distribution over some named entities e and a set of topics z. This assumption essentially encourages documents published around similar time that involve the same named entities and discuss similar topics to be grouped into the same storyline. As the storyline distribution is shared across documents with the same named entities and similar topics, it essentially preserves the ambiguity that for example, documents comprising the same person and location may or may not belong to the same storyline.

The generative process of DSDM is shown below:

For each time period t from 1 to T:

- Draw a distribution over storylines $\boldsymbol{\pi}_s^t \sim$ Dirichlet(γ_s^t).
- For each storyline $s \in \{1...S\}$:
  - Draw a distribution over topics $\boldsymbol{\theta}_s^t \sim$ Dirichlet(α_s^t).
  - Draw a distribution over named entities $\boldsymbol{\omega}_s^t \sim$ Dirichlet(ϵ_s^t).
  - For each topic $k \in \{1...K\}$, draw a word distribution $\boldsymbol{\varphi}_{s,k}^t \sim$ Dirichlet(β_s^t).
- For each document $d \in \{1...D\}$:
  - Choose a storyline indicator $\boldsymbol{s}_d^t \sim$ Multinomial(π_s^t).
  - For each named entity $e \in \{1...E_d\}$:
    - Choose a named entity $\boldsymbol{e} \sim$ Multinomial(ω_s^t).
  - For other word positions $n \in \{1...N_d\}$:
    - Choose a topic $\boldsymbol{z}_n \sim$ Multinomial(θ_s^t).
    - Choose a word $\boldsymbol{w}_n \sim$ Multinomial($\varphi_{s,z}^t$).

We define an evolutionary matrix of storyline indicator s and topic z, $\sigma_{s,z,m}^t$, where each column $\sigma_{s,z,m}^t$ denotes storyline-topic-word distribution of storyline indicator s and topic z at epoch m, an evolutionary topic matrix of storyline indicator s, τ_s^t, where each column $\tau_{s,m}^t$ denotes storyline-topic distribution of storyline indicator at epoch m, an evolutionary entity matrix of storyline indicator s, υ_s^t, where each column $\upsilon_{s,m}^t$ denotes storyline-entity distribution of storyline indicator s.

We attach a vector of $M+1$ weights $\mu_{s,z}^t = \{\mu_{s,z,m}^t\}_{m=0}^M (\mu_{s,z,m}^t > 0, \sum_{m=0}^M \mu_{s,z,m}^t = 1)$, with its components representing the weights that each $\sigma_{s,z,m}^t$ contributes to calculating the priors of $\varphi_{s,z}^t$. We do it similarly for θ_s^t and ω_s^t. The Dirichlet prior for the storyline-topic-word distribution, the storyline-topic distribution and the storyline-entity distribution, respectively, at epoch t are:

$$\beta_{s,z}^t = \sum_{m=0}^{M} \mu_{s,z,m}^t \times \sigma_{s,z,m}^t \quad (1)$$

$$\alpha_s^t = \sum_{m=0}^{M} \mu_{s,m}^t \times \tau_{s,m}^t \quad (2)$$

$$\epsilon_s^t = \sum_{m=0}^{M} \mu_{s,m}^t \times \upsilon_{s,m}^t \quad (3)$$

In our experiments, the weight parameters are set to be the same regardless of storylines or topics. They are only dependent on the time window using an exponential decay function, $\mu_m =$

$\exp(-0.5 \times m)$ where m stands for the mth epoch counting backwards in the past M epochs. That is, more recent documents would have a relatively stronger influence on the model parameters in the current epoch compared to earlier documents. It is also possible to estimate the weights directly from data. We leave it as our future work.

The storyline-topic-word distribution $\varphi^t_{s,z}$, the storyline-topic distribution θ^t_s and the storyline-entity distribution ω^t_s at the current epoch t are generated from the Dirichlet distribution parameterized by $\beta^t_{s,z}, \alpha^t_s, \epsilon^t_s, \varphi^t_{s,z} \sim Dir(\beta^t_{s,z}), \varphi^t_{s,k} \sim Dir(\alpha^t_s), \omega^t_s \sim Dir(\epsilon^t_s)$. With this formulation, we can ensure that the mean of the Dirichlet parameter for the current epoch becomes proportional to the weighted sum of the word, topic distribution, and entity distribution at previous epochs.

3 Inference and Parameter Estimation

We use collapsed Gibbs sampling (Griffiths and Steyvers, 2004) to infer the parameters of the model, given observed data D. Gibbs sampling is a Markov chain Monte Carlo method which allows us repeatedly sample from a Markov chain whose stationary distribution is the posterior of interest, s^t_d and $z^t_{d,n}$ here, from the distribution over that variable given the current values of all other variables and the data. Such samples can be used to empirically estimate the target distribution. Letting the subscript $-d$ denote the quantity that excludes counts in document d, the conditional posterior for s_d is:

$$
\begin{aligned}
P(s^t_d = j | \boldsymbol{s}^t_{-d}, \boldsymbol{z}, \boldsymbol{w}, \Lambda) \propto \frac{\{N_j\}_{-d} + \gamma}{D_{-d} + S\gamma} \\
\times \prod_{e=1}^{E} \frac{\prod_{b=1}^{n^{(d)}_{j,e}} N_{j,e} - b + \epsilon^t_{j,e}}{\prod_{b=1}^{n^{E(d)}_{j}} n^E_j - b + \sum_{e=1}^{E} \epsilon^t_{j,e}} \\
\times \prod_{k=1}^{K} \frac{\prod_{b=1}^{n^{(d)}_{j,k}} n_{j,k} - b + \alpha^t_{j,k}}{\prod_{b=1}^{n^{(d)}_{j}} n_j - b + \sum_{k=1}^{K} \alpha^t_{j,k}} \\
\times \prod_{v=1}^{V} \frac{\prod_{b=1}^{n^{(d)}_{j,k,v}} n_{j,k,v} - b + \beta^t_{j,k,v}}{\prod_{b=1}^{n^{(d)}_{j,k}} n_{j,k} - b + \sum_{v=1}^{V} \beta^t_{j,k,v}},
\end{aligned}
$$

where N_j denotes the number of documents assigned to storyline indicator j in the whole corpus, D is the total number of documents, $n_{j,e}$ is the number of times named entity e is assigned with storyline indicator j, n^E_j denotes the total number of named entities with storyline indicator j in the document collection, $n_{j,k}$ is the number of times words with topic label k with storyline indicator j, n_j is the total number of words (excluding named entities) in the corpus with storyline indicator j, $n_{j,k,v}$ is the number of words v with storyline indicator j and topic label k in the document collection, counts with (d) notation denote the counts relating to document d only.

Letting the index $x = (d, n)$ denote nth word in document d and the subscript $-x$ denote a quantity that excludes data from the nth word position in document d. We only sample a topic z_x if the nth word is not a named entity based on the following conditional posterior:

$$
\begin{aligned}
&P(z^t_x = k | s_d = j, \boldsymbol{z}_{-x}, \boldsymbol{w}, \Lambda) \\
&\propto \frac{\{n^t_{j,k}\}_{-x} + \alpha^t_{j,k}}{\{n_j\}_{-x} + \sum_{k=1}^{K} \alpha^t_{j,k}} \times \frac{\{n^t_{j,k,w_n}\}_{-x} + \beta^t_{j,k,v}}{\{n^t_{j,k}\}_{-x} + \sum_{v=1}^{V} \beta^t_{j,k,v}}
\end{aligned}
$$

Once the latent variables s and z are known, we can easily estimate the model parameters $\pi, \Theta, \varphi, \psi, \omega$. We set the hyperparameters $\alpha = \gamma = 0.1, \beta = \epsilon = 0.01$ for the current epoch (i.e., $m = 0$), and gather statistics in the previous 7 epochs (i.e., $M = 7$) to set the Dirichlet priors for the storyline-topic-word distribution $\varphi^t_{s,z}$, the storyline-topic distribution θ^t_s and the storyline-entity distribution ω^t_s in the current epoch t, and run Gibbs sampler for 1000 iterations and stop the iteration once the log-likelihood of the training data converges under the learned model.

4 Experiments

4.1 Dataset

We crawled and parsed the GDELT Event Database[1] containing news articles published in May 2014. We manually annotated one-week data containing 101,654 documents and identified 77 storylines for evaluation. We also report the results of our model on the one-month data containing 526,587 documents. But we only report the precision and not recall of the storylines extracted since it is time consuming to identify all the true storylines in such a large dataset. In our experiments, we used the Stanford Named Entity Recognizer for identifying the named entities. In addition, we removed common stopwords and only kept tokens

[1] http://data.gdeltproject.org/events/index.html

which are verbs, nouns, or adjectives in these news articles.

4.2 Baselines

We chose the following three methods as the baseline approaches.

1. K-Means + Cosine Similarity (KMCS): the method first applies K-Means to cluster news documents for each day, then link storylines detected in different days based on the cosine similarity measurement.

2. LDA + Cosine Similarity (LDCS): the method first splits news documents on a daily basis, then applies the Latent Dirichlet Allocation (LDA) model to detect the latent storylines for the documents in each day, in which each storyline is modelled as a joint distribution over named entities and words, and finally links storylines detected in different days using the cosine similarity measurement.

3. Dynamic LDA (DLDA)[2]: this is the dynamic LDA (Blei and Lafferty, 2006) where the topic-word distributions are linked across epochs based on the Markovian assumption. That is, the topic-word distribution at the current epoch is only influenced by the topic-word distribution in the previous epoch.

4.3 Evaluation Metric

To evaluate the performance of the proposed approach, we use precision, recall and F-score which are commonly used in evaluating information extraction systems. The precision is calculated based on the following criteria: 1) The entities and keywords extracted refer to the same storyline. 2) The duration of the storyline is correct. We assume that the start date (or end date) of a storyline is the publication date of the first (or last) news article about it.

4.4 Experimental Results

The proposed model is compared against the baseline approaches on the annotated one-week data which consist of 77 storylines. The number of storylines, S, and the number of topics, K, are both set to 100. The number of historical epochs, M, which is taken into account for setting the Dirichlet priors for the storyline-topic-word, the storyline-topic and the storyline-entity distributions, is set to 7. The evaluation results of our proposed approach in comparison to the three baselines are presented in Table 1.

Method	Precision	Recall	F-score
KMCS	22.73	32.47	26.74
LDCS	34.29	31.17	32.66
DLDA	62.67	61.03	61.84
DSDM	**70.67**	**68.80**	**69.27**

Table 1: Performance comparison of the storyline extraction results in terms of Precision (%), Recall (%) and F-score (%).

It can be observed from Table 1 that simply using K-means to cluster news articles in each day and linking similar stories across different days in hoping of identifying storylines gives the worst results. Using LDA to detect stories in each day improves the precision dramatically. The dynamic LDA model assumes topics (or stories) in the current epoch evolves from the previous epoch and further improves the storyline detection results significantly. Our proposed model aims to capture the long distance dependencies in which the statistics gathered in the past 7 days are taken into account to set the Dirichlet priors of the storyline-topic-word, storyline-topic and storyline-entity distributions in the current epoch. It gives the best performance and outperforms dynamic LDA by nearly 7% in F-measure.

To study the impact of the number of topics on the performance of the proposed model, we conducted experiments on the one-month data with different number of topics varying between 100 and 200. In all these experiments, the number of storylines, S, is set to 200, based on the speculation that about 40 storylines in the annotated one-week data last for one month and about 40 new storylines occur each week. Table 2 shows the precision of the proposed method under different number of topics. It can be observed that the performance of the proposed approach is quite stable across different number of topics.

K	100	150	200
Precision	69.6%	70.2%	69.9%

Table 2: The precision of our method with various number (K) of topics.

[2]Topic number is set to 100 for both DLDA and LDCS. Cluster number is also set to 100 for KMCS.

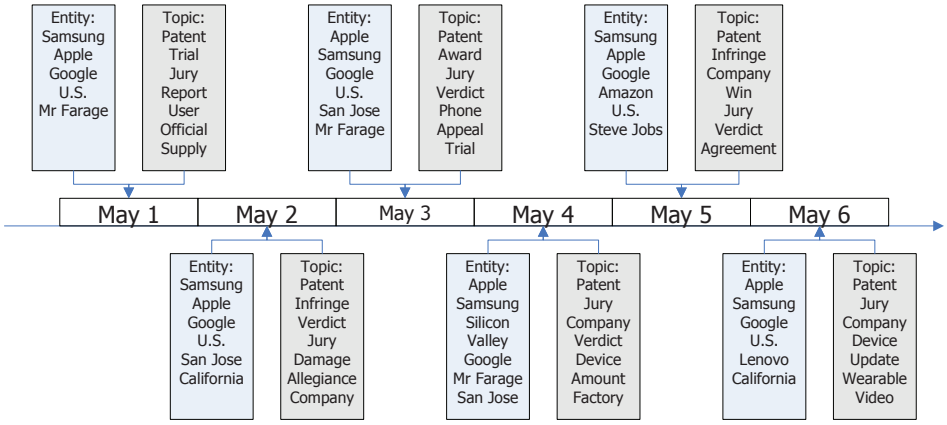

Figure 2: Storyline about the patent infringement case between Apple and Samsung was extracted by the proposed Model.

4.5 Structured Browsing

We illustrate the evolution of storylines by using structured browsing, from which the structured information (entity, topic, keywords) about storylines and the duration of storylines can be easily observed. Figure 2 shows the storyline about "The patent infringement case between Apple and Samsung". It can be observed that in the first two days, the hierarchical structure consists of entities (Apple, Samsung) and keywords (trial, patent, infringe). The case has gained significant attention in the next three days when US jury orders Samsung to pay Apple $119.6 million. It can be observed that the stories in the next three days also consist of entities (Apple, Samsung), but with different keywords (award, patent, win). The last day's story gives an overall summary and consists of entities (Apple, Samsung) and keywords (jury, patent, company).

To further investigate the storylines detected by the proposed model, we randomly selected three detected storylines. The first one is about "the patent infringement case between Apple and Samsung". It is a short-term storyline lasting for 6 day as shown in Figure 3. The second one is about "India election", which is a long-term storyline lasting for one month. The third one is about "Pistorius shoot Steenkamp", which is an intermittent storyline, lasting for a total of 22 days but with no relevant news reports in certain days as shown in Figure 3. It can be observed that the proposed model can detect not only continuous but also intermittent storylines, which further demonstrates the advantage of the proposed model.

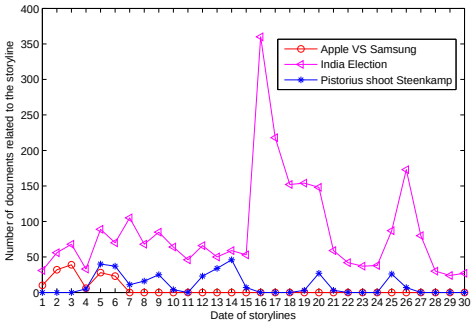

Figure 3: The number of documents on each day relating to the three storylines.

5 Conclusions and Future Work

In this paper, we have proposed an unsupervised Bayesian model to extract storylines from news corpus. Experimental results show that our proposed model is able to extract both continuous and intermittent storylines and outperforms a number of baselines. In future work, we will consider modelling background topics explicitly and investigating more principled ways in setting the weight parameters of the statistics gathered in the historical epochs. Moreover, we will also explore the impact of different scale of the dependencies from historical epochs on the distributions of the current epoch.

Abstract

We present an approach for extractive single-document summarization. Our approach is based on a weighted graphical representation of documents obtained by topic modeling. We optimize importance, coherence and non-redundancy simultaneously using ILP. We compare ROUGE scores of our system with state-of-the-art results on scientific articles from *PLOS Medicine* and on DUC 2002 data. Human judges evaluate the coherence of summaries generated by our system in comparision to two baselines. Our approach obtains competitive performance.

1 Introduction

Summarization systems take a long document as input and generate a concise document as output. Several summarization variants exist such as generic, query-based, multi-document and single document, but the basic requirements for summarization remain the same. Summaries should contain salient information so that the reader will not miss anything from the original document. Also, the reader is not interested in repetitive information, so summaries should not include redundant information. Finally, summaries should be coherent and of high readability.

We introduce a completely unsupervised graph-based summarization using latent drichlet allocation (LDA, Blei and Lafferty (2009)). LDA is a simple model for topic modeling where topic probabilities are assigned words in documents. The probabilities can be used to measure the semantic relatedness between words and hence the topical coherence of a document. We use topical coherence as a means to ensure the coherence of extractive single-document summaries. Remus and Biemann (2013) apply LDA to compute lexical chains while Gorinski and Lapata (2015) also develop a graph-based summarization system which takes coherence into account.

Our work is based on the bipartite entity graph introduced by Guinaudeau and Strube (2013). However, in their graph one set of nodes corresponds to entities whereas in our graph it corresponds to topics. The entity graph has already been used by Parveen and Strube (2015) for summarization. Their graph is unweighted and sparse, whereas our topical graph is weighted and dense.

We apply our topical graph on the dataset introduced by Parveen and Strube (2015). This dataset contains scientific articles from the journal *PLOS Medicine*[1]. Every *PLOS Medicine* article is accompanied by an editor's summary and an authors' abstract. We use both as gold summaries for evaluation. Results obtained on the *PLOS Medicine* dataset using the topical graph are as good as using the entity graph and significantly better than several baselines and the graph-based system *TextRank* (Mihalcea and Tarau, 2004). We use the DUC 2002 dataset to compare our results with state-of-the-art techniques. In contrast to the *PLOS Medicine* data the DUC 2002 dataset contains very small articles. Still, our technique gives comparable results to the state-of-the-art. This shows that our technique is flexible and scalable despite being unsupervised.

2 Our Method

2.1 Document Representation

A graph-based representation has been used by well known summarization systems such as LexRank (Erkan and Radev, 2004) and TextRank (Mihalcea and Tarau, 2004). The graph used by both is of one mode type where sentences are nodes which are connected by weighted edges.

[1] http://journals.plos.org/plosmedicine/

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1949–1954,
Lisbon, Portugal, 17-21 September 2015.

Weights express sentence similarity.

We use a bipartite graph representation of documents (Figure 1). The bipartite graph, $G = (V_s, V_t, E_{t,s})$, has two sets of nodes where V_s represents sentences and V_t topics. The two sets of nodes are connected with edge $E_{t,s}$, if a word in a sentence s is present in a topic t. If multiple words are present in topic t of sentence s, then the edge weight is the logarithmic sum of probabilities of words in topic t. We normalize the edge weight by dividing them by the length of the sentence. Hence long sentences will not benefit from their lengths. We call the resulting graph *topical graph*.

2.2 Sentence Ranking

The final summary should contain only important sentences. Therefore, we give a score to every sentence in a document to obtain important sentences. Following Parveen and Strube (2015) we apply the HITS (Hyperlink Induced Topic Search) (Kleinberg, 1999) algorithm for ranking sentences by importance, since our graph is a bipartite graph. It puts nodes of a graph in two sets: *hub nodes* and *authority nodes*.

For the HITS algorithm the rank of nodes needs to be initialized. We initialize the topic rank $Rank_{t_i} = 1$ and the sentence rank $Rank_{s_i} = 1 + sim(s_i, title)$. The $title$ in the sentence rank is the title of the article. $sim(s_i, title)$ is the cosine similarity between the sentence s_i and the title of the article. After initialization of all nodes in the weighted topical graph, the HITS algorithm is applied to obtain ranks of sentences.

2.3 Coherence Measure

Guinaudeau and Strube (2013) represent a document by the entity graph, a bipartite graph consisting of sentence and entity nodes. They perform a one-mode projection on sentence nodes, compute the coherence of a document on the basis of the one-mode projections and use the coherence measure for summary coherence rating. Building upon this work, Parveen and Strube (2015) integrate this coherence measure to directly generate coherent summaries. Instead of the entity graph we here use the topical graph to incorporate the coherence measure. Parveen and Strube (2015) use an unweighted projection graph whereas we use a weighted projection graph of a topical graph to compute the coherence. The weighted one mode projection of the topical graph is shown in Figure 1, bottom right.

$$weighted\_coh(s_i, P) = weighted\_Outdegree(s_i, P) \tag{1}$$

$$norm\_weighted\_coh(s_i, P) = \frac{weighted\_coh(s_i, P)}{\sum weighted\_coh(s_i, P)} \tag{2}$$

Equation 1 calculates the outdegree of every sentence from the weighted projection graph. However $weighted\_coh(s_i, P)$ in Equation 1 is not a normalized value. The normalized coherence value is in Equation 2. Afterwards, we use this coherence value in the optimization phase for the selection of sentences.

2.4 Optimization

McDonald (2007) introduces summarization as an optimization task which takes care of importance, redundancy and coherence simultaneously. In this paper, we also propose a model for single document summarization which is based on integer linear programming (ILP). We consider ranks obtained by the HITS algorithm as sentence importance. The weighted coherence measure is calculated using Equation 1 and Equation 2. *PLOS Medicine* articles are very long and contain repetitive information, so we have to deal with redundancy even in single-document summarization. Therefore we model non-redundancy as topic coverage in the final summary: the more topics in a summary, the less redundant the summary will be. The ILP objective function is shown in Equation 3. $f_i(X)$ is the function which maximizes importance, $f_c(X)$ maximizes coherence, and $f_t(Y)$ maximizes topic coverage.

$$Objective\,function : \max_{X,Y}(f_i(X) + f_c(X) + f_t(Y)) \tag{3}$$

X is a variable for sentences which contains boolean variables x_i, where $0 < i < n$ is the number of sentences. Y is a variable for topics which contains boolean variables y_j, where $0 < j < m$ is the number of topics.

$$f_t(Y) = \sum_{j=1}^{m} y_j \tag{4}$$

Constraints ensure that the system satisfies additional requirements such as summary length:

$$\sum_{i=1}^{n} x_i \leq Len(summary) \tag{5}$$

$$\sum_{j \in T_i} y_j \geq |Topics_{x_i}| \cdot x_i, \quad \text{for } i = 1, \ldots, n \tag{6}$$

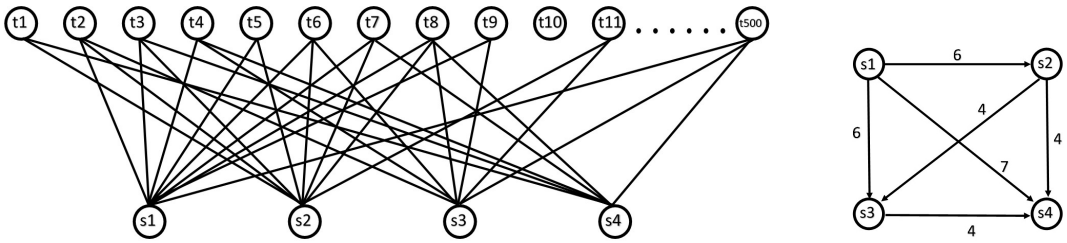

Figure 1: Abstract from *PLOS Medicine*, topical grid, bipartite topical graph, one-mode projection

$$\sum_{i \in S_j} x_i \geq y_j, \quad \text{for } j = 1, \ldots, m \tag{7}$$

The final summary should be shorter than the original text and it should also have a length limit (Equation 5). The results on *PLOS medicine* data (Section 3) are limited to 5 sentences. We have also experimented with multiple lengths. Increasing the summary length increases ROUGE scores. DUC 2002 summaries are limited to 100 words.

Equation 6 shows that topics present in sentence x_i are selected, when sentence x_i is selected. Therefore, $x_i = 1$ and $T_i = Topics_{x_i}$. The constraint holds, because $\sum_{j \in T_i} y_j = |Topics_{x_i}|$. Furthermore, if sentence $x_i = 0$, i.e., it is not selected, then there must be topics which are already present in selected sentences. Hence, the constraint holds, $\sum_{j \in T_i} y_j \geq 0$.

Equation 7 constrains the selection of topics. If topic $y_j = 1$, then at least one sentence containing this topic has been selected. Therefore $\sum_{i \in S_j} x_i \geq 1$, and the constraint holds. If topic $y_j = 0$, then sentences containing this topic are not selected, so $\sum_{i \in S_j} x_i = 0$, and the constraint holds.

3 Experiments

Following Parveen and Strube (2015), we evaluate on the science genre, i.e. *PLOS Medicine* articles, and on the news genre, i.e. DUC 2002 data.

3.1 Datasets

PLOS Medicine articles are considerably longer than DUC 2002 documents. The average number of sentences per document is 154 in *PLOS Medicine* and 25 in DUC 2002. Benefits of using *PLOS Medicine* articles for experiments are:

- They are accompanied by an authors' abstract.
- They have a summary written by an editor.
- They are formatted in XML.
- They contain explicit full forms of abbreviations.

Editor's summaries have a different perspective, writing style and length than authors' abstracts. We use both as gold summaries for evaluation. Following Parveen and Strube (2015) we report the results using editor's summaries and author's abstracts independently. To compare with the state-of-the-art in single-document summarization, we also evaluate on DUC 2002 data.

3.2 Experimental Setup

We use the XML version of *PLOS Medicine* articles. We extract the contents excluding figures, tables and references. Editor's summary and authors' abstract are separated from the content for evaluation. The *PLOS Medicine* XML provides explicit full forms when abbreviations are introduced. We replace abbreviations with their full form in the summary. We then remove non-alphabetical characters. After this we parse articles using the Stanford parser (Klein and Manning, 2003). We perform pronoun resolution using the coreference resolution system by Martschat (2013)[2]. We use *gensim* to generate the topics. For generating topics we use a dataset containing scientific articles from biology, which contains 221,385 documents and about 50 million sentences[3]. We also use Wikipedia to compare with topics from a general domain.

The HITS algorithm is applied on the bipartite graph for computing sentence importance. We calculate the coherence values of sentences on weighted one-mode projection graphs. The importance and coherence of a sentence is used in the optimization phase[4] which returns a binary value for each sentence.

3.3 Results

Results on *PLOS Medicine* are shown in Tables 1 and 2. We evaluate using ROUGE-SU4 and ROUGE-2 (Lin, 2004). We limit the length of the summaries to five sentences and the number of topics to 2000 in the topical graph. We also experimented with varying numbers of topics, i.e. 500, 1000 and 2000, and varying summary length limits. The results changed only marginally. The general trends remained the same.

We compare our system with four different baselines and two versions of the entity graph. *Lead* selects the top five sentences, *Random* five sentences randomly. *MMR* is an implementation of maximal marginal relevance (Carbonell and Goldstein, 1998). *TextRank* is the graph-based system by Mihalcea and Tarau (2004)[5]. *Egraph* is the entity graph based system by Parveen and Strube (2015). *Egraph + Coh.* is their system which includes a coherence measure, which is calculated by using the unweighted projection graph. *Egraph + Coh. + Pos.* combines the coherence measure and positional information.

Systems	R-SU4	R-2
Lead	0.067	0.055
Random	0.048	0.031

Egraph + Coh.	0.219	0.175
Egraph + Coh. + Pos.	0.224	0.189
Tgraph (n=2000)	0.217	0.173
Tgraph (n=2000) + Coh.	0.221	0.179
Tgraph (n=2000) + Coh. + Pos.	0.215	0.174

Table 2: *PLOS Medicine*, authors' abstracts

Our system outperforms all baselines substantially, as shown in Tables 1 (editor's summaries) and 2 (authors' abstracts). We observe improvements in the results when including coherence in the topical graph. We obtain best results with Tgraph + Coh., where the number of topics is 2000. In Tgraph, penalizing coherence measures with positional information lowers ROUGE scores. While including positional information into the entity graph obtains the best results on the *PLOS Medicine* dataset, positional information does not appear to be beneficial for the topical graph. Absolute ROUGE scores are higher when using abstracts as gold summaries, because the abstracts are shorter than editor's summaries.

We compare results using biology journals (Table 3) and Wikipedia (Table 4) to generate topics. The topical graph is denser when using biology journals compared to the graph generated from Wikipedia. Results using the in-domain biology journals as data to generate topics are better than using general domain Wikipedia data. The scores are highest with 2000 topics. For Bio topic the differences are negligible, however.

We also compare results on DUC 2002 to

Table 4: *PLOS Medicine*, editor's summ., Wiki topic

check against the state-of-the-art on a well-known dataset. *Lead* performs well on DUC 2002 as shown in Table 5, because important information appears in the initial lines of news articles. *DUC 2002 Best* is the result reported by the top performing system at DUC 2002. This system actually obtains better results than *TextRank* (Mihalcea and Tarau, 2004) and the more recent system *UniformLink* (Wan and Xiao, 2010). Our system *Tgraph + Coh.* performs better than the well known best systems on DUC 2002 and slightly better than *Egraph + Coh.* However the difference between the results of Tgraph and Egraph are not significant. In contrast to the entity graph based system, the coherence measure in our system is calculated by using a topic-based weighted projection graph, which is denser and hence more informative.

3.4 Human Coherence Judgements

In addition to ROUGE scores, we use human judgements for evaluating the coherence of our summaries. We asked four PhD students in natural language processing to evaluate our summaries on the basis of coherence. We randomly selected ten summaries of scientific articles from three different systems, *TextRank*, *Lead* and *Tgraph + Coh.* We asked the human judges to rank the summaries according to their coherence. So, the summary which is best in coherence gets rank 1, second best gets rank 2, and worst gets rank 3. We calculated the Kendall concordance coefficient (W) (Siegel and Castellan, 1988) to measure the judges' agreement. We obtain $W = 0.61$, which indicates a relatively high agreement.

Systems	R-1	R-2	R-SU4
Lead	0.459	0.180	0.201
DUC 2002 Best	0.480	0.228	
TextRank	0.470	0.195	0.217
UniformLink (k = 10)	0.471	0.201	
Egraph + Coh.	0.479	0.238	0.230
Tgraph (n=2000) + Coh.	0.481	0.243	0.242

Table 5: DUC 2002, single-document summarization

To compare the three systems, we take the average over the ranks. The overall rank of *TextRank* is 2.625, *Lead* is 1.675 and *Tgraph + Coh.* is 1.8. *Lead* performs best, because it selects the top five consecutive sentences, which are coherent as the original authors intended them to be. However, the overall ranks of *Lead* and *Tgraph + Coh.* are not significantly different, whereas *TextRank*'s overall rank is significantly worse than both. Hence, *Tgraph + Coh.* performs very well in our human judgement coherence experiment.

4 Discussion

In this paper we introduced the topical graph for single document summarization. We experimented with multiple numbers of topics on the scientific article dataset. Our system performs well when including the weighted coherence measure in the optimization phase. The results are comparable with the entity graph. However, the entity graph is less informative and very sparse as compared to the topical graph. Our system does not need annotated training data and, except for the number of topics, no optimization of parameters. Hence, we consider it unsupervised.

Abstract

We propose to automatically summarize student responses to reflection prompts and introduce a novel summarization algorithm that differs from traditional methods in several ways. First, since the linguistic units of student inputs range from single words to multiple sentences, our summaries are created from extracted phrases rather than from sentences. Second, the phrase summarization algorithm ranks the phrases by the number of students who semantically mention a phrase in a summary. Experimental results show that the proposed phrase summarization approach achieves significantly better summarization performance on an engineering course corpus in terms of ROUGE scores when compared to other summarization methods, including MEAD, LexRank and MMR.

1 Introduction

Educational research has demonstrated the effectiveness of *reflection prompts* (Boud et al., 2013) to enhance interaction between instructors and students (Van den Boom et al., 2004; Menekse et al., 2011). However, summarizing student responses to these prompts for large courses (e.g., introductory STEM, MOOCs) is an onerous task for humans and poses challenges for existing summarization methods. First, the linguistic units of student inputs range from single words to multiple sentences. Second, we assume that the concepts (represented as phrases) mentioned by more students should get more attention from the instructor. Based on this assumption, we introduce the notion of *student coverage*, defined as the number of students who semantically mention a particular phrase. The more student coverage a phrase has, the more important it is. To illustrate the new task, an example is shown in Table. 1.

Reflection prompt:
Describe what was confusing or needed more detail.

Student Responses:
S1: Graphs of attraction/repulsive & interatomic separation
S2: Property related to bond strength
S3: The activity was difficult to comprehend as the text fuzzing and difficult to read.
S4: Equations with bond strength and Hooke's law
S5: I didn't fully understand the concept of thermal expansion
S6: The activity (Part III)
S7: Energy vs. distance between atoms graph and what it tells us
S8: The graphs of attraction and repulsion were confusing to me...(*rest omitted, 53 student responses in total.*)

Human Reference Summary:
1) Graphs of attraction/ repulsive & atomic separation [10]
2) Properties and equations with bond strength [7]
3) Coefficient of thermal expansion [6]
4) Activity part III [4]

Table 1: An example reflection prompt, 53 student responses and a gold-standard summary. The numbers in the square brackets indicate the number of students who semantically mention each phrase (i.e., student coverage).

In this work, we propose a phrase summarization method that addresses the above challenges. First, our summaries are created from extracted phrases rather than from sentences. Phrases are easy to read and browse like keywords, and fit better on small devices when compared to sentences. For example, including phrases such as "*I didn't fully understand*" (S5) and "*were confusing to me*" (S8) in the summary is a waste of space. Second, we adopt a metric clustering paradigm with a semantic distance to estimate the student coverage of each phrase in the summary; a semantic metric allows similar phrases to be grouped together even if they are in different textual forms. Experimental

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1955–1960,
Lisbon, Portugal, 17-21 September 2015.

results demonstrate the utility of our approach.

Although not the focus of this paper, we have also built a mobile application called CourseMIR-ROR[1] that utilizes the proposed summarization algorithm (Luo et al., 2015). Fan et al. (2015) report a preliminary study about the usage of the application.

2 Related Work

While summarization systems that extract sentences are dominant, others have published in "summarization" at other levels besides the sentence. For example, Ueda et al. (2000) developed an "at-a-glance" summarization method with handcrafted rules. Recently, keyphrase extraction (Hasan and Ng, 2014; Liu et al., 2009; Medelyan et al., 2009; Wu et al., 2005) has received considerable attention, aiming to select important phrases from input documents, which is similar to phrase summarization. In this paper, we propose a general framework to adapt sentence summarization to phrase summarization.

Clustering has been used to score sentences and has shown good improvement in text summarization (Yang et al., 2012; Li and Li, 2014; Gung and Kalita, 2012). In this work, we are using a metric clustering with semantic similarity to estimate the student coverage at a phrase level. Similarly, both diversity-based summarization (Carbonell and Goldstein, 1998; Zhang et al., 2005; Zhu et al., 2007) and our proposed method aim to estimate and maximize student coverage by minimizing redundancy in the output phrases. Differently, our method performs the redundancy reduction at a cluster level (a group of phrases) rather than penalize redundancy with a greedy iterative procedure sentence by sentence, and not only the information content is considered, but also the information source.

3 Data

Our data consists of student responses collected from 53 undergraduates enrolled in an introduction to materials science and engineering class. The students were asked to complete a survey at the end of each of 25 lectures during a semester, consisting of three carefully designed reflection prompts: 1) "Describe what you found most interesting in today's class." 2) "Describe what was confusing or needed more detail." 3) "Describe what you learned about how you learn."

	min	max	mean	std
Student-WC	1	91	9.2	7.3
TA-PWC	1	26	7.1	4.9
TA-WC	6	103	29.4	23.2
TA-PC	2	12	4.2	2.2

Table 2: **W**ord **C**ount (WC) in student responses (Student-WC), WC per phrase in TA's summary (TA-PWC), WC in TA's summary (TA-WC) and phrase count in TA's summary (TA-PC)

In total, more than 900 responses were collected for each prompt. Currently, gold-standard summaries of 12 out of 25 lectures are created by the teaching assistant for that course for each reflection prompt. The summaries include not only the important phrases, but also the number of students who mentioned them (i.e., student coverage). 4 lectures are randomly selected as a development set and the remaining data used as a test set, yielding 12 sets of development data and 24 sets of testing data, each with a prompt, the students' responses and the gold-standard summary. [2]

The statistics of the student responses and the TA's summary are shown in Table 2. The phrases summarized by the TA are significantly shorter than the student responses (7.1 vs. 9.2, $p<0.001$).

4 Proposed Method

We formulate our task as a standard extractive summarization problem. Unlike standard sentence-level extraction where the input and output are sentences, the input of our task ranges from words or phrases to full sentences. The output is a list of important phrases and the summary length (either # of phrases or words) is no more than L.

The proposed algorithm involves three stages: *candidate phrase extraction*, *phrase clustering*, and *phrase ranking*.

4.1 Candidate phrase extraction

We extract noun phrases (NPs) from the input using a syntax parser from the Senna toolkit (Collobert, 2011), preserving the most important con-

[1]Homepage: http://www.coursemirror.com; free download link in Google Play Store: https://play.google.com/store/apps/details?id=edu.pitt.cs.mips.coursemirror

[2]This data is publicly available at the CourseMIR-ROR website: http://www.coursemirror.com/download/dataset.

tent from the original responses without losing too much context information compared to keywords. For example, "the concept of thermal expansion" (S5) is extracted as a candidate phrase. Only NPs are considered because all reflection prompts used in the task are asking about "what", and knowledge concepts are usually represented as NPs.[3]

Due to the noisy data, malformed phrases are excluded, including single stop words (e.g. "it", "I", "there", "nothing") and phrases starting with a punctuation mark (e.g. "'t", "+ indexing").

4.2 Phrase clustering

Although phrases are more meaningful and less ambiguous compared to keywords, they suffer from the sparsity problem, especially in our data set when 89.9% of the phrases appeared only once. The challenge is the fact that students use different words for the same meaning (e.g., "bicycle parts" and "bike elements").

We use a clustering paradigm with a semantic distance metric to address this issue. Among different clustering algorithms, K-Medoids (Kaufman and Rousseeuw, 1987) fits well for our problem. First, it works with an arbitrary distance matrix between datapoints. It allows to use pairwise semantic similarity-based distance between phrases, yielding metric clustering. Second, it is robust to noise and outliers because it minimizes a sum of pairwise dissimilarities instead of squared Euclidean distances. It shows better performance than an LDA-based approach to group students' short answers for the purpose of semi-automated grading (Basu et al., 2013). Since K-Medoids picks a random set of seeds to initialize as the cluster centers (called medoids), the clustering algorithm runs 100 times and the cluster with the minimal within-cluster sum of the distances is retained to reduce random effects.

Distance metric. The semantic similarity is implemented using SEMILAR (Rus et al., 2013), using the *latent semantic analysis* trained on the Touchstone Applied Science Associates corpus (Ştefănescu et al., 2014). The distance matrix D is constructed from the similarity matrix S by applying the following transformation: $D = e^{-S}$, which is similar to the common heat kernel but without normalization[4].

[3]In our data, no advantage is observed by including other constituents like verb and prepositional phrases.

[4]This is not normalized to the range between 0 and 1 since we only care about the relative distance.

Number of clusters. For setting the number of clusters without tuning, we adopted a method from Wan and Yang (2008), by letting $K = \sqrt{V}$. where K is the number of clusters and V is the number of candidate phrases instead of the number of sentences.

4.3 Phrase ranking

In order to estimate the *student coverage*, phrases are clustered with the algorithm introduced above. We assume the phrases in a cluster are semantically similar to each other and any phrase in a cluster can represent it as a whole. Therefore the coverage of a phrase is assumed to be the same as the coverage of a cluster, which is a union of the students covered by each phrase in the cluster.

To select the most representative phrase in a cluster, LexRank (Erkan and Radev, 2004), a graph-based algorithm for computing relative importance of textual units (working for both sentences and phrases), is used to score the extracted candidate phrases. The top ranked phrase in the cluster is added to the output summary. This process starts from the cluster that has the most estimated student coverage and repeats for the next cluster until the length limit is reached.

Note that when the student coverage is the same between two clusters, the score of the top-ranked phrases in the clusters according to LexRank is used to break the tie: the higher, the better.

5 Experiments

We use the ROUGE evaluation metric (Lin, 2004) and report R-1 (unigrams), R-2 (bigrams), and R-SU4 (bigrams with skip distance up to 4 words), including the recall (R), precision (P) and F-Measure (F). These scores measure the overlap between human-generated summaries and a machine-generated summary.

We design and compare a number of other summarization methods to evaluate the proposed phrase summarization approach.

Keyphrase extraction. Maui (Medelyan et al., 2009) is selected as the baseline, which is one of the state-of-the-art keyphrase extraction methods.

Sentence to phrase summarization. Existing sentence summarization techniques can be used for phrase summarization by extracting candidate phrases and treating them as sentences. Within this framework, we adapt MEAD (Radev et al., 2004) and LexRank (Erkan and Radev, 2004) to

	R-1			R-2			R-SU4		
	R	P	F	R	P	F	R	P	F
Keyphrase	.171	.364	.211	.057	.134	.071	.039	.168	.049
OriMEAD	**.397**	.185	.219	.117	.069	.073	**.157**	.051	.045
MEAD	.341	.269	.265	.122	.102	.099	.126	.094	.072
MEAD+MMR	.360	.279	.277	**.130**	.106	.104	.142	.099	.078
LexRank	.325	.355	.307	.107	.110	.102	.120	.145	.098
LexRank+MMR	.328	.367	.312	.111	.126	.110	.117	.154	.098
Clustering+Medoid	.279	**.473**	.327	.078	.129	.091	.068	**.216**	.087
Proposed	.319	$.448^{\dagger *}$	$\mathbf{.340}^{\dagger}$	.122	$\mathbf{.176}^{\dagger *}$	**.134**	.112	$.205^{\dagger *}$	$\mathbf{.109}^{\dagger}$

Table 3: Summarization performance. The last row is our proposed approach. The highest score for each column is shown in bold. † indicates that the improvement over the MEAD+MMR baseline is statistically significant. * indicates that the improvement over LexRank+MMR is statistically significant.

our task. We also include the original MEAD[5] for comparison (named as OriMEAD).

Diversity-based summarization. We applied the MMR (Carbonell and Goldstein, 1998), a popular diversity-based summarization method as a post-processing step to the MEAD (**MEAD+MMR**) and LexRank (**LexRank+MMR**) baselines.[6]

Clustering+Medoid. To show the performance using the clustering alone, this baseline selects the medoid phrase instead of using LexRank to rank the phrases in a cluster to form the summary.

Results. The performance on the test set is shown in Table 3 with the length limit L as 4 phrases (the average phrase number in the TA's summary). Similar results can be observed when the length limit is based on the number of words, but cannot be reported here due to page limit.

First, our proposed method (last row), which clusters the extracted phrases and uses LexRank to score them, can outperform all the baselines over all three ROUGE scores in terms of F-measure. In addition, the proposed model performs better than the clustering and LexRank alone. Through a paired *t*-test, our model outperforms LexRank statistically in terms of precision for all three ROUGE scores and significantly improves Clustering+Medoid on all R-2 scores (except the precision with 0.06 p-value). We believe that the semantic similarity based clustering complements LexRank in two ways: 1) LexRank depends on the cosine similarity of TF-IDF vectors to build the graph while the clustering takes semantic similarity into account. 2) The clustering performed a global selection to form a summary by grouping similar phrases and ranking them by the number of covered students (similar to what the human did). Compared to LexRank, our approach captures the student coverage explicitly. While modifying LexRank by using semantic similarity is possible, estimating the student coverage is not straightforward.

Second, OriMEAD tends to select long sentences, resulting in a high recall but a low precision. The phrase version (MEAD) improves both the P and F scores by removing unnecessary parts in the original sentences.

Lastly, the proposed method outperforms the MMR based baselines on the precision and F-measure of all three ROUGE scores. We observed that the MMR baselines suffer from the issue of diverse expressions used the students (e.g., "graphs" and "charts").

6 Conclusion

In this paper, we presented a novel application to summarize student feedback to reflection prompts by a combination of phrase extraction, phrase clustering and phrase ranking. It makes use of metric clustering to rank the phrases by their student coverage, taking the information source into account. Experimental results demonstrate the good effectiveness of the model. While the proposed method improved the performance against MMR, other summarization methods without an additional MMR component do exist, in-

[5]The default Length parameter in MEAD is changed to 1 from its default value 9 and the position feature is removed, yielding better performance.

[6]For each MMR based baseline, the parameter is optimized with a grid search on the development data set.

cluding SumBasic (Vanderwende et al., 2007), KLSUM and TopicSUM (Haghighi and Vanderwende, 2009). An initial experiment shows they do not yield better performance with default parameters. However, we will revisit it since these methods are meant for full sentences and are not optimized within the phrase framework.

In the future, we plan to have additional annotation to evaluate the relative importance using the student coverage numbers. We also deployed CourseMIRROR in a statistics class in Spring 2015 and have created gold-standard summaries, which will allow us to both replicate the intrinsic evaluation of this paper with a new and larger dataset as well conduct an extrinsic evaluation beyond ROUGE scores. Finally, we are interested in applying our summarization approach to other types of user-generated content from mobile-applications (e.g., review comments).

Abstract

The most successful approaches to extractive text summarization seek to maximize bigram coverage subject to a budget constraint. In this work, we propose instead to maximize semantic volume. We embed each sentence in a semantic space and construct a summary by choosing a subset of sentences whose convex hull maximizes volume in that space. We provide a greedy algorithm based on the Gram-Schmidt process to efficiently perform volume maximization. Our method outperforms the state-of-the-art summarization approaches on benchmark datasets.

1 Introduction

In artificial intelligence, changes in representation sometimes suggest new algorithms. For example, increased attention to distributed meaning representations suggests that existing combinatorial algorithms for NLP might be supplanted by alternatives designed specifically for embeddings. In this work, we consider summarization.

Classical approaches to extractive summarization represent each sentence as a bag of terms (typically bigrams) and seek a subset of sentences from the input document(s) that either (a) trade off between high relevance and low redundancy (Carbonell and Goldstein, 1998; McDonald, 2007), or (b) maximize bigram coverage (Yih et al., 2007; Gillick et al., 2008). The sentence representation is fundamentally *discrete*, and a range of greedy (Carbonell and Goldstein, 1998), approximate (Almeida and Martins, 2013), and exact optimization algorithms (McDonald, 2007; Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011) have been proposed.

Recent studies have explored *continuous* sentence representations, including the paragraph vector (Le and Mikolov, 2014), a convolutional neural network architecture (Kalchbrenner et al., 2014), and a dictionary learning approach (Jenatton et al., 2011). If sentences are represented as low-dimensional embeddings in a distributed semantic space, then we begin to imagine a geometric relationship between a summary and a document. We propose that the **volume** of a summary (i.e., the semantic subspace spanned by the selected sentences) should ideally be large. We therefore formalize a new objective function for summarization based on semantic volume (§2), and we provide a fast greedy algorithm that can be used to maximize it (§3). We show that our method outperforms competing extractive baselines under similar experimental conditions on benchmark summarization datasets (§4).

2 Extractive Summarization Models

Assume we are given a set of N sentences: $\mathcal{D} = \{s_1, s_2, \ldots, s_N\}$ from one or many documents, and the goal is to produce a summary by choosing a subset $\mathcal{S}$ of M sentences, where $\mathcal{S} \subseteq \mathcal{D}$ and $M \leq N$, and the length of the summary is less than or equal to L words. In this work, we assume no summaries are available as training data. Denote a binary indicator vector $\mathbf{y} \in \mathbb{R}^N$, where sentence i is included if and only if $y_i = 1$ and 0 otherwise. Extractive summarization can be written as an optimization problem:

$$\begin{aligned} &\max && \text{score}(\mathcal{S}) = \text{score}(\mathcal{D}, \mathbf{y}) \\ &\text{with respect to} && \mathcal{S} \text{ equivalently } \mathbf{y} \\ &\text{subject to} && \text{length}(\mathcal{S}) \leq L \end{aligned}$$

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1961–1966,
Lisbon, Portugal, 17-21 September 2015.

with a scoring function $\text{score}(\mathcal{D}, \mathbf{y})$. A good scoring function should assign higher scores to better summaries. In the following, we describe two commonly used scoring functions and our proposed scoring function.

2.1 Maximal Marginal Relevance

The Maximal Marginal Relevance (MMR) method (Carbonell and Goldstein, 1998) considers the following scoring function:

$$\text{score}(\mathcal{D}, \mathbf{y}) = \sum_{i=1}^{N} y_i \text{Rel}(s_i) - \sum_{i,j=1}^{N} y_i y_j \text{Sim}(s_i, s_j)$$

where $\text{Rel}(s_i)$ measures the relevancy of sentence i and $\text{Sim}(s_i, s_j)$ measures the (e.g., cosine) similarity between sentence i and sentence j. The intuition is to choose sentences that are highly relevant to the document(s) and avoid redundancy. The above maximization problem has been shown to be NP-hard, solvable exactly using ILP (McDonald, 2007). A greedy algorithm that approximates the global solution by adding one sentence at a time to maximize the overall score (Lin and Bilmes, 2010) is often used in practice.

2.2 Coverage-Based Summarization

Another popular scoring function aims to give higher scores for covering more diverse concepts in the summary. Gillick et al. (2008) use bigrams as a surrogate for concepts. Following convention, we extract bigrams from each sentence $s_i \in \mathcal{D}$. Denote the number of unique bigrams extracted from all sentences by B. We introduce another binary vector $\mathbf{z} \in \mathbb{R}^B$ to indicate the presence or absence of a bigram in the summary, and a binary indicator matrix $\mathbf{M} \in \mathbb{R}^{N \times B}$, where $m_{i,j}$ is 1 if and only if bigram j is present in sentence i and 0 otherwise. The scoring function is:

$$\text{score}(\mathcal{D}, \mathbf{y}, \mathbf{z}) = \sum_{j=1}^{B} b_j z_j$$

and the two additional constraints are:

$$\forall j \in [B], \forall i \in [N] \qquad y_i m_{i,j} \leq z_j$$

$$\forall j \in [B] \qquad \sum_{i=1}^{N} y_i m_{i,j} \geq z_j$$

where we use $[B]$ as a shorthand for $\{1, 2, \ldots, B\}$. The first constraint makes sure that selecting a sentence implies selecting all its bigrams, whereas the second constraint makes sure that selecting a bigram implies selecting at least one of the sentences that contains it. In this formulation, there is no explicit penalty on redundancy. However, insofar as redundant sentences cover fewer bigrams, they are implicitly discouraged. Although the above scoring function also results in an NP-hard problem, an off-the-shelf ILP solver (Gillick et al., 2008) or a dual decomposition algorithm (Almeida and Martins, 2013) can be used to solve it in practice.

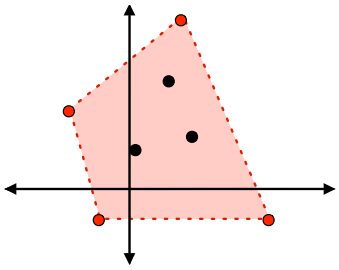

Figure 1: A toy example of seven sentences projected into a two-dimensional semantic space. Consider the case when the maximum summary length is four sentences. Our scoring function is optimized by chooseing the four sentences in red as the summary, since they maximize the volume (area in two dimensions).

2.3 Semantic Volume

We introduce a new scoring function for summarization. The main idea is based on the notion of coverage, but in a distributed semantic space: a good summary should have broad semantic coverage with respect to document contents. For every sentence $s_i, i \in [N]$, we denote its continuous semantic representation in a K-dimensional semantic space by $\Omega(s_i) = \mathbf{u}_i \in \mathbb{R}^K$, where Ω is a function that takes a sentence and returns its semantic vector representation. We denote embeddings of all sentences in $\mathcal{D}$ with the function Ω by $\Omega(\mathcal{D})$. We will return to the choice of Ω later. We propose to use a scoring function that maximizes the *volume* of selected sentences in this semantic space:

$$\text{score}(\mathcal{D}, \mathbf{y}) = \text{Volume}(\Omega(\mathcal{D}), \mathbf{y}) = \text{Volume}(\Omega(\mathcal{S}))$$

In the case when $K = 2$, this scoring function maximizes the area of a polytope, as illustrated in Figure 1. In the example, there exists a maximum number of sentences that can be selected such that adding more sentences does not increase the score, i.e., the set of selected sentences forms a convex hull of the set of all sentences. The sentences forming a convex hull may together be longer than

L words, so we seek to maximize the volume of the summary under this constraint.

There are many choices of Ω that we can use to produce sentence embeddings. As an exploratory study, we construct a vector of bigrams for each sentence, that is, $\mathbf{s}_i \in \mathbb{R}^B, \forall i \in [N]$. If bigram b is present in s_i, we let $s_{i,b}$ be the number of documents in the corpus that contain bigram b, and zero otherwise. We stack these vectors in columns to produce a matrix $\mathbf{S} \in \mathbb{R}^{N \times B}$, where N is the number of sentences in the corpus and B is the number of bigrams. We then perform singular value decomposition (SVD) on $\mathbf{S} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$. We use $\mathbf{U}_K \in \mathbb{R}^{N \times K}$ as the sentence representations, where K is a parameter that specifies the number of latent dimensions. Instead of performing SVD, we can also take $\mathbf{s}_i \in \mathbb{R}^B$ as our sentence representation, which makes our method resemble the bigram coverage-based summarization approach. However, this makes $\mathbf{s}_i$ a very sparse vector. Projecting to a lower dimensional space makes sense to allow the representation to incorporate information from (bigram) cooccurrences and share information across bigrams.

3 Volume Maximization

Given the semantic coverage scoring function in §2.3, our optimization problem is:

$$\begin{array}{ll} \max & \text{score}(\mathcal{S}) = \text{Volume}(\Omega(\mathcal{S})) \\ \text{with respect to} & \mathcal{S} \\ \text{subject to} & \text{length}(\mathcal{S}) \leq L \end{array}$$

For computational considerations, we propose to use a greedy algorithm that approximates the solution by iteratively adding a sentence that maximizes the current semantic coverage, given that the length constraint is still satisfied. The main steps in our algorithm are as follows. We first find the sentence that is farthest from the cluster centroid and add it to $\mathcal{S}$. Next, we find the sentence that is farthest from the first sentence and add it to $\mathcal{S}$. Given a set of already selected sentences, we choose the next one by finding the sentence farthest from the subspace spanned by sentences already in the set. We repeat this process until we have gone through all sentences, breaking ties arbitrarily and checking whether adding a sentence to $\mathcal{S}$ will result in a violation of the length constraint. This method is summarized in Algorithm 1. We note that related variants of our method for maximizing volume have appeared in other applications, such as remote sensing (Nascimento and Dias, 2005; Gomez et al., 2007) and topic modeling (Arora et al., 2012; Arora et al., 2013).

Algorithm 1 Greedy algorithm for approximately maximizing the semantic volume given a budget constraint.

Input: Budget constraint L, sentence representations $\mathcal{R} = \{\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_N\}$
$\mathcal{S} = \{\}, \mathcal{B} = \{\}$
Compute the cluster centroid $\mathbf{c}$: $\frac{1}{N}\sum_{i=1}^{N} \mathbf{u}_i$.
$p \leftarrow$ index of sentence that is farthest from $\mathbf{c}$.
$\mathcal{S} = \mathcal{S} \cup \{s_p\}$. ▶ add first sentence
$q \leftarrow$ index of sentence that is farthest from $\mathbf{s}_p$.
$\mathcal{S} = \mathcal{S} \cup \{s_q\}$. ▶ add second sentence
$\mathbf{b}_0 = \frac{\mathbf{u}_q}{\|\mathbf{u}_q\|}, \mathcal{B} = \mathcal{B} \cup \{\mathbf{u}_0\}$
total length = length(s_p) + length(s_q)
for $i = 1, \ldots, N-2$ **do**
  $r \leftarrow$ index of sentence that is farthest from the subspace of Span($\mathcal{B}$). ▶ see text
  if total length + length(s_r) $\leq L$ **then**
    $\mathcal{S} = \mathcal{S} \cup \{s_r\}$.
    $\mathbf{b}_r = \frac{\mathbf{u}_r}{\|\mathbf{u}_r\|}, \mathcal{B} = \mathcal{B} \cup \{\mathbf{b}_r\}$.
    total length = total length + length(s_r)
  end if
end for

Computing Distance to a Subspace Our algorithm involves finding a point farthest from a subspace (except for the first and second sentences, which can be selected by computing pointwise distances). In order for this algorithm to be efficient, we need this operation to be fast, since it is executed frequently. There are several established methods to compute the distance between a point to a subspace spanned by sentences in $\mathcal{S}$. For completeness, we describe one method based on the Gram-Schmidt process (Laplace, 1812) here.

We maintain a set of basis vectors, denoted by $\mathcal{B}$. Our first basis vector consists of one element: $\mathbf{b}_0 = \frac{\mathbf{u}_q}{\|\mathbf{u}_q\|}$, where q is the second sentence chosen above. Next, we project each candidate sentence i to this basis vector:

$$\text{Proj}_{\mathbf{b}_0}(\mathbf{u}_i) = (\mathbf{u}_i^\top \mathbf{b}_0)\mathbf{b_0},$$

and find the distance by computing $\text{Distance}(\mathbf{u}_i, \mathcal{B}) = \|\mathbf{u}_i - \text{Proj}_{\mathbf{b}_0}(\mathbf{u}_i)\|$. Once we find the farthest sentence r, we add a new basis vector $\mathcal{B} = \mathcal{B} \cup \{\mathbf{b}_r\}$, where $\mathbf{b}_r = \frac{\mathbf{u}_r}{\|\mathbf{u}_r\|}$ and repeat this process. When there are more than one

basis vectors, we find the distance by computing:

$$\text{Distance}(\mathbf{u}_i, \mathcal{B}) = \left\| \mathbf{u}_i - \sum_{\mathbf{b}_j \in \mathcal{B}} \text{Proj}_{\mathbf{b}_j}(\mathbf{u}_i) \right\|.$$

4 Experiments

4.1 Setup

We evaluate our proposed method on the non-update portion of TAC-2008 and TAC-2009. The datasets contain 48 and 44 multi-document summarization problems, respectively. Each problem has 10 news articles as input; each is to be summarized in a maximum of $L = 100$ words. There are 4 human reference summaries for each problem, against which an automatically generated summary is compared. We compare our method with two baselines: Maximal Marginal Relevance (MMR, §2.1) and the coverage-based summarization method (CBS, §2.2). ROUGE (Lin, 2004) is used to evaluate the summarization results.

For preprocessing, we tokenize, stem with the Porter (1980) stemmer, and split documents into sentences. We remove bigrams consisting of only stopwords and bigrams which appear in less than 3 sentences. As a result, we have 2,746 and 3,273 bigrams for the TAC-2008 and TAC-2009 datasets respectively. Unlabeled data can help generate better sentence representations. For each summarization problem in each dataset, we use other problems in the same dataset as unlabeled data. We concatenate every problem in each dataset and perform SVD on this matrix (§2.3). Note that this also means we only need to do one SVD for each dataset.

4.2 Results

Table 1 shows results on the TAC-2008 and TAC-2009 datasets. We report results for our method with $K = 500$ (Volume 500), and $K = 600$ (Volume 600). We also include results for an oracle model that has access to the human reference summaries and extracts sentences that maximize bigram recall as an upper bound. Similar to previous findings, CBS is generally better than MMR. Our method outperforms other competing methods, although the optimal value of K is different in each dataset. The improvements with our proposed approach are small in terms of R-2. This is likely because the R-2 score computes bigram overlaps, and the CBS method that directly maximizes bigram coverage is already a resonable approach to optimizing this metric (although still worse than the best of our methods).

Methods	TAC-2008		TAC-2009	
	R-1	R-2	R-1	R-2
MMR	34.08	9.30	31.87	7.99
CBS	35.83	9.43	32.70	8.84
Volume 500	37.40	9.17	34.08	**8.91**
Volume 600	**37.50**	**9.58**	**34.37**	8.76
Oracle	46.06	19.33	46.77	16.99

Table 1: Results on the TAC-2008 and TAC-2009 datasets. "Volume" refers to our method, shown with two embedding sizes.

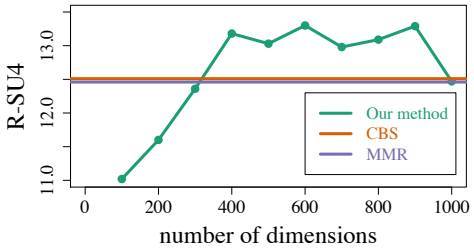

Figure 2: R-SU4 scores as we vary the number of dimensions (K) on the TAC-2008 datasets.

5 Discussion

Runtime comparisons In terms of inference running time, all methods perform reasonably fast. MMR is the slowest, on average it takes 0.38 seconds per problem, followed by our method at 0.17 seconds per problem, and CBS at 0.15 seconds per problem. However, our implementations of MMR and Algorithm 1 are in Python, whereas we use an optimzed solver from Gurobi for our CBS baseline. For preprocessing, our method is the slowest, since we need to compute sentence embeddings using SVD. There are about 10,000 sentences and 3,000 bigrams for each dataset. SVD takes approximately 2.5 minutes (150 seconds) using Matlab on our 12-core machine with 24GB RAM. Our method introduces another hyperparameter, the number of latent dimensions K for sentence embeddings. We observe that the optimal value depends on the dataset, although a value in the range of 400 to 800 seems best. Figure 2 shows R-SU4 scores on the TAC-2008 dataset as we vary K.

Other sentence projection methods We use SVD in this study for computing sentence embeddings. As mentioned previously, our summariza-

tion approach can benefit from advances in neural-network-based sentence representations (Jenatton et al., 2011; Le and Mikolov, 2014; Kalchbrenner et al., 2014). These models can also produce vector representations of sentences, so Algorithm 1 can be readily applied to the learned representations. Our work opens up a possibility to make summarization a future benchmark task for evaluating the quality of sentence representations.

Our method is related to determinantal point processes (DPPs; Gillenwater et al., 2012; Kulesza and Taskar, 2012) in that they both seek to maximize the volume spanned by sentence vectors to produce a summary. In DPP-based approaches, quality and selectional diversity correspond to vector magnitude and angle respectively. In this work, the length of a sentence vector is not tailored to encode quality in terms of representativeness directly. In contrast, we rely on sentence embedding methods to produce a semantic space and assume that a good summary should have a large volume in the semantic space. We show that a simple singular value decomposition embedding of sentences—one that is not especially tuned for this task—produces reasonably good results. We leave exploration of other sentence embedding methods to future work.

Future work Our method could be extended for compressive summarization, by simply including compressed sentences in the embedded space and running Algorithm 1 without any change. This resembles the summarization methods that jointly extracts and compresses (Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2012; Almeida and Martins, 2013). Another alternative is a pipeline approach, where extractive summarization is followed or preceded by a sentence compression module, which can be built and tuned independent of our proposed extractive method (Knight and Marcu, 2000; Lin, 2003; Zajic et al., 2007; Wang et al., 2013; Li et al., 2013).

We are also interested in exploring volume as a relevance function within MMR. MMR avoids redundancy by penalizing redundant sentences, whereas in our method semantic redundancy is inherently discouraged since the method chooses sentences to maximize volume. Depending on the method used to embed sentences, this might not translate directly into avoiding n-gram redundancy. Plugging our scoring function to an MMR objective is a simple way to enforce diversity.

Finally, an interesting future direction is finding an exact tractable solution to the volume maximization problem (or demonstrating that one does not exist).

6 Conclusion

We introduced a summarization approach based on maximizing volume in a semantic vector space. We showed an algorithm to efficiently perform volume maximization in this semantic space. We demonstrated that our method outperforms existing state-of-the-art extractive methods on benchmark summarization datasets.

{baotianchina,qingcai.chen, zhufangze123}@gmail.com

Abstract

Automatic text summarization is widely regarded as the highly difficult problem, partially because of the lack of large text summarization data set. Due to the great challenge of constructing the large scale summaries for full text, in this paper, we introduce a large corpus of Chinese short text summarization dataset constructed from the Chinese microblogging website Sina Weibo, which is released to the public[1]. This corpus consists of over 2 million real Chinese short texts with short summaries given by the author of each text. We also manually tagged the relevance of 10,666 short summaries with their corresponding short texts. Based on the corpus, we introduce recurrent neural network for the summary generation and achieve promising results, which not only shows the usefulness of the proposed corpus for short text summarization research, but also provides a baseline for further research on this topic.

1 Introduction

Nowadays, individuals or organizations can easily share or post information to the public on the social network. Take the popular Chinese microblogging website (Sina Weibo) as an example, the People's Daily, one of the media in China, posts more than tens of weibos (analogous to tweets) each day. Most of these weibos are well-written and highly informative because of the text length limitation (less than140 Chinese characters). Such data is regarded as naturally annotated web resources (Sun, 2011). If we can mine these high-quality data from these naturally annotated web resources, it will be beneficial to the research that has been hampered by the lack of data.

【江西高考被曝替考 有关考生已被警方控制】人民日报记者吴齐强消息，江西高考被曝光替考，7日中午江西省教育厅发布消息称，接到有人组织替考的举报后，江西省教育厅、江西省教育考试院立即部署南昌市教育考试院，联合南昌市警方开展调查核实，有关考生已被警方控制。调查进展情况将及时向社会公布。

Figure 1: A Weibo Posted by People's Daily.

In the Natural Language Processing (NLP) community, automatic text summarization is a hot and difficult task. A good summarization system should understand the whole text and re-organize the information to generate coherent, informative, and significantly short summaries which convey important information of the original text (Hovy and Lin, 1998), (Martins, 2007). Most of traditional abstractive summarization methods divide the process into two phrases (Bing et al., 2015). First, key textual elements are extracted from the original text by using unsupervised methods or linguistic knowledge. And then, unclear extracted components are rewritten or paraphrased to produce a concise summary of the original text by using linguistic rules or language generation techniques. Although extensive researches have been done, the linguistic quality of abstractive summary is still far from satisfactory. Recently, deep learning methods have shown potential abilities to learn representation (Hu et al., 2014; Zhou et al., 2015) and generate language (Bahdanau et al., 2014; Sutskever et al., 2014) from large scale data by utilizing GPUs. Many researchers realize that we are closer to generate abstractive summarizations by using the deep learning methods. However, the publicly available and high-quality large scale summarization data set is still very rare and not easy to be constructed manually. For example, the popular document summarization dataset DUC[2], TAC[3] and TREC[4] have only hundreds of human written English text summarizations. The problem is even worse for Chinese. In this pa-

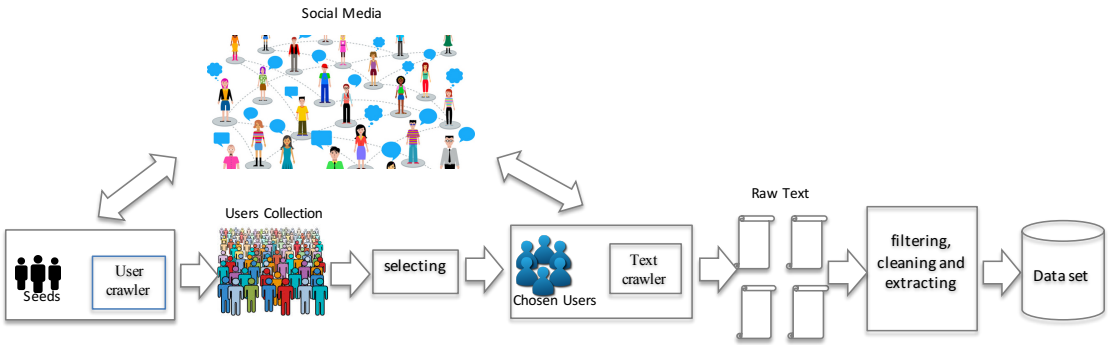

Figure 2: Diagram of the process for creating the dataset.

per, we take one step back and focus on constructing **LCSTS**, the **L**arge-scale **C**hinese **S**hort **T**ext **S**ummarization dataset by utilizing the naturally annotated web resources on Sina Weibo. Figure 1 shows one weibo posted by the People's Daily. In order to convey the import information to the public quickly, it also writes a very informative and short summary (in the blue circle) of the news. Our goal is to mine a large scale, high-quality short text summarization dataset from these texts.

This paper makes the following contributions: (1) We introduce a large scale Chinese short text summarization dataset. To our knowledge, it is the largest one to date; (2) We provide standard splits for the dataset into large scale training set and human labeled test set which will be easier for benchmarking the related methods; (3) We explore the properties of the dataset and sample 10,666 instances for manually checking and scoring the quality of the dataset; (4) We perform recurrent neural network based encoder-decoder method on the dataset to generate summary and get promising results, which can be used as one baseline of the task.

2 Related Work

Our work is related to recent works on automatic text summarization and natural language processing based on naturally annotated web resources, which are briefly introduced as follows.

Automatic Text Summarization in some form has been studied since 1950. Since then, most researches are related to extractive summarizations by analyzing the organization of the words in the document (Nenkova and McKeown, 2011) (Luhn, 1998); Since it needs labeled data sets for supervised machine learning methods and labeling dataset is very intensive, some researches focused on the unsupervised methods (Mihalcea, 2004). The scale of existing data sets are usually very small (most of them are less than 1000). For example, DUC2002 dataset contains 567 documents and each document is provided with two 100-words human summaries. Our work is also related to the headline generation, which is a task to generate one sentence of the text it entitles. Colmenares et.al construct a 1.3 million financial news headline dataset written in English for headline generation (Colmenares et al., 2015). However, the data set is not publicly available.

Naturally Annotated Web Resources based Natural Language Processing is proposed by Sun (Sun, 2011). Naturally Annotated Web Resources is the data generated by users for communicative purposes such as web pages, blogs and microblogs. We can mine knowledge or useful data from these raw data by using marks generated by users unintentionally. Jure et.al track 1.6 million mainstream media sites and blogs and mine a set of novel and persistent temporal patterns in the news cycle (Leskovec et al., 2009). Sepandar et.al use the users' naturally annotated pattern 'we feel' and 'i feel' to extract the 'Feeling' sentence collection which is used to collect the world's emotions. In this work, we use the naturally annotated resources to construct the large scale Chinese short text summarization data to facilitate the research on text summarization.

3 Data Collection

A lot of popular Chinese media and organizations have created accounts on the Sina Weibo. They use their accounts to post news and information. These accounts are verified on the Weibo and labeled by a blue 'V'. In order to guarantee the quality of the crawled text, we only crawl the verified organizations' weibos which are more likely to be clean, formal and informative. There are a lot of human intervention required in each step. The process of the data collection is shown as Figure 2 and

summarized as follows:

1) We first collect 50 very popular organization users as seeds. They come from the domains of politic, economic, military, movies, game and etc, such as People's Daily, the Economic Observe press, the Ministry of National Defense and etc. 2) We then crawl fusers followed by these seed users and filter them by using human written rules such as the user must be blue verified, the number of followers is more than 1 million and etc. 3) We use the chosen users and text crawler to crawl their weibos. 4) we filter, clean and extract (short text, summary) pairs. About 100 rules are used to extract high quality pairs. These rules are concluded by 5 peoples via carefully investigating of the raw text. We also remove those paris, whose short text length is too short (less than 80 characters) and length of summaries is out of [10,30].

4 Data Properties

The dataset consists of three parts shown as Table 1 and the length distributions of texts are shown as Figure 3.

Part I is the main content of LCSTS that contains 2,400,591 (short text, summary) pairs. These pairs can be used to train supervised learning model for summary generation.

Part II contains the 10,666 human labeled (short text, summary) pairs with the score ranges from 1 to 5 that indicates the relevance between the short text and the corresponding summary. '1' denotes " the least relevant " and '5' denotes "the most relevant". For annotating this part, we recruit 5 volunteers, each pair is only labeled by one annotator. These pairs are randomly sampled from Part I and are used to analysize the distribution of pairs in the Part I. Figure 4 illustrates examples of different scores. From the examples we can see that pairs scored by 3, 4 or 5 are very relevant to the corresponding summaries. These summaries are highly informative, concise and significantly short compared to original text. We can also see that many words in the summary do not appear in the original text, which indicates the significant difference of our dataset from sentence compression datasets. The summaries of pairs scored by 1 or 2 are highly abstractive and relatively hard to conclude the summaries from the short text. They are more likely to be headlines or comments instead of summaries. The statistics show that the percent of score 1 and 2 is less than 20% of the data, which can be filtered by using trained classifier.

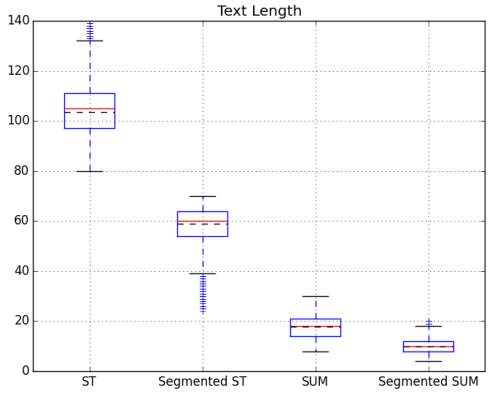

Figure 3: Box plot of lengths for short text(ST), segmented short text(Segmented ST), summary(SUM) and segmented summary(Segmented SUM). The red line denotes the median, and the edges of the box the quartiles.

Part III contains 1,106 pairs. For this part, 3 annotators label the same 2000 texts and we extract the text with common scores. This part is independent from Part I and Part II. In this work, we use pairs scored by 3, 4 and 5 of this part as the test set for short text summary generation task.

5 Experiment

Recently, recurrent neural network (RNN) have shown powerful abilities on speech recognition (Graves et al., 2013), machine translation (Sutskever et al., 2014) and automatic dialog response (Shang et al., 2015). However, there is rare research on the automatic text summarization by using deep models. In this section, we use RNN as encoder and decoder to generate the summary of short text. We use the Part I as the training set

Short Text: 水利部水资源司司长陈明忠今日在新闻发布会上透露，根据刚刚完成的水资源管理制度的考核，有部分省接近了红线的指标，有部分省超过红线的指标。在一些超过红线的地方，将对一些取用水项目进行区域的限批，严格地进行水资源论证和取水许可的批准。

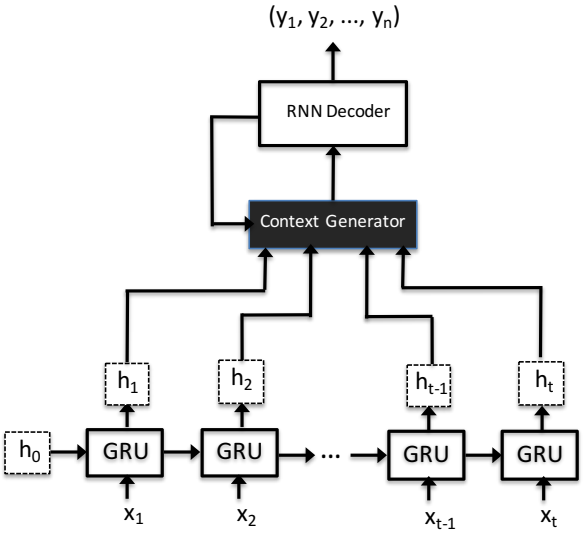

Figure 6: The graphical depiction of the RNN encoder and decoder framework with context.

text is segmented into Chinese words by using jieba[5]. The vocabulary is limited to 50,000. We adopt two deep architectures, 1) The local context is not used during decoding. We use the RNN as encoder and it's last hidden state as the input of decoder, as shown in Figure 5; 2) The context is used during decoding, following (Bahdanau et al., 2014), we use the combination of all the hidden states of encoder as input of the decoder, as shown in Figure 6. For the RNN, we adopt the gated recurrent unit (GRU) which is proposed by (Chung et al., 2015) and has been proved comparable to LSTM (Chung et al., 2014). All the parameters (including the embeddings) of the two architectures are randomly initialized and ADADELTA (Zeiler, 2012) is used to update the learning rate. After the model is trained, the beam search is used to generate the best summaries in the process of decoding and the size of beam is set to 10 in our experiment.

on word-based input contains many UNKs. This may attribute to that the segmentation may lead to many UNKs in the vocabulary and text such as the person name and organization name. For example, "愿景光电子" is a company name which is not in the vocabulary of word-based RNN, the RNN summarizer has to use the UNKs to replace the "愿景光电子" in the process of decoding.

6 Conclusion and Future Work

We constructed a large-scale Chinese short text summarization dataset and performed RNN-based methods on it, which achieved some promising results. This is just a start of deep models on this task and there is much room for improvement. We take the whole short text as one sequence, this may not be very reasonable, because most of short texts contain several sentences. A hierarchical RNN (Li et al., 2015) is one possible direction. The rare word problem is also very important for the generation of the summaries, especially when the input is word-based instead of character-based. It is also a hot topic in the neural generative models such as neural translation machine(NTM) (Luong et al., 2014), which can benefit to this task. We also plan to construct a large document summarization data set by using naturally annotated web resources.

Discourse Planning with an N-gram Model of Relations

Or Biran
Columbia University
orb@cs.columbia.edu

Kathleen McKeown
Columbia University
kathy@cs.columbia.edu

Abstract

While it has been established that transitions between discourse relations are important for coherence, such information has not so far been used to aid in language generation. We introduce an approach to discourse planning for concept-to-text generation systems which simultaneously determines the order of messages and the discourse relations between them. This approach makes it straightforward to use statistical transition models, such as n-gram models of discourse relations learned from an annotated corpus. We show that using such a model significantly improves the quality of the generated text as judged by humans.

1 Introduction

Discourse planning is a subtask of Natural Language Generation (NLG), concerned with determining the ordering of messages in a document and the discourse relations that hold among them (Reiter and Dale, 2000). Early approaches to discourse planning used manually written rules, often based on schemas (McKeown, 1985) or on Rhetorical Structure Theory (RST) (Mann and Thompson, 1987; Hovy, 1993; Power, 2000). In the past decade, various statistical approaches have emerged (Duboue and McKeown, 2001; Dimitromanolaki and Androutsopoulos, 2003; Soricut and Marcu, 2006; Konstas and Lapata, 2013). Other relevant statistical approaches to content ordering can also be found in the summarization literature (Barzilay et al., 2001; Lapata, 2003; Bollegala et al., 2005). These approaches overwhelmingly focus on determining the best order of messages using semantic conent, while discourse relations are in most cases either determined by manually-written derivation rules or completely ignored.

Meanwhile, researchers working on discourse relation disambiguation have observed that the sequence of discourse relations itself, independently of content, helps in disambiguating adjacent relations (Wellner et al., 2006; Pitler et al., 2008). Sequential discourse information has been used successfully in discourse parsing (Ghosh et al., 2011; Feng and Hirst, 2014), and discourse structure was shown to be as important for text coherence as entity-based content structure (Lin et al., 2011; Feng et al., 2014). Surprisingly, so far, discourse sequential information from existing discourse-annotated corpora, such as the Penn Discourse Treebank (PDTB) (Prasad et al., 2008) has not been used in generation.

In this paper, we present an NLG framework that generates texts from existing semantic web ontologies. We use an n-gram model of discourse relations to perform discourse planning for these stories. Through a crowd-sourced human evaluation, we show that the ordering of our documents and the choice of discourse relations is significantly better when using this model.

2 Generation Framework

In concept-to-text generation pipelines, discourse planning typically occurs after the content selection stage. The input, therefore, is an unordered set of messages that are not yet realized: instead of being represented as text, the messages have a structured semantic representation.

In this paper, we generate *comparison stories*, describing and comparing two similar entities, from an RDF ontology. The RDF semantic representation is commonly used in semantic web resources and free ontologies. An RDF message (called a *triple*) has three parts: a subject, a predicate and an object. For each story, we consider any triple whose subject is one of the participating entities as a potential message to be generated. We do only minimal processing on these messages:

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1973–1977,
Lisbon, Portugal, 17-21 September 2015.

where two triples have the same subject and predicate but different objects, we merge them into a single message with multiple objects; and where two triples have the same subject and object but different predicates, we merge them into a single message with multiple predicates.

Next, we build the set of potential discourse relations between all messages. We use the PDTB *class-level* relations, of which there are four: *expansion*, *comparison*, *contingency* and *temporal*. Each is an abstraction of a family of more specific relations, such as *cause*, *concession*, etc. We do not differentiate between explicit and implicit relations, and treat *entrel* as a type of *expansion*.

Potential discourse relations are implied in the semantics of the triples: messages that contain the same predicate and object may have an expansion relation among them (e.g. "John has a ball. Mary also has a ball"). Messages that contain the same predicate but different subjects and objects may have a comparison relation (e.g. "John likes apples but Mary likes oranges").

Specific predicate pairs will also have specific potential relations among them - for example, "birth place" and "residence" have a temporal relation (when applied to the same subject). The same is true for contingency relations (e.g., "city" and "country" for the same subject - if the subject is in a city, it implies which country it is in). We manually annotated the 59 predicate pairs that had potential temporal and contingency relations, as well as 8 pairs with special potential comparison relations (e.g., "birth place" and "residence" if the subject is the same but the object is not).

Once the potential relations are identified, we have a directed multigraph where each vertex is a message and each edge is a potential relation. There can be multiple edges between any two vertices, since messages may have more than one potential relation among them.

Once the graph is ready, we perform content selection. Given a desired number of messages to generate, we choose the set of messages that maximizes the number of edges in the resulting subgraph (thus ensuring that the selected messages are discourse-coherent). If there are multiple such sets, we choose one at random.

The task we are focused on in this paper is discourse planning, which in our formulation is the task of finding a Hamiltonian path through the selected subgraph, thus simultaneously selecting the order of the messages (nodes) as well as the relations (edges) that connect them. Our approach for choosing the best path is discussed in the next section. For the remainder of this section, we describe our simple implementations of the next stages of generation: sentence planning and realization.

For each of the four discourse relations we use, we selected a few explicit connectives from the PDTB that are often used to convey them. We specifically chose connectives that apply to the entire range of class-level relations (e.g., for *comparison* we chose "while" - since it applies to both *contrast* and *concession* in the PDTB, but not "in contrast" which applies only to the former). We also chose only those connectives which have the structure [ARG1 connective ARG2] or [ARG1. connective, ARG2]. During realization, we arbitrarily choose a connective to realize the relation.

Since the ordering and relations between messages is determined by the discourse plan, sentence planning falls naturally out of it: sentence breaks occur where the connective pattern creates them, or where there is no relation between adjacent messages.

To realize the messages themselves, we follow a single pattern: "the [predicate(s)] of [subject] (is/are) [object(s)]". Simple rules are used to pluralize the predicate when there are multiple objects and to create lists of multiples objects or predicates where needed.

These basic solutions for the various stages of NLG produce texts that are rich enough to be acceptable for human readers, but which have relatively little variation in grammatical and lexical quality. This crucial combination allows us to perform a human study to specifically evaluate the discourse planning component.

3 Discourse Planning

As explained in the previous section, we formulate the discourse planning task as finding a path through a multigraph of potential relations between messages. One major component of what makes a good path is the sequence of content: some content is more central and should appear earlier, for example; and some predicates and objects are semantically related and should appear near one another. In this paper we focus on a component that has so far been neglected in generation - the sequence of discourse relations - while trying to minimize the effect that content semantics

have on the evaluation (other than the semantics implicit in the relations). In order to quantify the likelihood of a sequence of relations, we build an n-gram model from a discourse-annotated corpus.

An n-gram model measures the transitional probabilities for sequences of the units that the n-grams are composed of. In this case, the units are discourse relations. The probability of a particular sequence of relations of length $n+1$ given an existing subsequence of length n is computed as a fraction of the number of times it appears in the corpus and the number of times the subsequence appears in the corpus, i.e.

$$P(r_i|r_{i-n},...,r_{i-1}) = \frac{C(r_{i-n},...,r_{i-1},r_i)}{C(r_{i-n},...,r_{i-1})}$$

Where $C(s)$ is the number of times sequence s appears in the corpus. Using this model to generate a discourse plan given a potential relation multigraph is a stochastic process: at each stage, we choose the next relation edge out of the last chosen message vertex (the first vertex is chosen at random) based on the selected sequence of relation edges and the probabilities for the next relation in the model. Once a vertex is added to the path edges leading to it can no longer be selected.

4 Evaluation

One method for evaluating a discourse plan independently of content is to produce pairs of generated short text documents, each containing the same content, but with different ordering and discourse relations (as dictated by the discourse plan). The only obvious way to decide which text is better is to have human judges make that decision. It is important to minimize the effects of other qualities of the texts (differences in content, word choice, grammatical style, etc.) as much as possible, so that the judgement is based only on the differences in order and discourse.

We used DBPedia (Auer et al., 2007) - an RDF ontology extracted from Wikipedia - to generate content. Each document generated was a *comparison story* of two entities in a single category (i.e., the messages in the stories were selected, as described in Section 2, from the set of triples where one of the entities was the subject). In order to experiment with different domains, we used four different categories: **Office Holder** (i.e., a person holding office such as a President or a Judge); **River**; **Television Show**; and **Military Unit**. The entity pairs from each category were chosen at random but were required to have at least 8 predicates and 3 objects in common, so that they were somewhat semantically related.

The birth place of Allen J. Ellender is Montegut, Louisiana, while the death place of Allen J. Ellender is Maryland. The birth place of Robert E. Quinn is Phoenix, Rhode Island. Subsequently, the death place of Robert E. Quinn is Rhode Island.
The birth place of Allen J. Ellender is Montegut, Louisiana. In comparison, the birth place of Robert E. Quinn is Phoenix, Rhode Island. The death place of Robert E. Quinn is Rhode Island, but the death place of Allen J. Ellender is Maryland.

Figure 1: Sample pair of comparison stories

To ensure that human judges can easily tell the differences between the stories on a sentential level, we limited the size of each story to 4 messages. For each pair of stories, everything but the discourse plan (i.e. the content selection, the realization of messages and the lexical choice of connectives) was identical. Figure 1 shows an example pair of stories from the Office Holder category.

4.1 Experiments

We conducted two crowd sourced experiments on the CrowdFlower platform. Each question consisted of two short stories that are completely identical in content, but each generated with a different discourse planner. The human judge was asked to decide which of the stories has a better flow (or whether they are equally good), and then to give each of the stories a score from 1 to 5, paying specific attention to the ordering of the prepositions and the relations between them. The stories were presented in a random order and were not given labels, to avoid bias. We generated 125 pairs of stories from each category - a total of 500 - for each experiment.

Each question was presented to three judges. In each experiment, there was complete disagreement among the three annotators in approximately 15% of the questions, and those were discarded. In approximately 20% there was complete agreement, and in the rest of the questions there were two judges who agreed and one who disagreed. We also computed inter-annotator agreement using Cohen's Kappa for 217 pairs of judges who

	Quality comparison			Avg. score	
	Base	Equal	Pdtb	Base	Pdtb
Of. Holder	27.4%	30.2%	**42.5%**	3.67	**3.76**

River	41.1%	11.2%	**47.7%**	3.68	**3.7**
Total	39.6%	12%	**48.4%**	3.61	**3.67**

Table 2: Results for the comparison between the Wikipedia model and the PDTB model

both answered at least 10 of the same questions. The average kappa value was 0.5, suggesting reasonable agreement.

In the first experiment, we compared stories generated by a planner using an n-gram model extracted from the PDTB with stories generated by a baseline planner, where all edges have identical probabilities. The results are shown in Table 1.

In the second experiment, we used a PDTB shallow discourse parser we developed (Biran and McKeown, 2015) to create a discourse-annotated version of the English Wikipedia. We then compared stories generated by a planner using an n-gram model extracted from the parsed Wikipedia corpus with those generated by a planner using the PDTB model. The results are shown in Table 2.

The total results in both tables are statistically significant ($p < 0.05$).

4.2 Discussion

The results in Table 1 show that the judges significantly preferred the stories created by the n-gram model-based planner to those created by the baseline planner, both in terms of the three-way decision and in terms of the numeric score. This is true for the total set as well as every specific topic, except for *River*. This may be because the predicates in the River category are much more cohesive than in other categories: virtually all predicates related to rivers describe an aspect of the location of the river. That fact may make it easier for a random planner to produce a story that seems coherent. Note, however, that while the judges preferred the baseline story more often in the *River* questions, the average score is higher for the model, which suggests that when the baseline was better it was only mildly so, while when the model was better is was significantly so.

The results in Table 2 show that the Wikipedia-based model produces better results than the PDTB-based model. We hypothesize that it is for two reasons. First, Wikipedia contains definitional texts and is closer in style and content to the stories we produce than the PDTB, which contains WSJ articles. Temporal relations constitute about 10% of both corpora, but contingency and comparison relations each make up almost 20% of the PDTB, while in Wikipedia they span only 10% and 12% of the corpus, respectively, making the share of expansion relations much larger. Second, since the PDTB is small, higher-order n-grams are sparsely found, which can add noise to the model. The Wikipedia corpus is significantly larger and does not suffer from this problem.

The differences in average scores seen in the experiments are relatively small. That is expected, since we have eliminated the content coherence factor, which is known to be significant. In addition, while judges were specifically asked to focus on the order of messages and relations between them, there is inevitably some noise due to accidental lexical or syntactic mismatches, ordering that is awkward content-wise, and other side-effects of the generation framework we employed.

5 Conclusion and Future Work

We introduced an approach to discourse planning that relies on a potential discourse multigraph, allowing for an n-gram model of relations to drive the discourse plan and efficiently determine both the ordering and the relations between messages.

We conducted two experiments, comparing stories generated with different discourse planners. The first shows that an n-gram model-based planner significantly outperforms the random baseline. The second suggests that using an n-gram model derived from a corpus that is larger and closer in style and content, though less accurately annotated, can further improve results.

In future work, we intend to combine this discourse-based view of coherence with a content-based view to create a unified statistical discourse planner. In addition, we will explore additional stochastic models of discourse that look at other, non-sequential collocational information.

Experiments with Generative Models for Dependency Tree Linearization

Richard Futrell and Edward Gibson
Department of Brain and Cognitive Sciences
Massachusetts Institute of Technology
{futrell, egibson}@mit.edu

Abstract

We present experiments with generative models for linearization of unordered labeled syntactic dependency trees (Belz et al., 2011; Rajkumar and White, 2014). Our linearization models are derived from generative models for dependency structure (Eisner, 1996). We present a series of generative dependency models designed to capture successively more information about ordering constraints among sister dependents. We give a dynamic programming algorithm for computing the conditional probability of word orders given tree structures under these models. The models are tested on corpora of 11 languages using test-set likelihood, and human ratings for generated forms are collected for English. Our models benefit from representing local order constraints among sisters and from backing off to less sparse distributions, including distributions not conditioned on the head.

1 Introduction

We explore generative models for producing linearizations of unordered labeled syntactic dependency trees. This specific task has attracted attention in recent years (Filippova and Strube, 2009; He et al., 2009; Belz et al., 2011; Bohnet et al., 2012; Zhang, 2013) because it forms a useful part of a natural language generation pipeline, especially in machine translation (Chang and Toutanova, 2007) and summarization (Barzilay and McKeown, 2005). Closely related tasks are generation of sentences given CCG parses (White and Rajkumar, 2012), bags of words (Liu et al., 2015), and semantic graphs (Braune et al., 2014).

Here we focus narrowly on testing probabilistic generative models for dependency tree linearization. In contrast, the approach in most previous work is to apply a variety of scoring functions to trees and linearizations and search for an optimally-scoring tree among some set. The probabilistic linearization models we investigate are derived from generative models for dependency trees (Eisner, 1996), as most commonly used in unsupervised grammar induction (Klein and Manning, 2004; Gelling et al., 2012). Generative dependency models have typically been evaluated in a parsing task (Eisner, 1997). Here, we are interested in the inverse task: inferring a distribution over linear orders given unordered dependency trees.

This is the first work to consider generative dependency models from the perspective of word ordering. The results can potentially shed light on how ordering constraints are best represented in such models. In addition, the use of probabilistic models means that we can easily define well-motivated normalized probability distributions over orders of dependency trees. These distributions are useful for answering scientific questions about crosslinguistic word order in quantitative linguistics, where obtaining robust estimates has proven challenging due to data sparsity (Futrell et al., 2015).

The remainder of the work is organized as follows. In Section 2 we present a set of generative linearization models. In Section 3 we compare the performance of the different models as measured by test-set probability and human acceptability ratings. We also compare our performance with other systems from the literature. Section 4 concludes.

2 Generative Models for Projective Dependency Tree Linearization

We investigate head-outward projective generative dependency models. In these models, an ordered dependency tree is generated by the following kind

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1978–1983,
Lisbon, Portugal, 17-21 September 2015.

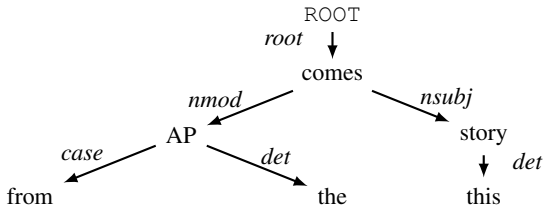

Figure 1: Example unordered dependency tree. Possible linearizations include (1) *This story comes from the AP* and (2) *From the AP comes this story*. Order 2 is the original order in the corpus, but order 1 is much more likely under our models.

of procedure. Given a head node, we use some generative process G to generate a depth-1 subtree rooted in that head node. Then we apply the procedure recursively to each of the dependent nodes. By applying the procedure starting at a ROOT node, we generate a dependency tree. For example, to generate the dependency tree in Figure 1 from the node *comes* down, we take the head *comes* and generate the subtree  , then we take the head *story* and generate , and so on. In this work, we experiment with different specific generative processes G which generate a local subtree conditioned on a head.

2.1 Model Types

Here we describe some possible generative processes G which generate subtrees conditioned on a head. These models contain progressively more information about ordering relations among sister dependents.

A common starting point for G is **Eisner Model C** (Eisner, 1996). In this model, dependents on one side of the head are generated by repeatedly sampling from a categorical distribution until a special stop-symbol is generated. The model only captures the propensity of dependents to appear on the left or right of the head, and does not capture any order constraints between sister dependents on one side of the head.

We consider a generalization of Eisner Model C which we call **Dependent N-gram** models. In a Dependent N-gram model, we generate dependents on each side the head by sampling a *sequence* of dependents from an N-gram model. Each dependent is generated conditional on the $N-1$ previously generated dependents from the head outwards. We have two separate N-gram sequence distributions for left and right dependents. Eisner Model C can be seen as a Dependent N-gram model with $N = 1$.

We also consider a model which can capture many more ordering relations among sister dependents: given a head h, sample a subtree whose head is h from a Categorical distribution over subtrees. We call this the **Observed Orders** model because in practice we are simply sampling one of the observed orders from the training data. This generative process has the capacity to capture the most ordering relations between sister dependents.

2.1.1 Distributions over Permutations of Dependents

We have discussed generative models for ordered dependency trees. Here we discuss how to use them to make generative models for word orders conditional on unordered dependency trees.

Suppose we have a generative process G for dependency trees which takes a head h and generates a sequence of dependents $\mathbf{w}_l$ to the left of h and a sequence of dependents $\mathbf{w}_r$ to the right of h. Let $\mathbf{w}$ denote the pair $(\mathbf{w}_l, \mathbf{w}_r)$, which we call the **configuration** of dependents. To get the probability of some $\mathbf{w}$ given an unordered subtree u, we want to calculate the probability of $\mathbf{w}$ given that G has generated the particular multiset $\mathbf{W}$ of dependents corresponding to u. To do this, we calculate:

$$\begin{aligned} p(\mathbf{w}|\mathbf{W}) &= \frac{p(\mathbf{w}, \mathbf{W})}{p(\mathbf{W})} \\ &= \frac{p(\mathbf{w})}{Z}, \end{aligned} \tag{1}$$

where

$$Z = \sum_{\mathbf{w}' \in \mathcal{W}} p(\mathbf{w}') \tag{2}$$

and $\mathcal{W}$ is the set of all possible configurations $(\mathbf{w}_l, \mathbf{w}_r)$ compatible with multiset $\mathbf{W}$. That is, $\mathcal{W}$ is the set of pairs of permutations of multisets $\mathbf{W}_l$ and $\mathbf{W}_r$ for all possible partitions of $\mathbf{W}$ into $\mathbf{W}_l$ and $\mathbf{W}_r$. The generative dependency model gives us the probability $p(\mathbf{w})$.

It remains to calculate the normalizing constant Z, the sum of probabilities of possible configurations. For the Observed Orders model, Z is the sum of probabilities of subtrees with the same dependents as subtree u. For the Dependent N-gram models of order N, we calculate Z using a dynamic programming algorithm, presented in Al-

gorithm 1 as memoized recursive functions. When $N = 1$ (Eisner Model C), Z is more simply:

$$Z_{\text{emc}} = p_L(\texttt{stop}) \times p_R(\texttt{stop}) \times \sum_{(\mathbf{W}_l, \mathbf{W}_r) \in \text{PARTS}(\mathbf{W})} |\mathbf{W}_l|! \times |\mathbf{W}_r|! \times \prod_{w \in \mathbf{W}_l} p_L(w) \prod_{w \in \mathbf{W}_r} p_R(w), \quad (3)$$

where $\text{PARTS}(\mathbf{W})$ is the set of all partitions of multiset $\mathbf{W}$ into two multisets $\mathbf{W}_l$ and $\mathbf{W}_r$, p_L is the probability mass function for a dependent to the left of the head, p_R is the function for a dependent to the right, and `stop` is a special symbol in the support of p_L and p_R which indicates that generation of dependents should halt. The probability mass functions may be conditional on the head h. These methods for calculating Z make it possible to transform a generative dependency model into a model of dependency tree *ordering* conditional on local subtree structure.

Algorithm 1 Compute the sum of probabilities of all configurations of dependents $\mathbf{W}$ under a Dependent N-gram model with two component N-gram models of order N: p_R for sequences to the right of the head and p_L for sequences to the left.

memoized function RIGHT_NORM($\mathbf{r}$, $\mathbf{c}$)
  if $|\mathbf{r}| = 0$ **then**
    return $p_R(\texttt{stop} \mid \mathbf{c})$
  end if
  $Z \leftarrow 0$
  for $i = 1 : |\mathbf{r}|$ **do**
    $\mathbf{r}' \leftarrow$ elements of $\mathbf{r}$ except the ith
    $\mathbf{c}' \leftarrow$ append r_i to $\mathbf{c}$ then truncate to length $N - 1$
    $Z \leftarrow Z + p_R(r_i|\mathbf{c}) \times \text{RIGHT\_NORM}(\mathbf{r}', \mathbf{c}')$
  end for
  return Z
end memoized function
memoized function LEFT_NORM($\mathbf{r}$, $\mathbf{c}$)
  $Z \leftarrow p_L(\texttt{stop} \mid \mathbf{c}) \times \text{RIGHT\_NORM}([\texttt{start}], \mathbf{r})$
  for $i = 1 : |\mathbf{r}|$ **do**
    $\mathbf{r}' \leftarrow$ elements of $\mathbf{r}$ except the ith
    $\mathbf{c}' \leftarrow$ append r_i to $\mathbf{c}$ then truncate to length $N - 1$
    $Z \leftarrow Z + p_L(r_i|\mathbf{c}) \times \text{LEFT\_NORM}(\mathbf{r}', \mathbf{c}')$
  end for
  return Z
end memoized function
Result is LEFT_NORM($\mathbf{W}$, [`start`])

2.2 Labelling

The previous section discussed the question of the structure of the generative process for dependency trees. Here we discuss an orthogonal modeling question, which we call **labelling**: what information about the *labels* on dependency tree nodes and edges should be included in our models. Dependency tree nodes are labeled with wordforms, lemmas, and parts-of-speech (POS) tags; and dependency tree edges are labeled with relation types. A model might generate orders of dependents conditioned on all of these labels, or a subset of them. For example, a generative dependnecy model might generate (relation type, dependent POS tag) tuples conditioned on the POS tag of the head of the phrase. When we use such a model for dependency linearization, we would say the model's labelling is relation type, dependent POS, and head POS. In this study, we avoid including wordforms or lemmas in the labelling, to avoid data sparsity issues.

2.3 Model Estimation and Smoothing

In order to alleviate data sparsity in fitting our models, we adopt two smoothing methods from the language modelling literature.

All categorical distributions are estimated using add-k smoothing where $k = 0.01$. For the Dependent N-gram models, this means adding k pseudocounts for each possible dependent in each context. For the Observed Orders model, this means adding k pseudocounts for each possible permutation of the head and its dependents.

We also experiment with combining our models into mixture distributions. This can be viewed as a kind of back-off smoothing (Katz, 1987), where the Observed Orders model is the model with the most context, and Dependent N-grams and Eisner Model C are backoff distributions with successively less context. Similarly, models with less information in the labelling can serve as backoff distributions for models with more information in the labelling. For example, a model which is conditioned on the POS of the head can be backed off to a model which does not condition on the head at all. We find optimal mixture weights using the Baum-Welch algorithm tuned on a held-out development set.

3 Evaluation

Here we empirically evaluate some options for model type and model labelling as described above. We are interested in how many of the possible orders of a sentence our model can generate (recall), and in how many of our generated orders really are acceptable (precision). As a recall-like measure, we quantify the probability of the word orders of held-out test sentences. Low probabil-

Table 1: Average log likelihood of word order per sentence in test set under various models. Under "Labelling", **HDR** means conditioning on Head POS, Dependent POS, and Relation Type, and **R** means conditioning on Relation Type alone (see Section 2.2). Under "Model", **oo** is the Observed Orders model, **n1** is the Dependent 1-gram model (Eisner Model C), **n2** is the Dependent 2-gram model, and **n3** is the Dependent 3-gram model (see Section 2.1). In both columns, x**+**y means a mixture of model x and model y; **n123** means n1+n2+n3.

ities assigned to held-out sentences indicate that there are possible orders which our model is missing. As a precision-like measure, we get human acceptability ratings for sentence reorderings generated by our model.

We carry out our evaluations using the dependency corpora of the Universal Dependencies project (v1.1) (Agić et al., 2015), with the train/dev/test splits provided in that dataset. We remove nodes and edges dealing with punctuation. Due to space constraints, we only present results from 11 languages here.

3.1 Test-Set Probability

Here we calculate average probabilities of word orders per sentence in the test set. This number can be interpreted as the (negative) average amount of information contained in the word order of a sentence beyond information about dependency relations.

The results for selected languages are shown in Table 1. The biggest gains come from using Dependent N-gram models with $N > 1$, and from backing off the model labelling. The Observed Orders model does poorly on its own, likely due to data sparsity; its performance is much improved when backing off from conditioning on the head. Eisner Model C (n1) also performs poorly, likely because it cannot represent any ordering constraints among sister dependents. The fact it helps to back off to distributions not conditioned on the head suggests that there are commonalities among distributions of dependents of different heads, which could be exploited in further generative dependency models.

3.2 Human Evaluation

We collected human ratings for sentence reorderings sampled from the English models from 54 native American English speakers on Amazon Mechanical Turk. We randomly selected a set of 90 sentences from the test set of the English Universal Dependencies corpus. We generated a reordering of each sentence according to each of 12 model configurations in Table 1. Each participant saw an original sentence and a reordering of it, and was asked to rate how natural each version of the sentence sounded, on a scale of 1 to 5. The order of presentation of the original and reordered forms was randomized, so that participants were not aware of which form was the original and which was a reordering. Each participant rated 56 sentence pairs. Participants were also asked whether the two sentences in a pair meant the same thing, with "can't tell" as a possible answer.

Table 2 shows average human acceptability ratings for reorderings, and the proportion of sentence pairs judged to mean the same thing. The original sentences have an average acceptability rating of 4.48/5. The very best performing models are those which do not back off to a distribution not conditioned on the head. However, in the case of the Observed Orders and other sparse models, we see consistent improvement from this backoff.

Figure 2 shows the acceptability ratings (out of 5) plotted against test set probability. We see that

Labelling	Model	Acceptability	Same Meaning
HDR	oo	2.92	0.58
	n1	2.06	0.44
	n2	3.42	0.78
	n3	3.48	**0.85**
	n123	**3.56**	0.79
	oo+n123	3.45	0.75
HDR+R	oo	3.11	0.72
	n1	2.11	0.49
	n2	3.32	0.80
	n3	3.52	0.77
	n123	3.31	0.76
	oo+n123	3.43	0.80

Table 2: Mean acceptability rating out of 5, and proportion of reordered sentences with the same meaning as the original, for English models. Labels as in Table 1.

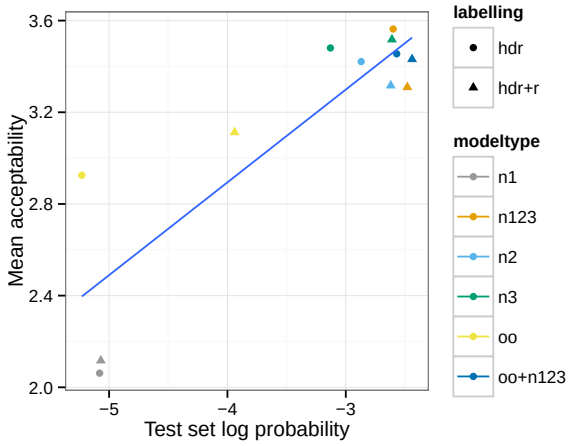

Figure 2: Comparison of test set probability (Table 1) and acceptability ratings (Table 2) for English across models. A least-squares linear regression line is shown. Labels as in Table 1.

the models which yield poor test set probability also have poor acceptability ratings.

3.3 Comparison with other systems

Previous work has focused on the ability to correctly reconstruct the word order of an observed dependency tree. Our goal is to explicitly model a distribution over possible orders, rather than to recover a single correct order, because many orders are often possible, and the particulator order that a dependency tree originally appeared in might not be the most natural. For example, our models typically reorder the sentence "From the AP comes this story" (in Figure 1) as "This story comes from the AP"; the second order is arguably more natural, though the first is idiomatic for this particular phrase. So we do not believe that BLEU scores and other metrics of similarity to a "correct" ordering are particularly relevant for our task.

Previous work uses BLEU scores (Papineni et al., 2002) and human ratings to evaluate generation of word orders. To provide some comparability with previous work, we report BLEU scores on the 2011 Shared Task data here. The systems reported in Belz et al. (2011) achieve BLEU scores ranging from 23 to 89 for English; subsequent work achieves BLEU scores of 91.6 on the same data (Bohnet et al., 2012). Drawing the highest-probability orderings from our models, we achieve a top BLEU score of 57.7 using the model configuration hdr/oo. Curiously, hdr/oo is typically the worst model configuration in the test set probability evaluation (Section 3.1). The BLEU performance is in the middle range of the Shared Task systems. The human evaluation of our models is more optimistic: the best score for Meaning Similarity in the Shared Task was 84/100 (Bohnet et al., 2011), while sentences ordered according to our models were judged to have the same meaning as the original in 85% of cases (Table 2), though these figures are based on different data. These comparisons suggest that these generative models do not provide state-of-the-art performance, but do capture some of the same information as previous models.

3.4 Discussion

Overall, the most effective models are the Dependent N-gram models. The naive approach to modeling order relations among sister dependents, as embodied in the Observed Orders model, does not generalize well. The result suggests that models like the Dependent N-gram model might be effective as generative dependency models.

4 Conclusion

We have discussed generative models for dependency tree linearization, exploring a path less traveled by in the dependency linearization literature. We believe this approach has value for answering scientific questions in quantitative linguistics and for better understanding the linguistic adequacy of generative dependency models.

Abstract

In this study, we consider a summarization method using the document level similarity based on embeddings, or distributed representations of words, where we assume that an embedding of each word can represent its "meaning." We formalize our task as the problem of maximizing a submodular function defined by the negative summation of the nearest neighbors' distances on *embedding distributions*, each of which represents a set of word embeddings in a document. We proved the submodularity of our objective function and that our problem is asymptotically related to the KL-divergence between the probability density functions that correspond to a document and its summary in a continuous space. An experiment using a real dataset demonstrated that our method performed better than the existing method based on sentence-level similarity.

1 Introduction

Document summarization aims to rephrase a document in a short form called a summary while keeping its "meaning." In the present study, we aim to characterize the meaning of a document using embeddings or distributed representations of words in the document, where an embedding of each word is represented as a real valued vector in a Euclidean space that corresponds to the word (Mikolov et al., 2013a; Mikolov et al., 2013b).

Many previous studies have investigated summarization (Lin and Bilmes, 2010; Lin and Bilmes, 2011; Lin and Bilmes, 2012; Sipos et al., 2012; Morita et al., 2013), but to the best of our knowledge, only one (Kågebäck et al., 2014) considered a direct summarization method using embeddings, where the summarization problem was formalized as maximizing a submodular function defined by the summation of cosine similarities based on sentence embeddings. Essentially, this method assumes linear meanings since the objective function is characterized by the summation of sentence-level similarities. However, this assumption is not always valid in real documents, and thus there may be a better combination of two other sentences than the best and second best sentences in terms of similarity in a document.

In this study, we consider a summarization method based on document-level similarity, where we assume the non-linearity of meanings. First, we examine an objective function defined by a cosine similarity based on document embeddings instead of sentence embeddings. Unfortunately, in contrast to our intuition, this similarity is not submodular, which we disprove later. Thus, we propose a valid submodular function based on *embedding distributions*, each of which represents a set of word embeddings in a document, as the document-level similarity. Our objective function is calculated based on the nearest neighbors' distances on embedding distributions, which can be proved to be asymptotically related to KL-divergence in a continuous space. Several studies (Lerman and McDonald, 2009; Haghighi and Vanderwende, 2009) have addressed summarization using KL-divergence, but they calculated KL-divergence based on word distributions in a discrete space. In other words, our study is the first attempt to summarize by asymptotically estimating KL-divergence based on embedding distributions in a continuous space. In addition, they involved the inference of complex models, whereas our method is quite simple but still powerful.

2 Preliminaries

We treat a document as a bag-of-sentences and a sentence as a bag-of-words. Formally, let D be a document, and we refer to an element

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1984–1989,
Lisbon, Portugal, 17-21 September 2015.

$s \in D$ of a sentence and $w \in s$ of a word. We denote the size of a set S by $|S|$. Note that D and s are defined as multisets. For example, we can define a document such as $D := \{s_1, s_2\}$ with $s_1 := \{\texttt{just}, \texttt{do}, \texttt{it}\}$ and $s_2 := \{\texttt{never}, \texttt{say}, \texttt{never}\}$, which correspond to two sentences "Just do it" and "Never say never," respectively. From the definition, we have $|s_1| = 3$ and $|s_2| = 3$.

2.1 Submodularity

Submodularity is a property of set functions, which is similar to the convexity or concavity of continuous functions.

We formally define submodularity as follows.

Definition 1 (Submodularity)**.** Given a set X, a set function $f : 2^X \rightarrow \mathbb{R}$ is called *submodular* if for any two sets S_1 and S_2 such that $S_1 \subset S_2 \subset X$ and element $x \in X \setminus S_2$,

$$f(S_1 \cup \{x\}) - f(S_1) \geq f(S_2 \cup \{x\}) - f(S_2).$$

For simplicity, we define $f_S(x) := f(S \cup \{x\}) - f(S)$, which is called *the marginal value of x with respect to S*. A set function f is called *monotone* if $f_S(x) \geq 0$ for any set $S \subset X$ and element $x \in X \setminus S$.

If a set function f is monotone submodular, we can approximate the optimal solution efficiently by a simple greedy algorithm, which iteratively selects $x^* = \mathrm{argmax}_{x \in X \setminus S_i} f_{S_i}(x)$ where ties are broken arbitrarily, and we substitute $S_{i+1} = S_i \cup \{x^*\}$ in the i-th iteration beginning with $S_0 = \emptyset$. This algorithm is quite simple but it is guaranteed to find a near optimal solution within $1 - 1/\mathrm{e} \approx 0.63$ (Calinescu et al., 2007).

2.2 Embedding

An embedding or distributed representation of a word is a real valued vector in an m-dimensional Euclidean space $\mathbb{R}^m$, which expresses the "meaning" of the word. We denote an embedding of a word w by $\vec{w} \in \mathbb{R}^m$. If for any two words w_1 and w_2, the meaning of w_1 is similar to that of w_2, then $\vec{w}_1$ is expected to be near to $\vec{w}_2$.

A recent study (Mikolov et al., 2013a) showed that a simple log-bilinear model can learn high quality embeddings to obtain a better result than recurrent neural networks, where the concept of embeddings was originally proposed in studies of neural language models (Bengio et al., 2003). In the present study, we use the CW Vector[1] and W2V Vector[2] which are also used in the previous study (Kågebäck et al., 2014).

3 Proposed Method

In this study, we focus on a summarization task as sentence selection in a document. The optimization framework in our task is the same as in the previous study and formalized in Algorithm 1, where w_s represents the pre-defined weight or cost of a sentence s, e.g., sentence length, and r is its scaling factor. This algorithm, called modified greedy, was proposed in (Lin and Bilmes, 2010) and interestingly performed better than the state-of-the-art abstractive approach as shown in (Lin and Bilmes, 2011). Note that we have omitted the notation of D from f for simplicity because D is fixed in an optimization process.

Algorithm 1: Modified greedy algorithm.

Data: Document D, objective function f, and summary size ℓ.
Result: Summary $C \subset D$.

$C \leftarrow \emptyset$; $U \leftarrow D$;
while $U \neq \emptyset$ **do**
  $s^* \leftarrow \mathrm{argmax}_{s \in U} f_C(s)/(w_s)^r$;
  if $\sum_{s \in C} w_s + w_{s^*} \leq \ell$ **then** $C \leftarrow C \cup \{s^*\}$;
  $U \leftarrow U \setminus \{s^*\}$;
$s^* \leftarrow \mathrm{argmax}_{s \in D : w_s \leq \ell} f(\{s\})$;
return $C \leftarrow \mathrm{argmax}_{C' \in \{C, \{s^*\}\}} f(C')$;

Similarity Based on Document Embeddings

First, we examine an objective function f^{Cos} defined by a cosine similarity based on document embeddings. An embedding of a document D is defined as $\mathbf{v}_D := \sum_{s \in D} \sum_{w \in s} \vec{w}$. We formalize the objective function f^{Cos} as follows.

$$f^{Cos}(C) := \frac{\mathbf{v}_C \cdot \mathbf{v}_D}{\|\mathbf{v}_C\| \, \|\mathbf{v}_D\|}.$$

Note that the optimal solution does not change, if we use an average embedding $\mathbf{v}_D / \sum_{s \in D} |s|$ instead of $\mathbf{v}_D$. The next theorem shows that a solution of f^{Cos} by Algorithm 1 is not guaranteed to be near optimal.

Theorem 1. *f^{Cos} is not submodular.*

[1] http://metaoptimize.com/projects/wordreprs

[2] https://code.google.com/p/word2vec

Proof. A simple counterexample is sufficient to prove the theorem. Let us consider $D := \{s_1 := \{w_1\},\ s_2 := \{w_2\},\ s_3 := \{w_3\},\ s_4 := \{w_4\}\}$ with corresponding vectors $\vec{w}_1 := (1,1)$, $\vec{w}_2 := (1,2)$, $\vec{w}_3 := (1,-1)$, and $\vec{w}_4 := (1,-2)$, respectively. In this case, the document embedding $\mathbf{v}_D$ is $(4,0)$. We set $C_1 := \{s_1\}$ and $C_2 := \{s_1, s_2\}$. Clearly, $C_1 \subset C_2$. However, we obtain $f^{Cos}_{C_1}(s_4) = f^{Cos}(\{s_1, s_4\}) - f^{Cos}(\{s_1\}) \approx 0.187$ and $f^{Cos}_{C_2}(s_4) = f^{Cos}(\{s_1, s_2, s_4\}) - f^{Cos}(\{s_1, s_2\}) \approx 0.394$. Therefore, we have $f^{Cos}_{C_2}(s_4) > f^{Cos}_{C_1}(s_4)$. □

Similarity Based on Embedding Distributions

We propose a valid submodular objective function f^{NN} based on embedding distributions. The key observation is that for any two embedding distributions A and B, when A is similar to B, each embedding in A should be near to some embedding in B. In order to formalize this idea, we define *the nearest neighbor of a word w in a summary C* as $n(w, C) := \mathrm{argmin}_{v \in s : s \in C, \vec{w} \neq \vec{v}}\, d(\vec{w}, \vec{v})$, where d is the Euclidian distance in the embedding space, i.e., $d(\vec{w}, \vec{v}) := \|\vec{w} - \vec{v}\|$. We denote the distance of w to its nearest neighbor $n := n(w, C)$ by $N(w, C) := d(\vec{w}, \vec{n})$. Finally, we define f^{NN} as follows:

$$f^{NN}(C) := -\sum_{s \in D} \sum_{w \in s} g(N(w, C)),$$

where g is a non-decreasing scaling function. The function f^{NN} represents the negative value $-\delta$ of dissimilarity δ between a document and summary based on embedding distributions. Note that we can use sentence embeddings instead of word embeddings as embedding distributions, although we focus on word embeddings in this section.

The next theorem shows the monotone submodularity of our objective function, which means that a solution of f^{NN} by Algorithm 1 is guaranteed to be near optimal.

Theorem 2. *f^{NN} is monotone submodular.*

Proof. (Monotonicity) First, we prove the monotonicity. For simplicity, we use the following two abbreviations: $C^s := C \cup \{s\}$ and $\sum_w^D := \sum_{s \in D} \sum_{w \in s}$. For any set $C \subset D$ of sentences and sentence $s \in D \setminus C$, we have $f^{NN}_C(s) = f^{NN}(C^s) - f^{NN}(C) = \sum_w^D (g(N(w, C)) - g(N(w, C^s)))$. Since $C \subset C^s$, obviously $N(w, C) \geq N(w, C^s)$ holds. Therefore, we obtain $f^{NN}_C(s) \geq 0$ from the non-decreasing property of g.

(Submodularity) Next, we prove the submodularity. For any two sets C_1 and C_2 of sentences such that $C_1 \subset C_2 \subset D$, and sentence $s \in D \setminus C_2$, we have $f^{NN}_{C_1}(s) - f^{NN}_{C_2}(s) = f^{NN}(C^s_1) - f^{NN}(C_1) - (f^{NN}(C^s_2) - f^{NN}(C_2)) = \sum_w^D (g(N(w, C_1)) - g(N(w, C^s_1)) - g(N(w, C_2)) + g(N(w, C^s_2)))$. Let $\alpha := g(N(w, C_1)) - g(N(w, C^s_1)) - g(N(w, C_2)) + g(N(w, C^s_2))$.

If $n(w, C^s_2) \in s$, then $n(w, C^s_1) \in s$ holds, since $C^s_1 \subset C^s_2$. This means that $N(w, C^s_2) = N(w, C^s_1) = N(w, \{s\})$. Clearly, $N(w, C_1) \geq N(w, C_2)$, since $C_1 \subset C_2$. Therefore, we obtain $\alpha \geq 0$ from the non-decreasing property of g.

If $n(w, C^s_2) \notin s$ and $n(w, C^s_1) \notin s$, we have $N(w, C^s_1) = N(w, C_1)$ and $N(w, C^s_2) = N(w, C_2)$. This indicates that $\alpha = 0$.

If $n(w, C^s_2) \notin s$ and $n(w, C^s_1) \in s$, so similarly $N(w, C^s_1) \leq N(w, C_1)$ and $N(w, C^s_2) = N(w, C_2)$ hold. Therefore, we obtain $\alpha \geq 0$. □

The objective function f^{NN} is simply heuristic for small documents, but the next theorem shows that f^{NN} is asymptotically related to an approximation of KL-divergence in a continuous space, if g is a logarithmic function. This result implies that we can use mathematical techniques of a continuous space for different NLP tasks, by mapping a document into a continuous space based on word embeddings.

Theorem 3. *Suppose that we have a document D and two summaries C_1 and C_2 such that $|C_1| = |C_2|$, which are samples drawn from some probability density functions p, q, and r, i.e., $D \sim p$, $C_1 \sim q$, and $C_2 \sim r$, respectively. If the scaling function g of f^{NN} is a logarithmic function, the order relation of the expectations of $f^{NN}(C_1)$ and $f^{NN}(C_2)$ is asymptotically the same as that of the KL-divergences $\mathcal{D}_{KL}(p \,||\, r)$ and $\mathcal{D}_{KL}(p \,||\, q)$, i.e., $\mathbb{E}[f^{NN}(C_1)] - \mathbb{E}[f^{NN}(C_2)] > 0 \Leftrightarrow \mathcal{D}_{KL}(p \,||\, r) - \mathcal{D}_{KL}(p \,||\, q) > 0$, as $|D| \to \infty$, $|C_1| \to \infty$, and $|C_2| \to \infty$.*

Proof. Let m be the dimension on embeddings. Using a divergence estimator based on nearest neighbor distances in (Pérez-Cruz, 2009; Wang et al., 2009), we can approximate $\mathcal{D}_{KL}(p \,||\, q)$ by $\widehat{\mathcal{D}}_{KL}(D, C_1) := \frac{m}{|D|} \sum_w^D \ln \frac{N(w,C_1)}{N(w,D)} + \ln \frac{|C_1|}{|D|-1}$. Therefore, we obtain $\widehat{\mathcal{D}}_{KL}(D, C_2) - \widehat{\mathcal{D}}_{KL}(D, C_1) \propto \sum_w^D \ln N(w, C_2) - \sum_w^D \ln N(w, C_1)$. Since $g(x) = \ln(x)$, we have $f^{NN}(C_1) - f^{NN}(C_2) > 0$ if

and only if $\widehat{\mathcal{D}}_{KL}(D, C_2) - \widehat{\mathcal{D}}_{KL}(D, C_1) > 0$ holds. The fact that $\mathbb{E}[\widehat{\mathcal{D}}_{KL}(D, C_1)] \rightarrow \mathcal{D}_{KL}(p \mid\mid q)$ as $|C_1| \rightarrow \infty$ and $|D| \rightarrow \infty$ concludes the theorem. □

4 Experiments

We compared our two proposed methods DocEmb and EmbDist with two state-of-the-art methods SenEmb and TfIdf. The first two methods DocEmb and EmbDist represent Algorithm 1 with our proposed objective functions f^{Cos} and f^{NN}, respectively. TfIdf represents Algorithm 1 with an objective function based on the sum of cosine similarities of tf-idf vectors that correspond to sentences, which was proposed in (Lin and Bilmes, 2011). SenEmb uses a cosine similarity measure based on embeddings instead of tf-idf vectors in the same framework as TfIdf, which was proposed in (Kågebäck et al., 2014).

We conducted an experiment with almost the same setting as in the previous study, where they used the Opinosis dataset (Ganesan et al., 2010). This dataset is a collection of user reviews in 51 different topics such as hotels, cars, and products; thus, it is more appropriate for evaluating summarization of user-generated content than well-known DUC datasets, which consist of formal news articles. Each topic in the collection comprises 50–575 sentences and includes four and five gold standard summaries created by human authors, each of which comprises 1–3 sentences.

We ran an optimization process to choose sentences within 100 words[3] by setting the summary size and weights as $\ell = 100$ and $w_s = |s|$ for any sentence s, respectively. As for TfIdf and SenEmb, we set a cluster size of k-means as $k = |D|/5$ and chose the best value for a threshold coefficient α, trade-off coefficient λ, and the scaling factor r, as in (Lin and Bilmes, 2011). Note that our functions DocEmb and EmbDist have only one parameter r, and we similarly chose the best value of r. Regarding DocEmb, EmbDist, and SenEmb, we used the best embeddings from the CW Vector and W2V Vector for each method, and created document and sentence embeddings by averaging word embeddings with tf-idf weights since it performed better in this experiment. In the case of EmbDist, we used a variant of f^{NN} based on distributions of sentence embeddings. In addition, we examined three scaling functions: logarithmic, linear, and exponential functions, i.e., $\ln x$, x, e^x, respectively.

[3]The previous work used a sentence-based constraint as $\ell = 2$ and $w_s = 1$, but we changed the setting since the variation in length has a noticeable impact on ROUGE scores as suggested in (Hong et al., 2014).

	R-1	R-2	R-3	R-4
ApxOpt	62.22	21.60	8.71	4.56
EmbDist ($\ln x$)	56.00	16.70	4.93	**1.89**
EmbDist (x)	55.70	15.73	4.59	1.84
EmbDist (e^x)	**56.29**	15.96	4.43	1.39
DocEmb	55.80	13.59	3.23	0.90
SenEmb	53.96	15.42	3.97	1.10
TfIdf	52.97	**17.24**	**5.40**	1.49

Table 1: ROUGE-N (R-N) metrics of DocEmb, EmbDist, SenEmb, and TfIdf.

We calculated the ROUGE-N metric (Lin, 2004)[4], which is a widely-used evaluation metric for summarization methods. ROUGE-N is based on the co-occurrence statistics of N-grams, and especially ROUGE-1 has been shown to have the highest correlation with human summaries (Lin and Hovy, 2003). ROUGE-N is similar to the BLEU metric for machine translation, but ROUGE-N is a recall-based metric while BLEU is a precision-based metric.

Table 1 shows the results obtained for ROUGE-N (N ≤ 4) using DocEmb, EmbDist, SenEmb, and TfIdf. ApxOpt represents the approximation results of the optimal solution in our problem, where we optimized ROUGE-1 with the gold standard summaries by Algorithm 1. The obtained results indicate that our proposed method EmbDist with exponential scaling performed the best for ROUGE-1, which is the best metric in terms of correlation with human summaries. The W2V Vector was the best choice for EmbDist. Furthermore, the other proposed method DocEmb performed better than the state-of-the-art methods SenEmb and TfIdf, although DocEmb is not theoretically guaranteed to obtain a near optimal solution. These results imply that our methods based on the document-level similarity can capture more complex meanings than the sentence-level similarity. On the other hand, TfIdf with tf-idf vectors performed the worst for ROUGE-1. A possible reason is that a wide variety of expressions by users made it difficult to calculate similarities. This also suggests that embedding-based methods

[4]We used their software ROUGE version 1.5.5 with the parameters: -n 4 -m -a -l 100 -x -c 95 -r 1000 -f A -p 0.5 -t 0.

naturally have robustness for user-generated content.

In the case of N $\geq$ 2, `TfIdf` performed the best for ROUGE-2 and ROUGE-3, while `EmbDist` with logarithmic scaling is better than `TfIdf` for ROUGE-4. According to (Lin and Hovy, 2003), the higher order ROUGE-N is worse than ROUGE-1 since it tends to score grammaticality rather than content. Conversely, Rankel et al. (2013) reports that there is a dataset where the higher order ROUGE-N is correlated with human summaries well. We may need to conduct human judgments to decide which metric is the best in this dataset for more accurate comparison. However, it is still important that our simple objective functions can obtain good results competing with the state-of-the-art methods.

5 Conclusion

In this study, we proposed simple but powerful summarization methods using the document-level similarity based on embeddings, or distributed representations of words. Our experimental results demonstrated that the proposed methods performed better than the existing state-of-the-art methods based on the sentence-level similarity. This implies that the document-level similarity can capture more complex meanings than the sentence-level similarity.

Recently, Kusner et al. (2015) independently discovered a similar definition to our objective function f^{NN} through a different approach. They constructed a dissimilarity measure based on a framework using Earth Mover's Distance (EMD) developed in the image processing field (Rubner et al., 1998; Rubner et al., 2000). EMD is a consistent measure of distance between two distributions of points. Interestingly, their heuristic lower bound of EMD is exactly the same as $-f^{NN}$ with a linear scaling function, i.e., $g(x) = x$. Moreover, they showed that this bound appears to be tight in real datasets. This suggests that our intuitive framework can theoretically connect the two well-known measures, KL-divergence and EMD, based on the scaling of distance. Note that, to the best of our knowledge, there is currently no known study that considers such a theoretical relationship.

In future research, we will explore other scaling functions suitable for our problem or different problems. A promising direction is to consider a relative scaling function to extract a biased summary of a document. This direction should be useful for query-focused summarization tasks.

Abstract

We restate the classical logical notion of generation/parsing reversibility in terms of feasible probabilistic sampling, and argue for an implementation based on finite-state factors. We propose a modular decomposition that reconciles generation accuracy with parsing robustness and allows the introduction of dynamic contextual factors. *(Opinion Piece)*

1 Introduction

The objective of Natural Language Understanding (NLU) is to map linguistic utterances to semantic representations, that of Natural Language Generation (NLG) to map semantic representations to linguistic utterances. In most of NLP practice, these two objectives are handled by different processes, and computational linguists rarely operate at the intersection of the two subdomains.

For a few years around the early nineties, based both on cognitive, linguistic, and engineering considerations, there was a surge of interest in so called *reversible grammar* approaches to NLP, where one and the same grammatical specification could serve both for parsing utterance x into logical form z, but also for generating x from z (Strzalkowski, 1994).

We start by a brief review of this historical non-probabilistic notion of reversibility and point out certain of its weaknesses, in particular regarding robustness; we then give in section 3 a new probabilistic definition of reversibility; then, in section 4 we argue for a reversibility model based on modular weighted finite-state transducers. We end with a discussion of recent related work.

*Work done while at XRCE.

2 Classical reversibility

The most direct approaches to NLU attempt to design procedures for semantic parsing that, given an input utterance x, produce a semantic representation z, by following a number of intermediate steps where the surface form is gradually transformed into semantic structure. Such "procedural" approaches to semantic parsing are typically very hard or impossible to invert: starting from a semantic representation z, there is no simple process that is able to find an x which, when given to the parser, would produce z. Formally, a Boolean relation $r(x, z)$ can be such that the question $?\exists z\ r(x, z)$ is decidable for all x's, while the reciprocal question $?\exists x\ r(x, z)$ is undecidable for some z's (Dymetman, 1991).[1] One of the motivations for the emerging paradigm of unification grammars at the end of the eighties was the clean separation they promised between specifying well-formed linguistic structures, both on the syntactic and semantic levels, through a formal description of the relation $r(x, z)$, and producing efficient implementations of the specification; in particular, there was much hope that such formalisms would be conductive to effective reversibility (by contrast to variable assignment, variable unification is inherently symmetrical), that is, to feasible (and if possible efficient) implementations of the parsing problem $r(x, ?)$ and of the generation problem $r(?, z)$.

To some extent, this hope was validated through a number of works at the time, mostly involving machine translation applications, and constraining in more or less explicit ways the specification of r (van Noord, 1990). However, for the non-statistical approaches to parsing then strongly dominant, *robustness* was an issue: a parser had to

[1]Some intuition into the issue may be gained by considering typical techniques of public key cryptography, which rely on the difficulty of inverting some simple arithmetic computations.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1990–1995, Lisbon, Portugal, 17-21 September 2015.

either accept or reject a given input x, with no intermediary options, and in order to be able to parse actual utterances, with all their empirical diversity, parsers had to be rather tolerant. In the procedural view of parsing, such robustness issues could often be mitigated through engineering tricks such as ordering the rules from strict to lax, where grammatical constructions were given preference over less conventional ones; however, when trying to move to reversible grammars, these tricks could not be reproduced: if the grammar was able to parse an x into z, then, by design, it was also able to generate x from z, and there was no obvious way, in these non-probabilistic approaches, to distinguish between producing a linguistically correct x or producing a deviant or incorrect one.

3 Probabilistic reversibility

In the classical non-probabilistic case, a (relative) consensus existed around the fact that a reversible grammar should be, as we indicated above, a formal specification of the relation $r(x, z)$ such that the problems $r(x, ?)$ and $r(?, z)$ were effectively solvable.

Transposing this to the probabilistic world, we propose the following semi-formal Definition:

A probabilistic reversible grammar is a formal specification of a joint probability distribution $p(x, z)$ over logical forms z and utterance strings x such that the conditional distributions $p(z|x) \stackrel{\text{def}}{=} \frac{p(x,z)}{\sum_{z'} p(x,z')}$ (parsing) and $p(x|z) \stackrel{\text{def}}{=} \frac{p(x,z)}{\sum_{x'} p(x',z)}$ (generation) can be efficiently sampled from.[2]

Why such focus on *sampling*? We could have chosen other definitions of parsing (and similarly for generation), for instance the ability to return the *most probable* z given x, i.e. to return $\text{argmax}_z\, p(z|x)$; however sampling is the most direct way of providing a concrete view of the underlying probabilistic distribution, and has many applications to learning, so we think the definition above is reasonable (see also footnote[4]).

[2]We note the "semi-formal" aspect of this definition: contrarily to the classical case, which has a formal notion of effective computation, there is no universally accepted notion of effective sampling from a probability distribution. For many probability distributions, the only feasible sampling approaches are the *MCMC* techniques (Robert and Casella, 2004), which typically do not come with convergence guarantees; in some situations, *exact sampling* techniques are applicable, which come with much better guarantees. We will see that the approach proposed in section 4 allows such exact sampling to take place.

4 Finite-state models for reversibility

Finite-state transducers have properties which make them uniquely suited to implementing reversible linguistic specifications in the above sense. Consider a simple weighted string-to-string transducer $\tau(s, t)$, where s, t are strings, and where the underlying semiring is the "probabilistic semiring" over the nonnegative reals, addition and multiplication having their usual interpretations. Such a transducer *preserves regularity*, both in the forward (resp. reverse) directions, meaning that the image through τ of any weighted regular language over s (resp. over t) is again a weighted regular language over t (resp. over s). In particular the forward (resp. reverse) image of a fixed string s_0 (resp t_0) can be computed *in a compact form* as a weighted finite-state automaton (FSA) over t (resp. s), which we can denote by $\tau(s_0, \cdot)$ (resp. $\tau(\cdot, t_0)$). A weighted FSA can be easily normalized into a probabilistic FSA[3] and, from this probabilitic FSA exact samplers for the "parser" $\tau(s_0, \cdot)$ and for the "generator" $\tau(\cdot, t_0))$ are directly obtained.[4]

In general, some of the properties that make weighted FSAs and FSTs — over strings or trees — specially relevant for probabilistic models of language are the following: (i) they allow compact representations of complex probability distributions over linguistic objects (automata) or pairs of linguistic objects (transducers), (ii) they permit efficient exact sampling (and efficient optimization over derivations (but not always over strings)), (iii) they support modularity: intersection of automata, composition of transducers, projections of an automaton through a transducer.[5]

Conceptual architecture Armed with these general considerations, let us now propose a conceptual architecture based on a small number of

[3]That is, into a weighted FSA such the weights of the transitions from each state sum to 1.

[4] While *sampling* strings from a weighted finite-state automaton is simple, finding the most probable *string* (not *path*) in a probabilistic FSA is an NP-hard problem (Casacuberta and de la Higuera, 2000), and one has to resort to the so-called Viterbi approximation (assuming that the most probable path projects into the most probable string). Contrary to popular belief, sampling can sometimes be simpler than optimization.

[5]Outside of the realm of finite-state machines, this modularity is typically impossible to obtain. Thus, in general, the availability of a sampler for a distribution $p(x)$ (resp. a distribution $q(x)$) does not imply that we can efficiently sample from the product (i.e. intersection) $p(x).q(x)$, but we can in case p and q are both represented by weighted FSAs.

finite-state modules, which attempts to satisfy the definition given above for probabilistic reversibility, to address the problem of robustness that we described earlier, and can also support contextual preferences. We illustrate the approach with some simple examples of human-machine dialogues (between a customer and a virtual agent), a domain for which reversibility has high relevance, due to effects such as self-monitoring (Neumann, 1998; Levelt, 1983), interleaving of understanding and generation (Otsuka and Purver, 2003), and lexical entrainment (Brennan, 1996).

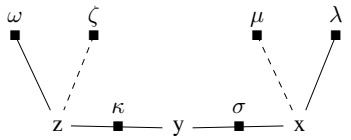

Figure 1: Reversible specification through finite-state factors.

The conceptual architecture is shown in Figure 1. Formally, the figure represents a probabilistic graphical model in so-called factor form, where the factors are $\omega, \kappa, \sigma, \lambda$ (we have also indicated for future reference the "contextual" factors ζ, μ, that we ignore for now). The factors take as arguments three types of objects: z is a logical form, that is, a structured object which can be naturally represented as a tree, x is a surface string, and y is a latent "underlying" string that corresponds to one of a small collection of "canonical" texts for realizing the logical form z (more about that later).

Each factor is realized through a weighted finite-state machine (acceptor or transducer) over strings or trees (Mohri, 2009; Fülöp and Vogler, 2009; Maletti, 2010; Graehl et al., 2008).

The λ factor is a string automaton that represents a standard ngram language model (typically specific to domain), in other words a probability distribution over utterances x. *Symmetrically*, the regular tree automaton ω represents a distribution over logical forms z, which can be seen as playing a similar role to the language model, but at the semantic level, namely telling us what are the possible/likely logical forms in a certain domain.[6]

The "canonical factor" κ is a weighted tree-to-string transducer (Graehl et al., 2008), which implements a relation between logical forms z and a small number of latent "canonical" texts y realizing these logical forms. For example, κ may associate the logical form (dialog act) $z = \texttt{wad}(\texttt{batLife}, \texttt{iphone6})$ — with `wad` an abbreviation for "what is the value of this attribute on this device?", and `batLife` an abbreviation for "battery life" —, with such a canonical text (among a few others) as: *What is the battery life of the Iphone 6?*.

The "similarity factor" σ is a weighted string-to-string finite state transducer which gives scores to x, y according to a notion of similarity. It has the role of "bridging" the gap between the actual utterances x and the latent canonical utterances y. The intention behind the similarity factor is to "decouple" the task of modeling some possible realizations of a given logical form from the task of recognizing that a given more or less well-formed input is a variant of such a realization. This factor relates the two strings y and x, where y is a possible canonical utterance in the limited repertory produced by κ, and x is an actual utterance, in particular any utterance that could be produced by a human speaker. So for instance suppose that the user's utterance is $x =$ *What about battery duration on this Iphone 6?*, we would like this x to have a significant similarity with the canonical utterance $y =$ *What is the battery life of the Iphone 6?* but a negligible similarity with another canonical utterance such as $y' =$ *What is the screen size of the Galaxy Trend?*.

Overall, the canonical factor $\kappa(z, y)$ concentrates more on a core "generation model", namely on producing some well-formed output y from a logical form z, while the similarity factor $\sigma(y, x)$ allows relating an actual user input x to a possible output y of the κ model. The main import of σ is then to allow to use the core generation *model defined by κ to be exploited for* robust semantic parsing.

Different instantiations of this scheme can be employed. In some preliminary experiments that we have performed,[7] σ is a simple edit-distance transducer (Mohri, 2003) which penalizes differently the discrepancies between x and y: strongly for some salient content words or named entities of the domain, weakly for less relevant content words and for non-content words, with limited use of local paraphrases (which can also be implemented

[6] In particular, the ω factor makes explicit the notion of a well-formed semantic representation, a notion often left implicit in semantic parsing.

[7] In these experiments, we used string-based approximations of the logical forms, and only employed string-based transducers from the OpenFST library.

through σ). This strategy seems to work reasonably well when the semantical repertory of the domain is restricted, because a large number of possible variants for x are "attracted" to the same underlying semantics. In domains where small nuances of expression may result in distinct semantics, the division of work between κ and σ may be different.

Parsing and Generation To understand the reversibility properties of the model of Figure 1, let us first simplify the description by assuming that z, instead of being a tree, is actually a string. Then both ω and λ are string automata, and both κ and σ string-to-string transducers. Such a specification satisfies our definition of probabilistic reversibility, exploiting well-known compositionality properties of weighted finite-state machines over strings (Mohri, 2009). For parsing, we start from a fixed x_0, and can project it through σ into a weighted FSA over y; in turn we can project this automaton onto an FSA over z, and finally intersect this automaton with ω, obtaining a final weighted "x_0-parser" automaton over z, representing a probability distribution from which we can draw exact samples as explained above.[8] Generation works in exactly the reverse way, starting from a z_0 and eventually building a "z_0-generator" automaton over x.

In the actual proposal, z is a tree, meaning that ω is a tree automaton, and κ a tree-to-string transducer. While finite-state tree automata correspond to a single concept, and share all the nice properties of string automata (Comon et al., 2007), the situation with tree-to-tree or tree-to-string transducers is more complicated (Maletti, 2010; Graehl et al., 2008): several variants exist, only some of which support the operations that our conceptual model requires (composition with the string transducer σ and intersection with the tree automaton ω). In particular, the "linear non-deleting top-down tree transducers" defined in (Maletti, 2010)[9] have the requisite properties.

Contextual factors We now briefly come back to the factors ζ (tree automaton) and μ (string automaton) of Figure 1, which highlight the usefulness of our modular finite-state architecture. These factors play similar roles to ω and λ, but they evolve dynamically with the context. In dialogue applications, utterances can often only be interpreted by reference to the current dialogue state (e.g. "ten hours" in the context of a question about battery life), and the ζ factor can be used as a compact representation of the current expectations of the dialogue manager about the next logical form, to be combined with the actual customer's utterance. Symmetrically, the μ factor can be used to represent such phenomena as lexical entrainment (Brennan, 1996), where the agent's utterance is oriented towards using similar wordings to the customer's.

5 Related work

The unique formal properties of finite-state machines, which favor modular decompositions of complex tasks, have long been exploited in Computational Linguistics. Tree transducers in particular have gained popularity in Statistical Machine Translation, starting with (Yamada and Knight, 2001), as described in the surveys (Maletti, 2010; Razmara, 2011).

The *reversibility* properties of finite-state transducers have been exploited to a more limited extent, starting with applications of non-weighted string-to-string transducers to morphological analysis and generation (Beesley, 1996).

Concerning the application of weighted finite-state tree machines to NLU/NLG reversibility, our proposal is strongly related on the one hand to the approach of (Jones et al., 2012), who explicitely proposes tree-to-string transducers as a tool for modelling semantic parsing and for training on semantically annotated data, and on the other hand to (Wong, 2007; Wong and Mooney, 2007), who focus more directly on the problem of inverting a semantic parser into a generator. Wong et al. do not explicitely use tree-based transducers, but rather a formalism inspired by SCFGs (synchronous context-free grammars), which essentially corresponds to a form of tree-to-string transducer. In relation to reversibility considerations, presentations in terms of synchronous formalisms have the interest that they are intrinsically symmetrical. Such formalisms have tight relations to tree-transducers (Shieber, 2004); one recently proposed generalization, "Interpreted Regular Tree Grammars" (Koller and Kuhlmann, 2011), allows

[8] We could also have precompiled a generic parser for all x's by first marginalizing the latent variable y through a composition of the transducers κ and σ, and then intersecting the resulting transducer with the automaton ω.

[9] The paper only defines tree-to-tree transducers, but tree-to-string variants can be derived easily.

multiple (possibly more than two) synchronized views of an underlying abstract derivation tree, and has the advantage of permitting a uniform treatment of strings and trees.

One important aspect in which our proposal differs from these previous approaches is in proposing to decouple the "core" task of mapping logical forms to well-formed latent canonical realizations from the task of relating these realizations to actual utterances, through an additional "similarity" transducer acting as a bridge.

This idea of a bridge is however close to another line of work in semantic parsing, not transducer based, namely (Berant and Liang, 2014; Wang et al., 2015). There, a simple generic grammar is used to generate canonical realizations from a repertory of possible logical forms (expressed in a variant of lambda calculus). Given an input to parse, simple heuristics are used to select a finite list of potential logical forms which are then ranked according to the (paraphrase-based) similarity of their associated canonical realization with the input. Thus in this approach, a form of generation plays an important role, not for its own sake, but as a tool for semantic parsing.

6 Conclusion

Because of their unique compositional properties, finite-state modules are a natural choice for implementing our definition of reversibility as efficient bidirectional sampling from a common specification. In this piece we have argued in favor of an architecture realizing this definition and displaying robustness and contextuality.

Acknowledgments We thank the anonymous reviewers for their detailed comments and for pointing us to some relevant literature that we had overlooked.

Abstract

Direct content analysis reveals important details about movies including those of gender representations and potential biases. We investigate the differences between male and female character depictions in movies, based on patterns of language used. Specifically, we use an automatically generated lexicon of linguistic norms characterizing gender ladenness. We use multivariate analysis to investigate gender depictions and correlate them with elements of movie production. The proposed metric differentiates between male and female utterances and exhibits some interesting interactions with movie genres and the screenplay writer gender.

1 Introduction

Gender has been an important research topic in the social sciences, with studies conducted on the effect of gender on various aspects of human perception and expression (Benshoff and Griffin, 2011) as well as investigations of the societal (Behm-Morawitz and Mastro, 2008) and career implications of gender and possible underlying biases. Previous studies report significant implications of gender on career progress in medicine (Sidhu et al., 2009), information technology (Cohoon and Aspray, 2006), politics (Niven, 2006) and show-business (Smith, 2010).

In this paper we investigate the depictions of the genders in feature films, through the analysis of their respective dialogues. The differences in depiction are a contentious subject, since aspects of these can be viewed as the result of stereotyping or gender bias, with the relative presence of women being a well investigated subject (Bielby and Bielby, 1996; Lincoln and Allen, 2004). We are interested in the existing gender depictions, regardless of relative frequencies, as well as any factors that may affect them. While popular tools such as the Bechdel test provide a test for detecting female presence in the movies, we hope to identify more subtle forms of gender differences across character gender from the dialogues. Our aim is to devise a non-binary metric that can be used to compare or rank movies, characters and perhaps individual utterances.

To analyze the dialogues we propose using a metric of language gender ladenness, a number representing a normative rating of the "perceived feminine or masculine association" (Paivio et al., 1968) of language. The metric, as originally defined, is meant to provide an indication of gender-specificity of individual words, with extreme values assigned to highly stereotypical concepts. Generating this rating for male and female character dialogues and comparing the character gender with this rating of "language gender" should allow us to observe stereotypical behavior.

Word based ratings such as the gender ladenness are referred to as linguistic norms (or psycholinguistic norms when corresponding to psychological constructs) and are popular in cognitive psychology (Clark and Paivio, 2004) and some computational disciplines, such as sentiment analysis (Nielsen, 2011) and opinion mining. To utilize gender ladenness, we follow an approach similar to simple sentiment analysis, with word-level norms automatically generated based on a small starting set of manually annotated norms and sentence (and higher) level norms estimated through word-level norm statistics. The resulting algorithm allows us to estimate gender ladenness at any arbitrary granularity.

We use these ratings of dialogue language to quantify the depictions of male and female characters and attempt to relate the observed gender ladenness with objective factors.

In section 2 and 3 we describe the data corpus

and the feature extraction process respectively. We detail the experimental procedure in section 4 and analysis in section 5 and conclude with future extensions in section 6.

2 Estimating Gender Ladenness

Gender Ladenness, as defined in (Clark and Paivio, 2004) represents the degree of perceived "feminine or masculine association" on a numerical scale ranging from very masculine to very feminine. It is important to note that there was no restriction to what "association" may mean: while it is reasonable to assume that associations of the form "A is B" or "A has B" would dominate annotator perception, that does not preclude other forms of association. Because of that, referring to the norms as indicators of how masculine or feminine the words are is not entirely accurate, though it is a reasonable approximation. The original ratings were re-scaled to $[-1, 1]$ for our purposes, with lower values indicating a masculine association and high values indicating a feminine association. Some sample words, utterances and their corresponding ratings are presented in Table 1 and Table 3. Figure 1 shows the average gender ladenness across all utterances for the major characters of a few movies. The annotations as a whole are reflective of stereotypical views of gender roles, e.g., words related to war and violence have a strong masculine association, whereas words related to family or positive emotions carry strong feminine associations.

The manual annotations from (Clark and Paivio, 2004) contain ratings for only 925 words, which are not enough to provide sufficient coverage. Therefore we use a lexicon expansion method, inspired by the work of (Malandrakis et al., 2013) to estimate the gender ladenness $\hat{g}(w_i)$ of word w_i using the semantic similarities $s()$ between w_i and reference words or concepts c_j, as

$$\hat{g}(w_i) = \theta_0 + \sum_{j=1}^{N} \theta_j s(w_i, c_j), \qquad (1)$$

where the terms θ_i are trained model parameters.

Given a manually annotated lexicon and a set of reference words, this equation can be used to create a linear system. Solving the system via Least Squares Estimation (LSE) gives us the parameters θ and an equation that can be used to generate gender ladenness for any new set of words.

Gender ladenness for larger lexical units is generated via simple statistics, as the average of word gender ladenness over all content words (adjectives, nouns, verbs and adverbs).

3 Data

Our primary data source is the Movie DiC corpus (Banchs, 2012) which includes 619 movie scripts parsed from The Internet Movie Script Database (IMSDb, 2015). The xml formatted scripts contain transcripts with speaker information as well as some structural information. Additional metadata for each movie were collected from the Internet Movie Database (IMDb, 2015).

Since our goal was to analyze gender depictions, we had to annotate each script utterance with a gender label. The process was complicated by inconsistencies between the information contained in the IMDb and Movie DiC corpora, like mismatched names, particularly for minor characters. Initially the script character names were cleaned using simple heuristics, such as the removal of all instances of the possessive "'s". The IMDb api (IMDbPY, 2015) was used to recover candidate movies matching the script movie name and, in the case of multiple candidates, the best candidate was selected based on the number of character names matching the script. Character names were compared using the Jaro-Winkler distance (Winkler, 1990). Having achieved a one to one mapping between IMDb and Movie DiC, we assigned a gender label to each matched character, using the gender predictor (NamSor Applied Onomastics, 2015). To make these predictions, we first use the name of the corresponding actor portraying that role; if there was no character match, we use the name of the character. Finally, we calculate a *confidence* score of our gender assignment per utterance for each movie, equal to the percentage of utterances with perfectly matched character name and a high confidence by the gender predictor. For the movies for which the confidence scores are not satisfactory, we manually match the script characters with IMDb's characters and annotate genders. In our experiments, we did this manual annotation with roughly 75 movies.

Having a mapping of scripts to IMDb entries, we collected more information about the movie such as the list of genres it belongs to and the members of the production team (producers, scriptwriters, directors), and followed a similar process as described above to assign genders to all persons. While movies may be created by multiple scriptwriters and directors, we retain only the first name, the primary credit, in each category. We removed infrequent genres and movies which belonged only to the removed genres. We also filtered out utterances with missing or incorrect character information and the utterances corresponding to characters for which the gender predictor fails to make confident predictions.

Movies with missing fields were also removed, leaving us with a total of 568 movies after the aforementioned pre-processing steps. Table 2 lists some descriptive statistics of the processed movie

Property Name	*Female*	*Male*	*Total*
Movie Utterances	107372	256274	363646
Producers	746	2974	3720
Directors	33	572	605
Assistant Directors	846	2739	3585
Screenplay Writers	130	1217	1347
Casting Directors	548	195	743

Table 2: Movie Dataset statistics

Utterance	*Avg. GL*
Flowers for the Diva.	0.77
Yeah, what a woman.	0.47
Got the house to yourselves?	-0.01
What about the crew?	-0.51
Yeah? You and what army?	-0.85

Table 3: Average gender ladenness for sample utterances from the dataset

corpus. At least in terms of raw frequencies, the gender ratio is clearly skewed towards male, particularly in the case of directors and with the exception of casting directors.

The norm generating equation (1) requires a semantic similarity estimate $s()$, which for the purposes of this paper is the cosine of context vectors generated over a large corpus of raw web text. The corpus was created by posing a query to the Yahoo! search engine for every word in the English version of the aspell spell-checker and collecting the top 500 result previews. Each preview is composed of a title and a sample of the content, each being a single sentence. Overall the collected corpus contains approximately 117 million sentences.

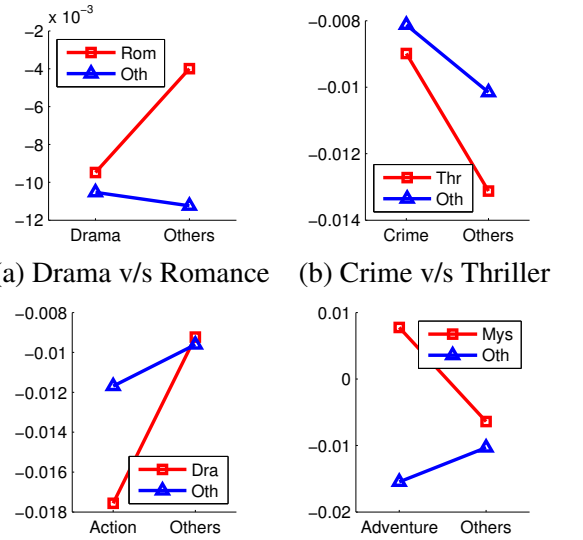
4 Experimental Procedure

The descriptive feature in this method is gender ladenness, so we extracted an estimate for each utterance of every movie. Initially, all utterances were part-of-speech tagged and non-content words were removed. Then, word-level gender landenness norms were generated for every remaining word.

To generate word-level norms, we used equation (1) with the intermediate seed words w_i being the top 10000 most frequent words in our corpus of web text with length longer that 3 characters. For each word in our corpus, we generated a binary weighted context vector (of window size 1) of size $\sim$ 125000. Then, for each word

of interest we calculated a 10000 place similarity vector, containing the cosine similarity scores between the context vector of said word and the context vectors of the 10000 intermediate seeds. Using the training set we generated a $K \times 10000$ matrix of similarities to the seed words and applied dimensionality reduction via Principal Component Analysis (PCA), keeping the first $N = 300$ components. These transformed similarities became the similarity terms $s()$ of equation (1) and were used to train the model. For any word in the scripts, a 10000 place similarity vector is generated and transformed using the pre-calculated PCA matrix, then equation (1) is used to create the gender ladenness estimate.

Ratings were generated at the utterance level, and collective ratings (per character, gender or movie) were calculated as utterance rating averages.



(a) Drama v/s Romance (b) Crime v/s Thriller

(c) Action v/s Drama (d) Adventure v/s Mystery

Figure 2: Interactions between genres

5 Results

To evaluate the word norm generation algorithm, we performed a 10-fold cross-validation experiment on the 925 manually annotated norms in (Paivio et al., 1968). The generated norms were evaluated against the ground truth and the method achieved a 0.801 Pearson correlation to the ground truth. While there is no comparable result in literature, the resulting performance appears sufficiently high.

We first investigated the overall gender ladenness of movies, represented as the average of all utterance level scores, with respect to the genre(s) the movie belongs to. The independent variables for this analysis were nine binary indicator variables, one for each of the most frequent genre labels in our movie corpus, with values of zero if the movie does not belong to the specific genre and one if it does. The particular representation of genres as separate variables was chosen because each movie can belong to multiple genres. Interaction terms were included. Running n-way ANOVA with the aggregate gender ladenness across both character genders as the dependent variable revealed significant differences between genres, with *Action* movies leaning towards the masculine ($p = 0.013$) compared to *Non-Action* movies, a not surprising result.

A few significant interactions between genres are shown in figure 2. Fig. 2a indicates that among non-drama movies, romantic movies tend to include more feminine language compared to non-romantic movies. However, if a movie belongs to the genre drama, its mean gender ladenness scores remain fairly constant, irrespective of its other genres. Similar interpretations can be drawn from the other plots in figure 2.

To analyze the effect of character gender on the gender ladenness scores, we next ran ANOVA with the character gender and the movie writer's gender as additional independent variables. The dependent variable in this case was the aggregate gender ladenness score across all utterances for male and female characters, so two scores per movie. The interaction of character gender and movie genre is shown in figure 3. The scores of male and female characters are correlated, which can be attributed to the underlying concepts in the utterances from these movies. The difference between genders is significant ($p = 0.034$), with male characters consistently using significantly more masculine language than their female counterparts, a finding that lends some credence to the metric used. Looking at the binary genre variables revealed that

Action movies contained significantly more masculine language than *Non-Action* movies ($p < 10^{-5}$) and the same holds for *Crime* movies ($p < 10^{-5}$). Conversely, *Romantic* movies leaned towards the more feminine language than non-*Romantic* movies ($p < 10^{-5}$) and similarly for *Comedy* movies compared to non-*Comedy* movies ($p = 0.02$). The male - female character gender

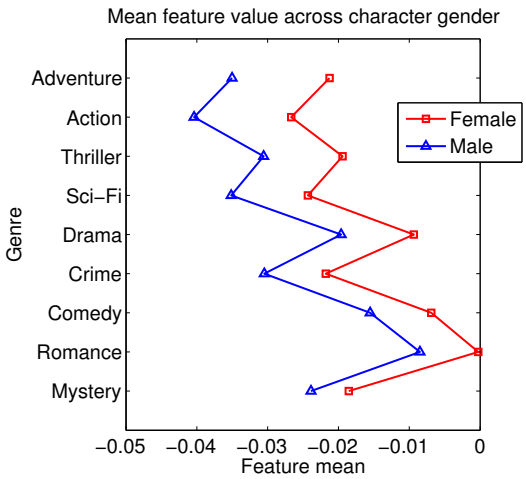


Figure 3: Interaction of movie genre with character gender

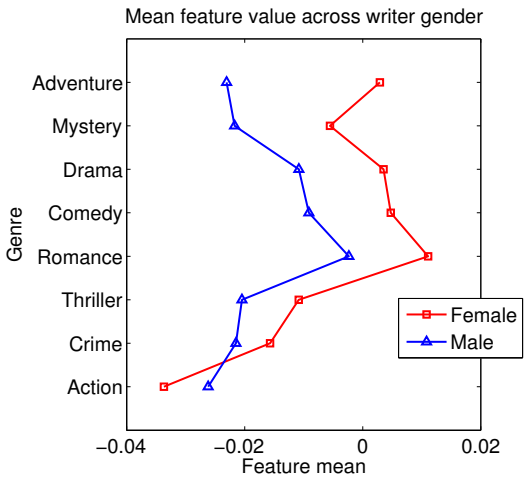

Figure 4: Interaction of screenplay writer's gender with genre

ladenness distance however is not affected in any significant way by the genre.

We include only the screenplay writer's gender in our analysis, though both the directors and screenplay writers influence the dialog lines (utterances), since the writers are more likely to directly influence the actual language used. In addition, the very small number of female directors in the data, as seen in table 2, leads to a violation of ANOVA's homoscedasticity assumption. Though the writer gender itself was not a significant factor, the interaction of writer's gender with the *Action* genre was significant ($p = 0.005$). The plot illustrating this interaction is shown in figure 4. It appears that female script writers write more masculine utterances compared to their male colleagues, at least for *Action* movies. We also investigated interactions between the writer and character gender, but none proved significant.

6 Conclusions and Future Work

We used regression to extrapolate manually annotated psycholinguistic normatives to movie utterances and investigated the use of these metrics to describe gender depictions. The metric proved successful, showing significant differences between the genders and predictable patterns with respect to movie genres.

Future work will include the use of further metrics, with those describing emotions being the first candidates. We also intend to collect more movie and character level metadata to be used in analysis. Finally, it is worth remembering that language provides only a partial description of depicted characters, so we should aim to augment with aural/visual information.

EMNLP versus ACL: Analyzing NLP Research Over Time

Sujatha Das Gollapalli, Xiao-Li Li
Institute for Infocomm Research, A*STAR, Singapore
{gollapallis,xlli}@i2r.a-star.edu.sg

Abstract

The conferences ACL (Association for Computational Linguistics) and EMNLP (Empirical Methods in Natural Language Processing) rank among the premier venues that track the research developments in Natural Language Processing and Computational Linguistics. In this paper, we present a study on the research papers of approximately two decades from these two NLP conferences. We apply keyphrase extraction and corpus analysis tools to the proceedings from these venues and propose probabilistic and vector-based representations to represent the topics published in a venue for a given year. Next, similarity metrics are studied over pairs of venue representations to capture the progress of the two venues with respect to each other and over time.

1 Introduction

Scientific findings in a subject-area are typically published in conferences, journals, patents, and books in that domain. These research documents constitute valuable resources from the perspective of data mining applications. For instance, the citation links among research documents are used in computing bibliometric quantities for authors (Alonso et al., 2009) whereas topic models on research corpora are used to distinguish between influential and impactful researchers (Kataria et al., 2011) and to capture temporal topic trends (He et al., 2009).

Despite several potential benefits mentioned above and the free availability of most research proceedings in NLP through the ACL Anthology[1], the topical and temporal aspects of this corpus are yet to be fully studied in current literature. In this paper, we present our study on research proceedings of approximately two decades from two leading NLP conferences, namely ACL and EMNLP, to complement a previous study on this topic by Hall et al (2008). To the best of our knowledge, we are the first to characterize the developments in the NLP domain using a comparative study of two of its leading publication venues. Our contributions are summarized below:

1. We represent the NLP research corpus from approximately two decades as a keyphrase-document matrix and apply Latent Dirichlet Allocation (Blei et al., 2003) to extract coherent topics from it (Newman et al., 2010).

2. We propose two novel representations for summarizing the venue proceedings in a given year. (1) The **probabilistic** representation expresses each venue as a probability distribution over topics, whereas (2) the **TP-ICP** representation captures topics that are the major focus in the venue for a particular year via *Topic Proportion* (TP) as well as topic importance as measured with *inverse corpus proportion* (ICP).

3. We apply Jensen-Shannon divergence and cosine similarity on our proposed venue representations to analyze the venues over time. Specifically, we ask the following questions: What are the popular topics in ACL and EMNLP in a particular year? Is the topical focus in EMNLP different from ACL? How

[1] https://aclweb.org/anthology/

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2002–2006,
Lisbon, Portugal, 17-21 September 2015.

did the topical focus in each venue change over time?

Organization: We describe our novel venue representations and the measures used to compare them in Section 2. The details of our datasets and experiments are presented in Section 3 along with results and observations. We summarize related research in Section 4 before concluding the paper in Section 5.

2 Methods

Let $Y = \{y_1, y_2 \dots y_T\}$ be the consecutive years in which the research proceedings are available from V, set of publication venues under consideration ($V = \{$"ACL", "EMNLP"$\}$ in this paper). If D is the set of all documents over the years, each document $d \in D$ is associated with $\{K_d, y, v\}$ where K_d refers to the content of d whereas v and y refer to the venue and year in which d was published.

2.1 Venues as Probability Distributions

Let $t_1, t_2 \dots t_k$ denote the topics capturing the content of documents in D. Using probabilistic topic modeling and dimension reduction tools such as Latent Dirichlet Allocation or pLSA (Hofmann, 1999; Blei et al., 2003), we extract for each $d \in D$, $P(t_i|d), i = 1 \dots k$, the multinomial distribution over the topics associated with d.

The venue-topic probability distribution $P(t_i|v_y)$ for a given (venue, year) pair $(v = l, y = m)$ can be computed using $D_{l,m}$, the set of documents published in venue l, in the year m. That is,

$$P_{l,m}(t_i) = \frac{1}{|D_{l,m}|} \sum_{d \in D_{l,m}} P(t_i|d) \qquad (1)$$

Note that the above probabilistic representation facilitates a quantitative measure to compare two venues: the divergence between the probability distributions of the two venues. The Kullback−Leibler divergence (KLD) between two (discrete) probability distributions P and Q is given by: $D_{KL}(P||Q) = \sum_i P(i) log \frac{P(i)}{Q(i)}$. Due to the unsymmetric nature of KLD, we use the Jensen-Shannon divergence, a symmetric and finite measure ($0 \leq JSD(P||Q) \leq 1$) based on KLD. Let $M = \frac{1}{2}(P + Q)$,

$$JSD(P||Q) = \frac{1}{2}[D_{KL}(P||M) + D_{KL}(Q||M)]$$

2.2 Venues as TP-ICP Vectors

Discrete probability distributions are often represented in computations as normalized vectors. For instance, the $P(t_i|v)$ values comprise the components of a k-dimensional vector. This topic proportion (TP) vector is similar to the normalized term frequency vector commonly used in Information Retrieval (IR) (Manning et al., 2008). TP values are fractions indicating the percentage of a given topic among all topics covered in a particular year. Thus these values are higher for topics that are the major focus in the venue for a particular year .

We also extend *inverse document frequency*, a popular concept that is used to weigh terms in IR (Manning et al., 2008) to describe **Inverse Corpus Proportion** or ICP. Our objective in defining ICP is to capture the importance of a topic by diminishing the effect of topics that are common across all years. Let $\mathbf{TP}_{v,y}(i)$ represents the proportion of topic t_i in venue v for year y, then $ICP(t_i) =$

$$\log\left(\frac{\sum_{y=1}^{|Y|}\sum_{v=1}^{|V|}\sum_{j=1}^{k}\mathbf{TP}_{v,y}(j)}{\sum_{y=1}^{|Y|}\sum_{v=1}^{|V|}\mathbf{TP}_{v,y}(i)}\right) = \left(\frac{|D|}{\sum_{y=1}^{|Y|}\sum_{v=1}^{|V|}\mathbf{TP}_{v,y}(i)}\right)$$

since $\sum_{j=1}^{k}\mathbf{TP}(j) = 1$, $\mathbf{TP}$ being a probability distribution vector and $|Y| \times |V| = |D|$. The TP-ICP vector for a venue is defined as: $[TP(1) \times ICP(1), \dots TP(k) \times ICP(k)]$ and captures in each component the weighted proportion of a topic in that venue for a year. This novel representation can be considered the topic-level counterpart of the popular TF-IDF representation in IR. Given two TP-ICP vectors $P = [p_1, p_2, \dots p_k]$ and $Q = [q_1, q_2, \dots q_k]$, the similarity between them using the cosine measure is given by:

$$cosine(P, Q) = \frac{\sum_{i=1}^{k} p_i.q_i}{||P||_2.||Q||_2}$$

2.3 Keyphrases for representing documents

Corpus analysis tools often use bag-of-words models and term frequencies for representing documents (Heinrich, 2005). However, research documents are often well-structured, and contain various sections with author information, citations,

and content-related sections such as *abstract*, *related work*, and *experiments*. To best represent the topical content of these documents, we harness the latest work on keyphrase extraction for research documents and represent documents using keyphrases (Hasan and Ng, 2014).

We use the ExpandRank algorithm (Wan and Xiao, 2008) to extract top n-grams $\forall d \in D$. ExpandRank effectively combines PageRank values on word graphs with text similarity scores between documents to score n-grams for a document and was shown to outperform other unsupervised keyphrase extraction methods on research documents in absence of other information such as citations (Gollapalli and Caragea, 2014).

3 Experiments

Datasets and setup: We crawled the ACLWeb for research papers from EMNLP and ACL from the year 1996 through 2014[2] using the Java-based crawler, Heritrix[3]. The text from the PDF documents was extracted using the PDFBox software[4] after which simple rules similar to the ones used in CiteSeer (Li et al., 2006) were employed to extract the "body" of the research document[5]. The numbers of papers for each year at the end of this process are listed in Table 2. From these numbers, it appears that the paper "intake" in each conference has gone up overall during the last decade although occasionally the increase is due to co-location with related conferences such as IJCNLP and HLT[6].

We construct the keyphrase-document matrix using top-100 keyphrases of each document extracted with ExpandRank. The LDA implementation provided in Mallet (McCallum, 2002) was used to extract topics from this matrix. The LDA algorithm was run along with hyperparameter optimization (Minka, 2003) for different numbers of topics between $10 \ldots 100$ in increments of 10. We use the average corpus likelihood over ten randomly-initialized runs to choose the optimal number of topics that best "explain" the corpus (Heinrich, 2005). As indicated by the left plot in Figure 1 this optimum is obtained when the number of topics is 30.

3.1 Results and Observations

The top phrases that reflect the "theme" captured by a topic are shown in Table 1. As indicated in this table, we are able to extract coherent topics from the corpus using LDA on a document-keyphrase matrix (AlSumait et al., 2009; Newman et al., 2010).

Top research topics in NLP: We select five timepoints $\{1996, 2000, 2005, 2010, 2014\}$ by splitting the 1996-2014 period into roughly-

[2] Since our goal is to compare the two venues, we start from 1996 when EMNLP branched off into a full conference from a workshop on Very Large Corpora although ACL proceedings are available from 1979.

EMNLP	226	207	141	149	125	164	115	131	73	28	53	27	33	10	27	34	13	23	14

Table 2: Number of papers for each venue for different years

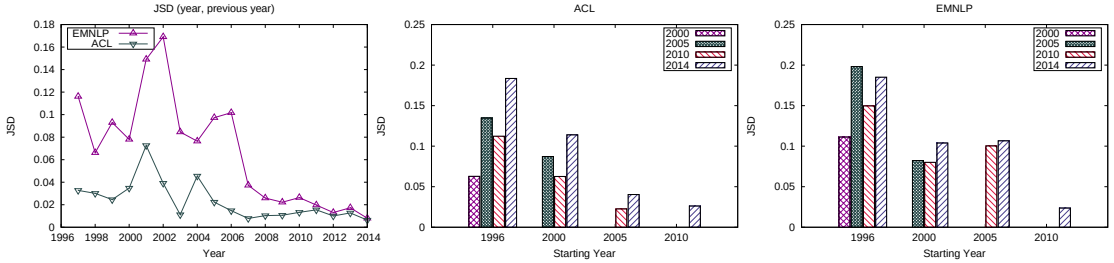

Figure 2: Comparing EMNLP and ACL over the years. Each point in the *Left* plot shows the JSD between a given year y and the year $y-1$. The *Middle* (ACL) and *Right* (EMNLP) plots show the JSD between a timepoint with preceding timepoints in the set $\{1996, 2000, 2005, 2010, 2014\}$.

equal parts and examine the top topics for ACL and EMNLP at these time points. We rank the topics in each conference by their TP-ICP values and list the top 3 topics in the right table of Figure 1. "Semantic relation extraction", "sentiment analysis", and "topic models" are the top research topics in NLP last year (2014) whereas in the year 1996, the topics "noun phrase extraction", "summarization", "corpus modeling", and "speech recognition" dominated the NLP research arena. From the table, it can be seen that "information retrieval" (topicID: 18) ranks among the top topics in EMNLP for all three timepoints during 2000-2010 whereas "natural language generation" (topicID: 9) was consistently addressed during 1996-2005 in ACL.

EMNLP versus ACL: We compare the venues using JSD and Cosine similarity measures in the middle plot of Figure 1. The plot shows decreasing divergence between the topical distributions over the years and increasing cosine similarity between the TP-ICP vectors for the venues. These trends indicate that over the two decades the two venues ACL and EMNLP seem to have "become like each other" although their topical focus was different during the initial years. Increasingly, both venues seem to publish papers on similar topics. This behavior could be interpreted to mean that the NLP research field is more stable now with two of its leading conferences addressing problems on similar topics.

Changing topical focus over the years: In the first plot of Figure 2, we show the Jensen-Shannon divergence between the topic distributions of a particular venue for a given year y and $(y-1)$, the year preceding it. The curve indicates that in the years between 1997-2008, the rate of change from year to year is higher than in the years following 2008. We split the time period 1996-2014 into five roughly-equal parts to form the set $\{1996, 2000, 2005, 2010, 2014\}$. The JSD between the distribution in a particular year and the years preceding it in the above set is shown for ACL (middle plot) and EMNLP (right plot) in Figure 2. For example, the first cluster in the middle plot, shows the JSD values between the distributions for the years 2000, 2005, 2010, 2014 with the starting year 1996 for ACL. For both venues, the divergences of a given year are higher with the early starting years 1996 and 2000 than with the later starting years 2005 and 2010, indicating that the topics being addressed currently in NLP research are significantly different from those addressed a decade back.

4 Related Work

Temporal analysis of corpora is an upcoming research topic in text mining groups. Topic models were particularly investigated for detecting activity patterns in corpora annotated with time information (Huynh et al., 2008; Shen et al., 2009). Evolution of topics and their trends were studied on research corpora from NIPS (Wang and McCallum, 2006) as well as CiteSeer (He et al., 2009).

In contrast with existing approaches that seek to model the detection of new topics and their evolution, we focus on representing different venues pertaining to a research field and examine their development over time by comparing them against each other. In a similar study, Hall et al. (2008) examined the emergence of topics in NLP literature. They proposed "topic entropy" to measure the diversity in three conferences from the ACL Anthology during the years 1978-2006. They also noted that all the venues seem to converge in the topics they cover over the years based on the JSD between their topic distributions.

5 Conclusions

We presented our study on research proceedings of approximately two decades from the leading NLP conference venues: EMNLP and ACL. We extracted coherent topics from this corpus by applying topic modeling on the corresponding keyphrase-document matrix. Next, the extracted topics were used to characterize each venue through probabilistic and vector representations and compared against each other and over the years using various similarity measures. To the best of our knowledge, we are the first to present insights related to the development of a research field by studying two leading conferences in the area using various techniques from NLP and IR.

Answering Elementary Science Questions by Constructing Coherent Scenes using Background Knowledge

Abstract

Much of what we understand from text is not explicitly stated. Rather, the reader uses his/her knowledge to fill in gaps and create a coherent, mental picture or "scene" depicting what text appears to convey. The scene constitutes an understanding of the text, and can be used to answer questions that go beyond the text.

Our goal is to answer elementary science questions, where this requirement is pervasive; A question will often give a partial description of a scene and ask the student about implicit information. We show that by using a simple "knowledge graph" representation of the question, we can leverage several large-scale linguistic resources to provide missing background knowledge, somewhat alleviating the knowledge bottleneck in previous approaches. The coherence of the best resulting scene, built from a question/answer-candidate pair, reflects the confidence that the answer candidate is correct, and thus can be used to answer multiple choice questions. Our experiments show that this approach outperforms competitive algorithms on several datasets tested. The significance of this work is thus to show that a simple "knowledge graph" representation allows a version of "interpretation as scene construction" to be made viable.

1 Introduction

Elementary grade science tests are challenging as they test a wide variety of commonsense knowledge that human beings largely take for granted, yet are very difficult for machines (Clark, 2015). For example, consider a question from a NY Regents 4th Grade science test:

Question 1 *"When a baby shakes a rattle, it makes a noise. Which form of energy was changed to sound energy?" [Answer: mechanical energy]*

Science questions are typically quite different from the entity-centric factoid questions extensively studied in the question answering (QA) community, e.g., "In which year was Bill Clinton born?" (Ferrucci et al., 2010; Yao and Van Durme, 2014). While factoid questions are usually answerable from text search or fact databases, science questions typically require deeper analysis. A full understanding of the above question involves not just parsing and semantic interpretation; it involves adding implicit information to create an overall picture of the "scene" that the text is intended to convey, including facts such as: noise is a kind of sound, the baby is holding the rattle, shaking involves movement, the rattle is making the noise, movement involves mechanical energy, etc. This mental ability to create a scene from partial information is at the heart of natural language understanding (NLU), which is essential for answering these kinds of question. It is also very difficult for a machine because it requires substantial world knowledge, and there are often many ways a scene can be elaborated.

We present a method for answering multiple-choice questions that implements a simple version of this. A scene is represented as a "knowledge graph" of nodes (words) and relations, and the scene is elaborated with (node,relation,node) tuples drawn from three large-scale linguistic knowledge resources: WordNet (Miller, 1995), DART (Clark and Harrison, 2009), and the Free-Association database (Nelson et al., 2004). These elaborations reflect the mental process of "filling in the gaps", and multiple choice questions can then be answered by finding which answer option creates the most coherent scene.

The notion of NLU as constructing a most coherent scene is not new, and has has been studied in several contexts including work on scripts (Schank and Abelson, 1977), interpretation as ab-

*Work was done while the author was an intern at Allen Institute for Artificial Intelligence.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2007–2012,
Lisbon, Portugal, 17-21 September 2015.

duction (Hobbs et al., 1988; Hobbs, 1979; Ovchinnikova et al., 2014), bridging anaphora (Asher and Lascarides, 1998; Fan et al., 2005), and paragraph understanding (Zadrozny and Jensen, 1991; Harabagiu and Moldovan, 1997). These methods are inspiring, but have previously been limited by the lack of background knowledge to supply implicit information, and with the complexity of their representations. To make progress, we have chosen to work with a simple "knowledge graph" representation of nodes (words) and edges (relations). Although we lose some subtlety of expression, we gain the ability to leverage several vast resources of world knowledge to supply implicit information. The significance of this work is thus to show that, by working with a simple "knowledge graph" representation, we can make a viable version of "interpretation as scene construction". Although the approach makes several simplifying assumptions, our experiments show that it outperforms competitive algorithms on several datasets of (real) elementary science questions.

2 Approach

The input to our question-answering system is a multiple choice question Q, a set of answer options a_k, and one or more background knowledge base(s) each containing a set of $(word_i, relation, word_j)$ tuples, each denoting that $word_1$ is plausibly related to $word_j$ by $relation$. The output is a ranked list of the K answer options.

We define a *scene* S as a "knowledge graph" of *nodes* (words) and *edges* (relations between words), where all $(word_i, relation, word_j)$ edges are sanctioned by (contained in) at least one of the background knowledge bases. Each scene node has an associated measure of $coherence$ (described shortly), denoting how well-connected it is. The question-answering objective is, for each answer option a_k, to find the most coherent scene containing (at least) the question keywords $kw_i \in Q$ and answer option a_k, and then return the answer option with the overall highest coherence score. Our implementation approximates this objective using a simple elaborate-and-prune algorithm, illustrated in Figure 1[1] and now described.

[1]The system constructs 4 alternative graphs, each contains only one answer option plus some additional related nodes. Figure 1 shows just one of these 4 graphs, namely the graph containing answer option "food".

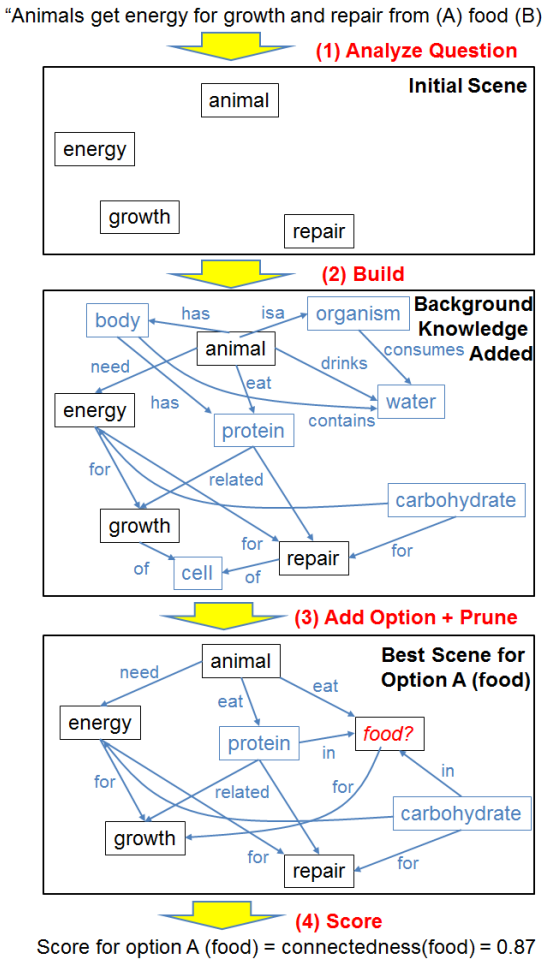

Figure 1: (1) Question keywords are extracted to form the initial scene. (2) The scene is elaborated with background knowledge to add plausible relationships. (3) For each answer option, it is added into the scene and connected with additional relationships. Then the scene is pruned. (4) A score is derived from the final scene, reflecting confidence that the answer option is correct.

2.1 Question Analyzer

The initial scene is simply the keywords (non-stop words) $KW = \{kw_i\}$ in the question Q, along with a measure of importance $IS(kw_i)$ for each word kw_i. For our purposes we compute importance by sending the question to Google, grouping the top 20 result snippets into a document d, and computing:

$$IS(kw) = \frac{tf_d(kw)}{df_Q(kw)}, \quad (1)$$

where $tf_d(kw)$ is the term frequency of kw in document d, and $df_Q(kw)$ is the document frequency of kw in question set Q containing all the available elementary science questions. The intuition here is

KB	Size (# tuples)	Examples
WordNet	235k	(dog,isa,animal) (sunlight,isa,energy)
DART	2.3M	(nutrients,in,food) (animal,eat,food)
FreeAssoc	64k	(car,relate_to,tire) (ice,relate_to,cold)

Table 1: Knowledge Bases Used

that the words frequently mentioned in variations of the question should be important (reflected by "tf"), while the descriptive words (e.g. "following", "example") which are widely used in many questions should be penalized (reflected by "idf"). Other methods could equally be used to compute importance.

2.2 Builder

In this step our goal is to inject implicit knowledge from the background KBs to form an elaborated knowledge graph. To do this, we first fetch all the triples $(kw, relation, w)$ that are directly connected with any keyword $kw \in KW$ from the background KBs, as well as all $(kw_i, relation, kw_j)$ triples between keywords. In our experiments we use three background knowledge bases to supply implicit knowledge, although in principle any triple store could be used: WordNet (Miller, 1995), DART (Clark and Harrison, 2009), and the FreeAssociation database (Nelson et al., 2004). Table 1 shows examples of each [2].

These triples introduce new nodes w into the graph. As we may get a large number of such nodes, we score them and retain only the top scoring ones (and all edges connecting to it). Informally, a new word w is preferred if it is connected to many important keywords kw with strong relationships. Formally, the scoring function is:

$$score(w) = \sum_{kw \in K} IS(kw) * rel(kw, w) \quad (2)$$

where $IS(kw)$ is the importance score of keyword kw and $rel(kw, w)$ is the relatedness score between kw and w. In this work we use the cosine similarity between word2vec (Mikolov et al., 2013) word vectors to measure two words' relatedness, as a rough proxy for the strength of relatedness in the KBs (the KBs themselves do not provide meaningful strengths of relationship). After the ranking, the top $N \times |KW|$ neighbor words w are retained[3], along with their edges to keywords kw and each other.

Note that at this point the elaboration process is independent of any answer option; rather, the graph depicts the question scenario.

2.3 Elaborate and Prune

To score the K different answer options, the system now builds K alternative elaborations of the scene so far, each one with answer option a_k added, and assesses the coherence of the addition. The answer option a_k that fits "most coherently" with the scene is returned as the answer to the question.

To do this for a given option a_k, we add a_k to the graph along with all triples $(w_i, relation, a_k)$ in the KBs that relate any node w_i in the graph to a_k. Now that the focus a_k of the question is known, some of the earlier added nodes w in the graph may be only weakly relevant to the question and answer, and so we add a pruning step to remove these nodes. The goal of this pruning is to find a dense subgraph (i.e. the coherent scene) that would ideally contain all the question keywords kw, the answer option a_k, and extra words w_k that are highly connected with them.

Inspired by Sozio et al's work (Sozio and Gionis, 2010) on finding strongly interconnected subgroups in social networks, we have developed an iterative node removal algorithm for extracting this subgraph. We define the coherence of a node as the summed weight of its incident edges:

$$coherence(w) = \sum_{w' \in \{(w,r,w')\}} rel(w, w') \quad (3)$$

where $rel(w, w')$ is the weight of edge (w, r, w') in the graph, again computed using cosine similarity between w and w'. We then iteratively remove the non-keyword node (and attached edges) with least coherence until the answer option a_k is about to removed. The resulting graph is thus maximally pruned, subject to the constraint it must still describe the question plus answer option.

Finally, we use the coherence of the answer option a_k in this final scene as the confidence that a_k is the correct answer. The system repeats this

[2] WordNet: all relationships types are used. DART: The NVN and NPN databases with frequency counts > 10 are used. FreeAssoc: The top 3 associations per word were used.

[3] The optimal N (here 6) was selected using an independent set of training questions

for all K answer options and selects the a_k with highest confidence.

3 Evaluation

The system was developed using a dataset of natural (unedited) elementary science exam questions, and then tested on three similar, unseen (hidden) datasets. Its performance was compared with two other state-of-the-art systems for this task. As our system only fields questions where the answer options are all single words, we evaluate it, and the other systems, only on these subsets. These subsets are in general easier than other questions, but this advantage is the same for all systems being compared so it is still a fair test.

3.1 Evaluation Datasets

The datasets used are the non-diagram, multiple-choice questions with single-word answer options drawn from the following exams:

- **Dev (System Development):** New York Regents 4th Grade Science [4] (47 questions in 6 years)
- **Test1:** New York Regents 4th Grade Science (23 questions in 3 years)
- **Test2:** Additional 4th Grade Science (from multiple States) (26 questions)
- **Test3:** 5th Grade Science (from multiple States) (197 questions)

Although these datasets are small (real exam questions of this type are in limited supply), the numbers are large enough to draw conclusions.

3.2 Experiments

We compared our system (called **SceneQA**) with two other state-of-the-art systems for this task:

- **LSModel** (Lexical semantics model): SVM combination of several language models (likelihood of answer given question) and information retrieval scores (score of top retrieved sentence matching question plus answer), trained on a set of questions plus answers. (An expanded version of Section 4.3 of (Jansen et al., 2014))
- **A*Rules**: "Prove" the answer option from the question by applying lexical inference rules automatically extracted from science texts. Select the option with the strongest "proof". (Clark et al., 2014)

[4] http://www.nysedregents.org/Grade4/Science/home.html

	Dev	Test1	Test2	Test3
LSModel	65.96	58.70	28.85	30.08
A*Rules	65.96	67.00	47.00	29.22
SceneQA	**83.51**	66.30	**65.38**	**55.20**

Table 2: SceneQA outperforms two competitive systems on two of the three test sets. The highlighted improvements are statistically significant.

The results (% scores, Table 2) show SceneQA significantly outperforms the two other systems on two of the three test sets, including the largest (Test3, 197 questions), suggesting the approach has merit.

We also performed some case studies to identify what kinds of questions SceneQA does well on, relative to the baselines. In general, SceneQA performs well when the question words and the (correct) answer can be tightly related by background knowledge, including through intermediate nodes (words). For example, in Question 2 below:

Question 2 *Which type of energy does a person use to pedal a bicycle? (A) light (B) sound (C) mechanical (D) electrical*

the KB relates the correct answer "mechanical" to the question words "energy", "pedal", "bicycle", and the intermediate node "power" forming a tight graph. In contrast, the other algorithms select the wrong answer "light" due to frequent mentions of "bicycle lights" in their supporting text corpora that confuses their algorithms.

3.3 Ablations

We also performed ablations to assess which parts of our method are contributing the most:

- **-NewNodes**: Only add edges but no new nodes w during the Build step.
- **-Prune**: Do not prune nodes during the Elaborate and Prune step.
- **-Both**: No new nodes, no pruning

	Dev	Test1	Test2	Test3
SceneQA	**83.51**	66.30	**65.38**	**55.20**
-NewNodes	65.96	69.57	42.31	51.78
-Prune	70.74	57.61	47.12	50.13
-Both	59.57	65.22	42.31	50.25

Table 3: SceneQA outperforms all the ablations on two of the three test sets. The highlighted improvements are statistically significant.

The results (% scores, Table 3) suggest that the two most important algorithmic features - adding

concepts implied but not explicitly stated in the text (NewNodes), and later removing implied information that is of low relevance to the answer (Prune) - are important for answering the questions correctly. (The small gain without adding NewNodes on Test1 is not statistically significant).

3.4 Error Analysis

We also examined cases where SceneQA gave the wrong answer. Two problems were particularly common:

(1) There were two answer options with opposite meanings, and one of them was correct. For example:

Question 3 *An animal that has a backbone is called a(n) (A) invertebrate (B) vertebrate (C) exoskeleton (D) sponge*

Since the relatedness measure we use (i.e. word2vec) cannot distinguish words with similar distributional semantics (a common property of antonyms), our method cannot confidently identify which of the opposites (e.g., here, vertebrate vs. invertebrate) is correct.

(2) The word ordering in the question is particularly important, e.g., questions about processes or sequences. For example:

Question 4 *The process that changes a gas to liquid is called (A) condensation (B) melting (C) evaporation (D) vaporization*

Because our method ignores word order (the knowledge graph is initially populated with keywords in the question), the representation is inherently incapable of capturing sequential information (e.g., here, gas to liquid vs. liquid to gas). As a result, it struggles with such questions.

4 Discussion and Conclusion

Our goal is to answer simple science questions. Unlike entity-centric factoid QA tasks, science questions typically involve general concepts, and answering them requires identifying implicit relationships in the question. Our approach is to view question-answering as constructing a coherent scene. While the notion of scene construction is not new, our insight is that this can be done with a simple "knowledge graph" representation, allowing several massive background KBs to be applied, somewhat alleviating the knowledge bottleneck. Our contribution is to show this works well in the elementary science domain.

Despite this, there are clearly many limitations with our approach: we are largely ignoring syntactic structure in the questions; the KBs are noisy, contributing errors to the scenes; the graph representation has limited expressivity (e.g., no quantification or negation); the word2vec measure of relationship strength does not account for the question context; and contradictions are not detected within the scene. These all contributed to QA failures in the tests. However, the approach is appealing as it takes a step towards a richer picture of language understanding, the empirical results are encouraging, and there are many ways these initial limitations can be addressed going forward. We are confident that this is a rich and exciting space, worthy of further exploration.

Abstract

We describe the WIKIQA dataset, a new publicly available set of question and sentence pairs, collected and annotated for research on open-domain question answering. Most previous work on answer sentence selection focuses on a dataset created using the TREC-QA data, which includes editor-generated questions and candidate answer sentences selected by matching content words in the question. WIKIQA is constructed using a more natural process and is more than an order of magnitude larger than the previous dataset. In addition, the WIKIQA dataset also includes questions for which there are no correct sentences, enabling researchers to work on answer triggering, a critical component in any QA system. We compare several systems on the task of answer sentence selection on both datasets and also describe the performance of a system on the problem of answer triggering using the WIKIQA dataset.

1 Introduction

Answer sentence selection is a crucial subtask of the open-domain question answering (QA) problem, with the goal of extracting answers from a set of pre-selected sentences (Heilman and Smith, 2010; Yao et al., 2013; Severyn and Moschitti, 2013). In order to conduct research on this important problem, Wang et al. (2007) created a dataset, which we refer to by QASENT, based on the TREC-QA data. The QASENT dataset chose questions in TREC 8-13 QA tracks and selected sentences that share one or more non-stopwords from the questions. Although QASENT has since become the benchmark dataset for the answer selection problem, its creation process actually introduces a strong bias in the types of answers that are included. The following example illustrates an answer that does not share any content words with the question and would not be selected:

Q: *How did Seminole war end?*
A: *Ultimately, the Spanish Crown ceded the colony to United States rule.*

One significant concern with this approach is that the lexical overlap will make sentence selection easier for the QASENT dataset and might inflate the performance of existing systems in more natural settings. For instance, Yih et al. (2013) find that simple word matching methods outperform many sophisticated approaches on the dataset. We explore this possibility in Section 3.

A second, more subtle challenge for question answering is that it normally assumes that there is at least one correct answer for each question in the candidate sentences. During the data construction procedures, all the questions without correct answers are manually discarded.[1] We address a new challenge of *answer triggering*, an important component in QA systems, where the goal is to detect whether there exist correct answers in the set of candidate sentences for the question, and return a correct answer if there exists such one.

We present WIKIQA, a dataset for open-domain question answering.[2] The dataset contains 3,047 questions originally sampled from Bing query logs. Based on the user clicks, each question is associated with a Wikipedia page presumed to be the topic of the question. In order to eliminate answer sentence biases caused by keyword matching, we consider all the sentences in

*Work conducted while interning at Microsoft Research.

[1] The policy is adopted both by the official QASENT tracks (Voorhees and Tice, 1999) and by Wang et al. (2007).

[2] The data and evaluation script can be downloaded at http://aka.ms/WikiQA.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2013–2018,
Lisbon, Portugal, 17-21 September 2015.

the summary paragraph of the page as the candidate answer sentences, with labels on whether the sentence is a correct answer to the question provided by crowdsourcing workers. Among these questions, about one-third of them contain correct answers in the answer sentence set.

We implement several strong baselines to study model behaviors in the two datasets, including two previous state-of-the-art systems (Yih et al., 2013; Yu et al., 2014) on the QASENT dataset as well as simple lexical matching methods. The results show that lexical semantic methods yield better performance than sentence semantic models on QASENT, while sentence semantic approaches (e.g., convolutional neural networks) outperform lexical semantic models on WIKIQA. We propose to evaluate answer triggering using question-level precision, recall and F_1 scores. The best F_1 scores are slightly above 30%, which suggests a large room for improvement.

2 WIKIQA Dataset

In this section, we describe the process of creating our WIKIQA dataset in detail, as well as some comparisons to the QASENT dataset.

2.1 Question & Sentence Selection

In order to reflect the true information need of general users, we used Bing query logs as the question source. Taking the logs from the period of May 1st, 2010 to July 31st, 2011, we first selected question-like queries using simple heuristics, such as queries starting with a WH-word (e.g., "what" or "how") and queries ending with a question mark. In addition, we filtered out some entity queries that satisfy the rules, such as the TV show "how I met your mother." In the end, approximately 2% of the queries were selected. To focus on factoid questions and to improve the question quality, we then selected only the queries issued by at least 5 unique users and have clicks to Wikipedia. Among them, we sampled 3,050 questions based on query frequencies.

Because the summary section of a Wikipedia page provides the basic and usually most important information about the topic, we used sentences in this section as the candidate answers. Figure 1 shows an example question, as well as the summary section of a linked Wikipedia page.

Question: Who wrote second Corinthians?

Second Epistle to the Corinthians The Second Epistle to the Corinthians, often referred to as Second Corinthians (and written as 2 Corinthians), is the eighth book of the New Testament of the Bible. Paul the Apostle and "Timothy our brother" wrote this epistle to "the church of God which is at Corinth, with all the saints which are in all Achaia".

Figure 1: An example question and the summary paragraph of a Wikipedia page.

2.2 Sentence Annotation

We employed crowdsourcing workers through a platform, which is similar to Amazon MTurk, to label whether the candidate answer sentences of a question are correct. We designed a cascaded Web UI that consists of two stages. The first stage shows a testing question, along with the title and the summary paragraph of the associated Wikipedia page, asking the worker "Does the short paragraph answer the question?" If the worker chooses "No", then equivalently all the sentences in this paragraph are marked incorrect and the UI moves to the next question. Otherwise, the system enters the second stage and puts a checkbox along each sentence. The worker is then asked to check the sentences that can answer the question *in isolation*, assuming coreference is resolved. To ensure the label quality, each question was labeled by three workers. Sentences with inconsistent labels would be verified by a different set of crowdsourcing workers. The final decision was based on the majority vote of all the workers. In the end, we included 3,047 questions and 29,258 sentences in the dataset, where 1,473 sentences were labeled as answer sentences to their corresponding questions.

Although not used in the experiments, each of these answer sentence is associated with the *answer phrase*, which is defined as the shortest substring of the sentence that answers the question. For instance, the second sentence in the summary paragraph shown in Figure 1 is an answer sentence. Its substring "Paul the Apostle and Timothy our brother" can be treated as the answer phrase. The annotations of the answer phrases were given by the authors of this paper. Because the answer phrase boundary can be highly ambiguous, each sentence is associated with at most two answer phrases that are both acceptable, given by two different labelers. We hope this addition to the WIKIQA data can be beneficial to future researchers for building or evaluating an end-to-end question answering system.

	Train	Dev	Test	Total

2.3 WIKIQA vs. QASENT

Our WIKIQA dataset differs from the existing QASENT dataset in both question and candidate answer sentence distributions. Questions in QASENT were originally used in TREC 8-13 QA tracks and were a mixture of questions from query logs (e.g., Excite and Encarta) and from human editors. The questions might be outdated and do not reflect the true information need of a QA system user. By contrast, questions in WIKIQA were sampled from real queries of Bing without editorial revision. On the sentence side, the candidate sentences in QASENT were selected from documents returned by past participating teams in the TREC QA tracks, and sentences were only included if they shared content words from the questions. These procedures make the distribution of the candidate sentence skewed and unnatural. In comparison, 20.3% of the answers in the WIKIQA dataset share no content words with questions. Candidate sentences in WIKIQA were chosen from relevant Wikipedia pages directly, which could be closer to the input of an answer sentence selection module of a QA system.

To make it easy to compare results of different QA systems when evaluated on the WIKIQA dataset, we randomly split the data to training (70%), development (10%) and testing (20%) sets. Some statistics of the QASENT and WIKIQA datasets are presented in Tables 1 and 2.[3] WIKIQA contains an order of magnitude more questions and three times more answer sentences compared to QASENT. Unlike QASENT, we did not filter questions with only incorrect answers, as they are still valuable for model training and more importantly, useful for evaluating the task of answer triggering, as described in Section 3. Specifically, we find nearly two-thirds of questions contain no correct answers in the candidate sentences.

Class	QASENT	WIKIQA
Location	37 (16%)	373 (12%)
Human	65 (29%)	494 (16%)
Numeric	70 (31%)	658 (22%)
Abbreviation	2 (1%)	16 (1%)
Entity	37 (16%)	419 (14%)
Description	16 (7%)	1087 (36%)

Table 3: Question classes of the QASENT and WIKIQA datasets.

The distributions of question types in these two datasets are also different, as shown in Table 3.[4] WIKIQA contains more description or definition questions, which could be harder to answer.

3 Experiments

Many systems have been proposed and tested on the QASENT dataset, including lexical semantic models (Yih et al., 2013) and sentence semantic models (Yu et al., 2014). We investigate the performance of several systems on WIKIQA and QASENT. As discussed in Section 2, WIKIQA offers us the opportunity to evaluate QA systems on answer triggering. We propose simple metrics and perform a feature study on the new task. Finally, we include some error analysis and discussion at the end of this section.

3.1 Baseline Systems

We consider two simple word matching methods: Word Count and Weighted Word Count. The first method counts the number of non-stopwords in the question that also occur in the answer sentence. The second method re-weights the counts by the IDF values of the question words.

We reimplement LCLR (Yih et al., 2013), an answer sentence selection approach that achieves very competitive results on QASENT. LCLR

[3] We follow experimental settings of Yih et al. (2013) on the QASENT dataset. Although the training set in the original data contains more questions, only 94 of them are paired with sentences that have human annotations.

[4] The classifier is trained using a logistic regression model on the UIUC Question Classification Datasets (`http://cogcomp.cs.illinois.edu/Data/QA/QC`). The performance is comparable to (Li and Roth, 2002).

Model	QASENT		WIKIQA	
	MAP	MRR	MAP	MRR
Word Cnt	0.5919	0.6662	0.4891	0.4924
Wgt Word Cnt	0.6095	0.6746	0.5099	0.5132
LCLR	**0.6954**	0.7617	0.5993	0.6086
PV	0.5213	0.6023	0.5110	0.5160
CNN	0.5590	0.6230	0.6190	0.6281
PV-Cnt	0.6762	0.7514	0.5976	0.6058
CNN-Cnt	0.6951	**0.7633**	**0.6520**	**0.6652**

Table 4: Baseline results on both QASENT and WIKIQA datasets. Questions without correct answers in the candidate sentences are removed in the WIKIQA dataset. The best results are in **bold**.

Model	Prec	Rec	F_1
CNN-Cnt	26.09	37.04	30.61
+QLen	27.96	37.86	32.17
+SLen	26.14	37.86	30.92
+QClass	27.84	33.33	30.34
+All	28.34	35.80	31.64

Table 5: Evaluation of answer triggering on the WIKIQA dataset. Question-level precision, recall and F_1 scores are reported.

makes use of rich lexical semantic features, including word/lemma matching, WordNet and vector-space lexical semantic models. We do not include features for Named Entity matching.[5]

We include two sentence semantic methods, Paragraph Vector[6] (PV; Le and Mikolov, 2014) and Convolutional Neural Networks (CNN; Yu et al., 2014). The model score of PV is the cosine similarity score between the question vector and the sentence vector. We follow Yu et al. (2014) and employ a bigram CNN model with average pooling. We use the pre-trained word2vec embeddings provided by Mikolov et al. (2013) as model input.[7] For computational reasons, we truncate sentences up to 40 tokens for our CNN models.

Finally, we combine each of the two sentence semantic models with the two word matching features by training a logistic regression classifier, referring as PV-Cnt and CNN-Cnt. CNN-Cnt has been shown to achieve state-of-the-art results on the QASENT dataset (Yu et al., 2014).

3.2 Evaluation of Answer Triggering

The task of answer sentence selection assumes that there exists at least one correct answer in the candidate answer sentence set. Although the assumption simplifies the problem of question answering, it is unrealistic for practical QA systems. Modern QA systems rely on an independent component to pre-select candidate answer sentences, which utilizes various signals such as lexical matching and user behaviors. However, the candidate sentences are not guaranteed to contain the correct answers, no matter what kinds of pre-selection components are employed. We propose the answer triggering task, a new challenge for the question answering problem, which requires QA systems to: (1) detect whether there is at least one correct answer in the set of candidate sentences for the question; (2) if yes, select one of the correct answer sentences from the candidate sentence set.

Previous work adopts MAP and MRR to evaluate the performance of a QA system on answer sentence selection. Both metrics evaluate the relative ranks of correct answers in the candidate sentences of a question, and hence are not suitable for evaluating the task of answer triggering. We need metrics that consider both the presence of answers with respect to a question and the correctness of system predictions.

We employ precision, recall and F_1 scores for answer triggering, at the question level. In particular, we compute these metrics by aggregating all the candidate sentences of a question. A question is treated as a positive case only if it contains one or more correct answer sentences in its candidate sentence pool. For the prediction of a question, we only consider the sentence in the candidate set that has the highest model score. If the score is above a predefined threshold and the sentence is labeled as a correct answer to the question, then it means that the prediction is correct and the question is answered correctly.

3.3 Results

WIKIQA vs. QASENT The MAP and MRR results are presented in Table 4. We only evaluate questions with answers in the WIKIQA dataset under these metrics. On the QASENT dataset, as found by prior work, the two word matching methods are very strong baselines, in which they sig-

[5]The improvement gains from the features are marginal on the QASENT dataset.

[6]We choose the Distributed Bag of Words version of Paragraph Vector, as we found it significantly outperforms the Distributed Memory version of Paragraph Vector.

[7]Available at https://code.google.com/p/word2vec/

nificantly outperform sentence semantic models. By incorporating rich lexical semantic information, LCLR further improves the results. CNN-Cnt gives results that match LCLR, and PV-Cnt performs worse than CNN-Cnt.[8]

The story on the WIKIQA dataset is different. First, methods purely rely on word matching are not sufficient to achieve good results. Second, CNN significantly outperforms simple word matching methods and performs slightly better than LCLR, which suggests that semantic understanding beyond lexical semantics is important for obtaining good performance on WIKIQA. Finally, word matching features help to further boost CNN results by approximately 3 to 4 points in both MAP and MRR.

Evaluation of answer triggering on WIKIQA We evaluate the best system CNN-Cnt on the task of answer triggering, and the results are shown in Table 5. We tune the model scores for making predictions with respect to F_1 scores on the dev set, due to the highly skewed class distribution in training data. The absolute F_1 scores are relative low, which suggests a large room for improvement.

We further study three additional features: the length of question (QLen), the length of sentence (SLen), and the class of the question (QClass). The motivation for adding these features is to capture the hardness of the question and comprehensiveness of the sentence. Note that the two question features have no effects on MAP and MRR. As shown in Table 5, the question-level F_1 score is substantially improved by adding a simple QLen feature. This suggests that designing features to capture question information is very important for this task, which has been ignored in the past. SLen features also give a small improvement in the performance, and QClass feature has slightly negative influence on the results.

3.4 Error Analysis & Discussion

The experimental results show that for the same model, the performance on the WIKIQA dataset is inferior to that on the QASENT dataset, which suggests that WIKIQA is a more challenging dataset. Examining the output of CNN-Cnt, the best performing model, on the WIKIQA dev set seems to suggest that deeper semantic understanding and answer inference are often required. Below are two examples selected that CNN-Cnt does not correctly rank as the top answers:

Q1: *What was the GE building in Rockefeller Plaza called before?*
A1: [GE Building] *Known as the RCA Building until 1988, it is most famous for housing the headquarters of the television network NBC.*

Q2: *How long was I Love Lucy on the air?*
A2: [I Love Lucy] *The black-and-white series originally ran from October 15, 1951, to May 6, 1957, on the Columbia Broadcasting System (CBS).*

Answering the first question may require a better semantic representation that captures the relationship between "called before" and "known ... until". As for the second question, knowing that on a TV channel (e.g., CBS) implies "on the air" and a time span between two dates is legitimate to a "how long" question is clearly beneficial.

4 Conclusion

We present WIKIQA, a new dataset for open-domain question answering. The dataset is constructed in a natural and realistic manner, on which we observed different behaviors of various methods compared with prior work. We hope that WIKIQA enables research in the important problem of answer triggering and enables further research in answer sentence selection in more realistic settings. We also hope that our empirical results will provide useful baselines in these efforts.

Abstract

Machine Translation (MT) has advanced in recent years to produce better translations for clients' specific domains, and sophisticated tools allow professional translators to obtain translations according to their prior edits. We suggest that MT should be further personalized to the end-user level – the receiver or the author of the text – as done in other applications. As a step in that direction, we propose a method based on a recommender systems approach where the user's preferred translation is predicted based on preferences of similar users. In our experiments, this method outperforms a set of non-personalized methods, suggesting that user preference information can be employed to provide better-suited translations for each user.

1 Introduction

Technologies are increasingly personalized, accommodating their behavior for each user. Such personalization is done through user modeling where the goal is to "get to know" the user. To that end, personalization is based on users' attributes, such as demographics (gender, age etc.), personalities, and preferences. For example, in Information Retrieval, results are customized according to the user's information and search history (Speretta and Gauch, 2005), performance of Automatic Speech Recognition substantially improves when adapted to a specific speaker (Neumeyer et al., 1995), and Targeted Advertising makes use of the user's location and prior purchases (Kölmel and Alexakis, 2002).

Personalization in machine translation has a somewhat different nature. Providers of MT tools and services offer means to "customize" or "personalize" the translation engine for each client, mostly through domain adaptation techniques, and a great deal of effort is made to make the human-involved translation process more efficient (see Section 2.2). Most of the focus, though, goes to customization for companies or professional translators. We argue that *Personalized Machine Translation* (PMT below) should and can take the next step and directly address individual end-users.

The difficulty to objectively determine whether one (automatic) translation is better than another has been repeatedly revealed in the MT literature. Our conjecture is that one reason is individual preferences, to which we refer as *Translational Preferences* (TP). TP come into play both when the alternative translations are all correct, and when each of them is wrong in a different way. In the former case, a preference may be a stylistic choice, and in the latter, a matter of comprehension or a selection of the least intolerable error in one's opinion. For instance, one user may prefer shorter sentences than others; she may favor a more formal style, while another would rather have it casual. A user could be fine with some reordering errors but be more picky concerning punctuations. One user will not be bothered if some words are left untranslated (perhaps because the source language belongs to the same language family as the target language that he speaks), while another will find it utterly displeasing. Such differences may be the result of the type of translation system being employed (e.g. syntax- vs. phrased-based), the specific training data or many other factors. On the user's side, a preference may be attributed, for example, to her mother tongue, her age or her personality.

Two aspects of end-user PMT may be considered: (i) Personalized translation of texts written by a specific user, and (ii) PMT to provide better translations for a specific reader. In this work we address the second task, aiming to identify translations each user is more likely to prefer.[1] Specifically, we consider a setting where at least two MT systems are available, and the goal is to predict which of the translation systems the user would choose, assuming we have no knowledge about her preference between them. Benchmarking the systems in advance with respect to a reference set, or estimating the quality of the translations (Specia et al., 2009) are viable alternatives for translation selection; these, however, are not personalized to the target user. Instead, we employ a user-user Collaborative Filtering approach, common in Recommender Systems, which we map to the TP prediction task.

We assess this approach using a collection of user rankings of MT systems from a shared translation task

*This work was done while the first author was at Xerox Research Centre Europe.

[1] In (Mirkin et al., 2015) we investigate the first task, assessing whether the author's demographic and personality traits are preserved over machine translation.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2019–2025,
Lisbon, Portugal, 17-21 September 2015.

(see Section 3). Our results show that the personalized method modestly, but consistently, outperforms several other approaches that rank the systems in general, disregarding the specific user. We consider this as an indication that user feedback can be employed towards a more personalized approach to machine translation.

2 Background

2.1 Collaborative filtering

Collaborative filtering (CF) is a common approach employed by recommender systems for suggesting to users items, such as books or movies. A recommender system may simply suggest to all users the most popular items; often, however, the recommendations are personalized for each individual user to fit her taste or preferences. User-user CF relies on community preferences. The idea is to recommend to the user items that are liked by users similar to her, as manifested, for example, by high rating. Similar users are those that agree with the current user on previously-rated items. In k-nearest-neighbors CF, a user is typically represented by a vector of her preferences, where each entry of the vector is, e.g., a rating of a movie. k similar users are then identified by measuring the similarity between the users' vectors. Cosine similarity is a popular function for that purpose, and we also use it in our work (Resnick et al., 1994; Sarwar et al., 2001; Ricci et al., 2011). An alternative to cosine, Pearson's correlation coefficient (Pearson, 1895), allows addressing different rating patterns across users. In comparison to cosine, here vector entries are normalized with respect to the user's average rating. In our case, such normalization is not very meaningful since the entries of the users vectors represent comparisons rather than absolute ratings, as will be made clear in Section 4. Nevertheless, we have experimented with Pearson correlation as well, and found no advantage in using it instead of cosine.

2.2 Customization, personalization and adaptation in MT

Various means of customization and personalization are available, in both academic and commercial MT. Many of them target the company, rather than the individual user, and much of the effort is invested in designing tools for professional translators, aiming to improve their productivity, through intelligent Computer Aided Translation (CAT).

Domain adaptation methods are commonly used to adapt to the topic, the genre and even the style of the translated material. Using the company's own corpora is one of the simplest techniques to do so, but many more approaches have been proposed, including data-selection (Axelrod et al., 2011; Gascó et al., 2012; Mirkin and Besacier, 2014), mixture models (Foster and Kuhn, 2007) and table fill-up (Bisazza et al., 2011). Clients can utilize their own glossaries (Federico et al., 2014), corpora (parallel or monolingual) and translation memories (TM), either shared or private ones (Caskey and Maskey, 2014; Federico et al., 2014). Through Adaptive and Interactive MT (Nepveu et al., 2004), the system learns from the translator's edits, in order to avoid repeating errors that have already been corrected. Post-editions can continuously be added to the translator's TM or be used as additional training material, for tighter adaptation to the domain of interest, through batch or incremental training.

2.3 User preferences in MT

Many tasks that require annotation by humans are affected by the annotator and not only by the item being judged. Metrics for inter-rater reliability or inter-annotator agreement, such as Cohen's Kappa (Cohen, 1960), help measuring the extent to which annotators disagree. Disagreement may be due to untrained or inattentive annotators, a result of a task that is not well defined, or when there is no obvious "truth". Such is the case with the evaluation of translation quality – it is not always straightforward to tell whether one translation is better than another. A single sentence can be translated in multiple correct ways. The decision becomes even harder when the translations are automatically produced and are imperfect: Is one error worse than another? The answer is in the eye of the beholder. MT papers regularly report rather low Kappa levels, even when measured on simpler tasks, such as short segments (Macháček and Bojar, 2015).

Turchi et al. (2013) refer to the issue of "subjectivity" of human annotators. They address the task of binary classification of "good" vs. "bad" translations, and show that relying on human annotation for training a binary quality estimator is less effective than using automatically-generated labels. This subjectivity is exactly what we are after. We treat it as a *preference*, trying to identify the systems or specific translations which the user subjectively prefers.

Kichhoff et al. (2012) analyze user preferences with respect to MT errors. They show that some types, e.g. word order errors, are the most dis-preferred by users, and that this is a more important factor than the number of errors. While very relevant for our research, their analysis is aggregated over all users participating in the study, and is not focusing on individuals' preferences.

3 Data

In this work we used the data provided for the MT Shared Task in the 2013 Workshop on Statistical Machine Translation (WMT) (Bojar et al., 2013).[2] This data was of a particularly large scale, with crowd-sourced human judges, either volunteer researchers or paid Amazon Turkers. For each source sentence, a judge was presented with the source sentence itself, a reference translation, and the outputs of five machine translation systems. The five systems were randomly selected from the pool of participating systems,

[2] http://www.statmt.org/wmt13/translation-task.html

and were anonymized and randomly-ordered when presented to the judge. The judge had to rank the translations, with ties allowed (i.e. two system can receive the same ranking). Hence, each annotation point provided with 10 pairwise rankings between systems. Translations of 10 language pairs were assessed, with 11 to 19 systems for each pair. In total, over 900K non-tied pairwise rankings were collected. The Turkers' annotation included a control task for quality assurance, rejecting Turkers failing more than 50% of the control points. The inter-annotator score showed on average a fair to moderate level of agreement.

4 Translational preferences with collaborative filtering

Our method, denoted CTP (*Collaborative Translational Preferences*), is based on a k-nearest-neighbors approach for user-user CF. That is, we predict the translational preferences of a user based on those of similar users. In our setting, a user preference is the choice between two translation systems – which system's translations does the user prefer. Given two systems (or models of the same system) we wish to predict which one the user would prefer, without assuming the user has ever expressed her preference between these two specific systems. It is important to emphasize that the method presented here considers the users' overall preferences of systems, and does not regard the specific sentence that is being translated. In future work we intend to make use of this information as well.

4.1 Representation

As mentioned in Section 3, each annotation consists of a ranking of five systems. From that, we extract pairwise rankings for every pair of systems that were ranked for a given language pair. For each user $u \in \mathcal{U}$ (where $\mathcal{U}$ are all users who annotated the language pair), we create a user-preference vector, p_u, that contains an entry for each pair of translation systems. Denoting the set of systems with $\mathcal{S}$, we have $\frac{|\mathcal{S}|\cdot(|\mathcal{S}|-1)}{2}$ system pairs. E.g., for Czech-English, with 11 participating systems, the user vector size is 55. Each entry (i, j) of the vector is assigned the following value:

$$p_u{}^{(i,j)} = \frac{w_u^{(i,j)} - l_u^{(i,j)}}{w_u^{(i,j)} + l_u^{(i,j)}} \quad (1)$$

where $w_u^{(i,j)}$ and $l_u^{(i,j)}$ are the number of wins and loses of system s_i vs. system s_j as judged by user u.[3]

With this representation, a user vector contains values between -1 (if s_i always lost to s_j) and 1 (if s_i always won). If the user always ranked the two systems identically, the value is 0, and if she has never evaluated the pair, the entry is regarded as a missing value (*NA*). Altogether, we have a matrix of users by system pairs, as depicted in Figure 1.

[3]We have also considered including ties in the denominator of the equation; discarding them was found superior.

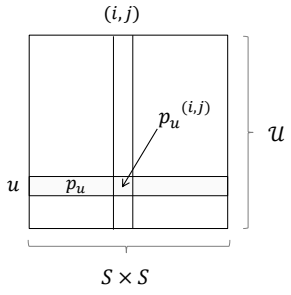

Figure 1: The user-preferences matrix.

4.2 Finding similar users

Given a user preference to predict for a pair of systems (s_i, s_j), we compute the similarity between p_u and each one of $p_{u'}$ for all other $u' \in \mathcal{U}$. In our experiments we used cosine as the similarity measure. The k most-similar-users (MSU) are then selected. To be included in $MSU(u)$, we require that u and u' have judged at least 2 common system pairs.

4.3 Preference prediction

Given the similarity scores, to predict the user's preference for the target system pair, we compute a weighted average of the predictions of the users in $MSU(u)$.

We include in the average only users with similarity scores above a certain positive threshold (0.05). We then require that a minimum number of users meet the above criteria of common annotations and minimum similarity (we used 5). If not enough such similar users are found, we turn to a fallback, where we use the non-weighted average preference across all users (AVPF presented in Section 5).[4] The prediction is then the sign of the weighted average. A positive value means s_i is the preferred system; a negative one means it is s_j, and a zero is a draw. In our evaluation we compare this prediction to the sign of the actual preference of the user, $p_u{}^{(i,j)}$. Formally, CTP computes the following prediction function f for a given user u and a system pair (s_i, s_j):

$$f_{\text{CTP}}(u)^{(i,j)} = sign\left(\frac{\sum_{u'} p_{u'}{}^{(i,j)} \cdot sim(u, u')}{\sum_{u'} sim(u, u')}\right) \quad (2)$$

where $u' \in MSU(u)$ are the most similar users (the nearest neighbors) of u; $p_{u'}{}^{(i,j)}$ are the preferences of user u' for (s_i, s_j) and $sim(u, u')$ is the similarity score between the two users.[5]

5 Experiments and results

5.1 Evaluation methodology

In our experiments we try to predict which one of two translation systems would be preferred by a given user.

[4]The fallback was used 0.1% of the times.

[5]The denominator is not required as long as we predict only the sign since all used similarity scores are positive. We keep it in order to obtain a normalized score that can be used for other decisions, e.g. ranking multiple systems.

We evaluate our method, as well as several other prediction functions, when compared with the user's pairwise system preference according to the annotation – ${p_u}^{(i,j)}$, shown in Equation 1. For each user this is an aggregated figure over all her pairwise rankings for the pair, determining the preferred system as the one chosen by the user (i.e. ranked higher) more times.

We conduct a leave-one-out experiment. For each language pair, we iterate over all non-*NA* entries in the user-preferences matrix, remove the entry and try to predict it. User similarity scores are re-computed for each evaluation point, to ensure they do not consider the target pair. The "gold" preference is positive when the user prefers s_i, negative when she prefers s_j and 0 when she has no preference between them. Hence, each of the assessed methods is measured by the accuracy of predicting the sign of the preference.

5.2 Non-personalized methods

We compare CTP to the following prediction methods:

Always i (ALI) This is a naïve baseline showing the score when always predicting that system i wins. Note that the baseline is not simply 50% due to ties.

Average rank (RANK) Here, two systems are compared by the average of their rankings across all annotations ($r \in \{1, 2, 3, 4, 5\}$):

$$f_{\text{RANK}}(u)^{(i,j)} = sign(\overline{r}_j - \overline{r}_i) \tag{3}$$

$\overline{r}_j$ and $\overline{r}_i$ are the average ranks of s_j and s_i respectively. Since a smaller value of r corresponds to a higher rank, we subtract the rank of s_i from s_j and not the other way around. This way, if for instance, s_i is ranked on averaged higher than s_j, the prediction would be positive, as desired.

Expected (EXPT) This metric, proposed by Koehn (2012) and used by Bojar et al. (2013) in order to rank the participating systems in the WMT benchmark, compares the *expected wins* of the two systems. Its intuition is explained as follows: "If the system is compared against a randomly picked opposing system, on a randomly picked sentence, by a randomly picked judge, what is the probability that its translation is ranked higher?" The expected wins of s_i, $e(s_i)$, is the probability of s_i to win when compared to another system, estimated as the total number of wins of s_i relative to the total number of comparisons involving it, excluding ties, and normalized by the total number of systems excluding s_i, $|\{s_k\}|$:

$$e(i) = \frac{1}{|\{s_k\}|} \sum_{k \neq i} \frac{w^{(i,k)}}{w^{(i,k)} + l^{(i,k)}} \tag{4}$$

where $w^{(i,k)}$ and $l^{(i,k)}$ are summed over all users. The preference prediction is therefore:

$$f_{\text{EXPT}}(u)^{(i,j)} = sign(e(i) - e(j)) \tag{5}$$

RANK and EXPT predict preferences based on a system's performance in general, when compared to **all** other systems. We propose an additional prediction function for comparison which uses only the information concerning the system pair under consideration.

Average user preference (AVPF) This method takes into account only the specific system pair and averages the user preferences for the pair. Formally:

$$f_{\text{AVPF}}(u)^{(i,j)} = sign(\frac{\sum_{u'} p_{u'}^{(i,j)}}{|\{u'\}|}) \tag{6}$$

where $u' \neq u$, and $\{u'\}$ are all users except u.

This method can be viewed as a non-personalized version of CTP, with two differences:

(1) It considers all users, and not only similar ones.
(2) It does not weight the preferences of the other users by their similarity to the target user.

5.3 Results

Table 1 shows the results of an experiment comparing the performance of the various methods in terms of prediction accuracy. Figure 2 shows the micro-average scores, when giving each of the 97,412 test points an equal weight in the average. CTP outperforms all others for 9 out of 10 language pairs, and in the overall micro-averaged results. The difference between CTP and each of the other metrics was found statistically significance with $p < 5 \cdot 10^{-6}$ at worse, as measured with a paired Wilcoxon signed rank test (Wilcoxon, 1945) on the predictions of the two methods. The significance test captures in this case the fact that the methods disagreed in many more cases than is visible by the score difference.

Our method was found superior to all others also when computing macro-average, taking the average of the scores of each language pair, as well as when the ties are included in the computation of p_u.

The parameters with which the above results were obtained are found within the method's description in Section 4. Yet, in our experiments, CTP turned out to be rather insensitive to their values. In this experiment we used a global set of parameters and did not tune them for each language pair separately. It is reasonable to assume that such tuning would improve results. For instance, choosing k, the number of users to include in the average, depends on the total number of users. E.g., for *en-es*, where there are only 57 users in total, reducing k's value from 50 to 25, improves results of CTP from 62.6% to 63.2%, higher than all other methods (whose scores are not affected).

Specifically in comparison to AVPF, weighting by the similarity scores was found to be a more significant factor than selecting a small subset of the users. This may not come as a surprise, since less similar users that are added to $MSU(u)$ have a smaller impact on the final decision since their weight in the average is smaller.

Table 1: Results in accuracy percentage for the 10 language pairs, including the languages: Czech (*cs*), English (*en*), German (*de*), Spanish (*es*), French (*fr*) and Russian (*ru*). The best results is in bold. The difference between CTP and each of the other methods is highly statistically significant. Figure 2 shows a micro-average of these results.

One weakness of CTP, as well as of other methods, is that it poorly predict ties. In the above experiment, approximately 13.5% of the preferences were 0, none of them was correctly identified. Our analysis showed that numerical accuracy is not the main cause; setting any prediction that is smaller than some values of $|\varepsilon|$ to 0 was not found helpful. Arguably, ties need not be predicted, since if the user has no preference between two systems, any choice is just as good. Still, we believe that better ties prediction could lead to general improvement of our method and we wish to address it in future work.

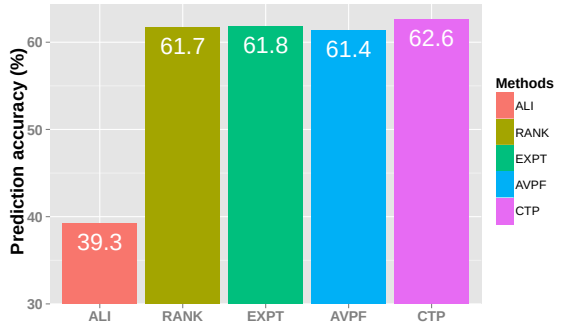

Figure 2: Micro-average over all 97,412 test points.

6 Discussion

We addressed the task of predicting user preference with respect to MT output via a collaborative filtering approach whose prediction is based on preferences of similar users. This method predicts TP better than a set of non-personalized methods. The gain is modest in absolute numbers, but the results are highly statistically significant and stable over parameter values.

We consider this work as a step towards more personalized MT. This line of research can be extended in multiple ways. First and foremost, as mentioned, we did not consider the actual content of the sentences, but rather identified a general preference for one system over another. It is plausible, however, that one system is better – from the user's perspective – at translating one type of text, while another is preferred for other texts. Taking the actual texts into account seems therefore essential. Content-based methods for recommender systems may be useful for this purpose. Another factor that may be affecting preferences is translation quality: when compared translations are all poor, preferences play a less significant role. Hence, it may be informative to assess TP prediction separately across different levels of translation quality.

Large parallel corpora are typically required for training reasonable statistical translation models. Yet, parallel corpora, and even more so in-domain ones, are hard to gather. It is virtually impossible to find a user-specific parallel corpus, and methods for monolingual domain adaptation are easier to envisage if one wishes to address author-aware PMT (the first PMT task mentioned in Section 1). Collecting user feedback is another challenge, especially since most end-users do not speak the source language. For that and other reasons, it currently seems more feasible to collect preference information from professional translators, explicitly or implicitly.Yet, in this research we aim at end-users rather than translators whose preferences are often driven by the ease of correction more than anything else. We believe that one way to tackle this issue is to exploit other kinds of feedback, from which we can infer user preferences and similarity. Online MT providers are recently collecting end-user feedback for their proposed translations which may be useful for TP prediction. For instance, in early 2015 Facebook introduced a feature letting users rate (Bing) translations, and Google Translate asks for suggested improvements. We are hopeful that such data becomes publicly available. Nevertheless, it remains unlikely to obtain feedback from each and every user. A potential direction for both corpora and feedback collection is personalizing models and identifying preferences for groups of users based on socio-demographic traits, such as gender, age or mother tongue, or based on (e.g. Big 5) personality traits. These can even be inferred by automatically analyzing user texts.

Abstract

This paper addresses the question of how language use affects community reaction to comments in online discussion forums, and the relative importance of the message vs. the messenger. A new comment ranking task is proposed based on community annotated karma in Reddit discussions, which controls for topic and timing of comments. Experimental work with discussion threads from six subreddits shows that the importance of different types of language features varies with the community of interest.

1 Introduction

Online discussion forums are a popular platform for people to share their views about current events and learn about issues of concern to them. Discussion forums tend to specialize on different topics, and people participating in them form communities of interest. The reaction of people within a community to comments posted provides an indication of community endorsement of opinions and value of information. In most discussions, the vast majority of comments spawn little reaction. In this paper, we look at whether (and how) language use affects the reaction, compared to the relative importance of the author and timing of the post.

Early work on factors that appear to influence crowd-based judgments of comments in the Slashdot forum (Lampe and Resnick, 2004) indicate that timing, starting score, length of the comment, and poster anonymity/reputation appear to play a role (where anonymity has a negative effect). Judging by differences in popularity of various discussion forums, topic is clearly important. Evidence that language use also matters is provided by recent work (Danescu-Niculescu-Mizil et al., 2012; Lakkaraju et al., 2013; Althoff et al., 2014; Tan et al., 2014). Teasing these different factors apart, however, is a challenge. The work presented in this paper provides additional insight into this question by controlling for these factors in a different way than previous work and by examining multiple communities of interest. Specifically, using data from Reddit discussion forums, we look at the role of author reputation as measured in terms of a karma k-index, and control for topic and timing by ranking comments in a constrained window within a discussion.

The primary contributions of this work include findings about the role of author reputation and variation across communities in terms of aspects of language use that matter, as well as the problem formulation, associated data collection, and development of a variety of features for characterizing informativeness, community response, relevance and mood.

2 Data

Reddit[1] is the largest public online discussion forum with a wide variety of subreddits, which makes it a good data source for studying how textual content in a discussion impacts the response of the crowd. On Reddit, people initiate a discussion thread with a post (a question, a link to a news item, etc.), and others respond with comments. Registered users vote on which posts and comments are important. The total amount of up votes minus the down votes (roughly) is called *karma*; it provides an indication of community endorsement and popularity of a comment, as used in (Lakkaraju et al., 2013). Karma is valued as it impacts the order in which the posts or comments are displayed, with the high karma content rising to the top. Karma points are also accumulated by members of the discussion forum as a function of the karma associated with their comments.

Table 2: Percentage of discussions where the top comment is made by the top k-index person (or top 3 people) in the discussion.

The Reddit data is highly skewed. Although there are thousands of active communities, only a handful of them are large. Similarly, out of the more than a million comments made per day[2], most of them receive little to no attention; the distributions of positive comment karma and author karma are Zipfian. Slightly more than half of all comments have exactly one karma point (no votes beyond the author), and only 5% of comments have less than one karma point.

For this study, we downloaded all the posts and associated comments made to six subreddits over a few weeks, as summarized in Table 1, as well as karma of participants in the discussion[3]. All available comments on each post were downloaded at least 48 hours after the post was made.[4]

3 Uptake Factors

Factors other than the language use that influence whether a comment will have uptake from the community include the topic, the timing of the message, and the messenger. These factors are all evident in the Reddit discussions. Some subreddits are more popular and thus have higher karma comments than others, reflecting the influence of topic. Comments that are posted early in the discussion are more likely to have high karma, since they have more potential responses.

Previous studies on Twitter show that the reputation of the author substantially increases the chances of the retweet (Suh et al., 2010; Cha et al., 2010), and reputation is also raised as a factor in Slashdot (Lampe and Resnick, 2004). On Reddit most users are anonymous, but it is possible that members of a forum become familiar with particular usernames associated with high karma comments. In order to see how important personal reputation is, we looked at how often the top karma comments are associated with the top karma participants in the discussion. Since an individual's karma can be skewed by a few very popular posts, we measure reputation instead using a measure we call the *k-index*, defined to be equal to the number of comments in each user's history that have karma $\geq k$. The k-index is analgous to the h-index (Hirsch, 2005) and arguably a better indicator of extended impact than total karma.

The results in Table 2 address the question of whether the top karma comments always come from the top karma person. The Top1 column shows the percentage of threads where the top karma comment in a discussion happens to be made by the highest k-index person participating in the discussion; the next column shows the percentage of threads where the comment comes from any one of the top 3 k-index people. We find that, in fact, the highest karma comment in a discussion is rarely from the highest k-index people. The highest percentage is in ASKSCIENCE, where expertise is more highly valued. If we consider whether any one of the multiple comments that the top k-index person made is the top karma comment in the discussion, then the frequency is even lower.

4 Methods

4.1 Tasks

Having shown that the reputation of the author of a post is not a dominating factor in predicting high karma comments, we propose to control for topic and timing by ranking a set of 10 comments that were made consecutively in a short window of time within one discussion thread according to the karma they finally received. The ranking has access to the comment history about these posts. This simulates the view of an early reader of these posts, i.e., without influence of the ratings of oth-

[3]Our data collection is available online at https://ssli.ee.washington.edu/tial/data/reddit

[4]Based on our initial look at the data, we noticed that most posts receive all of their comments within 48 hours. Some comments are deleted before we are able to download them.

ers, so that the language content of the post is more likely to have an impact. Very long threads are sampled, so that these do not dominate the set of lists. Approximately 75% of the comment lists are designated for training and the rest is for testing, with splits at the discussion thread level. Here, feature selection is based on mean precision of the top-ranked comment (P@1), so as to emphasize learning the rare high karma events. (Note that P@1 is equivalent to accuracy but allows for any top-ranking comment to count as correct in the case of ties.) The system performance is evaluated using both P@1 and normalized discounted cumulative gain (NDCG) (Burges et al., 2005), which is a standard criterion for ranking evaluation when the samples to be ranked have meaningful differences in scores, as is the case for karma of the comments.

In addition, for analysis purposes, we report results for three surrogate tasks that can be used in the ranking problem: i) the binary ranker trained on all comment pairs within each list, in which low karma comments dominate, ii) a positive vs. negative karma classifier, and iii) a high vs. medium karma classifier. All use class-balanced data; the second two are trained and tested on a biased sampling of the data, where the pairs need not be from the same discussion thread.

4.2 Classifier

We use the support vector machine (SVM) rank algorithm (Joachims, 2002) to predict a rank order for each list of comments. The SVM is trained to predict which of a pair of comments has higher karma. The error term penalty parameter is tuned to maximize P@1 on a held-out validation set (20% of the training samples).

Since much of the data includes low-karma comments, there will be a tendancy for the learning to emphasize features that discriminate comments at the lower end of the scale. In order to learn features that improve P@1, and to understand the relative importance of different features, we use a greedy automatic feature selection process that incrementally adds one feature whose resulting feature set achives the highest P@1 on the validation set. Once all features have been used, we select the model with the subset of features that obtains the best P@1 on the validation set.

4.3 Features

The features are designed to capture several key attributes that we hypothesize are predictive of comment karma motivated by related work. The features are categorized in groups as summarized below, with details in supplementary material.

- **Graph and Timing (G&T):** A baseline that captures discourse history (response structure) and comment timing, but no text content.
- **Authority and Reputation (A&R):** K-index, whether the commenter was the original poster, and in some subreddits "flair" (display next to a comment author's username that is subject to a cursory verification by moderators).
- **Informativeness (Info.):** Different indicators suggestive of informative content and novelty, including various word counts, named entity counts, urls, and unseen n-grams.
- **Lexical Unigrams (Lex.):** Miscellaneous word class indicators, puncutation, and part-of-speech counts
- **Predicted Community Response (Resp.):** Probability scores from surrogate classification tasks (reply vs. no reply, positive vs. negative sentiment) to measure the community response of a comment using bag-of-words predictors.
- **Relevance (Rel.):** Comment similarity to the parent, post and title in terms of topic, computed with three methods: i) a distributed vector representation of topic using a non-negative matrix factorization (NMF) model (Xu et al., 2003), ii) the average of skip-gram word embeddings (Mikolov et al., 2013), and iii) word set Jaccard similarity (Strehl et al., 2000).
- **Mood:** Mean and std. deviation of sentence sentiment in the comment; word list indicators for politeness, argumentativeness and profanity.
- **Community Style (Comm.):** Posterior probability of each subreddit given the comment using a bag-of-words model.

The various word lists are motivated by feature exploration studies in surrogate tasks. For example, projecting words to a two dimensional space of positive vs. negative and likelihood of reply showed that self-oriented pronouns were more likely to have no response and second-person pronouns were more likely to have a negative response. The politeness and argumentativeness/profanity lists are generated by starting with hand-specified seed lists used to train an SVM to classify word embeddings (Mikolov et al., 2013)

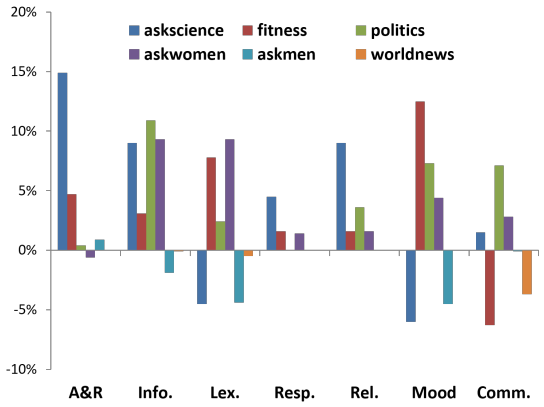

Figure 1: Relative improvement in P@1 over G&T for individual feature groups.

into these categories, and expanding the lists with 500 words farthest from the decision boundary.

Both the NMF and the skip-gram topic models use a cosine distance to determine topic similarity, with 300 as the word embedding dimension. Both are trained on approximately 2 million comments in high karma posts taken across a wide variety of subreddits. We use topic models in various measures of comment relevance to the discussion, but we do not use topic of the comment on its own since topic is controlled for by ranking within a thread.

5 Ranking Experiments

We present three sets of experiments on comment karma ranking, all of which show very different behavior for the different subreddits. Fig. 1 shows the relative gain in P@1 over the G&T baseline associated with using different feature groups. The importance of the different features reflect the nature of the different communities. The authority/reputation features help most for ASKSCIENCE, consistent with our k-index study. Informativeness and relevance help all subreddits except ASKMEN and WORLDNEWS. Lexical, mood and community style features are useful in some cases, but hurt others. The predicted probability of a reply was least useful, possibly because of the low-karma training bias.

Tables 3 and 4 summarize the results for the P@1 and NDCG criteria using the greedy selection procedure (which optimizes P@1) compared to a random baseline and the G&T baseline. The random baseline for P@1 is greater than 10% because of ties. The G&T baseline results show that the graph and timing features alone obtain 21-32%

subreddit	Random	G&T	All

of top karma comments depending on subreddits. Adding the textual features gives an improvement in P@1 performance over the G&T baseline for all subreddits except ASKMEN and WORLDNEWS. The trends for performance measured with NDCG are similar, but the benefit from textual features is smaller. The results in both tables show different ways of reporting performance of the same system, but the system has been optimized for P@1 in terms of feature selection. In initial exploratory experiments, this seems to have a small impact: when optimizing for NDCG in feature selection we obtain 0.61 vs. 0.60 with the P@1-optimized features.

A major challenge with identifying high karma comments (and negative karma comments) is that

subreddit	Pos/Neg	High/Mid	Ranking

Average	79.6	61.7	59.1

Table 5: Accuracy of binary classifiers trained on balanced data to distinguish: positive vs. negative karma (Pos/Neg), high vs. mid-level karma (High/Mid), and ranking between any pair (Ranking).

they are so rare. Although our feature selection tunes for high rank precision, it is possible that the low-karma data dominate the learning. Alternatively, it may be that language cues are mainly useful for identifying distinguishing the negative or mid-level karma comments, and that the very high karma comments are a matter of timing. To better understand the role of language for these different types, we trained classifiers on balanced data for positive vs. negative karma and high vs. mid levels of karma. For these models, the training pairs could come from different threads, but topic is controlled for in that all topic features are relative (similarity to original post, parent, etc.). We compared the results to the binary classifier used in ranking, where all pairs are considered. In all three cases, random chance accuracy is 50%.

Table 5 shows the pairwise accuracy of these classifiers. We find that distinguishing positive from negative classes is fairly easy, with the notable exception of the more information-oriented subreddit ASKSCIENCE. Averaging across the different subreddits, the high vs. mid task is slightly easier than the general ranking task, but the variation across subreddits is substantial. The high vs. mid distinction for FITNESS falls below chance (likely overtraining), whereas it seems to be an easier task for the ASKWOMEN, ASKMEN, and WORLDNEWS.

6 Related Work

Interest in social media is rapidly growing in recent years, which includes work on predicting the popularity of posts, comments and tweets. Danescu-Niculescu-Mizil et al. (2012) investigate phrase memorability in the movie quotes. Cheng et al. (2014) explore prediction of information cascades on Facebook. Weninger et al. (2013) analyze the hierarchy of the Reddit discussions, topic shifts, and popularity of the comment, using among the others very simple language analysis. Lampos et al. (2014) study the problem of predicting a Twitter user impact score (determined by combining the numbers of user's followers, followees, and listings) using text-based and non-textual features, showing that performance improves when user participation in particular topics is included.

Most relevant to this paper are studies of the effect of language in popularity predictions. Tan et al. (2014) study how word choice affects the popularity of Twitter messages. As in our work, they control for topic, but they also control for the popularity of the message authors. On Reddit, we find that celebrity status is less important than it is on Twitter since on Reddit almost everyone is anonymous. Lakkaraju et al. (2013) study how timing and language affect the popularity of posting images on Reddit. They control for content by only making comparisons between reposts of the same image. Our focus is on studying comments within a discussion instead of standalone posts, and we analyze a vast majority of language features. Althoff et al. (2014) use deeper language analysis on Reddit to predict the success of receiving a pizza in the Random Acts of Pizza subreddit. To our knowledge, this is the first work on ranking comments in terms of community endorsement.

7 Conclusion

This paper addresses the problem of how language affects the reaction of community in Reddit comments. We collect a new dataset of six subredit discussion forums. We introduce a new task of ranking comments based on karma in Reddit discussions, which controls for topic and timing of comments. Our results show that using language features improve the comment ranking task in most of the subreddits. Informativeness and relevance are the most broadly useful feature categories; reputation matters for ASKSCIENCE, and other categories could either help or hurt depending on the community. Future work involves improving the classification algorithm by using new approaches to learning about rare events.

What Your Username Says About You

Aaron Jaech and Mari Ostendorf
Dept. of Electrical Engineering
University of Washington
{ajaech,ostendor}@uw.edu

Abstract

Usernames are ubiquitous on the Internet, and they are often suggestive of user demographics. This work looks at the degree to which gender and language can be inferred from a username alone by making use of unsupervised morphology induction to decompose usernames into sub-units. Experimental results on the two tasks demonstrate the effectiveness of the proposed morphological features compared to a character n-gram baseline.

1 Introduction

There is much interest in automatic recognition of demographic information of Internet users to improve the quality of online interactions. Researchers have looked into identifying a variety of factors about users, including age, gender, language, religious beliefs and political views. Most work leverages multiple sources of information, such as search query history, Twitter feeds, Facebook likes, social network links, and user profiles. However, in many situations, little of this information is available. Conversely, usernames are almost always available.

In this work, we look specifically at classifying gender and language based only on the username. Prior work by sociologists has established a link between usernames and gender (Cornetto and Nowak, 2006), and studies have linked usernames to other attributes, such as individual beliefs (Crabill, 2007; Hassa, 2012) and shown how usernames shape perceptions of gender and ethnicity in the absence of common nonverbal cues (Pelletier, 2014). The connections to ethnicity motivate the exploration of language identification.

Gender identification based on given names is very effective for English (Liu and Ruths, 2013), since many names are strongly associated with a particular gender, like "Emily" or "Mark". Unfortunately, the requirement that each username be unique precludes use of given names alone. Instead, usernames are typically a combination of component words, names and numbers. For example, the Twitter name @taylorswift13 might decompose into "taylor", "swift" and "13". The sub-units carry meaning and, importantly, they are shared with many other individuals. Thus, our approach is to leverage automatic decomposition of usernames into sub-units for use in classification.

We use the Morfessor algorithm (Creutz and Lagus, 2006; Virpioja et al., 2013) for unsupervised morphology induction to learn the decomposition of the usernames into sub-units. Morfessor has been used successfully in a variety of language modeling frameworks applied to a number of languages, particularly for learning concatenative morphological structure. The usernames that we analyze are a good match to the Morfessor framework, which allows us to push the boundary of how much can be done with only a username.

The classifier design is described in the next section, followed by a description of experiments on gender and language recognition that demonstrate the utility of morph-based features compared to character n-gram features. The paper closes with a discussion of related work and a summary of key findings.

2 General Classification Approach

2.1 Unsupervised Morphology Learning

In linguistics, a morpheme is the "minimal linguistic unit with lexical or grammatical meaning" (Booij, 2012). Morphemes are combined in various ways to create longer words. Similarly, usernames are frequently made up of a concatenated sequence of smaller units. These sub-units will be referred to as u-morphs to highlight the fact that they play an analogous role to morphemes but for

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2032–2037,
Lisbon, Portugal, 17-21 September 2015.

purposes of encoding usernames rather than standard words in a language. The u-morphs are subunits that are small enough to be shared across different usernames but retain some meaning.

Unsupervised morphology induction using Morfessor (Creutz and Lagus, 2006) is based on a minimum description length (MDL) objective, which balances two competing goals: maximizing both the likelihood of the data and of the model. The likelihood of the data is maximized by longer tokens and a bigger lexicon whereas the likelihood of the model is maximized by a smaller lexicon with shorter tokens. A parameter controls the trade-off between the two parts of the objective function, which alters the average u-morph length. We tune this parameter on held-out data to optimize the classification performance of the demographic tasks.

Maximizing the Morfessor objective exactly is computationally intractable. The Morfessor algorithm searches for the optimal lexicon using an iterative approach. First, the highest probability decomposition for each training token is found given the current model. Then, the model is updated with the counts of the u-morphs. A u-morph is added to the lexicon when it increases the weighted likelihood of the data by more than the cost of increasing the size of the lexicon.

Usernames can be mixed-case, e.g. "JohnDoe". The case change gives information about a likely u-morph boundary, but at the cost of doubling the size of the character set. To more effectively leverage this cue, all characters are made lowercase but each change from lower to uppercase is marked with a special token, e.g. "john$doe". Using this encoding reduces the u-morph inventory size, and we found it to give slightly better results in language identification.

Character 3-grams and 4-grams are used as baseline features. Before extracting the n-grams a "#" token is placed at the start and end of each username. The n-grams are overlapping to give them the best chance of finding a semantically meaningful sub-unit.

2.2 Classifier Design

Given a decomposition of the username into a sequence of u-morphs (or character n-grams), we represent the relationship between the observed features and each class with a unigram language model. If a username u has decomposition $m_1, \ldots, m_n$ then it is assigned to the class c_i for which the unigram model gives it the highest posterior probability, or equivalently:

$$\text{argmax}_i \; p_C(c_i) \prod_{k=1}^{n} p(m_k|c_i),$$

where $p_C(c_i)$ is the class prior and $p(m_k|c_i)$ is the class-dependent unigram.[1]

For some demographics, the class prior can be very skewed, as in the case of language detection where English is the dominant language. The choice of smoothing algorithm can be important in such cases, since minority classes have much less training data for estimating the language model and benefit from having more probability mass assigned to unseen words. Here, we follow the approach proposed in (Frank and Bouckaert, 2006) that normalizes the token count vectors for each class to have the same L_1 norm, specifically:

$$p(m_k|c_i) = \frac{1}{Z}\left(1 + \frac{\beta \cdot n(m_k, c_i)}{n(c_i)}\right),$$

where $n(\cdot)$ indicates counts and β controls the strength of the smoothing. Setting β equal to the number of training examples approximately matches the strength of the smoothing to the add-one-smoothing algorithm. $Z = \beta + |M|$ is a constant to make the probabilities sum to one.

Only a small portion of usernames on the Internet come with gender labels. In these situations, semi-supervised learning algorithms can use the unlabeled data to improve the performance of the classifier. We use a self-training expectation-maximization (EM) algorithm similar to that described in (Nigam et al., 2000). The algorithm first learns a classifier on the labeled data. In the E-step, the classifier assigns probabilistic labels to the unlabeled data. In the M-step, the labeled data and the probabilistic labels are combined to learn a new classifier. These steps are iterated until convergence, which usually requires three iterations for our tasks.

[1] Note that the unigram model used here, which considers only the observed u-morphs or n-grams, is not the same as using a Naive Bayes (NB) classifier based on a vector of u-morph counts. In the former, unobserved u-morphs do not impact the class-dependent probability, whereas the zero counts do impact the probability for the NB classifier. Since the vast majority of possible u-morphs are unobserved in a username, it is better to base the decision only on the observed u-morphs. The n-gram model is actually a unigram with an n-gram "vocabulary" rather than an n-gram language model.

Nigam et al. (2000) call their method EM-λ because it uses a parameter λ to reduce the weight of the unlabeled examples relative to the labeled data. This is important because the independence assumptions of the unigram model lead to over-confident predictions. We used another method that directly corrects the estimated posterior probabilities. Using a small validation set, we binned the probability estimates and calculated the true class probability for each bin. The EM algorithm used the corrected probabilities for each bin for the unlabeled data during the maximization step. Samples with a prediction confidence of less than 60% are not used for training.

3 Experiments

3.1 Gender Identification

Data was collected from the OkCupid dating site by downloading up to 1,000 profiles from 27 cities in the United States, first for men seeking women and again for women seeking men to obtain a balanced set of 44,000 usernames. The data is partitioned into three sets with 80% assigned to training and 10% each to validation and test. We also use 3.5M usernames from the photo messaging app Snapchat (McCormick, 2014): 1.5M are used for u-morph learning and 2M are for self-training. All names in this task used only lower case, due to the nature of the available data.

	Male	**Female**
u-morph	guy, mike, matt, josh	girl, marie, lady, miss
trigram	guy, uy#, kev, joe	irl, gir, grl, emm

Table 1: Top Gender Identification Features

The top features ranked by likelihood ratios are given in Table 1. The u-morphs clearly carry semantic meaning, and the trigram features appear to be substrings of the top u-morph features. The trigram features have an advantage when the u-morphs are under-segmented such as if the u-morph "niceguy" or "thatguy" is included in the lexicon. Conversely, the n-grams can suffer from over-segmentation. For example, the trigram "guy" is inside the surname "Nguyen" even though it is better to ignore that substring in this context. Many other tokens suffer from this problem, e.g. "miss" is in "mission".

The variable-length u-morphs are longer on average than the character n-grams (4.9 characters). The u-morph inventory size is similar to that for 3-grams but 5-10 times smaller than the 4-gram inventory, depending on the amount of data used since the inventory is expanded in semi-supervised training. By using the MDL criterion in unsupervised morphology learning, the u-morphs provide a more efficient representation of usernames than n-grams and make it easier to control the trade-off between vocabulary size and average segment length. The smaller inventory is less sensitive to sparse data in language model training.

	Error Rate	
Features	Supervised	Self-Training
3-gram	28.7%	32.0%
4-gram	28.7%	29.4%
u-morph	27.8%	25.8%

Table 2: Gender Classification Results

The experiment results are presented in Table 2. For the supervised learning method, the character 3-gram and 4-gram features give equivalent performance, and the u-morph features give the lowest error rate by a small amount (3% relative). More significantly, the character n-gram systems do not benefit from semi-supervised learning, but the u-morph features do. The semi-supervised u-morph features obtain an error rate of 25.8%, which represents a 10% relative reduction over the baseline character n-gram results.

3.2 Language Identification on Twitter

This experiment takes usernames from the Twitter streaming API. Each username is associated with a tweet, for which the Twitter API identifies a language. The language labels are noisy, so we remove approximately 35% of the tweets where the Twitter API does not agree with the langid.py classifier (Lui and Baldwin, 2012). Both training and test sets are restricted to the nine languages that comprise at least 1% of the training set. These languages cover 96% of the observed tweets (see Table 4). About 110,000 usernames were reserved for testing and 430,000 were used for training both u-morphs and the classifier. Semi-supervised methods are not used because of the abundant labeled data. For each language, we train a one-vs.-all classifier. The mixed case encoding technique (see sec. 2.1) gives a small increase (0.5%) in the

Model	Prec.	Recall	F1
4-gram	.67	.75	.70
u-morph	.77	.67	.71
Combination	.73	.73	.73

Table 3: Precision, recall and F1 score for language identification using the 4-gram, u-morph representations and a combination system, averaging over all users.

accuracy of the model and reduces the u-morph model size by 5%.

The results in Tables 3 and 4 contrast systems using 4-grams, u-morphs, and a combination model, showing precision-recall trade-offs for all users together and F1 scores broken down by specific languages, respectively. The combination system simply uses the average of the posterior log-probabilities for each class giving equal weight to each model. While the overall F1 scores are similar for the 4-gram and u-morph systems, their precision and recall trade-offs are quite different, making them effective in combination. The 4-gram system has higher recall, and the u-morph system has higher precision. With the combination, we obtain a substantial gain in precision over the 4-gram system with a modest loss in recall, resulting in a 3% absolute improvement in average F1 score.

Looking at performance on the different languages, we find that the F1 score for the combination model is higher than the 4-gram for every language, with precision always improving. For the dominant languages, the difference in recall is negligible. The infrequent languages have a 4-8% drop in recall, but the gains in precision are substantial for these languages, ranging from 50-100% relative. The greatest contrast between the 4-gram and the combination system can be seen for the least frequent languages, i.e. the languages with the least amount of training data. In particular, for French, the precision of the combination system (0.36) is double that of the 4-gram model (0.18) with only a 34% loss in recall (0.24 to 0.16).

Looking at the most important features from the classifier highlights the ability of the morphemes to capture relevant meaning. The presence of the morpheme "juan", "jose" or "flor" increase the probability of a Spanish language tweet by five times. The same is true for Portuguese and the morpheme "bieber". The morpheme "q8" increases the odds of an Arabic language tweet by thirteen times due to its phonetic similarity to the name of the Arabic speaking country Kuwait. Other features may simply reflect cultural norms. For example, having an underscore in the username makes it five percent less likely to observe an English tweet. These highly discriminative morphemes are both long and short. It is hard for the fixed-length n-grams to capture this information as well as the morphemes do.

Language	Freq	4-gr	u-m	Comb
English	43.5	.78	.78	.79
Japanese	21.6	.75	.76	.77
Spanish	15.1	.66	.65	.68
Arabic	7.9	.66	.65	.68
Portuguese	6.2	.50	.55	.58
Russian	1.8	.40	.58	.45
Turkish	1.8	.59	.36	.65
French	1.1	.18	.13	.22
Indonesian	1.1	.34	.30	.43

4 Related Work

Of the many studies on automatic classification of online user demographics, few have leveraged names or usernames at all, and the few that do mainly explore their use in combination with other features. The work presented here differs in its use of usernames alone, but more importantly in the introduction of morphological analysis to handle a large number of usernames.

Two studies on gender recognition are particularly relevant. Burger *et al.* (2011) use the Twitter username (or screen name) in combination with other profile and text features to predict gender, but they also look at the use of username features alone. The results are not directly comparable to ours, because of differences in the data set used (150k Twitter users) and the classifier framework (Winnow), but the character n-gram performance is similar to ours (21-22% different from the majority baseline). The study uses over 400k character n-grams (n=1-5) for screen names alone; our study indicatess that the u-morphs can reduce this number by a factor of 10. Burger *et al.* (2011) used the same strategy with the self-identified full

name of the user as entered into their profile, obtaining 89% gender recognition (vs. 77% for screen names). Later, Liu and Ruths (2013) use the full first name from a user's profile for gender detection, finding that for the names that are highly predictive of gender, performance improves by relying on this feature alone. However, more than half of the users have a name that has an unknown gender association. Manual inspection of these cases indicated that the majority includes strings formed like usernames, nicknames or other types of word concatenations. These examples are precisely what the u-morph approach tries to address.

Language identification is an active area of research (Bergsma et al., 2012; Zubiaga et al., 2014), but the username has not been used as a feature. Again, results are difficult to compare due to the lack of a common test set, but it is notable that the average F1 score for the combination model approaches the scores obtained on a similar Twitter language identification task where the algorithm has access to the full text of the tweet (Lui and Baldwin, 2014): 73% vs. 77% .

A study that is potentially relevant to our work is automatic classification of ethnicity of Twitter users, specifically whether a user is African-American (Pennacchiotti and Popescu, 2011). Again, a variety of content, profile and behavioral features are used. Orthographic features of the username are used (e.g. length, number of numeric/alpha characters), and names of users that a person retweets or replies to. The profile name features do not appear to be useful, but examples of related usernames point to the utility of our approach for analysis of names in other fields.

5 Conclusions

In summary, this paper has introduced the use of unsupervised morphological analysis of usernames to extract features (u-morphs) for identifying user demographics, particularly gender and language. The experimental results demonstrate that usernames contain useful personal information, and that the u-morphs provide a more efficient and complementary representation than character n-grams.[2] The result for language identification is particularly remarkable because it comes close to matching the performance achieved by using the full text of a tweet. The work is complementary to other demographic studies in that the username prediction can be used together with other features, both for the user and members of his/her social network.

The methods proposed here could be extended in different directions. The unsupervised morphology learning algorithm could incorporate priors related to capitalization and non-alphabetic characters to better model these phenomena than our simple text normalization approach. More sophisticated classifiers could also be used, such as variable-length n-grams or neural-network-based n-gram language models, as opposed to the unigram model used here. Of course the sophistication of the classifier will be limited by the amount of training data available.

A large amount of data is not necessary to build a high precision username classifier. For example, less than 7,000 training examples were available for Turkish in the language identification experiment and the classifier had a precision of 76%. Since little data is required, there may be many more applications of this type of model.

Prior work on unsupervised morphological induction focused on applying the algorithm to natural language input. By using those techniques with a new type of input, this paper shows that there are other applications of morphology learning.

[2] In order to allow the replicability of the experiments, software and data for building and evaluating our classifiers using pre-trained Morfessor models is available at `http://github.com/ajaech/username_analytics`.

Abstract

Large-scale Knowledge Bases (such as NELL, Yago, Freebase, etc.) are often sparse, i.e., a large number of valid relations between existing entities are missing. Recent research have addressed this problem by augmenting the KB graph with additional edges mined from a large text corpus while keeping the set of nodes fixed, and then using the Path Ranking Algorithm (PRA) to perform KB inference over this augmented graph. In this paper, we extend this line of work by augmenting the KB graph not only with edges, but also with *bridging entities*, where both the edges and bridging entities are mined from a 500 million web text corpus. Through experiments on real-world datasets, we demonstrate the value of bridging entities in improving the performance and running time of PRA in the KB inference task.

1 Introduction

Large-scale knowledge bases (KB) like Freebase (Bollacker et al., 2008), Yago (Suchanek et al., 2007), NELL (Mitchell et al., 2015) can be useful in a variety of applications like natural language question answering, semantic search engines, etc. These knowledge bases consist of millions of real world entities and relationships between them which are stored in the form of a directed graph where links represent relations and nodes represent the entities. Although such KBs contain millions of entities, they are still very sparse, i.e., they are missing a large number of relations between existing entities (West et al., 2014).

Performing inference over the knowledge graph for predicting relations between two entities is one way of densifying the KB graph. For example, from *(Germany, playsinTournament, FIFA)* and *(FIFA, tournamentofSport, Soccer)*, we can infer *(Germany, playsSport, Soccer)*. The Path Ranking Algorithm (PRA) (Lao and Cohen, 2010), (Lao et al., 2011) performs such an inference by learning inference rules over the knowledge graph.

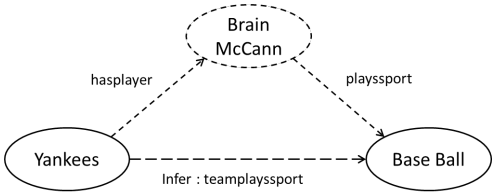

Figure 1: Example showing how addition of the *bridging entity*, *Brian McCain*, and the two edges incident on it can help the PRA algorithm (Lao and Cohen, 2010) to infer the initially missing relation instance *teamPlaysSport(Yankees, BaseBall)*. The original KB graph consisted only of two nodes, *Yankees* and *Baseball*, and no edges.

If the knowledge graph is sparse, i.e., if there are a very few or no paths between source and target entities, then PRA is unable to predict the existence of a relation. To address this shortcoming, (Lao et al., 2012) augmented the knowledge graph with paths obtained from an external corpus. The added paths consisted of unlexicalized dependency labels obtained from a dependency parsed external corpus. To improve the expressivity of the added paths, instead of the unlexicalized labels, (Gardner et al., 2013) augmented the KB graph with verbs (surface relations) from a corpus containing over 600 million Subject-Verb-Object (SVO) triples. These verbs act as edges that connect previously unconnected entities thereby increasing the connectivity of the KB graph which can potentially improve PRA performance.

However, naïvely adding these edges increases the feature sparsity which degrades the discriminative ability of the logistic regression classifier

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2038–2043,
Lisbon, Portugal, 17-21 September 2015.

used in PRA. This can be addressed by adding latent relations obtained by clustering the surface relations, instead of directly adding the surface relations. This reduces feature sparsity and has been shown to improve PRA inference (Gardner et al., 2013) , (Gardner et al., 2014).

In this article we propose a scheme for augmenting the KB using paths obtained by mining noun phrases that connect two SVO triples from an external corpus. We term these noun phrases as *bridging entities* since they bridge two KB relations to form a path. This is different from the scheme in (Gardner et al., 2013) and (Gardner et al., 2014), which adds edges between KB nodes by mining surface relations from an external corpus. We search for such bridging entities in the corpus by performing a limited depth DFS (depth first search) on the corpus graph in an *on-demand* fashion.

We term this procedure as **On-Demand Augmentation (ODA)**, because the search can be performed during test time in an on-demand manner. In contrast, the previous approaches of adding edges or embeddings to the KB (Gardner et al., 2013), and vector space random walk PRA (Gardner et al., 2014) are batch procedures. As we shall see in Section 4, due to a limited search space, on-demand augmentation is much faster compared to algorithms in (Gardner et al., 2013; Gardner et al., 2014). Furthermore, since edges are not added blindly, on-demand augmentation does not increase feature sparsity which is responsible for performance degradation. Our experiments suggest that ODA provides better performance than (Gardner et al., 2013) and nearly the same prediction performance as provided by (Gardner et al., 2014), but in both cases with the added advantage of faster running time and greater flexibility due to its online and on-demand nature. The code along with the results can be obtained at https://github.com/malllabiisc/pra-oda.

2 Related Work

Using surface level relations and noun phrases for extracting meaningful relational facts is not a new idea (Hearst, 1992),(Brin, 1999), (Etzioni et al., 2004). However, none of them make use of Knowledge Bases for improving information extraction.

The Path Ranking Algorithm (PRA) first proposed in (Lao and Cohen, 2010) was used for performing inference over a KB in (Lao et al., 2011). It was extended by (Lao et al., 2012), to improve the inference by augmenting the KB with syntactic information obtained from a dependency parsed corpus. Augmenting the KB for improving PRA inference using surface relations mined from an external corpus and using latent edge labels obtained by performing PCA on the surface relations was explored in (Gardner et al., 2013). Instead of hard mapping of surface relations to latent embeddings, (Gardner et al., 2014) perform a 'soft' mapping using vector space random walks. This allows the random walker to traverse an edge semantically similar to the current edge type more frequently than other edges.

Although, like others, we too use an external corpus to augment the KB, the crucial difference in our approach is that apart from adding surface relations, we also add bridging entities that enable us to create new paths in the KB. Furthermore, the procedure is targeted so that only paths that play a part in inferring the relations that are of interest are added. Thus, the number of paths added in this manner is much lower than the number of surface relations added using the procedure in (Gardner et al., 2013). As we shall see in Section 4, this results in a more effective algorithm with faster runtime.

3 Method

3.1 Background: Path Ranking Algorithm (PRA)

We first present a brief overview of the Path Ranking Algorithm (PRA) (Lao and Cohen, 2010). The PRA uses paths as features for a logistic regression classifier which predicts if the given relation exists between a pair of entities. For a given pair of entities s and t, the *path type* connecting s to t form the feature vector. A *path types* π is an ordered set of relations. Paths with the same ordered relations but different intermediate or terminal entities belong to the same path type. For example, $s_1 \xrightarrow{v_0} x_1 \xrightarrow{v_1} t_1$ and $s_2 \xrightarrow{v_0} x_2 \xrightarrow{v_1} t_2$ belong to path type $\xrightarrow{v_0}\xrightarrow{v_1}$. The value of a feature, is taken to be $P(s \rightarrow t; \pi)$, where $P(s \rightarrow t; \pi)$ is the probability of reaching t from s by traversing paths of type π. PRA approximates these probabilities by running a random walk (RW) on the KB graph. Let $F = \{\pi_1, \pi_2, ..., \pi_k\}$ be the set of all path types. For predicting the existence of relation r between entities s and t, the logistic regression classifier outputs a score which is a measure of the

Query	Candidate Answer	Path added by PRA-ODA with bridging entity (in bold)

teamPlaysInLeague(Cleveland Indians, ?)	MLB	Cleveland Indians $\overset{play}{\longrightarrow}$ **Detroit Tigers** $\overset{blew}{\longrightarrow}$ MLB

Table 1: Examples of paths involving bridging entities (marked in bold) added to the KB by PRA-ODA.

confidence that r exists between s and t. It does so by first assigning weights to the features in the training phase. The score is given by

$$S(s,t,r) = \sum_{\pi \in F} P(s \rightarrow t; \pi) \times \theta_{\pi}^{r} \qquad (1)$$

where θ_{π}^{r} is the weight learned by the logistic regression classifier during training specially for relation r and path type π. During the test phase, since targets are not available, the PRA gathers candidate targets by performing a random walk and then computes feature vectors and the score.

3.2 PRA-SVO and PRA-VS

PRA-SVO and PRA-VS are the systems proposed in (Gardner et al., 2013) and (Gardner et al., 2014) respectively, where the KB graph is augmented with edges mined from a large subject-verb-object (SVO) triple corpus. In these two systems, only new edges are added over the fixed set of nodes, and the augmentation happens in a batch, offline setting. In contrast, PRA-ODA, the method proposed in the paper, also expands the set of nodes through bridging entities, and performs the augmentation in an on-demand manner.

3.3 PRA On-Demand Augmentation (PRA-ODA)

Training: Let s and t be any two KB entities and let $s^{(n)}$ and $t^{(n)}$ be their corresponding noun phrase representations or aliases. We search for bridging entities $x_1, x_2, ..x_n$ by performing limited depth first search (DFS) starting with s^n such that we obtain a path $s \overset{ALIAS}{\longrightarrow} s^{(n)} \overset{v_0}{\longrightarrow} x_1 \overset{v_1}{\longrightarrow} ... \overset{v_{n-1}}{\longrightarrow} x_n \overset{v_n}{\longrightarrow} t^{(n)} \overset{ALIAS}{\longrightarrow} t$, where v_i are verbs present in the corpus graph. This is done for all $n \leq d_{max} - 1$, where d_{max} is the maximum depth of DFS. We add an 'ALIAS' edge between the KB entity and its noun phase representation. The usefulness of bridging entities is illustrated in Fig. 1.

We mine bridging entities from a corpus containing over 600 million SVO triples which were obtained from the ClueWeb09 corpus (Callan et al., 2009) parsed using the MALT parser (Nivre et al., 2007). We use Mongo DB to store the triples as an adjacency list. During training time, for any relation that is being inferred, both the source and its corresponding target entities are known. A limited depth DFS is performed for *all depths* less then d_{max} on the SVO graph with the aliases of subject entity acting as the starting points. Such aliases are available for the NELL and Freebase knowledge bases. The DFS is said to discover a path if the terminating entity of the path matches any alias of the target entity. We choose to use aliases to perform string match, since it is easy to change the softness of the match by simply adding more aliases. This is done for all training source-target pairs. A few examples of added paths are shown in Table 1.

The SVO graph is noisy since it is obtained by parsing the ClueWeb corpus which was obtained by scraping the web. To reduce noise, we add the top K most frequent discovered SVO path types, where K is a tunable parameter. By SVO path type we refer to a set of ordered verbs mined from the SVO corpus. There is a possibility that the bridging entities, extracted from the corpus, may be present in the KB. If the bridging entity matches any alias, then it is treated as an alias to an existing KB entity. If not, then the bridging entity is added to the KB as a new entity. To avoid overfitting we add negative data to the training set. Furthermore, only high quality expressive bridging entities result in meaningful and discriminative paths. Although the quality of bridging entities depend on the corpus, low quality bridging entities can be filtered out by adding negative training data. Low quality bridging entities connect source target pairs from both positive and negative training sets, and hence are eliminated by the sparse logistic regression classifier. The negative dataset is generated using the closed world assumption by performing a random walk.

After augmenting the KB, we run the training phase of the PRA algorithm to obtain the feature (path) weights computed by the logistic regression

KB Relations	PRA	PRA-SVO	PRA-VS	PRA-ODA

Average (MRR)	0.649	0.75	**0.9**	**0.9**

Table 2: Comparison of Mean Reciprocal Rank (MRR) metric for 10 relations from NELL (higher is better). PRA-SVO, PRA-VS are the systems proposed in (Gardner et al., 2013; Gardner et al., 2014). PRA-ODA is the approach proposed in this paper. Improvements in PRA-ODA over PRA-SVO is statistically significant with $p < 0.007$, with PRA-SVO as null hypothesis.

classifier.

Query Time: The set of target entities corresponding to a source entity and the relation being predicted is not available during query (test) time. We use all the entities included in the range of the relation being predicted as candidate target entities. For example, if the relation is *riverFlowsThroughCity*, the candidate target set would include entities in the KB that are *cities*. The DFS is now performed starting from source entities as during training, but this time only restricting to paths with positive weights learned during training. Any path (along with bridging entities) found during this search are added to the KB, and the PRA algorithm is now run over this augmented graph.

4 Experiments

We used the implementation of PRA provided by the authors of (Gardner et al., 2014). For our experiments, we used the same 10 NELL relation data as used in (Gardner et al., 2014). The augmentation resulted in the addition of 1086 paths during training and 1430 paths during test time.

We split the NELL data into 60% training data, 15 % development data and 25% test data. Values for d_{max}, and K, the most frequent paths, were obtained by tuning on a development set for 4 relations (athleteplaysforsport,actorstarredinmovie,citylocatedincountry and journalistwritesforpublication). The hyperparameter values $d_{max} = 2$, $K = 10$ reported the highest MRR and were used for the rest of the relations. For the L_1 and L_2 regularization parameters in the logistic regression classifier, we used the same values as used in (Gardner et al., 2013; Gardner et al., 2014), viz., $L_1 = 0.005$, and $L_2 = 1.0$. This is because the parameters were reported to be robust, and seemed to work well even when the knowledge base was augmented.

Timings (seconds)	PRA	PRA-SVO	PRA-VS	PRA-ODA
Training	635.6	574.5	564.2	913.3
Test	354.3	322.0	301.2	436.7
Batch augmentation	n/a	797	797	n/a
Embedding computation	n/a	n/a	812	n/a
Total Time	989.9	1693.5	2474.4	1350

Table 3: Runtime comparison for the entire experiment (lower is better). PRA-SVO, PRA-VS are the systems proposed in (Gardner et al., 2013; Gardner et al., 2014). PRA-ODA is the approach proposed in this paper. Between the two top performing systems, i.e., PRA-ODA and PRA-VS, PRA-ODA is faster by a factor of 1.8.

We compare the results (PRA-ODA) with the PRA algorithm executed on the NELL KB, NELL KB augmented with surface relations (PRA-SVO) (Gardner et al., 2013) and vector space random walk PRA (PRA-VS) (Gardner et al., 2014). The run times, i.e, the time taken to perform an entire experiment for PRA-SVO and PRA-VS includes the time taken to augment NELL KB with SVO edges. The PRA-VS runtime also includes the time taken for generating embeddings to perform the vector space random walk. As can be seen from Table 2 and Table 3, our scheme, PRA-ODA, provides performance equivalent to PRA-VS with faster running time (speed up of 1.8). In addition to the time taken for the full SVO augmentation, PRA-VS takes additional time to generate embeddings (13 minutes) from the added verbs. We note that the batch augmentation in case of PRA-SVO and PRA-VS, and embedding computation in case of PRA-VS are all specific to the relations in the evaluation set, and hence can't be ignored as a one-time offline cost. In other words, these costs are likely to increase as more relations (and their instances) are included during training and testing. Runtime gains with PRA-ODA are likely to be even more pronounced in such settings.

An additional advantage of the proposed algorithm is that it can also be run on the top of any PRA based algorithm such as the PRA-SVO and PRA-VS.

5 Conclusion

In this paper, we investigated the usefulness of adding paths to a Knowledge Base for improving its connectivity by mining *bridging entities* from an external corpus. While previous KB augmentation methods focused only on augmentation using mined surface verbs while keeping the node set fixed, we extended these approaches by also adding *bridging entities* in an online fashion. We used a large corpus of 500 million web text corpus to mine these additional edges and bridging entities. Through experiments on real-world datasets, we demonstrate that the proposed approach is not only comparable or better than other state-of-the-art baselines, but more importantly provides faster overall runtime compared with the alternatives.

Specializing Word Embeddings for Similarity or Relatedness

Douwe Kiela, Felix Hill and Stephen Clark
Computer Laboratory
University of Cambridge
douwe.kiela|felix.hill|stephen.clark@cl.cam.ac.uk

Abstract

We demonstrate the advantage of specializing semantic word embeddings for either similarity or relatedness. We compare two variants of retrofitting and a joint-learning approach, and find that all three yield specialized semantic spaces that capture human intuitions regarding similarity and relatedness better than unspecialized spaces. We also show that using specialized spaces in NLP tasks and applications leads to clear improvements, for document classification and synonym selection, which rely on either similarity or relatedness but not both.

1 Introduction

Most current models of semantic word representation exploit the *distributional hypothesis*: the idea that words occurring in similar contexts have similar meanings (Harris, 1954; Turney and Pantel, 2010; Clark, 2015). Such representations (or embeddings) can reflect human intuitions about similarity and relatedness (Turney, 2006; Agirre et al., 2009), and have been applied to a wide variety of NLP tasks, including bilingual lexicon induction (Mikolov et al., 2013b), sentiment analysis (Socher et al., 2013) and named entity recognition (Turian et al., 2010; Guo et al., 2014).

Arguably, one of the reasons behind the popularity of word embeddings is that they are "general purpose": they can be used in a variety of tasks without modification. Although this behavior is sometimes desirable, it may in other cases be detrimental to downstream performance. For example, when classifying documents by topic, we are particularly interested in related words rather than similar ones: knowing that *dog* is associated with *cat* is much more informative of the topic than knowing that it is a synonym of *canine*. Conversely, if our embeddings indicate that *table* is closely related to *chair*, that does not mean we should translate *table* into French as *chaise*.

This distinction between "genuine" similarity and associative similarity (i.e., relatedness) is well-known in cognitive science (Tversky, 1977). In NLP, however, semantic spaces are generally evaluated on how well they capture *both* similarity and relatedness, even though, for many word combinations (such as *car* and *petrol*), these two objectives are mutually incompatible (Hill et al., 2014b). In part, this oversight stems from the distributional hypothesis itself: *car* and *petrol* do not have the same, or even very similar, meanings, but these two words may well occur in similar contexts. Corpus-driven approaches based on the distributional hypothesis therefore generally learn embeddings that capture both similarity and relatedness reasonably well, but neither perfectly.

In this work we demonstrate the advantage of specializing semantic spaces for either similarity or relatedness. Specializing for similarity is achieved by learning from both a corpus and a thesaurus, and for relatedness by learning from both a corpus and a collection of psychological association norms. We also compare the recently-introduced technique of graph-based retrofitting (Faruqui et al., 2015) with a skip-gram retrofitting and a skip-gram joint-learning approach. All three methods yield specialized semantic spaces that capture human intuitions regarding similarity and relatedness significantly better than unspecialized spaces, in one case yielding state-of-the-art results for word similarity. More importantly, we show clear improvements in downstream tasks and applications: specialized similarity spaces improve synonym detection, while association spaces work better than both general-purpose and similarity-specialized spaces for document classification.

2 Approach

The underlying assumption of our approach is that, during training, word embeddings can be "nudged" in a particular direction by including information from an additional semantic data

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2044–2048,
Lisbon, Portugal, 17-21 September 2015.

source. For directing embeddings towards genuine similarity, we use the MyThes thesaurus developed by the OpenOffice.org project[1]. It contains synonyms for almost 80,000 words in English. For directing embeddings towards relatedness, we use the University of South Florida (USF) free association norms (Nelson et al., 2004). This dataset contains scores for free association (an experimental measure of cognitive association) of over 10,000 concept words. For raw text data we use a dump of the English Wikipedia plus newswire text (8 billion words in total)[2].

2.1 Evaluations (Intrinsic and Extrinsic)

For instrinsic comparisons with human judgements, we evaluate on SimLex (Hill et al., 2014b) (999 pairwise comparisons), which explicitly measures similarity, and MEN (Bruni et al., 2014) (3000 comparisons), which explicitly measures relatedness. We also consider two downstream tasks and applications. In the TOEFL synonym selection task (Landauer and Dumais, 1997), the objective is to select the correct synonym for a target word from a multiple-choice set of possible answers. For a more extrinsic evaluation, we use a document classification task based on the Reuters Corpus Volume 1 (RCV1) (Lewis et al., 2004). This dataset consists of over 800,000 manually categorized news articles.[3]

2.2 Joint Learning

The standard skip-gram training objective for a sequence of training words $w_1, w_2, ..., w_T$ and a context size c is the log-likelihood criterion:

$$\frac{1}{T}\sum_{t=1}^{T} J_\theta(w_t) = \frac{1}{T}\sum_{t=1}^{T}\sum_{-c\leq j\leq c} \log p(w_{t+j}|w_t)$$

where $p(w_{t+j}|w_t)$ is obtained via the softmax:

$$p(w_{t+j}|w_t) = \frac{\exp^{u_{w_{t+j}}^\top v_{w_t}}}{\sum_{w'}\exp^{u_{w'}^\top v_{w_t}}}$$

where u_w and v_w are the context and target vector representations for word w, respectively, and w' ranges over the full vocabulary (Mikolov et al., 2013a). For our *joint learning* approach, we supplement the skip-gram objective with additional contexts (synonyms or free-associates) from an external data source. In the **sampling** condition, for target word w_t, we modify the objective to include an additional context w^a sampled uniformly from the set of additional contexts A_{w_t}:

$$\frac{1}{T}\sum_{t=1}^{T}\left(J_\theta(w_t) + [w^a \sim \mathcal{U}_{A_{w_t}}]\log p(w^a|w_t)\right)$$

In the **all** condition, all additional contexts for a target word are added at each occurrence:

$$\frac{1}{T}\sum_{t=1}^{T}\left(J_\theta(w_t) + \sum_{w^a\in A_{w_t}} \log p(w^a|w_t)\right)$$

The set of additional contexts A_{w_t} contains the relevant contexts for a word w_t; e.g., for the word *dog*, A_{dog} for the thesaurus is the set of all synonyms of dog in the thesaurus.

2.3 Retrofitting

Faruqui et al. (2015) introduced retrofitting as a post-hoc graph-based learning objective that improves learned word embeddings. We experiment with their method, calling it *graph-based retrofitting*. In addition, we introduce a similar approach that instead uses the same objective function that was used to learn the original skip-gram embeddings. In other words, we first train a standard skip-gram model, and then learn from the additional contexts in a second training stage as if they form a separate corpus:

$$\frac{1}{T}\sum_{t=1}^{T}\sum_{w^a\in A_{w_t}} \log p(w^a|w_t)$$

We call this approach *skip-gram retrofitting*. In all cases, our embeddings have 300 dimensions, which has been found to work well (Mikolov et al., 2013a; Baroni et al., 2014)

3 Results for Intrinsic Evaluation

We compare standard skip-gram embeddings with retrofitted and jointly learned specialized embeddings, as well as with "fitted" embeddings that were randomly initialized and learned only from the additional semantic resource. In each case, the

Table 1: Spearman ρ on a genuine similarity (SimLex-999) and relatedness (MEN) dataset.

training algorithm was run for a single iteration (results from more iterations are presented later).

As shown in Table 1, embeddings that were specialized for similarity using a thesaurus perform better on SimLex-999, and those specialized for relatedness using association data perform better on MEN. Fitting, or learning only from the additional semantic resource without access to raw text, does not perform well. Skip-gram retrofitting with the thesaurus performs best on SimLex-999; joint learning with sampling from the USF norms performs best on MEN, although the two retrofitting approaches are close. There is an interesting difference between the two joint learning approaches: while **sampling** a single free associate as additional context works best for relatedness, presenting **all** additional contexts (synonyms) works best for similarity. In both cases, skip-gram retrofitting matches or outperforms graph-based retrofitting.

More training iterations All the results above were obtained using a single training iteration. When retrofitting, however, it is easy to learn from multiple iterations of the thesaurus or the USF norms. The results are shown in Figure 1, where the dashed lines are the joint learning and standard skip-gram results for comparison with retrofitting scores. As would be expected, too many iterations leads to overfitting on the semantic resource, with performance eventually decreasing after the initial increase. The results show that retrofitting is particularly useful for similarity, as indicated by the large increase in performance on SimLex-999. The highest performance obtained, at 5 iterations, is a Spearman ρ_s correlation of 0.53, which, as far as we know, matches the current state-of-the-art.[4]

For relatedness-specific embeddings, the effect is less clear: joint learning performs comparatively much better. Retrofitting does outperform it, at around 2-10 iterations on the USF norms, but the improvement is marginal. The highest retrofitting score is 0.74; the highest joint learning score is 0.72. Both are highly competitive results on MEN, and outperform e.g. GloVe at 0.71 (Pennington et al., 2014). Joint learning with a thesaurus, however, leads to poor performance on MEN, as expected: the embeddings get dragged away from relatedness and towards similarity.

3.1 Curriculum learning?

The fact that joint learning works better when supplementing raw text input with free associates, but skip-gram retrofitting works better with additional thesaurus information, could be due to *curriculum learning* effects (Bengio et al., 2009). Unlike the USF norms, many of the words from the thesaurus are unusual and have low frequency. This suggests that the thesaurus is more 'advanced' (from the perspective of the learning model) than the USF norms as an information source. Its information may be detrimental to model optimization when encountered early in training (in the joint learning condition) because the model has not acquired the basic concepts on which it builds. However, with retrofitting the model first acquires good representations for frequent words from the raw text, after which it can better understand, and learn from, the information in the thesaurus.

4 Downstream Tasks and Applications

4.1 TOEFL Synonym Task

Unsupervised synonym selection has many applications including the generation of thesauri and other lexical resources from raw text (Kageura et al., 2000). In the well-known TOEFL evaluation (Freitag et al., 2005) models are required to identify true synonyms to question words from a selection of possible answers. To test our models on this task, for each question in the dataset, we rank the multiple-choice answers according to the cosine similarity between their word embeddings and that of the target word, and choose the highest-ranked option.

[4]Hill et al. (2014a) obtain a score of 0.52 using neural translation embeddings.

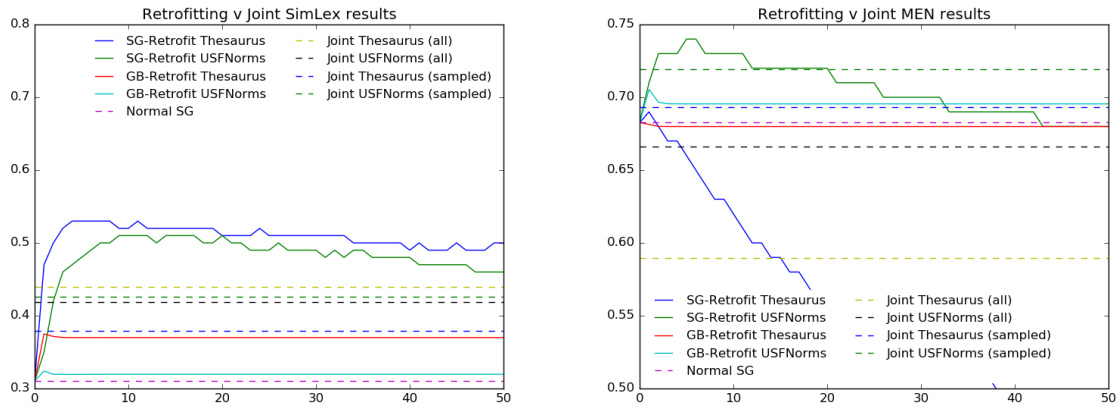

Figure 1: Varying the number of iterations when retrofitting

Method	TOEFL		Doc
Skip-gram	77.50		83.96

SG-Retrofit-Norms	80.00		84.56
SG-Retrofit-Thesaurus	**88.75**		84.55

Table 2: TOEFL synonym selection and document classification accuracy (percentage of correctly answered questions/correctly classified documents).

As Table 2 shows, similarity-specialized embeddings perform much better than standard embeddings and relatedness-specialized embeddings. Retrofitting outperforms joint learning, and skip-gram retrofitting matches or outperforms graph-based retrofitting.

4.2 Document Classification

To investigate how well the various semantic spaces perform on document classification, we first construct document-level representations by summing the vector representations for all words in a given document. After setting aside a small development set for tuning the hyperparameters of the supervised algorithm, we train a support vector machine (SVM) classifier with a linear kernel and evaluate document topic classification accuracy using ten-fold cross-validation.

The results are reported in the rightmost column of Table 2. Relatedness-specialized embeddings perform better on document topic classification than similarity embeddings, except with graph-based retrofitting, which in fact performs below the standard skip-gram model. The joint-learning model with all relevant free association norms presented as context for each target word is the best performing model. The differences in the table appear small, but the dataset contains more than 10,000 documents, so every percentage point is worth more than 100 documents. Joint learning while presenting all relevant association norms for each target word performs best on this task.

5 Conclusion

We have demonstrated the advantage of specializing embeddings for the tasks of genuine similarity and relatedness. In doing so, we compared two retrofitting methods and a joint learning approach. Specialized embeddings outperform standard embeddings by a large margin on instrinsic similarity and relatedness evaluations. We showed that the difference in how embeddings are specialized carries to downstream NLP tasks, demonstrating that similarity embeddings are better at the TOEFL synonym selection task and relatedness embeddings at a document topic classification task. Lastly, we varied the number of iterations that we use for retrofitting, showing that performance could be improved even further by going over several iterations of the semantic resource.

Abstract

Unsupervisedly learned word vectors have proven to provide exceptionally effective features in many NLP tasks. Most common intrinsic evaluations of vector quality measure correlation with similarity judgments. However, these often correlate poorly with how well the learned representations perform as features in downstream evaluation tasks. We present QVEC—a computationally inexpensive intrinsic evaluation measure of the quality of word embeddings based on alignment to a matrix of features extracted from manually crafted lexical resources—that obtains strong correlation with performance of the vectors in a battery of downstream semantic evaluation tasks.[1]

1 Introduction

A major attraction of vector space word representations is that they can be derived from large unannotated corpora, and they are useful as a source of features for downstream NLP tasks that are learned from small amounts of supervision. Unsupervised word vectors have been shown to benefit parsing (Lazaridou et al., 2013; Bansal et al., 2014), chunking (Turian et al., 2010), named entity recognition (Guo et al., 2014) and sentiment analysis (Socher et al., 2013), among others.

Despite their ubiquity, there is no standard scheme for intrinsically evaluating the quality of word vectors: a vector quality is traditionally judged by its utility in downstream NLP tasks. This lack of standardized evaluation is due, in part, to word vectors' major criticism: word vectors are linguistically opaque in a sense that it is still not clear how to interpret individual vector dimensions, and, consequently, it is not clear how to score a non-interpretable representation. Nevertheless, to facilitate development of better word vector models and for better error analysis of word vectors, it is desirable (1) to compare word vector models easily, without recourse to multiple extrinsic applications whose implementation and runtime can be costly; and (2) to understand how features in word vectors contribute to downstream tasks.

We propose a simple intrinsic evaluation measure for word vectors. Our measure is based on component-wise correlations with manually constructed "linguistic" word vectors whose components have well-defined linguistic properties (§2). Since vectors are typically used to provide features to downstream learning problems, our measure favors *recall* (rather than precision), which captures our intuition that meaningless dimensions in induced vector representations are less harmful than important dimensions that are missing. We thus align dimensions in a distributional word vector model with the linguistic dimension vectors to maximize the cumulative correlation of the aligned dimensions (§3). The resulting sum of correlations of the aligned dimensions is our evaluation score. Since the dimensions in the linguistic vectors are linguistically-informed, the alignment provides an "annotation" of components of the word vector space being evaluated.

To show that our proposed score is meaningful, we compare our intrinsic evaluation model to the standard (semantic) extrinsic evaluation benchmarks (§4). For nine off-the-shelf word vector representation models, our model obtains high correlation ($0.34 \leq r \leq 0.89$) with the extrinsic tasks (§5).

2 Linguistic Dimension Word Vectors

The crux of our evaluation method lies in quantifying the similarity between a distributional word vector model and a (gold-standard) linguistic re-

[1] The evaluation script and linguistic vectors described in this paper are available at
https://github.com/ytsvetko/qvec

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2049–2054,
Lisbon, Portugal, 17-21 September 2015.

source capturing human knowledge. To evaluate the semantic content of word vectors, we exploit an existing semantic resource—SemCor (Miller et al., 1993). From the SemCor annotations we construct a set of linguistic word vectors, details are given in the rest of this section; table 1 shows an example of the vectors.

WordNet (Fellbaum, 1998, WN) partitions nouns and verbs into coarse semantic categories known as supersenses (Ciaramita and Altun, 2006; Nastase, 2008).[2] There are 41 supersense types: 26 for nouns and 15 for verbs, for example, NOUN.BODY, NOUN.ANIMAL, VERB.CONSUMPTION, or VERB.MOTION. SemCor is a WordNet-annotated corpus that captures, among others, supersense annotations of WordNet's 13,174 noun lemmas and 5,686 verb lemmas at least once. We construct term frequency vectors normalized to probabilities for all nouns and verbs that occur in SemCor at least 5 times. The resulting set of 4,199 linguistic word vectors has 41 interpretable columns.

WORD	NN.ANIMAL	NN.FOOD	...	VB.MOTION
fish	0.68	0.16	...	0.00
duck	0.31	0.00	...	0.69
chicken	0.33	0.67	...	0.00

Table 1: Oracle linguistic word vectors, constructed from a linguistic resource containing semantic annotations.

3 Word Vector Evaluation Model

We align dimensions of distributional word vectors to dimensions (linguistic properties) in the linguistic vectors described in §2 to maximize the cumulative correlation of the aligned dimensions. By projecting linguistic annotations via the alignments, we also obtain plausible annotations of dimensions in the distributional word vectors. In this section, we formally describe the model, which we call the QVEC.

Let the number of common words in the vocabulary of the distributional and linguistic word vectors be N. We define, the distributional vector matrix $\mathbf{X} \in \mathbb{R}^{D \times N}$ with every row as a dimension vector $\mathbf{x} \in \mathbb{R}^{1 \times N}$. D denotes word vector dimensionality. Similarly, $\mathbf{S} \in \mathbb{R}^{P \times N}$ is the linguistic property matrix with every row as a linguistic property vector $\mathbf{s} \in \mathbb{R}^{1 \times N}$. P denotes linguistic properties obtained from a manually-annotated linguistic resource. We obtain an alignment between the word vector dimensions and the linguistic dimensions which maximizes the correlation between the aligned dimensions of the two matrices. This is 1:n alignment: one distributional dimension is aligned to at most one linguistic property, whereas one linguistic property can be aligned to n distributional dimensions; see figure 1.

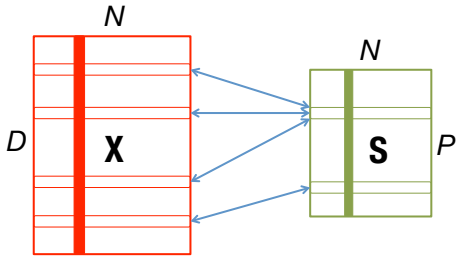

Figure 1: The filled vertical vectors represent the word vector in the word vector matrix $\mathbf{X}$ and the linguistic property matrix $\mathbf{S}$. The horizontal hollow vectors represent the "distributional dimension vector" in $\mathbf{X}$ and "linguistic dimension vector" in $\mathbf{S}$. The arrows show mapping between distributional and linguistic vector dimensions.

Let $\mathbf{A} \in \{0,1\}^{D \times P}$ be a matrix of alignments such that $a_{ij} = 1$ iff $\mathbf{x}_i$ is aligned to $\mathbf{s}_j$, otherwise $a_{ij} = 0$. If $r(\mathbf{x}_i, \mathbf{s}_j)$ is the Pearson's correlation between vectors $\mathbf{x}_i$ and $\mathbf{s}_j$, then our objective is defined as:

$$\text{QVEC} = \max_{\mathbf{A} | \sum_j a_{ij} \leq 1} \sum_{i=1}^{L} \sum_{j=1}^{P} r(\mathbf{x}_i, \mathbf{s}_j) \times a_{ij} \quad (1)$$

The constraint $\sum_j a_{ij} \leq 1$, warrants that one distributional dimension is aligned to at most one linguistic dimension. The total correlation between two matrices QVEC is our intrinsic evaluation measure of a set of word vectors relative to a set of linguistic properties.

The QVEC's underlying hypothesis is that dimensions in distributional vectors correspond to linguistic properties of words. It is motivated, among others, by the effectiveness of word vectors in linear models implying that linear combinations of features (vector dimensions) produce relevant, salient content. Via the alignments a_{ij} we obtain labels on dimensions in the distributional word vectors. The magnitude of the correlation $r(\mathbf{x}_i, \mathbf{s}_j)$ corresponds to the annotation confidence: the higher the correlation, the more salient the linguistic content of the dimension. Clearly, dimensions in the linguistic matrix S do not capture every possible linguistic property, and low correlations often correspond to the missing information in the linguistic matrix. Thus, QVEC is a recall-oriented measure: highly-

[2] Supersenses are known as "lexicographer classes" in WordNet documentation, `http://wordnet.princeton.edu/man/lexnames.5WN.html`

correlated alignments provide evaluation and annotation of vector dimensions, and missing information or noisy dimensions do not significantly affect the score since the correlations are low.

4 Experimental Setup

4.1 Word Vector Models

To test the QVEC, we select a diverse suite of popular/state-of-the-art word vector models. All vectors are trained on 1 billion tokens (213,093 types) of English Wikipedia corpus with vector dimensionality 50, 100, 200, 300, 500, 1000.

CBOW and Skip-Gram (SG). The WORD2VEC tool (Mikolov et al., 2013) is fast and widely-used. In the SG model, each word's Huffman code is used as an input to a log-linear classifier with a continuous projection layer and words within a given context window are predicted. In the CBOW model a word is predicted given the context words.[3]

CWindow and Structured Skip-Gram (SSG). Ling et al. (2015b) propose a syntactic modification to the WORD2VEC models that accounts for word order information, obtaining state-of-the-art performance in syntactic downstream tasks.[4]

CBOW with Attention (Attention). Ling et al. (2015a) further improve the WORD2VEC CBOW model by employing an attention model which finds, within the contextual words, the words that are relevant for each prediction. These vectors have been shown to benefit both semantically and syntactically oriented tasks.

GloVe. Global vectors for word representations (Pennington et al., 2014) are trained on aggregated global word-word co-occurrence statistics from a corpus, and the resulting representations show interesting linear substructures of the vector space.[5]

Latent Semantic Analysis (LSA). We construct word-word co-occurrence matrix $\mathbf{X}$; every element in the matrix is the pointwise mutual information between the two words (Church and Hanks, 1990). Then, truncated singular value decomposition is applied to factorize $\mathbf{X}$, where we keep the k largest singular values. Low dimensional word vectors of dimension k are obtained from $\mathbf{U_k}$ where $\mathbf{X} \approx \mathbf{U_k}\Sigma\mathbf{V_k}^\mathsf{T}$ (Landauer and Dumais, 1997).

GloVe+WN, GloVe+PPDB, LSA+WN, LSA+PPDB. We use retrofitting (Faruqui et al., 2015) as a post-processing step to enrich GloVe and LSA vectors with semantic information from WordNet and Paraphrase database (PPDB) (Ganitkevitch et al., 2013).[6]

4.2 Semantic Evaluation Benchmarks

We compare the QVEC to six standard extrinsic semantic tasks for evaluating word vectors; we now briefly describe the tasks.

Word Similarity. We use three different benchmarks to measure word similarity. The first one is the **WS-353** dataset (Finkelstein et al., 2001), which contains 353 pairs of English words that have been assigned similarity ratings by humans. The second is the **MEN** dataset (Bruni et al., 2012) of 3,000 words pairs sampled from words that occur at least 700 times in a large web corpus. The third dataset is **SimLex-999** (Hill et al., 2014) which has been constructed to overcome the shortcomings of WS-353 and contains 999 pairs of adjectives, nouns and verbs. Word similarity is computed using cosine similarity between two words and the performance of word vectors is computed by Spearman's rank correlation between the rankings produced by vector model against the human rankings.[7]

Text Classification. We consider four binary categorization tasks from the 20 Newsgroups **(20NG)** dataset.[8] Each task involves categorizing a document according to two related categories with training/dev/test split in accordance with Yogatama and Smith (2014). For example, a classification task is between two categories of Sports: baseball vs hockey. We report the average classification accuracy across the four tasks. Our next downstream semantic task is the sentiment analysis task **(Senti)** (Socher et al., 2013) which is a binary classification task between positive and negative movie reviews using the standard training/dev/test split and report accuracy on the test set. In both cases, we use the average of the word vectors of words in a document (and sentence, respectively) and use them as features in an ℓ_2-regularized logistic regression classifier. Finally, we evaluate vectors on the metaphor detection **(Metaphor)** (Tsvetkov et al.,

[7] We employ an implementation of a suite of word similarity tasks at wordvectors.org (Faruqui and Dyer, 2014).

[8] http://qwone.com/~jason/20Newsgroups

2014a).[9] The system uses word vectors as features in a random forest classifier to label adjective-noun pairs as literal/metaphoric. We report the system accuracy in 5-fold cross validation.

5 Results

To test the efficiency of QVEC in capturing the semantic content of word vectors, we evaluate how well QVEC's scores correspond to the scores of word vector models on semantic benchmarks. We compute the Pearson's correlation coefficient r to quantify the linear relationship between the scorings. We begin with comparison of QVEC with one extrinsic task—Senti—evaluating 300-dimensional vectors.

Model	QVEC	Senti
CBOW	40.3	90.0
SG	35.9	80.5
CWindow	28.1	76.2
SSG	40.5	81.2
Attention	40.8	80.1
GloVe	34.4	79.4
GloVe+WN	42.1	79.6
GloVe+PPDB	39.2	79.7
LSA	19.7	76.9
LSA+WN	29.4	77.5
LSA+PPDB	28.4	77.3
Correlation (r)	**0.87**	

Table 2: Intrinsic (QVEC) and extrinsic scores of the 300-dimensional vectors trained using different word vector models and evaluated on the Senti task. Pearson's correlation between the intrinsic and extrinsic scores is $r = 0.87$.

As we show in table 2, the Pearson's correlation between the intrinsic and extrinsic scores is $r = 0.87$. To account for variance in WORD2VEC representations (due to their random initialization and negative sampling strategies, the representations are different for each run of the model), and to compare QVEC to a larger set of vectors, we now train three versions of vector sets per model. This results in 21 word vector sets: three vector sets per five WORD2VEC models plus GloVe, LSA, and retrofitting vectors shown in table 2. The Pearson's correlation computed on the extended set of comparison points (in the same experimental setup as in table 2) is $r = 0.88$. In the rest of this section we report results on the extended suite of word vectors.

We now extend the table 2 results, and show correlations between the QVEC and extrinsic scores across all benchmarks for 300-dimensional vectors. Table 3 summarizes the results. The QVEC obtains high positive correlation with all the semantic tasks.

Table 4 shows, for the same 300-dimensional vectors, that QVEC's correlation with the downstream text classification tasks is on par with or higher than the correlation between the word similarity and text classification tasks. Higher correlating methods—in our experiments, QVEC and MEN—are better predictors of quality in downstream tasks.

	20NG	Metaphor	Senti
WS-353	0.55	0.25	0.46
MEN	**0.76**	0.49	0.55
SimLex	0.56	0.44	0.51
QVEC	0.74	**0.75**	**0.88**

Table 4: Pearson's correlations between word similarity/QVEC scores and the downstream text classification tasks.

Next, we measure correlations of QVEC with the extrinsic tasks across word vector models with different dimensionality. The results are shown in figure 2.

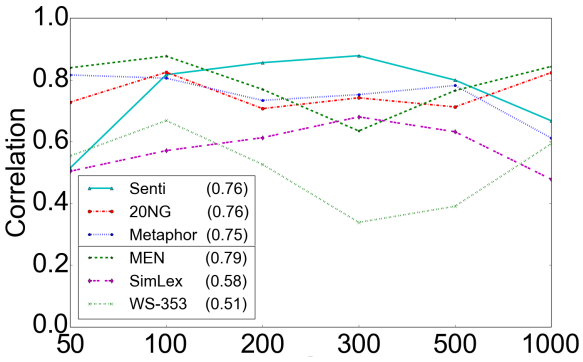

Figure 2: Pearson's correlation between QVEC scores and the semantic benchmarks across word vector models on vectors of different dimensionality. The scores at dimension 300 correspond to the results shown in table 3. The scores in the legend show average correlation across dimensions.

To summarize, we observe high positive correlation between QVEC and the downstream tasks, consistent across the tasks and across different models with vectors of different dimensionalities.

Since QVEC favors recall over precision, larger numbers of dimensions will *ceteris paribus* result in higher scores—but not necessarily higher correlations with downstream tasks. We therefore impose the restriction that QVEC only be used to compare vectors of the same size, but we now show that its correlation with downstream tasks is stable, conditional on the size of the vectors being compared. We aggregate rankings by individual

downstream tasks into a global ranking using the Kemeny–Young rank aggregation algorithm, for each dimension separately (Kemeny, 1959). The algorithm finds a ranking which minimizes pairwise disagreement of individual rankers. Table 5 shows Spearman's rank correlation between the rankings produced by the QVEC and the Senti task/the aggregated ranking. For example, ranking of 300-dimensional models produced by Senti is *{SSG, CBOW, SG, Attention, GloVe+PPDB, GloVe+WN, GloVe, LSA+WN, LSA+PPDB, LSA, CWindow}*, and the QVEC's ranking is *{GloVe+WN, Attention, SSG, CBOW, GloVe+PPDB, SG, GloVe, LSA+WN, LSA+PPDB, CWindow, LSA}*. The Spearman's ρ between the two rankings is 0.78. We note, however, that there is a considerable variation between rankings across all models and across all dimensions, for example the SimLex ranking produced for the same 300-dimensional vectors is *{GloVe+PPDB, GloVe+WN, SG, LSA+PPDB, SSG, CBOW, Attention, CWindow, LSA+WN, GloVe, LSA}*, and ρ(Senti, SimLex) $= 0.46$. In a recent related study, Schnabel et al. (2015) also observe that existing word similarity and text categorization evaluations yield different orderings of word vector models. This task-specifity of rankings emphasizes the deficiency of evaluating word vector models solely on downstream tasks, and the need of a standardized intrinsic evaluation approach that quantifies linguistic content of word vectors.

6 Future Work

Aligning dimensions of linguistic and distributional vectors enables projection of linguistic annotations via the alignments, and thereby facilitates qualitative analysis of individual dimensions in distributional vectors. Albeit noisy, we find correspondence between the projected labels of distributional columns and the column content. For example, in the 50-dimensional SG model top-10 ranked words in a dimension aligned to NOUN.BODY with r=0.26 are *amputated, sprained, palsy, semenya, lacerations, genital, cervical, concussion, congenital, abdominal*. This interesting by-product of our method will be addressed in future work.

While we experiment with linguistic vectors capturing semantic concepts, our methodology is generally applicable to other linguistic resources (Faruqui and Dyer, 2015). For example, part-of-speech annotations extracted from a treebank would yield linguistic vectors capturing syntactic content of vectors. Thus, QVEC can be used as a task-specific evaluator; we will investigate this in future work.

A useful property of supersenses (features in our linguistic vectors) is that they are stable across languages (Schneider et al., 2013; Tsvetkov et al., 2014b). Cross-lingual vector evaluation and evaluation of multilingual word vectors with QVEC is thus an additional promising research avenue.

7 Conclusion

We propose a method for intrinsic evaluation of word vectors which shows strong relationship—both linear and monotonic—with the scores/rankings produced by the downstream tasks.

Abstract

We present a higher-order inference system based on a formal compositional semantics and the wide-coverage CCG parser. We develop an improved method to bridge between the parser and semantic composition. The system is evaluated on the FraCaS test suite. In contrast to the widely held view that higher-order logic is unsuitable for efficient logical inferences, the results show that a system based on a reasonably-sized semantic lexicon and a manageable number of non-first-order axioms enables efficient logical inferences, including those concerned with generalized quantifiers and intensional operators, and outperforms the state-of-the-art first-order inference system.

1 Introduction

Entailment relations are of central importance in the enterprise of both formal and computational semantics. Traditionally, formal semanticists have concentrated on a relatively small set of linguistic inferences. However, since the emergence of statistical parsers based on sophisticated syntactic theories (Clark and Curran, 2007), an open domain system has been developed that supports certain degree of robust semantic interpretation with wide coverage (Bos et al., 2004). It is then reasonable to expect that a state-of-the-art formal semantics provides an accurate computational basis of natural language inferences.

However, there are still obstacles in the way of achieving this goal. One is that the statistical parsers on which semantic interpretations rely do not necessarily reflect the best syntactic analysis as assumed in the formal semantics literature (Honnibal et al., 2010). Another persistent problem is the gap between the logics employed in the two communities; while it is generally assumed among formal semanticists that adequate semantic representations for natural language demand higher-order logic or type theory (Carpenter, 1997), the dominant view in computational linguistics is that inferences based on higher-order logic are hopelessly inefficient for practical applications (Bos, 2009a). Accordingly, it is claimed that some approximation of higher-order representations in terms of first-order logic (Hobbs, 1985), or a more efficient "natural logic" system based on surface structures is needed. However, it is often not a trivial task to give an approximation of rich higher-order information within a first-order language (Pulman, 2007). Moreover, the coverage of existing natural logic systems is limited to single-premise inferences (MacCartney and Manning, 2008).

In this paper, we first present an improved compositional semantics that fills the gap between the parser syntax and a composition derivation. We then develop an inference system that is capable of higher-order inferences in natural languages. We combine a state-of-the-art higher-order proof system (Coq) with a wide-coverage parser based on a modern syntactic theory (Combinatory Categorial Grammar, CCG). The system is designed to handle multi-premise inferences as well as single-premise ones.

We test our system on the FraCaS test suite (Cooper et al., 1994), which is suitable for evaluating the linguistic coverage of an inference system. The experiments show that our higher-order system outperforms the state-of-the-art first-order system with respect to the speed and accuracy of making logical inferences.

2 CCG and Compositional Semantics

As an initial step of compositional semantics, we use the C&C parser (Clark and Curran, 2007), a statistical CCG parser trained on CCGbank (Hockenmaier and Steedman, 2007). Parser out-

puts are mapped onto semantic representations in a standard way (Bos, 2008), using λ-calculus as an interface between syntax and semantics.

The strategy we use to build a semantic lexicon is similar to that of Bos et al. (2004). A lexical entry for each open word class consists of a syntactic category in CCG (possibly with syntactic features) and a semantic representation encoded as a λ-term. Fig. 1 gives an example.[1] For a limited number of closed words such as logical or functional expressions, a λ-term is directly assigned to a surface form (see Fig. 2). The output formula is obtained by combining each λ-term in accordance with meaning composition rules and then by applying β-conversion.

There is a non-trivial gap between the parser output and the standard CCG-syntax as presented in Steedman (2000). Due to this gap, it is not straightforward to obtain desirable semantic representations for a wide range of constructions. One major difference from the standard CCG-syntax is the treatment of post-NP modifiers; for instance, the relative clause *who works* is assigned not the category $N\backslash N$, but the category $NP\backslash NP$, which applies to the whole NP. To derive correct truth-conditions for quantificational sentences, we assign to determiners a semantic term having an extra predicate variable as shown in Fig. 2, namely, $\lambda F\lambda G\lambda H.\forall x(Fx \wedge Gx \rightarrow Hx)$, in a similar way to the continuation semantics for event predicates (Bos, 2009b; Champollion, 2015). The extra predicate variable G can be filled by the semantically empty predicate $\lambda x.\mathsf{True}$ in a verb phrase (see Fig. 1). Fig. 3 gives an example derivation.

Note that the changes in the lexical entries as illustrated in Fig. 1 and Fig. 2 are made for the correct semantic parsing, namely, the compositional

[1]Here we use a non-standard semantics for intransitive verbs. We will explain it in the next paragraph.

Examples	Semantic Types
most	$(\mathsf{E}\rightarrow\mathsf{Prop})\rightarrow(\mathsf{E}\rightarrow\mathsf{Prop})\rightarrow\mathsf{Prop}$
might	$\mathsf{Prop}\rightarrow\mathsf{Prop}$
true	$\mathsf{Prop}\rightarrow\mathsf{Prop}$
manage	$\mathsf{Prop}\rightarrow\mathsf{E}\rightarrow\mathsf{Prop}$
believe	$\mathsf{Prop}\rightarrow\mathsf{E}\rightarrow\mathsf{Prop}$

Table 1: A classification of key linguistic elements having higher-order denotations.

derivation of semantic representations. Usually, inferences are conducted on those output semantic representations in which additional complexities, such as lambda operators and extra predicate variables, disappear. Accordingly, the changes in the lexical entries do not affect the efficiency of inferences.

The present analysis of post NP-modifiers can also handle non-restrictive relative clauses such as "*the president, who ...*". In this case, the modifier "*who ...*" can be taken to apply to the whole NP *the president*, thus its syntactic category can be regarded as $NP\backslash NP$, not as $N\backslash N$. Thus, although the $NP\backslash NP$ analysis of relative clauses is a non-standard one, it has an advantage in that it provides a unified treatment of restrictive and non-restrictive relative clauses.

3 Representation and Inference in HOL

We present a higher-order representation language and describe apparently higher-order phenomena that have received attention in formal semantics.

3.1 Semantic representations in HOL

We use the language of higher-order logic (HOL) with two basic types, E for entities and Prop for propositions. Here we distinguish between propositions and truth-values, as is standard in modern type theory (Ranta, 1994; Luo, 2012). Key higher-order constructs are summarized in Table 1.[2] A first-order language can be taken as a fragment of this language. Thus, adopting a higher-order language does not lead to the loss of the expressive power of the first-order language.

Apart from sub-sentential utterances such as short answers to *wh*-questions (Ginzburg, 2005), there are important constructions that are naturally

[2]We write a function from objects of type A to objects of type B as $A\rightarrow B$. Here $\rightarrow$ is right-associative: $A\rightarrow B\rightarrow C$ means $A\rightarrow(B\rightarrow C)$. We use the symbol $\rightarrow$ both for logical implication and function-type constructor, following the so-called Curry-Howard isomorphism (Carpenter, 1997).

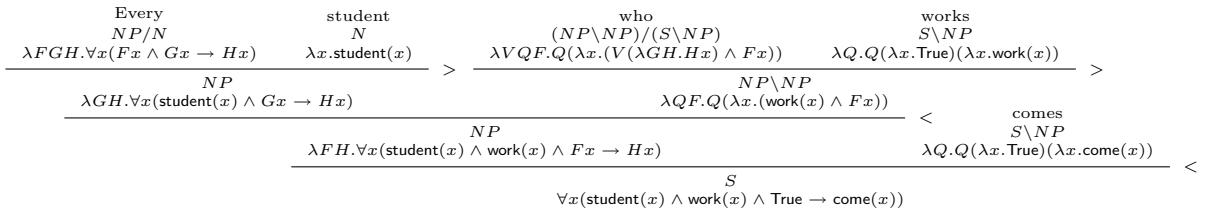

Figure 3: A CCG derivation of the semantic representation for the sentence *Every student who works comes*. $\lambda FGH.X$ is an abbreviation for $\lambda F \lambda G \lambda H.X$. "True" denotes the tautology, hence the final formula is equivalent to $\forall x(\mathsf{student}(x) \wedge \mathsf{work}(x) \rightarrow \mathsf{come}(x))$.

represented in higher-order languages.[3]

Generalized quantifiers A classical example of non-first-orderizable expressions is a proportional generalized quantifier like *most* and *half of* (Barwise and Cooper, 1981). Model-theoretically, they denote relations between sets. We represent them as a two-place higher-order predicate taking first-order predicates as arguments. For instance, *Most students work* is represented as follows.

(1) $\mathsf{most}(\lambda x.\mathsf{student}(x), \lambda x.\mathsf{work}(x))$

Here, most is a higher-order predicate in the sense that it takes first-order predicates $\lambda x.\mathsf{student}(x)$ and $\lambda x.\mathsf{work}(x)$ as arguments. We take the entailment patterns governing *most* as axioms, along the same lines of natural logic and monotonicity calculus (Icard and Moss, 2014), where determiners are taken as primitive two-place operators.

Standard quantifiers like *every* and *some* could also be treated as binary operators in the same way as the binary most in (1). But we choose to adopt the first-order decomposition in such cases (see Fig. 2 for the lexical entry of *every*).

Modals Modal auxiliary expressions like *might*, *must* and *can* are represented as unary sentential operators. For instance, the sentence *Some student might come* is represented as:

(2) $\exists x(\mathsf{student}(x) \wedge \mathsf{might}(\mathsf{come}(x)))$.

An important inference role of such a modal operator is to distinguish modal contexts from actual contexts and thus block an inference from one context to another (might A does not entail A).

Alternatives to the higher-order approach include the first-order decomposition of modal operators using world variables (Blackburn et al., 2001) and the first-order modal semantic representations implemented in Boxer (Bos, 2005). We prefer the higher-order approach, because the first-order approaches introduce additional quantifiers and variables at the level of the semantic representations on which one makes inferences.

Veridical and anti-veridical predicates A sentential operator O is *veridical* if $O(A)$ entails A, and *anti-veridical* if $O(A)$ entails $\neg A$. While modal auxiliary verbs like *might* are neither veridical nor anti-veridical, there is a class of expressions licensing these patterns of inference. Typical examples are adjectives taking an embedded proposition, such as *true/correct* and *false/incorrect*. Note that sentences like *Everything/what he said is false* involve a quantification over propositions, which is problematic for the first-order approach.

The so-called implicative verbs like *manage* and *fail* (Nairn et al., 2006) are also an instance of this class. For example, *Some student manages to come* is formalized as

(3) $\exists x(\mathsf{student}(x) \wedge \mathsf{manage}(x, \mathsf{come}(x)))$

where *manage* is a veridical predicate taking a proposition as the second argument; it licenses an inference to $\exists x(\mathsf{student}(x) \wedge \mathsf{come}(x))$.

Attitude verbs A wide range of propositional attitude verbs such as *believe* and *hope* are similar to modals in that they do not license an inference from attitude contexts to actual contexts. But factives like *know* and *remember* are an exception; they are veridical.[4]

A first-order translation can be given along the lines of Hintikka (1962). (4) is translated as (5).

(4) $\mathsf{know}(\mathsf{john}, \exists x(\mathsf{student}(x) \wedge \mathsf{come}(x)))$

(5) $\forall w_1(R_{\mathsf{john}} w_0\, w_1 \rightarrow \exists x(\mathsf{student}(w_1, x) \wedge \mathsf{come}(w_1, x)))$

[3] See also Blackburn and Bos (2005) for some discussion on inferences that go beyond first-order logic.

[4] Factive predicates show the important inference patterns known as *presupposition projection* (van der Sandt, 1992), which are beyond the scope of this paper.

Inference pattern	Axiom
Existential import	$\forall F \forall G\,(\mathsf{most}(F,G) \rightarrow \exists x(Fx \wedge Gx))$
Conservativity	$\forall F \forall G\,(\mathsf{most}(F,G) \rightarrow \mathsf{most}(F, \lambda x.(Fx \wedge Gx)))$
Monotonicity (right-upward)	$\forall F \forall G \forall H\,(\mathsf{most}(F,G) \rightarrow (\forall x(Gx \rightarrow Hx) \rightarrow \mathsf{most}(F,H)))$
Veridicality	$\forall P(\mathsf{true}(P) \rightarrow P)$ $\forall x \forall P(\mathsf{manage}(x,P) \rightarrow P)$ $\forall x \forall P(\mathsf{know}(x,P) \rightarrow P)$
Anti-veridicality	$\forall P(\mathsf{false}(P) \rightarrow \neg P)$ $\forall x \forall P(\mathsf{fail}(x,P) \rightarrow \neg P)$

Table 2: Axioms for non-first-order constructions.

However, one drawback is that the compositional semantics becomes complicated, so we prefer the non-decomposition approach for attitude verbs.

3.2 Inferences in HOL

Following Chatzikyriakidis and Luo (2014), we use a proof-assistant Coq (Castéran and Bertot, 2004) to implement a specialized prover for higher-order features in natural languages, and combine it with efficient first-order inferences. We use Coq's built-in tactics for first-order inferences. Coq also has a language called *Ltac* for user-defined automated tactics (Delahaye, 2000). The additional axioms and tactics specialized for natural language constructions are written in Ltac. We ran Coq fully automated, by feeding to its interactive mode a set of predefined tactics combined with user-defined proof-search tactics.

Table 2 shows the axioms we implemented. Modals and non-veridical predicates (by which we mean predicates that are neither veridical nor anti-veridical) do not have particular axioms, with the consequence that actual and hypothetical contexts are correctly distinguished.

4 Experiments

We evaluated our system on the FraCaS test suite (Cooper et al., 1994), a set of entailment problems that is designed to evaluate theories of formal semantics.[5] We used the version provided by MacCartney and Manning (2007). The whole data set is divided into nine sections, each devoted to linguistically challenging problems. Of these, we used six sections, excluding three sections (nominal anaphora, ellipsis and temporal reference) that involve a task of resolving context-dependency, a task beyond the scope of this paper. Each problem consists of one or more premises, followed by a hypothesis. There are three types of answer: *yes* (the premise set entails the hypothesis), *no* (the premise set entails the negation of the hypothesis), and *unknown* (the premise set entails neither the hypothesis nor its negation). Fig. 4 shows some examples.

[5]Our system will be publicly available at `https://github.com/mynlp/ccg2lambda`.

Section	#	Ours	Nut	L&S 13	Tian 14
Quantifiers	74	.77	.53	.62	**.80**
Plurals	33	**.67**	.52	–	–
Adjectives	22	**.68**	.32	–	–
Comparatives	31	**.48**	.45	–	–
Verbs	8	.62	.62	–	–
Attitudes	13	**.77**	.46	–	–
Total	181	**.69**	.50	–	–

Table 3: Accuracy on the FraCaS test suite. The first column shows the number of problems. Of the total 188 problems, we excluded seven problems that lack a well-defined answer.

Currently, our system has 57 templates for general syntactic categories and 80 lexical entries for closed words. In a similar way to Bos et al. (2004), closed words are confined to a limited range of logical and functional expressions such as quantifiers and connectives. These templates and lexical entries are not specific with respect to the FraCaS test suite. We use WordNet (Miller, 1995) as the knowledge base for antonymy; logical axioms relevant to given inferences are extracted from this knowledge base.

We compared our system with the state-of-the-art CCG-based first-order system Boxer (Bos, 2008), which is one of the most well-known logic-based approaches to textual entailment. We used the Nutcracker system based on Boxer that utilizes a first-order prover (*Bliksem*) and a model builder (*Mace*) with the option enabling access to WordNet. We did not use the option enabling modal semantics, since it did not improve the results. All experiments were run on a 4-core@1.8Ghz, 8GB RAM and SSD machine with Ubuntu.

Experimental results are shown in Table 3. Our system improved on Nutcracker. We set a time-out of 30 seconds, after which we output the label "unknown". Nutcracker timed-out in one third of the problems (57 out of 181), whereas there was no time-out in our system.

Table 4 shows parse times and inference times for the FraCaS test suite. The inference speed

fracas-067

Our system with higher-order inference	3.72
Our system with higher-order rules ablated	3.46
Nutcracker with first-order inference (first-order prover + model builder)	11.23

Table 4: Comparison of inference time on the FraCaS test suite. CCG parsing is common to both our system and Nutcracker.

of our system is significantly higher than that of Nutcracker. Our system's total accuracy with higher-order rules is 69%, and drops to 59% when ablating the higher-order rules.

We are aware of two other systems tested on FraCaS that are capable of multiple-premise inferences: the CCG-based first-order system of Lewis and Steedman (2013) and the dependency-based compositional semantics of Tian et al. (2014). These systems were only evaluated on the Quantifier section of FraCaS. As shown in Table 3, our results improve on the former and are comparable with the latter.

Other important studies on FraCaS are those based on natural logic (MacCartney and Manning, 2008; Angeli and Manning, 2014). These systems are designed solely for single-premise inferences and hence are incapable of handling the general case of multiple-premise problems (which cover about 45% of the problems in FraCaS). Our system improves on these natural-logic-based systems by making multiple-premise inferences as well.

Main errors we found are due to various parse errors caused by the CCG parser, including the failure to handle multiwords like *a lot of*. The performance of our system will be further improved with correct syntactic analyses. Our experiments on FraCaS problems do not constitute an evaluation on real texts nor on unseen test data. Note, however, that a benefit of using a linguistically controlled set of entailment problems is that one can check not only whether, but also *how* each semantic phenomenon is handled by the system. In contrast to the widely held view that higher-order logic is less useful in computational linguistics, our results demonstrate the logical capacity of a higher-order inference system integrated with the CCG-based compositional semantics.

5 Conclusion

We have presented a framework for a compositional semantics based on the wide-coverage CCG parser, combined with a higher-order inference system. The experimental results on the FraCaS test suite have shown that a reasonable number of lexical entries and non-first-order axioms enable various logical inferences in an efficient way and outperform the state-of-the-art first-order system. Future work will focus on incorporating a robust model of lexical knowledge (Lewis and Steedman, 2013; Tian et al., 2014) to our framework.

Abstract

We present a multilingual corpus of Wikipedia and Twitter texts annotated with FRAMENET 1.5 semantic frames in nine different languages, as well as a novel technique for weakly supervised cross-lingual frame-semantic parsing. Our approach only assumes the existence of linked, comparable source and target language corpora (e.g., Wikipedia) and a bilingual dictionary (e.g., Wiktionary or BABELNET). Our approach uses a truly interlingual representation, enabling us to use the *same* model across all nine languages. We present average error reductions over running a state-of-the-art parser on word-to-word translations of 46% for target identification, 37% for frame identification, and 14% for argument identification.

1 Introduction

Frame-semantic parsing is the task of automatically finding semantically salient targets in text, disambiguating the targets by assigning a sense (frame) to them, identifying their arguments, and labeling these arguments with appropriate roles. The FRAMENET 1.5 lexicon[1] provides a fixed repository of semantic frames and roles, which we use in the experiments below.

Several learning and parsing algorithms have been developed for frame-semantic analysis (Johansson and Nugues, 2007; Das et al., 2014; Täckström et al., 2015), and frame semantics has been successfully applied to question-answering (Shen and Lapata, 2007), information extraction (Surdeanu et al., 2003) and knowledge extraction (Søgaard et al., 2015b).

[1] https://framenet.icsi.berkeley.edu/

In contrast to Propbank-style semantic-role labeling (Titov and Klementiev, 2012), only very limited frame-semantic resources exist for languages other than English. We therefore focus on *multilingual* or cross-language frame-semantic parsing, leveraging resources for English and other major languages to build *any*-language parsers. We stress that we learn frame-semantic parsing models that can be applied to *any* language, rather than cross-lingual transfer models for specific target languages. Our approach relies on inter-lingual word embeddings (Søgaard et al., 2015a), which are built from topic-aligned documents. Word embeddings have previously been used for monolingual frame-semantic parsing by Hermann et al. (2014).

Contributions This paper makes the following three contributions. We present a new multilingual frame-annotated corpus covering five topics, two domains (Wikipedia and Twitter), and nine languages. We implement a simplified version of the frame-semantic parser introduced in Das et al. (2014). Finally, we show how to modify this parser to learn any-language frame-semantic parsing models using inter-lingual word embeddings (Søgaard et al., 2015a).

2 Data annotation

Figure 1 depicts a FRAMENET 1.5 frame-semantic analysis of a German sentence from Wikipedia. The annotator marked two words, *Idee* and *kam*, as targets. In frame-semantic parsing, target identification is the task of deciding which words (i.e. targets) trigger FRAMENET frames. Frame identification is the problem of disambiguating targets by labeling them with frames, e.g., COGITATION or COMING_UP_WITH. Argument identification is the problem of identifying the arguments of frames, e.g., *Idee* for COMING_UP_WITH.

We had linguistically trained students anno-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2062–2066,
Lisbon, Portugal, 17-21 September 2015.

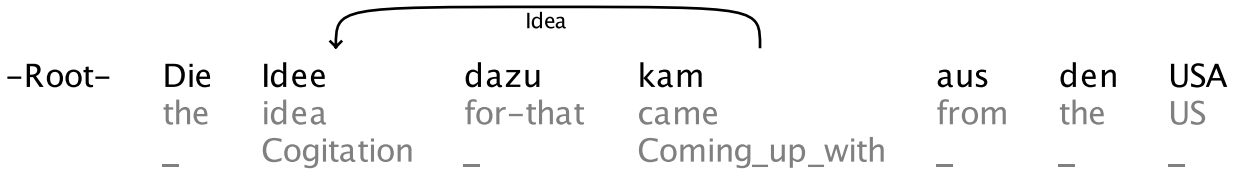

Figure 1: Frame semantic annotation from the German Wikipedia data (Women's Rights)

tate about 200 sentences from Wikipedia and 200 tweets each in their native language. The data was pre-annotated by obtaining all English translation equivalents of the source language words through BABELNET[2], finding associated frames in the FRAMENET 1.5 training data. We presented annotators with *all* frames that could be triggered by any of the target word's translations. Both data from Wikipedia and Twitter cover the same five topics: Google, Angelina Jolie, Harry Potter, Women's Rights, and Christiano Ronaldo. The topics were chosen to guarantee coverage for all nine languages, both in Wikipedia and Twitter. Our corpus, which covers nine languages, is publicly available at `https://github.com/andersjo/any-language-frames` The languages we cover are Bulgarian (BG), Danish (DA), German (DE), Greek (EL), English (EN), Spanish (ES), French (FR), Italian (IT) and Swedish (SV). English is included as a sanity check of our cross-lingual annotation setup.

The English, Danish, and Spanish datasets were doubly-annotated in order to compute inter-annotator agreement (IAA). The overall target identification IAA was 82.4% F_1 for English, 81.6% for Danish, and 80.0% for Spanish. This is lower than a similar monolingual annotation experiment recently reporting target identification IAA at 95.3% (Søgaard et al., 2015b). The frame identification IAA scores were also higher in that study, at 84.5% and 78.1% F_1. The drop in agreement seems mostly due to pre-tagging errors caused by erroneous or irrelevant word-to-word translations. The Spanish data has the lowest agreement score.

We compute test-retest reliability of our annotations as the correlation coefficient (Pearson's ρ) between the two annotations. In Cronbach's α internal consistency table, the cut-off for acceptable reliability is 0.7. While there is certainly noise in our annotations, these are still consistently above the Cronbach cut-off. Also, we evaluate our models across 18 datasets, covering nine different languages with two domains each; although for readability, we combine the Wiktionary and Twitter datasets for each language below.

[2] `http://babelnet.org/`

	Language		
	EN	DA	ES
Twitter and Wikipedia			
TARGET	82.4	81.6	80.0
FRAME	73.5	72.3	60.8
ARGUMENT	70.7	55.0	83.5
Test-retest reliability	74.4	78.6	71.8
Twitter			
TARGET	79.1	80.7	80.5
FRAME	68.8	72.3	58.6
ARGUMENT	70.0	86.2	57.5
Test-retest reliability	71.0	78.7	73.1

Table 1: Inter-annotator agreement (F_1 in %)

The relatively low reliability compared to previous annotation efforts is due to the cross-lingual pre-annotation step, which was necessary to make annotation feasible. All languages, including English, have been pre-annotated using BABELNET. We expect annotators to only assign frames when meaningful frames can be assigned, so the main source of error is that the pre-annotation may exclude valid frames. Hence, we will not only report F_1-scores in our evaluations, but also precision, since recall may be misleading, penalizing for frames that could not be chosen by the annotators.

3 Frame semantic parsing

3.1 Target identification

Following Das et al. (2014), we use part-of-speech heuristics to identify the words that evoke frames (target words). Frame-evoking words typically belong to a narrow range of part of speech. Therefore, we only consider words as target candidates

when tagged with one of the top k part-of-speech tags most commonly seen as targets in the training set. The k parameter is optimized to maximize F_1 on our development language, Spanish, where we found $k = 7$.[3] Surviving candidates are then translated into English by mapping the words into multi-lingual BABELNET synsets, which represent sets of words with similar meaning across languages. All English words in the BABELNET synsets are considered possible translations. If any of the translations are potential targets in FRAMENET 1.5, the current word is identified as a frame-evoking word.

3.2 Frame identification

A target word is, on average, ambiguous between three frames. We use a multinomial log-linear classifier[4] (with default parameters) to decide which of the possible frames evoked by the target word that fits the context best. Our feature representation replicates that of Das et al. (2014) as far as possible, considering the multilingual setting where lexical features cannot be directly used. To compensate for the lack of lexical features, we introduce two groups of language-independent features that rely on multilingual word embeddings. One feature group uses the embedding of the target word directly, while the other is based on distance measures between the target word and the set of English words used as targets for a possible frame. We measure the minimum and mean distance (in embedding space) from the target word to the set of English target words, as well as the distances to each word individually.

Several of the features in the original representation are built on top of automatic POS annotation and syntactic parses. We use the Universal Dependencies v1.1 treebanks for the languages in our data to train part-of-speech taggers (TREETAGGER[5]) and a dependency parser (TURBOPARSER[6]) to generate the syntactic features. In contrast to Das et al. (2014), we use dependency subtrees instead of spans.

[3]The white-listed POS are nouns, verbs, adjectives, proper nouns, adverbs, and determiners.

[4]http://hunch.net/~vw/

[5]http://www.cis.uni-muenchen.de/~schmid/tools/TreeTagger/

[6]http://www.cs.cmu.edu/~ark/TurboParser/

3.3 Argument identification

A frame contains a number of named arguments that may or may not be expressed in a given sentence. Argument identification is concerned with assigning frame arguments to spans of words in the sentence. While this task can benefit from information on the joint assignment of arguments, Das et al. (2014) report only an improvement of less than 1% in F_1 using beam search to approximate a global optimal configuration for argument identification. To simplify our system, we take all argument-identification decisions independently. We use a single classifier for argument identification, computing the most probable argument for each frame element. Each word index is associated with a span by the transitive closure of its syntactic dependencies (i.e. subtree). Our greedy approach to argument identification thus amounts to scoring the $n + 1$ possible realisations of an argument for an n-length sentence (i.e. subtrees plus the empty argument), selecting the highest scoring subtree for each argument type allowed by the frame.

As the training data contains very few examples of each frame or role (e.g., *Buyer* in the frame COMMERCE_SCENARIO), we enable sharing of features for frame arguments that have the same name. The assumption is that arguments with identical names have similar semantic properties across frames; that is the argument *Perpetrator*, for example, is similar for the frames ARSON and THEFT.

The scores are the confidences of a binary classifier trained on <*frame*, *argument*, *subtree*> tuples. Positive examples are the observed arguments. We use the remaining n incorrect subtrees for a given <*frame*, *argument*> pair to generate negative training examples . A single binary classification model is trained for the whole data set.

As with frame identification, our features are similar to those of Das et al. (2014), with a few exceptions and additions. We use dependency subtrees instead of spans and replace all lexical features (which do not transfer cross-lingually) with features based on the interlingual word embeddings from Søgaard et al. (2015a). We use the embeddings to find the 20 most similar words in the training data and use these words to generate lexical features that matched the source-language training data. Each feature is weighted by its cosine similarity with the target-language word.

Table 2: Frame semantic parsing results (precision and F_1 in %)

Baseline Our approach to multi-lingual frame semantics parsing extends Das et al. (2014) to cross-lingual learning using the interlingual embeddings from Søgaard et al. (2015a). Our baseline is a more direct application of the SEMAFOR system[7] (Das et al., 2014), translating target language text to English using word-to-word translations and projecting annotation back. For word-to-word translation we use Wiktionary bilingual dictionaries (Ács, 2014), and we use frequency counts from UKWAC[8] to disambiguate words with multiple translations, preferring the most common one. The baseline and our system both use the training data supplied with FRAMENET for learning.

4 Results

Consider first the target identification results in Table 2. We observe that using BABELNET and our re-implementation of Das et al. (2014) performs considerably better than running SEMAFOR on Wiktionary word-by-word translations.

Our frame identification results are also presented in Table 2. Our system is better in six out of nine cases, whereas the most frequent sense baseline is best in two. It is unsurprising that English fares best in this setup, because it does not undergo the word-to-word translation of the other data sets.

Argument identification is a harder task, and scores are generally lower; see the lower part of Table 2. Also, note that errors percolate: If we do not identify a target, or mislabel a frame, we can no longer retrieve the correct arguments. Nevertheless, we observe that we are better than running SEMAFOR on word-by-word translations in eight out of nine languages—all, except English.

Generally, we obtain error reductions over our baseline of 46% for target identification, 37% for frame identification, and 14% for argument identification. For English, we are only 2% (absolute) below IAA for target identification, but about 40% below IAA for frame and argument identification. For Danish, the gap is smaller.

If we compare performance on Wikipedia and Twitter datasets, we see that target identification and frame identification scores are generally higher for Wikipedia, while argument identification scores are higher for Twitter. While Wikipedia is generally more similar to the

[7] http://www.ark.cs.cmu.edu/SEMAFOR/
[8] http://wacky.sslmit.unibo.it/

newswire/balanced corpus in FRAMENET 1.5, the sentence length is shorter in tweets, making it easier to identify the correct arguments.

5 Conclusions

We presented a multi-lingual frame-annotated corpus covering nine languages in two domains. With this corpus we performed experiments to predict target, frame and argument identification, outperforming a word-to-word translated baseline running on SEMAFOR. Our approach is a delexicalized version of Das et al. (2014) with a simpler decoding strategy and, crucially, using multilingual word embeddings to achieve any-language frame-semantic parsing. Over a baseline of using SEMAFOR with word-to-word translations, we obtain error reductions of 46% for target identification, 37% for frame identification, and 14% for argument identification.

What's in an Embedding? Analyzing Word Embeddings through Multilingual Evaluation

Arne Köhn
Department of Informatics
Universität Hamburg
koehn@informatik.uni-hamburg.de

Abstract

In the last two years, there has been a surge of word embedding algorithms and research on them. However, evaluation has mostly been carried out on a narrow set of tasks, mainly word similarity/relatedness and word relation similarity and on a single language, namely English.

We propose an approach to evaluate embeddings on a variety of languages that also yields insights into the structure of the embedding space by investigating how well word embeddings cluster along different syntactic features.

We show that all embedding approaches behave similarly in this task, with dependency-based embeddings performing best. This effect is even more pronounced when generating low dimensional embeddings.

1 Introduction

Word embeddings map words into a vector space, allowing to reason about words in this space. They have been shown to be beneficial for several tasks such as machine translation (Botha and Blunsom, 2014), parsing (Lei et al., 2014), and named entity recognition (Passos et al., 2014). Recently, word embedding techniques have been studied for their mathematical properties (Levy and Goldberg, 2014b; Stratos et al., 2015), yielding a better understanding of the underlying optimization criteria. However, word embeddings have mostly been studied and evaluated on a single language (English). Therefore, validation on languages other than English is lacking and the question whether word embeddings work the same way across languages has not been empirically evaluated. Evaluations of complex systems – such as parsers – employing word embeddings generally give only little insight into the type of contribution to the result and the structure of word embeddings.

We aim to fill these gaps by evaluating several word embedding algorithms on a set of different languages using tasks that enable additional insight into the learned structures using easily obtainable data. At the same time, we provide baseline results for using word embeddings in several syntax-based classification tasks.

We focus on syntax-related measures because data is available for several languages and we expect a correlation with usefulness of word embeddings for syntax-related tasks such as named entity recognition, parsing, and morphological analysis.

2 Related Work

Previous approaches to word embedding evaluation have either used relatively basic word finding and classification tasks (as this paper also proposes) or application-oriented end-to-end evaluations as part of a larger system. Word finding tasks are of the form "given a pair of words (x, y), find a y' for a given x'", e.g. given (Rome, Italy), find a word for Oslo. These tasks have been introduced by Mikolov et al. (2013a). The downside of this kind of task is that the data is not readily available and has to be constructed for each language. This type of evaluation primarily describes the similarity between vector differences and not similarity between vectors. In addition, Levy et al. (2015) showed for this task that word embedding-based classifiers actually mostly learn whether a word is a *general hypernym* and not, as would be expected, the relation between two words.

Another approach to evaluate embeddings, used by Pennington et al. (2014) amongst others, is to rank a fixed set of words relative to a reference word. The results are then compared to human judgments, e.g. from the WS353 corpus (Finkelstein et al., 2002). This approach has a limited coverage and additional data is expensive to obtain.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2067–2073,
Lisbon, Portugal, 17-21 September 2015.

Botha and Blunsom (2014) propose to factorize word vectors into morpheme vectors to better capture similarities between morphologically related words and evaluate their word representations using log-bilinear language models based on their word vectors.[1] They measure model perplexity reduction relative to n-gram language models and include their model into a machine translation system, gaining between 0 (English → German) and 1.2 (English → Russian) BLEU points.

Lei et al. (2014) introduce a syntactic dependency parser using (amongst others) a low-rank tensor component for scoring dependency edges. This scoring can employ word embeddings. Doing so yields an improvement of 0.2 to 0.5 percentage points. If no Part-of-Speech (PoS) tags are available, this difference rises to up to four percentage points. Köhn et al. (2014) show that this gain from using word embeddings is even more pronounced in complete absence of morphological information (including PoS tags), reporting a difference of five to seven percentage points,depending on the language, using the same parser. With these findings, it can be assumed that word embeddings encode some kind of morphological information. Neither, however, investigated what kind of information the word embeddings actually contain.

3 The Embedding Algorithms

To assess the differences between embedding algorithms, we will evaluate six different approaches. The continuous bag-of-words (**cbow**) approach described by Mikolov et al. (2013a) is learned by predicting the word vector based on the context vectors. The skip-gram approach (**skip**) from the same authors is doing the reverse: it predicts the context word vectors based on the embedding of the current word. We use the version of **cbow** and **skip** as described in (Mikolov et al., 2013b) which use negative sampling, i.e. they train by distinguishing the correct word in its context against words not occurring in that context.

Levy and Goldberg (2014a) alter the skipgram approach by not using the neighboring words wrt. the sentence's word sequence but wrt. the dependency tree of the sentence. Therefore, the context of w is defined as all words that are either the head or dependents of w. We will call this approach **dep**.

[1] Their approach has not been evaluated in this paper as the corresponding code is not available as of now.

GloVe, introduced by Pennington et al. (2014), optimizes the ratio of co-occurrence probabilities instead of the co-occurrence probabilities themselves, getting rid of the negative sampling used for the approaches previously mentioned.

Stratos et al. (2015) describe a method to derive word embeddings using canonical correlation analysis. We will call this approach **cca**.

brown clusters (Brown et al., 1992) are constructed by clustering words hierarchically into a binary search tree in a way that maximizes mutual information for a language model. To construct an embedding for a cluster c, we use the following procedure: For each edge on the path from the root to c, add either 1 or -1, depending on the direction of descent. Because not every path has the same depth, we pad missing dimensions with 0. This way, we obtain an embedding interpretation of the clusters. Note that, in contrast to clustering embeddings, no information is lost.

4 Our Evaluation by Classification Tasks

We classify words separately according to several tasks with an L2-regularized linear classifier. All classification tasks are based on the word embedding of a single word alone, without any other information about the word or its context; in particular, the word's lexicalization is not used as a feature. By using the continuous features directly instead of clustering them (as e.g. done by Bansal et al. (2014)), we ensure that no information is lost during preprocessing.

All tasks can be carried out on dependency treebanks with morphological annotation. From each word in the treebank, we extract a data point *(word embedding, class)* for training/testing, where *class* is of one of the following, depending on the task:

pos The Part-of-Speech of the word
headpos The PoS of the word's head
label The label of the word's dependency edge
gender* The gender of the word
case* The case of the word
number* The number of the word
tense* The tense of the word

Tasks marked with an asterisk are only carried out on words with a corresponding feature. Some of these features are absent in some languages, e.g. Basque is mostly genderless and the corpus of English we used is not annotated with morphological information. These combinations of language and feature have been omitted.

We use a one-versus-all linear classifier for two reasons: First, the feature dimensionality is relatively high. Second, and more importantly, training a linear classifier yields insights into the structure of the vector space because the classifier also serves as a tool to obtain a supervised clustering of the vector space.

Let $\mathbf{C}$ be set set of classes. A one-versus-all linear classifier learns a linear function $f_c \in \mathbb{R}^n \rightarrow \mathbb{R}$ for each class $c \in \mathbf{C}$. The classifier assigns to a vector X the best matching class based on these functions:

$$\text{class}(X) = \arg\max_{c \in \mathbf{C}} f_c(X)$$

Due to the linearity of the functions f_c, the vector space is partitioned into convex polytopes, which each represent exactly one class (see Appendix A). Therefore, the classification accuracies can also be interpreted as supervised clustering accuracies. This means that if the classifier yields a high accuracy, the members of each class are clustered in a single convex region of the vector space. We think that this is a fairly strong statement about the structure of the vector space.

To better gauge how well the embeddings are actually clustered, we use a majority baseline which classifies all elements as the one class that occurred most often during training. This is the accuracy a classifier would yield without any information and therefore the information gain obtainable by using word embeddings as features is the difference between the achieved accuracy and the baseline accuracy.

In addition to the lower bound described above, we also provide an approximate upper bound for the accuracy. Because no context information is used during classification, the word vector corresponding to a word will always be classified the same, even though the correct classification might depend on the context, e. g. the word *put* can belong to different tense classes depending on the context. Therefore, an upper bound for the classification task is to assign each word the most probable class for that word (computed on the training set). Assuming that no sparsity issues exist, embedding-based classification can yield at most accuracies as high as this approach. Note that because in reality data sparsity unfortunately does exist, this is only an approximation of the upper bound. We call this approximation *up-approx* and compute it omitting words not seen during training.

5 Experimental Setup

Evaluation was carried out on Basque, English, French, German, Hungarian, Polish, and Swedish datasets. For English, automatically labeled data was obtained by tagging and parsing a subset of the English Wikipedia dump provided by Al-Rfou et al. (2013) using TurboTagger and TurboParser (Martins et al., 2013). The Penn Treebank (Marcus et al., 1994), converted using the LTH converter (Johansson and Nugues, 2007), was used as the corresponding manually annotated resource.

For all other languages, datasets including both automatically and manually annotated data provided as part of the Shared Task on parsing morphologically rich languages (Seddah et al., 2014) were used.[2]

For all languages, we trained embeddings on the automatically labeled data using the approaches described in Section 3, with different window sizes (5 and 11, where applicable) and dimensions (10, 100, 200). The rare word limit was set to five words occurrences. **brown** was only trained with 1024 clusters equaling about 10 dimensions, as the number of clusters can not be increased to generate higher-dimensional embeddings. **dep** was not evaluated on French because the French automatically labeled dataset lacks dependency information.

6 Results

Figure 1 a) shows the accuracies for the evaluated word embeddings on all tasks for the different languages. The results were obtained using the best-performing hyperparameters (200 dimensions for all, window size = 5 for **cca**, **cbow** and **skip**, window size = 11 for **GloVe**, compare Table 1).

All embeddings capture the PoS well. To a lesser degree, the dependency label and head PoS can also be recovered. The better-performing embeddings achieve results near the approximate upper bound for all tasks.

The embeddings also mostly cluster well with respect to tense, number, gender, and case, with tense showing the best correlations. For some of these tasks, the baseline is however fairly high because the number of classes is lower.

[2]Basque: (Aduriz et al., 2003; Aldezabal et al., 2008), French: (Abeillé et al., 2003; Candito et al., 2010), German: (Brants et al., 2002; Seeker and Kuhn, 2012), Hungarian: (Csendes et al., 2005; Vincze et al., 2010), Polish: (Woliński et al., 2011; Świdziński and Woliński, 2010; Wróblewska, 2012), Swedish: (Nivre et al., 2006)

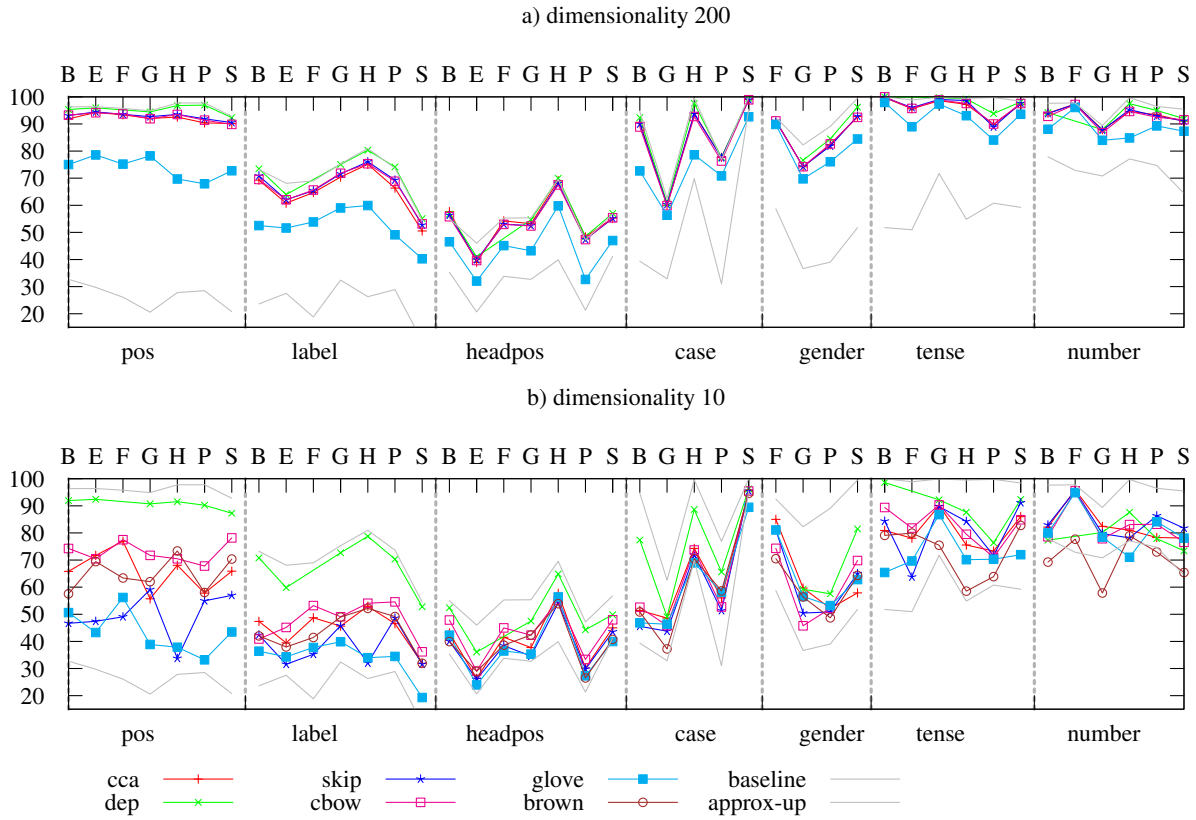

Figure 1: Results with window = 5 (for cbow, cca & skip) / 11 (for GloVe) for **B**asque, **E**nglish, **F**rench, **G**erman, **H**ungarian, **P**olish, **S**wedish. Note: brown is only present in b).

w	d	cca	skip	cbow	dep	GloVe
5	200	80.41	80.69	80.42	82.35	70.05
	100	−1.38	−1.16	−3.31	−0.39	−2.24
	10	−18.06	−22.92	−16.18	−8.38	−16.12
11	200	−1.31	−0.04	−0.05	n/a	+0.57
	100	−3.56	−1.16	−1.17	n/a	−1.73
	10	−23.51	−22.94	−16.34	n/a	−15.64

Table 1: Mean accuracy across tasks for **d**imension=200 and **w**indow=5, and change in mean accuracy when deviating, measured in percentage points. **dep** has no window parameter.

cbow, **cca** and **skip** perform nearly identical, while **dep** performs slightly better. Interestingly, **GloVe** performs consistently worse than all other embeddings, contrary to the findings published in Pennington et al. (2014), but in line with Stratos et al. (2015). **dep** performs best on nearly all tasks, which may indicate that dependency-based context is not only beneficial for preserving dependency-related information, but also for morphology.

This finding is even more pronounced in the evaluation using only ten dimensions (Figure 1 b)): While **dep** can capture the different aspects tested for nearly as well as with 200 dimensions, the other embeddings suffer larger degradations, especially for PoS and label prediction. **cbow** seems to be able to cope better with low dimensionality than **skip**, although they perform nearly identical on the high dimensionality tasks. **brown** behaves similar to the other approaches despite being quite different algorithmically and only producing low-granular data (with values for each dimension being either 1, 0, or −1). Note that results near the baseline signify that the embeddings yield only minimal benefit since the baseline does not use any features at all.

Table 1 gives an overview of the average change in accuracy when changing hyperparameters. Using 200 dimensions instead of 100 is beneficial for all word embeddings. The difference is however not nearly as pronounced as between ten and 100 dimensions. **skip** and **cbow** yield slightly better results with a window of five, whereas for **GloVe** a larger window is advantageous. **dep** achieves both the highest average score and has the lowest degradation when lowering the dimensionality.

Bansal et al. (2014) evaluate word embeddings

wrt. how they cluster along PoS tags. They first divide the embeddings into 1000 clusters using k-means and then associate each cluster with a PoS tag. They report a clustering accuracy of 81.1% for $w = 11$ and 85.8% for $w = 5$ using **skip**. Our results, however, show an accuracy of 94.4% and 94.4%, respectively, i.e. no such difference. That means that the PoS are still mostly linearly separable with larger window sizes. The differences observed by them could result from information getting lost during clustering.

7 Conclusions

Word embeddings are able to capture a range of syntactic and morphological information. They align especially well with the word's part of speech. With a high dimensionality, most embeddings perform similarly, with **GloVe** performing on average ten percentage points worse. With a low dimensionality, the differences become more pronounced and **dep** is the clear choice for applications where using high-dimensional vectors is not feasible and a correlation to the features tested in this paper is wanted.

We have shown that the different word embedding algorithms behave similar over a variety of languages and perform well relative to the task's upper bounds.

The evaluation approach proposed yields insights into the usefulness of embeddings for syntax-related tasks, works on a wide variety of languages and avoids inaccuracies introduced when employing unsupervised clustering for evaluation. We hope that this evaluation approach will be useful for evaluating future embedding techniques.

The software to replicate the experiments for this paper is available on `http://arne.chark.eu/emnlp2015`.

A Proof: Convexity of regions

To show that a one-versus-all classifier generates exactly one convex polytope for each class, we have to show that for any two points belonging to a class, each point between them belongs to the same class.

Let $c \in \mathbf{C}$ be a class and $\mathbf{r}_c \subseteq \mathbb{R}^n$ be the region(s) of c in the vector space[3] , i. e. where the following holds true:

$$f_c > f_o \; \forall o \in \mathbf{C} \setminus c$$

[3]the vector space is assumed to have one dimension for the bias.

Let $x, y \in \mathbf{r}_c$ be two points classified into c. Then the following statement needs to be true:

$$z \in \mathbf{r}_c, \;\; z := (1 - \lambda)x + \lambda y \quad \forall \lambda \in [0, 1]$$

Assume that $z \notin \mathbf{r}_c$. Then, by definition, $f_o(z) > f_c(z)$ for some $o \in \mathbf{C} \setminus c$. We can substitute z with its definition:

$$f_o((1 - \lambda)x + \lambda y) > f_c((1 - \lambda)x + \lambda y)$$

And therefore due to the linearity of f_o and f_c:

$$(1 - \lambda)f_o(x) + \lambda f_o(y) > (1 - \lambda)f_c(x) + \lambda f_c(y)$$

But this cannot be, as by definition, $f_o(x) < f_c(x)$ and $f_o(y) < f_c(y)$. Therefore, there is only one region for c and that region is convex. □

Joint Event Trigger Identification and Event Coreference Resolution with Structured Perceptron

Jun Araki and **Teruko Mitamura**
Language Technologies Institute
Carnegie Mellon University
Pittsburgh, PA 15213, USA
{junaraki,teruko}@cs.cmu.edu

Abstract

Events and their coreference offer useful semantic and discourse resources. We show that the semantic and discourse aspects of events interact with each other. However, traditional approaches addressed event extraction and event coreference resolution either separately or sequentially, which limits their interactions. This paper proposes a document-level structured learning model that simultaneously identifies event triggers and resolves event coreference. We demonstrate that the joint model outperforms a pipelined model by 6.9 BLANC F1 and 1.8 CoNLL F1 points in event coreference resolution using a corpus in the biology domain.

1 Introduction

Events convey semantic information such as who did what to whom where and when. They also corefer to each other, playing a role of discourse connection points to form a coherent story. These aspects of events have been already utilized in a wide variety of natural language processing (NLP) applications, such as automated population of knowledge bases (Ji and Grishman, 2011), topic detection and tracking (Allan, 2002), question answering (Bikel and Castelli, 2008), text summarization (Li et al., 2006), and contradiction detection (de Marneffe et al., 2008). This fact illustrates the importance of event extraction and event coreference resolution.

Those semantic and discourse aspects of events are not independent from each other, and in fact often work in interactive manners. We give two examples of the interactions:

(1) British bank Barclays had agreed to **buy**(E1) Spanish rival Banco Zaragozano for 1.14 billion euros. The **combination**(E2) of the banking operations of Barclays Spain and Zaragozano will bring together two complementary businesses.

(2) The Palestinian Authority condemned the **attack**(E3), saying **it**(E4) would divert international sympathy away from the far higher Palestinian civilian death toll.

E1 corefers to E2, and E3 does to E4. E2 is more abstract than E1, and has less evidence of being an event. E4 is a pronoun, and thus may seem to refer to an entity rather than an event. Thus, E2 and E4 are relatively difficult to be recognized as events by themselves. However, event coreference E1-E2, which is supported primarily by E2's participants *Barclays* and *Zaragozano* shared with E1, helps determine that E2 is an event. The same logic applies to E3 and E4. On the other hand, previous works typically rely on a pipelined model that extracts events (e.g., E1 and E3) at the first stage, and then resolves event coreference at the second stage. Although this modularity is preferable from development perspectives, the pipelined model limits the interactions. That is, the first stage alone is unlikely to detect E2 and E4 as events due to the difficulties described above. These missing events make it impossible for the second stage to resolve event coreference E1-E2 and E3-E4.

In this work, we address the problem using the ProcessBank corpus (Berant et al., 2014). Following the terminology defined in the corpus, we introduce several terms:

- **Event**: an abstract representation of a change of state, independent from particular texts.
- **Event trigger**: main word(s) in text, typically a verb or a noun that most clearly expresses an event.
- **Event arguments**: participants or attributes in text, typically nouns, that are involved in an event.
- **Event mention**: a clause in text that describes an event, and includes both a trigger and arguments.
- **Event coreference**: a linguistic phenomenon that two event mentions refer to the same event.

We aim to explore the interactions between event mentions and event coreference. As a first step toward the goal, we focus on the task of identifying event triggers and resolving event coreference, and

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2074–2080,
Lisbon, Portugal, 17-21 September 2015.

propose a document-level joint learning model using structured perceptron (Collins, 2002) that simultaneously predicts them. Our assumption is that the joint model is able to capture the interactions between event triggers and event coreference adequately, and such comprehensive decision improves the system performance. For instance, the joint model is likely to extract E2 as well as E1 successfully via their event coreference by simultaneously looking at coreference features.

Our contributions are as follows:

1. This is the first work that simultaneously predicts event triggers and event coreference using a single joint model. At the core of the model is a document-level structured perceptron algorithm that learns event triggers and event coreference jointly.
2. The incremental token-based prediction in joint decoding poses a challenge of synchronizing the assignments of event triggers and coreference. To avoid this problem, we propose an incremental decoding algorithm that combines the segment-based decoding and best-first clustering algorithm.
3. Our experiments indicate that the joint model achieves a substantial performance gain in event coreference resolution with a corpus in the biology domain, as compared to a pipelined model.

2 Related Work

No previous work deals with event extraction and event coreference resolution simultaneously. We thus describe how these two tasks have been addressed separately, and how joint structured learning has been studied in other NLP tasks.

Event extraction has been studied mainly in the newswire domain and the biomedical domain as the task of detecting event triggers and determining their event types and arguments. In the former domain, most work took a pipelined approach where local classifiers identify triggers first, and then detect arguments (Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011). Li et al. (2013) presented a structured perceptron model to detect triggers and arguments jointly. Similarly, joint dependencies in events were also addressed in the latter domain (Poon and Vanderwende, 2010; McClosky et al., 2011; Riedel and McCallum, 2011; Venugopal et al., 2014). However, none of them incorporated event coreference into their model.

Event coreference resolution is more challenging and less explored. To set up event triggers as a starting point of the task, some works use human annotation in a corpus (Bejan and Harabagiu, 2014; Liu et al., 2014), and others use the output of a separate event extraction system (Lee et al., 2012). Berant et al. (2014) presented a model that jointly predicts event arguments and event coreference (as well as other relations between event triggers). However, none of them tries to predict event triggers and event coreference jointly.

Joint structured learning has been applied to several NLP tasks, such as word segmentation and part-of-speech (POS) tagging (Zhang and Clark, 2008a), POS tagging and dependency parsing (Bohnet and Nivre, 2012), dependency parsing and semantic role labeling (Johansson and Nugues, 2008), the extraction of event triggers and arguments (Li et al., 2013), and the extraction of entity mentions and relations (Li and Ji, 2014). Their underlying ideas are similar to ours. That is, one can train a structured learning model to globally capture the interactions between two relevant tasks via a certain kind of structure, while making predictions specifically for these respective tasks. However, no prior work has studied the interactions between event trigger identification and event coreference resolution.

3 Approach

We formalize the extraction of event triggers and event coreference as a problem of structured prediction. The output structure is a document-level event graph where each node represents an event trigger, and each edge represents an event coreference link between two event triggers.

3.1 Corpus

The ProcessBank corpus consists of 200 paragraphs from the textbook *Biology* (Campbell and Reece, 2005). Table 1 shows statistics of our data splits. The original corpus provides 150 paragraphs as training data, and we split them into 120 and 30 for our training and development, respectively. We chose ProcessBank instead of a larger corpus such as the Automatic Content Extraction (ACE) 2005 corpus for the following two reasons. First, the human annotation of event coreference links in ProcessBank enables us to apply the best-first clustering directly; on the other hand, this is

not readily feasible in ACE 2005 since it annotates event coreference as clusters, and gold standard event coreference links required for the best-first clustering are not available. Second, event coreference resolution using ProcessBank is novel since almost no previous work on the task used that corpus. The only exception could be (Berant et al., 2014), where they extracted several types of relations between event triggers, including event coreference. However, they did not report any performance scores of their system specifically on event coreference, and thus their work is not comparable to ours.

	Train	Dev	Test	Total
# of paragraphs	120	30	50	200
# of event triggers	823	224	356	1403
# of event coreferences	73	28	30	131

Table 1: Statistics of our dataset.

Unlike previous work (Berant et al., 2014; Li et al., 2013), we explicitly allow an event trigger to have multiple tokens, such as verb phrase 'look into' and compound proper noun 'World War II'. This is a more realistic setting for event trigger identification since in general there are a considerable number of multi-token event triggers[1].

3.2 Event Graph Learning

Let x denote an input document with n tokens where x_i is the i-th token in the document. For event graph learning, we use structured perceptron (Collins, 2002), and average weights to reduce overfitting as suggested in (Collins, 2002). The algorithm involves decoding to generate the best event graph for each input document. We elaborate on our decoding algorithm in Section 3.3. Since an event graph has an exponentially large search space, we use beam search to approximate exact inference. We extract a range of features by using Stanford CoreNLP (Manning et al., 2014), MATE (Björkelund et al., 2009), OpenNLP[2], Nomlex (Macleod et al., 1998), and Levin verb classes (Levin, 1993). For brevity, we provide details of the structured perceptron algorithm and features in the supplementary material.

We use the standard-update strategy in our structured perceptron model. As variants of structured perceptron, one could employ the early update (Collins and Roark, 2004) and max-violation update (Huang et al., 2012) to our model. Our initial experiments indicated that early updates happen too early to gain sufficient feedback on weights from entire documents in training examples, ending up with a poorer performance than the standard update. This contrasts with the fact that the early-update strategy was successfully applied to other NLP tasks such as constituent parsing (Collins and Roark, 2004) and dependency parsing (Zhang and Clark, 2008b). The main reason why the early update fell short of the standard update in our setting is that joint event trigger identification and event coreference resolution is a much more difficult task since they require more complex knowledge and argument structures. Due to the difficultly of the task, it is also very difficult to develop such an effective feature set that beam search can explore the search space of an entire document thoroughly with early updates. This observation follows (Björkelund and Kuhn, 2014) on entity coreference resolution. In contrast, the max-violation update showed almost the same performance as the standard update on the development data. From these results, we chose the standard-update strategy for simplicity.

3.3 Joint Decoding

Given that an event trigger has one or more tokens, event trigger identification could be solved as a token-level sequential labeling problem with `BIO` or `BILOU` scheme in the same way as named entity recognition (Ratinov and Roth, 2009). If one uses this approach, a beam state may represent a partial assignment of an event trigger. However, event coreference can be explored only from complete assignments of an event trigger. Thus, one would need to synchronize the search process of event coreference by comparing event coreferences from the complete assignment at a certain position with those from complete assignments at following positions. This makes it complicated to implement the formalization of token-level sequential labeling for joint decoding in our task. One possible way to avoid this problem is to extract event trigger candidates with a preference on high recall first, and then search event coreference from those candidates, regarding them as complete assignments of an event trigger. This recall-oriented pre-filtering is often used in entity coreference resolution (Lee et al., 2013; Björkelund

[1]For example, around 13.4% of the 1403 event triggers in ProcessBank have multiple tokens.

[2]http://opennlp.apache.org/

Algorithm 1 Joint decoding for event triggers and coreference with beam search.

Input: input document $x = (x_1, x_2, \ldots, x_n)$
Input: beam width k, max length of event trigger l_{max}
Output: best event graph $\hat{y}$ for x

```
 1: initialize empty beam history B[1..n]
 2: for i ← 1..n do
 3:   for l ← 1..l_max do
 4:     for y ∈ B[i − l] do
 5:       e ← CreateEventTrigger(l, i).
 6:       AppendEventTrigger(y, e)
 7:       B[i] ← k-Best(B[i] ∪ y)
 8:       for j ← 1..i − 1 do
 9:         c ← CreateEventCoref(j, e).
10:         AddEventCoref(y, c)
11:         B[i] ← k-Best(B[i] ∪ y)
12: return B[n][0]
```

and Farkas, 2012). In our initial experiments, we observed that our rule-based filter gained around 97% recall, but extracted around 12,400 false positives against 823 true positives in the training data. This made it difficult for our structured perceptron to learn event triggers, which underperformed on event coreference resolution.

We, therefore, employ segment-based decoding with multiple-beam search (Zhang and Clark, 2008a; Li and Ji, 2014) for event trigger identification, and combine it with the best-first clustering (Ng and Cardie, 2002) for event coreference resolution in document-level joint decoding. The key idea of segment-based decoding with multiple-beam search is to keep previous beam states available, and use them to form segments from previous positions to the current position. Let l_{max} denote the upper bound on the number of tokens in one event trigger. The k-best partial structures (event subgraphs) in beam B at the j-th token is computed as follows:

$$B[j] = \underset{y \in \{y_{[1:j-l]} \in B[j-l],\ y_{[j-l+1,j]}=s\}}{k\text{-BEST}} \Phi(x, y) \cdot \mathbf{w}$$

where $1 \leq l \leq l_{max}$, $y_{[1:j]}$ is an event subgraph ending at the j-th token, and $y_{[j-l+1,j]} = s$ means that partial structure $y_{[j-l+1,j]}$ is a segment, i.e., an event trigger candidate with a subsequence of tokens $x_{[j-l+1,j]}$. This approximates Viterbi decoding with beam search.

The best-first clustering incrementally makes coreference decisions by selecting the most likely antecedent for each trigger. Our joint decoding algorithm makes use of the incremental process to combine the segment-based decoding and best-first clustering. Algorithm 1 shows the summary of the joint decoding algorithm. Line 3 - 7 implements the segment-based decoding, and line 8 - 11 implements the best-first clustering. Once a new event trigger is appended to an event subgraph at line 6, the decoder uses it as a referring mention regardless of whether the event subgraph is in the beam, and seeks the best antecedent for it. This enables the joint model to make a more global decision on event trigger identification and event coreference decision, as described in Section 1.

4 Experimental Settings

When training our model, we observed that 20-iteration training almost reached convergence, and thus we set the number of iterations to 20. We set l_{max} to 6 because we observed that the longest event trigger in the entire ProcessBank corpus has six tokens. When tuning beam width k on the development set, large beam width did not give us a significant performance difference. We attribute this result to the small size of the development data. In particular, the development data has only 28 event coreferences, which makes it difficult to reveal the effect of beam width. We thus set k to 1 in our experiments.

4.1 Baseline Systems

Our baseline is a pipelined model that divides the event trigger decoding and event coreference decoding in Algorithm 1 into two separate stages. It uses the same structured perceptron with the same hyperparameters and feature templates. We choose this baseline because it clearly reveals the effectiveness of the joint model by focusing only on the architectural difference. One could develop other baseline systems. One of them is a deterministic sieve-based approach by Lee et al. (2013). A natural extension to the approach for performing event trigger identification as well as event coreference resolution would be to develop additional sieves to classify singletons into real event triggers or spurious ones. We leave it for future work.

4.2 Evaluation

We evaluate our system using a reference implementation of coreference scoring algorithms (Pradhan et al., 2014; Luo et al., 2014). As for event trigger identification, this scorer computes precision (P), recall (R), and the F1 score. With respect to event coreference resolution, the scorer computes MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), two CEAF metrics CEAF_m and CEAF_e (Luo, 2005), and

	MUC			B^3			$CEAF_m$			$CEAF_e$			BLANC			CoNLL
System	R	P	F1	R	P	F1	R	P	F1	R	P	F1	R	P	F1	F1
Baseline	26.66	19.51	22.53	55.47	58.64	57.01	53.08	60.38	56.50	52.68	63.14	57.44	30.13	25.10	25.05	45.66
Joint	20.00	37.50	26.08	53.37	63.36	57.93	53.93	62.95	58.09	55.06	62.11	58.38	27.51	38.43	31.91	47.45

Table 2: Results of event coreference resolution. 'Baseline' refers to the second stage of our baseline.

BLANC (Recasens and Hovy, 2011) extended by Luo et al. (2014). We also report the CoNLL average (Denis and Baldridge, 2009), which is the average of MUC F1, B^3 F1, and $CEAF_e$ F1.

5 Results and Discussions

We first show the result of event coreference resolution on the test data in Table 2. The joint model outperforms the baseline by 6.9 BLANC F1 and 1.8 CoNLL F1 points. We observed that this overall performance gain comes largely from a precision gain, more specifically, substantially reduced false positives. We explain the superiority of the joint model as follows. In the baseline, the second stage uses the output of the first stage. Since event triggers are fixed at this point, the baseline explores coreference links only between these event triggers. In contrast, the joint model seeks event triggers and event coreference simultaneously, and thus it explores a larger number of false positives in the search process, thereby learning to penalize false positives more adequately than the baseline.

System	Recall	Precision	F1
Baseline	57.02	64.85	60.68
Joint	55.89	65.24	60.21

Table 3: Results of event trigger identification. 'Baseline' refers to the first stage of our baseline.

Table 3 shows the results of event trigger identification on the test data. We observed that the joint model also reduced false positives, similarly in event coreference resolution. However, its improvement on precision is small, ending up with almost the same F1 point as the baseline. We speculate that this is due to the small size of the corpus, and the joint model was unable to show its advantages in event trigger identification.

Below are two error cases in event coreference resolution, where our model fails to resolve E5-E6 and E7-E8. The model was unable to adequately extract features for both event triggers and event coreference, particularly because their surface strings are not present in training data, they are lexically and syntactically different, and they do not share key semantic roles (e.g., agents and patients) in a clear argument structure.

(3) When the cell is stimulated, gated channels open that facilitate Na+ **diffusion**(E5). Sodium ions then **"fall"**(E6) down their electrochemical gradient, ...

(4) The next seven steps **decompose**(E7) the citrate back to oxaloacetate. It is this **regeneration**(E8) of oxaloacetate that makes this process a cycle.

6 Conclusion and Future Work

We present a joint structured prediction model for event trigger identification and event coreference resolution. To our knowledge, this is the first work that solves these two tasks simultaneously. Our experiment shows that the proposed method effectively penalizes false positives in joint search, thereby outperforming a pipelined model substantially in event coreference resolution.

There are a number of avenues for future work. One can further ensure the advantage of the joint model using a larger corpus. Our preliminary experiment on the ACE 2005 corpus shows that due to its larger document size and event types, one will need to reduce training time by a distributed learning algorithm such as mini-batches (Zhao and Huang, 2013). Another future work is to incorporate other components of events into the model. These include event types, event arguments, and other relations such as subevents. One could leverage them as other learning targets or constraints, and investigate further benefits of joint modeling.

A Joint Dependency Model of Morphological and Syntactic Structure for Statistical Machine Translation

Rico Sennrich and **Barry Haddow**
School of Informatics, University of Edinburgh
rico.sennrich@ed.ac.uk, bhaddow@inf.ed.ac.uk

Abstract

When translating between two languages that differ in their degree of morphological synthesis, syntactic structures in one language may be realized as morphological structures in the other, and SMT models need a mechanism to learn such translations. Prior work has used morpheme splitting with flat representations that do not encode the hierarchical structure between morphemes, but this structure is relevant for learning morphosyntactic constraints and selectional preferences. We propose to model syntactic and morphological structure jointly in a dependency translation model, allowing the system to generalize to the level of morphemes. We present a dependency representation of German compounds and particle verbs that results in improvements in translation quality of 1.4–1.8 BLEU in the WMT English–German translation task.

1 Introduction

When translating between two languages that differ in their degree of morphological synthesis, syntactic structures in one language may be realized as morphological structures in the other. Machine Translation models that treat words as atomic units have poor learning capabilities for such translation units, and morphological segmentations are commonly used (Koehn and Knight, 2003). Like words in a sentence, the morphemes of a word have a hierarchical structure that is relevant in translation. For instance, compounds in Germanic languages are head-final, and the head is the segment that determines agreement within the noun phrase, and is relevant for selectional preferences of verbs.

1. sie erheben eine Hand|gepäck|gebühr.
   they charge a carry-on bag fee.

In example 1, agreement in case, number and gender is enforced between *eine* 'a' and *Gebühr* 'fee', and selectional preference between *erheben* 'charge' and *Gebühr* 'fee'. A flat representation, as is common in phrase-based SMT, does not encode these relationships, but a dependency representation does so through dependency links.

function/postion	English/German example
finite (main)	he **walks away** quickly er **geht** schnell **weg**
finite (sub.)	[...] because he **walks away** quickly [...] weil er schnell **weggeht**
bare infinitive	he can **walk away** quickly er kann schnell **weggehen**
to/zu-infinitive	he promises **to walk away** quickly er verspricht, schnell **wegzugehen**

Table 1: Surface realizations of particle verb *weggehen* 'walk away'.

In this paper, we investigate a dependency representation of morphologically segmented words for SMT. Our representation encodes syntactic and morphological structure jointly, allowing a single model to learn the translation of both. Specifically, we work with a string-to-tree model with GHKM-style rules (Galley et al., 2006), and a relational dependency language model (Sennrich, 2015). We focus on the representation of German syntax and morphology in an English-to-German system, and two morphologically complex word classes in German that are challenging for translation, compounds and particle verbs.

German makes heavy use of compounding, and compounds such as *Abwasserbehandlungsanlage* 'waste water treatment plant' are translated into complex noun phrases in other languages, such as French *station d'épuration des eaux résiduaires*.

German particle verbs are difficult to model because their surface realization differs depending on the finiteness of the verb and the type of clause. Verb particles are separated from the finite verb in

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2081–2087,
Lisbon, Portugal, 17-21 September 2015.

main clauses, but prefixed to the verb in subordinated clauses, or when the verb is non-finite. The infinitive marker *zu* 'to', which is normally a premodifying particle, appears as an infix in particle verbs. Table 1 shows an illustrating example.

2 A Dependency Representation of Compounds and Particle Verbs

The main focus of research on compound splitting has been on the splitting algorithm (Popovic et al., 2006; Nießen and Ney, 2000; Weller et al., 2014; Macherey et al., 2011). Our focus is not the splitting algorithm, but the representation of compounds. For splitting, we use an approach similar to (Fritzinger and Fraser, 2010), with segmentation candidates identified by a finite-state morphology (Schmid et al., 2004; Sennrich and Kunz, 2014), and statistical evidence from the training corpus to select a split (Koehn and Knight, 2003).

German compounds are head-final, and premodifiers can be added recursively. Compounds are structurally ambiguous if there is more than one modifier. Consider the distinction between *(Stadtteil)projekt* (literally: '(city part) project)') and *Stadt(teilprojekt)* 'city sub-project'. We opt for a left-branching representation by default.[1] We also split linking elements, and represent them as a postmodifier of each non-final segment, including the empty string ("ϵ"). We use the same representation for noun compounds and adjective compounds.

An example of the original[2] and the proposed compound representation is shown in Figure 1. Importantly, the head of the compound is also the parent of the determiners and attributes in the noun phrase, which makes a bigram dependency language model sufficient to enforce agreement. Since we model morphosyntactic agreement within the main translation step, and not in a separate step as in (Fraser et al., 2012), we deem it useful that inflection is marked at the head of the compound. Consequently, we do not split off inflectional or derivational morphemes.

For German particle verbs, we define a common representation that abstracts away from the various surface realizations (see Table 1). Separated

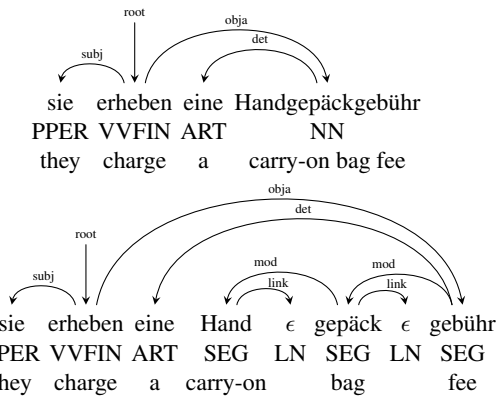

Figure 1: Original and proposed representation of German compound.

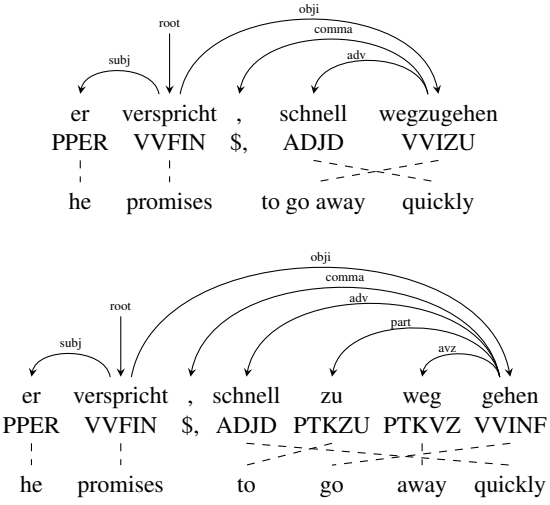

Figure 2: Original and proposed representation of German particle verb with infixed *zu*-marker.

verb particles are reordered to be the closest premodifier of the verb. Prefixed particles and the *zu*-infix are identified by the finite-state-morphology, and split from the verb so that the particle is the closest, the *zu* marker the next-closest premodifier of the verb, as shown in Figure 2. Agreement, selectional preferences, and other phenomena involve the verb and its dependents, and the proposed representation retains these dependency links, but reduces data sparsity from affixation and avoids discontinuity of the verb and its particle.

3 Tree Binarization

We follow Williams et al. (2014) and map dependency trees into a constituency representation, which allows for the extraction of GHKM-style translation rules (Galley et al., 2006). This conversion is lossless, and we can still apply a de-

[1] We follow prior work in leaving frequent words or subwords unsplit, which has a disambiguating effect. With more aggressive splitting, frequency information could be used for the structural disambiguation of internal structure.

[2] The original dependency trees follow the annotation guidelines by Foth (2005).

pendency language model (RDLM). Figure 3 (a) shows the constituency representation of the example in Figure 1.

Our model should not only be able to produce new words productively, but also to memorize words it has observed during training. Looking at the compound *Handgepäckgebühr* in Figure 3 (a), we can see that it does not form a constituent, and cannot be extracted with GHKM extraction heuristics. To address this, we binarize the trees in our training data (Wang et al., 2007).

A complicating factor is that the binarization should not impair the RDLM. During decoding, we map the internal tree structure of each hypothesis back to the unbinarized form, which is then scored by the RDLM. Virtual nodes introduced by the binarization must also be scorable by RDLM if they form the root of a translation hypothesis. A simple right or left binarization would produce virtual nodes without head and without meaningful dependency representation. We ensure that each virtual node dominates the head of the full constituent through a mixed binarization.[3] Specifically, we perform right binarization of the head and all pre-modifiers, then left binarization of all post-modifiers. This head-binarized representation is illustrated in Figure 3 (b).[4]

Head binarization ensures that even hypotheses whose root is a virtual node can be scored by the RDLM. This score is only relevant for pruning, and discarded when the full constituent is scored. Still, these hypotheses require special treatment in the RDLM to mitigate search errors. The virtual node labels (such as $\overline{\text{OBJA}}$) are unknown symbols to the RDLM, and we simply replace them with the original label (OBJA). The RDLM uses sibling context, and this is normally padded with special start and stop symbols, analogous to BOS/EOS symbols in n-gram models. These start and stop symbols let the RDLM compute the probability that a node is the first or last child of its ancestor node. However, computing these probabilities for virtual nodes would unfairly bias the search, since the first/last child of a virtual node is not necessarily the first/last child of the full constituent. We adapt the representation of virtual nodes in

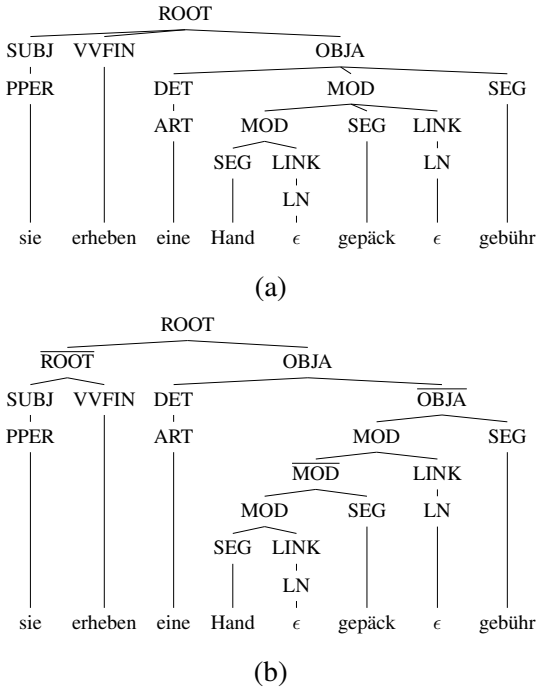

Figure 3: Unbinarized (a) and head-binarized (b) constituency representation of Figure 1.

RDLM to take this into account. We distinguish between virtual nodes based on whether their span is a string prefix, suffix, or infix of the full constituent. For prefixes and infixes, we do not add a stop symbol at the end, and use null symbols, which denote unavailable context, for padding to the right. For suffixes and infixes, we do the same at the start.

4 Post-Processing

For SMT, all German training and development data is converted into the representation described in sections 2–3. To restore the original representation, we start from the tree output of the string-to-tree decoder. Merging compounds is trivial: all segments and linking elements can be identified by the tree structure, and are concatenated.

For verbs that dominate a verb particle, the original order is restored through three rules:

1. non-finite verbs are concatenated with the particle, and *zu*-markers are infixed.

2. finite verbs that head a subordinated clause (identified by its dependency label) are concatenated with the particle.

3. finite verbs that head a main clause have the

[3] In other words, every node is a fixed well-formed dependency structure (Shen et al., 2010) with our binarization.

[4] Note that our definition of head binarization is different from that of Wang et al. (2007), who left-binarize a node if the head is the first child, and right-binarize otherwise. Our algorithm also covers cases where the head has both pre- and post-modifiers, as *erheben* and *gepäck* do in Figure 3.

particle moved to the right clause bracket.[5]

Previous work on particle verb translation into German proposed to predict the position of particles with an n-gram language model (Nießen and Ney, 2001). Our rules have the advantage that they are informed by the syntax of the sentence and consider the finiteness of the verb.

Our rules only produce projective trees. Verb particles may also appear in positions that violate projectivity, and we leave it to future research to determine if our limitation to projective trees affects translation quality, and how to produce non-projective trees.

5 SMT experiments

5.1 Data and Models

We train English–German string-to-tree SMT systems on the training data of the shared translation task of the Workshop on Statistical Machine Translation (WMT) 2015. The data set consists of 4.2 million sentence pairs of parallel data, and 160 million sentences of monolingual German data.

We base our systems on that of Williams et al. (2014). It is a string-to-tree GHKM translation system implemented in Moses (Koehn et al., 2007), and using the dependency annotation by ParZu (Sennrich et al., 2013). Additionally, our baseline system contains a dependency language model (RDLM) (Sennrich, 2015), trained on the target-side of the parallel training data.

We report case-sensitive BLEU scores on the newstest2014/5 test sets from WMT, averaged over 3 optimization runs of k-batch MIRA (Cherry and Foster, 2012) on a subset of newstest2008-12.[6]

We split all particle verbs and hyphenated compounds, but other compounds are only split if they are rare (frequency in parallel text < 5).

For comparison with the state-of-the-art, we train a *full system* on our restructured representation, which incorporates all models and settings of our WMT 2015 submission system (Williams et al., 2015).[7] Note that our WMT 2015 submission uses the dependency representation of compounds and tree binarization introduced in this paper; we achieve additional gains over the submission system through particle verb restructuring.

system	newstest2014	newstest2015
baseline	20.7	22.0
+split compounds	21.3	22.4
+particle verbs	21.4	22.8
head binarization	20.9	22.7
+split compounds	22.0	23.4
+particle verbs	22.1	23.8
full system	22.6	24.4

Table 2: English–German translation results (BLEU). Average of three optimization runs.

system	compound	particle verb		
		sep.	pref.	*zu*-infix
reference	2841	553	1195	176
baseline	845	96	847	71
+head binarization	798	157	858	106
+split compounds	1850	160	877	94
+particle verbs	1992	333	953	169

5.2 SMT Results

Table 2 shows translation quality (BLEU) with different representations of German compounds and particle verbs. Head binarization not only yields improvements over the baseline, but also allows for larger gains from morphological segmentation. We attribute this to the fact that full compounds, and prefixed particle verbs, are not always a constituent in the segmented representation, and that binarization compensates this theoretical drawback.

With head binarization, we find substantial improvements from compound splitting of 0.7–1.1 BLEU. On newstest2014, the improvement is almost twice of that reported in related work (Williams et al., 2014), which also uses a hierarchical representation of compounds, albeit one that does not allow for dependency modelling. Examples of correct, unseen compounds generated include *Staubsauger|roboter* 'vacuum cleaner robot', *Gravitation|s|wellen* 'gravitational waves', and *NPD|-|verbot|s|verfahren* 'NPD banning process'.[8]

[5] We use the last position in the clause as default location, but put the particle before any subordinated and coordinated clauses, which occur in the *Nachfeld* (the 'final field' in topological field theory).

[6] We use *mteval-v13a.pl* for comparability to official WMT results; all significance values reported are obtained with MultEval (Clark et al., 2011).

[7] In contrast to our other systems in this paper, RDLM is trained on all monolingual data for the full system, and two models are added: a 5-gram Neural Network language model (Vaswani et al., 2013), and soft source-syntactic constraints (Huck et al., 2014).

[8] Note that *Staubsauger*, despite being a compound, is not

Particle verb restructuring yields additional gains of 0.1–0.4 BLEU. One reason for the smaller effect of particle verb restructuring is that the difficult cases – separated particle verbs and those with infixation – are rarer than compounds, with 2841 rare compounds [that would be split by our compound splitter] in the reference texts, in contrast to 553 separated particle verbs, and 176 particle verbs with infixation, as Table 3 illustrates. If we only evaluate the sentences containing a particle verb with *zu*-infix in the reference, 165 in total for newstest2014/5, we observe an improvement of 0.8 BLEU on this subset (22.1→22.9), significant with $p < 0.05$.

The positive effect of restructuring is also apparent in frequency statistics. Table 3 shows that the baseline system severely undergenerates compounds and separated/infixed particle verbs. Binarization, compound splitting, and particle verb restructuring all contribute to bringing the distribution of compounds and particle verbs closer to the reference.

In total, the restructured representation yields improvements of 1.4–1.8 BLEU over our baseline. The *full system* is competitive with official submissions to the WMT 2015 shared translation tasks. It outperforms our submission (Williams et al., 2015) by 0.4 BLEU, and outperforms other phrase-based and syntax-based submissions by 0.8 BLEU or more. The best reported result according to BLEU is an ensemble of Neural MT systems (Jean et al., 2015), which achieves 24.9 BLEU. In the human evaluation, both our submission and the Neural MT system were ranked 1–2 (out of 16), with no significant difference between them.

5.3 Synthetic LM Experiment

We perform a synthetic experiment to test our claim that a dependency representation allows for the modelling of agreement between morphemes. For 200 rare compounds [that would be split by our compound splitter] in the newstest2014/5 references, we artificially introduce agreement errors by changing the gender of the determiner. For instance, we create the erroneous sentence *sie erheben ein Handgepäckgebühr* as a complement to Example 1. We measure the ability of language models to prefer (give a higher probability to) the original reference sentence over the erroneous one. In the original representation, both a Kneser-Ney 5-gram LM and RDLM perform poorly due to data sparseness, with 70% and 57.5% accuracy, respectively. In the split representation, the RDLM reliably prefers the correct agreement (96.5% accuracy), whilst the performance of the 5-gram model even deteriorates (to 60% accuracy). This is because the gender of the first segment(s) is irrelevant, or even misleading, for agreement. For instance, *Handgepäck* is neuter, which could lead a morpheme-level n-gram model to prefer the determiner *ein*, but *Handgepäckgebühr* is feminine and requires *eine*.

segmented due to its frequency.

6 Conclusion

Our main contribution is that we exploit the hierarchical structure of morphemes to model them jointly with syntax in a dependency-based string-to-tree SMT model. We describe the dependency annotation of two morphologically complex word classes in German, compounds and particle verbs, and show that our tree representation yields improvements in translation quality of 1.4–1.8 BLEU in the WMT English–German translation task.[9]

The principle of jointly representing syntactic and morphological structure in dependency trees can be applied to other language pairs, and we expect this to be helpful for languages with a high degree of morphological synthesis. However, the annotation needs to be adapted to the respective languages. For example, French compounds such as *arc-en-ciel* 'rainbow' are head-initial, in contrast to head-final Germanic compounds.

Variable-Length Word Encodings for Neural Translation Models

Rohan Chitnis and **John DeNero**
Computer Science Division
University of California, Berkeley
{ronuchit,denero}@berkeley.edu

Abstract

Recent work in neural machine translation has shown promising performance, but the most effective architectures do not scale naturally to large vocabulary sizes. We propose and compare three variable-length encoding schemes that represent a large vocabulary corpus using a much smaller vocabulary with no loss in information. Common words are unaffected by our encoding, but rare words are encoded using a sequence of two pseudo-words. Our method is simple and effective: it requires no complete dictionaries, learning procedures, increased training time, changes to the model, or new parameters. Compared to a baseline that replaces all rare words with an *unknown word* symbol, our best variable-length encoding strategy improves WMT English-French translation performance by up to 1.7 BLEU.

1 Introduction

Bahdanau et al. (2014) propose a neural translation model that learns vector representations for individual words as well as word sequences. Their approach jointly predicts a translation and a latent word-level alignment for a sequence of source words. However, the architecture of the network does not scale naturally to large vocabularies (Jean et al., 2014).

In this paper, we propose a novel approach to circumvent the large-vocabulary challenge by preprocessing the source and target word sequences, encoding them as a longer token sequence drawn from a small vocabulary that does not discard any information. Common words are unaffected, but rare words are encoded as a sequence of two pseudo-words. The exact same learning and inference machinery applied to these transformed data yields improved translations.

We evaluate a family of 3 different encoding schemes based on Huffman codes. All of them eliminate the need to replace rare words with the *unknown word* symbol. Our approach is simpler than other methods recently proposed to address the same issue. It does not introduce new parameters into the model, change the model structure, affect inference, require access to a complete dictionary, or require any additional learning procedures. Nonetheless, compared to a baseline system that replaces all rare words with an *unknown word* symbol, our encoding approach improves English-French news translation by up to 1.7 BLEU.

2 Background

2.1 Neural Machine Translation

Neural machine translation describes approaches to machine translation that learn from corpora in a single integrated model that embeds words and sentences into a vector space (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014). We focus on one recent approach to neural machine translation, proposed by Bahdanau et al. (2014), that predicts both a translation and its alignment to the source sentence, though our technique is relevant to related approaches as well.

The architecture consists of an encoder and a decoder. The encoder receives a source sentence $\mathbf{x}$ and encodes each prefix using a recurrent neural network that recursively combines embeddings x_j for each word position j:

$$\overrightarrow{h}_j = f(x_j, \overrightarrow{h}_{j-1}) \quad (1)$$

where f is a non-linear function. Reverse encodings $\overleftarrow{h}_j$ are computed similarly to represent suffixes of the sentence. These vector representations are stacked to form h_j, a representation of the

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2088–2093,
Lisbon, Portugal, 17-21 September 2015.

whole sentence focused on position j.

The decoder predicts each target word y_i sequentially according to the distribution

$$P(y_i|y_{i-1}, ..., y_1, \mathbf{x}) = g(y_{i-1}, s_i, c_i) \quad (2)$$

where s_i is a hidden decoder state summarizing the prefix of the translation generated so far, c_i is a summary of the entire input sequence, and g is another non-linear function. Encoder and decoder parameters are jointly optimized to maximize the log-likelihood of a training corpus.

Depending on the approach to neural translation, c can take multiple forms. Bahdanau et al. (2014) propose integrating an attention mechanism in the decoder, which is trained to determine on which portions of the source sentence to focus. The decoder computes c_i, the summarizing context vector, as a convex combination of the h_j. The coefficients of this combination are proportional (softmax) to an alignment model prediction $\exp a(h_j, s_i)$, where a is a non-linear function.

The speed of prediction scales with the output vocabulary size, due to the denominator of Equation 2 (Jean et al., 2014). The input vocabulary size is also a challenge for storage and learning. As a result, neural machine translation systems only consider the top 30K to 100K most frequent words in a training corpus, replacing the other words with an *unknown word* symbol.

2.2 Related Work

There has been much recent work in improving translation quality by addressing these vocabulary size challenges. Luong et al. (2014) describe an approach that, similar to ours, treats the translation system as a black box. They eliminate unknown symbols by training the system to recognize from where in the source text each unknown word in the target text came, so that in a postprocessing phase, the unknown word can be replaced by a dictionary lookup of the corresponding source word. In contrast, our method does not rely on access to a complete dictionary, and instead transforms the data to allow the system itself to learn translations for even the rare words.

Some approaches have altered the model to circumvent the expensive normalization computation, rather than applying preprocessing and postprocessing on the text. Jean et al. (2014) develop an importance sampling strategy for approximating the softmax computation. Mnih and Kavukcuoglu (2013) present a technique for approximation of the target word probability using noise-contrastive estimation.

Sequential or hierarchical encodings of large vocabularies have played an important role in recurrent neural network language models, primarily to address the inference time issue of large vocabularies. Mikolov et al. (2011b) describe an architecture in which output word types are grouped into classes by frequency: the network first predicts a class, then a word in that class. Mikolov et al. (2013) describe an encoding of the output vocabulary as a binary tree. To our knowledge, hierarchical encodings have not been applied to the input vocabulary of a machine translation system.

Other methods have also been developed to work around large-vocabulary issues in language modeling. Morin and Bengio (2005), Mnih and Hinton (2009), and Mikolov et al. (2011a) develop hierarchical versions of the softmax computation; Huang et al. (2012) and Collobert and Weston (2008) remove the need for normalization, thus avoiding computation of the summation term over the entire vocabulary.

2.3 Huffman Codes

An encoding can be used to represent a sequence of tokens from a large vocabulary $\mathcal{V}$ using a small vocabulary $\mathcal{W}$. In the case of translation, let $\mathcal{V}$ be the original corpus vocabulary, which can number in the millions of word types in a typical corpus. Let $\mathcal{W}$ be the vocabulary size of a neural translation model, typically set to a much smaller number such as 30,000.

A deterministically invertible, variable-length encoding maps each $v \in \mathcal{V}$ to a sequence $w \in \mathcal{W}+$ such that no other $v' \in \mathcal{V}$ is mapped to a prefix of w. Encoding simply replaces each element of $\mathcal{V}$ according to the map, and decoding is unambiguous because of this prefix restriction. An encoding can be represented as a tree in which each leaf corresponds to an element of $\mathcal{V}$, each node contains a symbol from $\mathcal{W}$, and the encoding of any leaf is its path from the root.

A Huffman code is an optimal encoding that uses as few symbols from $\mathcal{W}$ as possible to encode an original sequence of symbols from $\mathcal{V}$. Although binary codes are typical, $\mathcal{W}$ can have any size. An optimal encoding can be found using a greedy algorithm (Huffman, 1952).

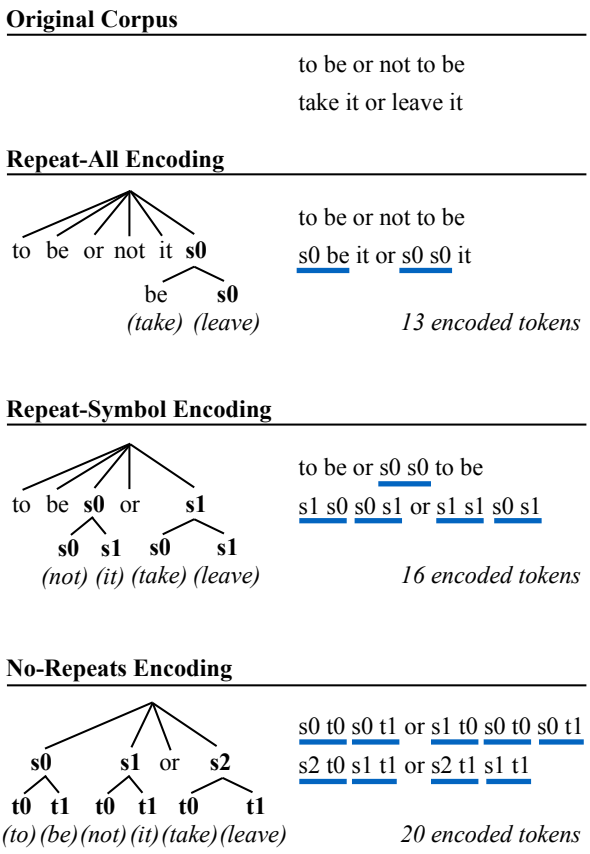

Figure 1: Our three encoding schemes are applied to a two-sentence toy corpus for which each word type appears one or two times, and the total vocabulary size V is 7. An optimal encoding tree under each scheme is shown for an encoded vocabulary size W of 6. As stricter constraints are imposed on the encoding, the encoded corpus length increases and the number of elements of V that can be represented using a single symbol decreases. Two-symbol encodings of rare words are underlined.

3 Variable-Length Encoding Methods

We consider three different encoding schemes that are based on Huffman codes. The encoding for a toy corpus under each scheme is depicted in Figure 1. While a Huffman code achieves the shortest possible encoded length using a fixed vocabulary size W, symbols are often shared between both common words and rare words. The variants we consider are designed to prevent specific forms of symbol sharing across encodings.

3.1 Encoding Schemes

Repeat-All. The first scheme is a standard Huffman code. In our experiments with $V \approx 2 \cdot 10^6$, $W = 3 \cdot 10^4$, and frequencies drawn from the WMT corpus, all words in $\mathcal{V}$ are encoded as either a single symbol or two symbols of $\mathcal{W}$. We denote the single-symbol words (which have the highest frequency) as *common*, and we call the other words *rare*. The *Repeat-All* encoding scheme has the highest number of common words. In Figure 1, common words are represented as themselves. Rare words are represented by two words, and the first is always a pseudo-word symbol introduced into $\mathcal{W}$ of the form **sX** for an integer X.

Repeat-Symbol. The *Repeat-Symbol* encoding scheme does not allow common-word symbols to appear in the encoding of rare words. Instead, each rare word is encoded as a two-symbol sequence of the form "**sX sY**," where X and Y are integers that may be the same or different. This scheme decreases the number of common words in order to encode all rare words using a restricted set of symbols. In this scheme, a common word in the encoded vocabulary always corresponds to a common word in the original vocabulary, reducing ambiguity of common word symbols at the expense of increasing ambiguity of pseudo-word symbols.

No-Repeats. Our final encoding scheme, *No-Repeats*, uses a different vocabulary for the first and second symbols in each rare word. That is, rare words are represented as "**sX tY**," where X and Y are integers that may be the same or different. In this scheme, common words and rare words do not share symbols, and each symbol can immediately be identified as common, the first of a rare encoding pair, or the second of a rare encoding pair.

3.2 Symbol Counts

To maximize performance, it is critical to set the number of common words (which transform to themselves) as high as possible while satisfying the desired total vocabulary size, counting all the newly introduced symbols. In this section, we algebraically derive this optimal number of common words for each encoding scheme. We define the following:

V: Size of the original vocabulary.

W: Size of the encoded vocabulary.

C: Number of common words.

S: Number of pseudo-words of the form **sX**.

T: Number of pseudo-words of the form **tX**.

We are interested in maximizing C so that total encoding length is minimized.

Repeat-All. We would like to encode the $V - C$ rare words, using only $W - C$ new symbols. To do so, for each new symbol (non-terminal node in our encoding tree), we have all W symbols under it in that branch. Therefore, we maximize C satisfying the constraint that

$$V - C \leq (W - C) \cdot W$$

Repeat-Symbol. Out of the $V - C$ rare words, we would like to pack them into a complete tree so that they may be encoded using our remaining $W - C$ symbols. Therefore, we maximize C satisfying the constraint that

$$V - C \leq (W - C)^2$$

No-Repeats. Again, we desire to pack $V - C$ rare words into a complete tree where we may use $W - C$ symbols. To maximize C, we let $S = T$. Because $S + T + C = W$, we have that $2S + C = W$. Therefore, we maximize C satisfying the constraint that

$$V - C \leq \left(\frac{W - C}{2}\right)^2$$

4 Experimental Results

We trained a public implementation[1] of the system described in Bahdanau et al. (2014) on the English-French parallel corpus from ACL WMT 2014, which contains 348M tokens. We evaluated on news-test-2014, also from WMT 2014, which contains 3003 sentences. All experiments used the same learning parameters and vocabulary size of 30,000.

We constructed each encoding by the following method. First, we used the formulas derived in the previous section to calculate the optimal number of common words C for each encoding scheme, using V to be the true vocabulary size of the training corpus and $W = 30,000$. We then found the C most common words in the text and encoded them as themselves. For the remaining rare words, we encoded them using a distinct symbol whose form matched the one prescribed for each encoding scheme. The encoding was then applied separately to both the source text and the target text. Our encoding schemes all increased the total number of tokens in the training corpus by approximately 4%.

Encoding	BLEU	# Common Words
None	25.77	30,000
Repeat-All	27.45	29,940
Repeat-Symbol	26.52	28,860
No-Repeats	25.79	27,320

Table 1: BLEU scores (%) on detokenized test set for each encoding scheme after training for 5 days.

To construct the mapping from rare words to their 2-word encodings, we binned rare words by frequency into branches. Thus, rare words of similar frequency in the training corpus tended to have encodings with the same first symbol. Similarly, the standard Huffman construction algorithm groups together rare words with similar frequencies within subtrees. More intelligent heuristics for constructing trees, such as using translation statistics instead of training corpus frequency, would be an interesting area of future work.

4.1 Results

We used the RNNsearch-50 architecture from Bahdanau et al. (2014) as our machine translation system. We report results for this system alone, as well as for each of our three encoding schemes, using the BLEU metric (Papineni et al., 2002). Table 1 summarizes our results after training each variant for 5 days, corresponding to roughly 2 passes through the 180K-sentence training corpus.

Alternative techniques that leverage bilingual resources have been shown to provide larger improvements. Jean et al. (2014) demonstrate an improvement of 3.1 BLEU by using bilingual word co-occurrence statistics in an aligned corpus to replace *unknown word* tokens. Luong et al. (2014) demonstrate an improvement of up to 2.8 BLEU over a series of stronger baselines using an unknown word model that also makes predictions using a bilingual dictionary.

4.2 Analysis

Our results indicate that the encoding scheme that keeps the highest number of common words, *Repeat-All*, performs best. Table 2 shows the unigram precision of each output. The common word translation accuracy is higher for all encoding schemes than for the baseline, although all preci-

Encoding	Common	Rare	1st Symbol
None	62.0	0.0	-
Repeat-All	65.8	28.0	64.8
Repeat-Symbol	65.5	16.5	24.8
No-Repeats	63.6	15.8	25.7

Table 2: Test set precision (%) on common words and rare words for each encoding strategy. *1st Symbol* denotes the precision of the first pseudo-word symbol in an encoded rare word.

sions are similar. Larger differences appear in the precision of rare words. The scheme that encodes rare words using both pseudo-words and common words gives substantially higher rare word accuracy than any other approach.

The final column of Table 2 shows the unigram precision of the first pseudo-word in an encoded rare word. The *Repeat-All* scheme uses only 60 different first symbols to encode all rare words. The other schemes require over 1,000. The fact that *Repeat-All* has a constrained set of rare word first symbols may account for its higher rare word precision.

It is possible for the model to predict an invalid encoded sequence that does not correspond to any word in the original vocabulary. However, in our experiments, we did not observe any such sequences in the decoding of the test set. A reasonable way to deal with invalid sequences would be to drop them from the output during decoding.

5 Conclusion and Future Work

We described a novel approach for encoding the source and target text based on Huffman coding schemes, eliminating the use of the *unknown word* symbol. An important continuation of our work would be to develop heuristics for effectively grouping "similar" words in the source and target text, so that they tend to have encodings that share a symbol. Even with our naive grouping by corpus frequency, our approach offers a simple way to predict both common and rare words in a neural translation model. As a result, performance improves by up to 1.7 BLEU. We expect that the simplicity of our technique will allow for straightforward combination with other enhancements and neural models.

Abstract

The neural network joint model (NNJM), which augments the neural network language model (NNLM) with an m-word source context window, has achieved large gains in machine translation accuracy, but also has problems with high normalization cost when using large vocabularies. Training the NNJM with noise-contrastive estimation (NCE), instead of standard maximum likelihood estimation (MLE), can reduce computation cost. In this paper, we propose an alternative to NCE, the binarized NNJM (BNNJM), which learns a binary classifier that takes both the context and target words as input, and can be efficiently trained using MLE. We compare the BNNJM and NNJM trained by NCE on various translation tasks.

1 Introduction

Neural network translation models, which learn mappings over real-valued vector representations in high-dimensional space, have recently achieved large gains in translation accuracy (Hu et al., 2014; Devlin et al., 2014; Sundermeyer et al., 2014; Auli et al., 2013; Schwenk, 2012; Sutskever et al., 2014; Bahdanau et al., 2015).

Notably, Devlin et al. (2014) proposed a neural network joint model (NNJM), which augments the n-gram neural network language model (NNLM) with an m-word source context window, as shown in Figure 1a. While this model is effective, the computation cost of using it in a large-vocabulary SMT task is quite expensive, as probabilities need to be normalized over the entire vocabulary. To solve this problem, Devlin et al. (2014) presented a technique to train the NNJM to be self-normalized and avoided the expensive normalization cost during decoding. However, they also

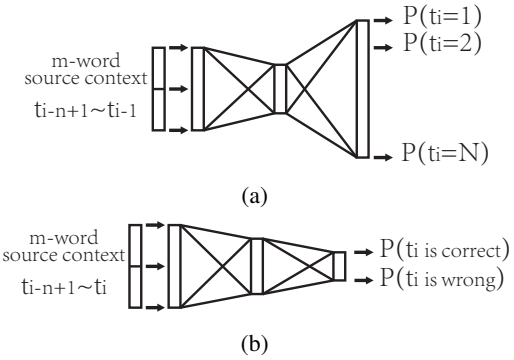

Figure 1: (a) the traditional NNJM and (b) the proposed BNNJM

note that this self-normalization technique sacrifices neural network accuracy, and the training process for the self-normalized neural network is very slow, as with standard maximum likelihood estimation (MLE).

To remedy the problem of long training times in the context of NNLMs, Vaswani et al. (2013) used a method called noise contrastive estimation (NCE). Compared with MLE, NCE does not require repeated summations over the whole vocabulary and performs nonlinear logistic regression to discriminate between the observed data and artificially generated noise.

This paper proposes an alternative framework of binarized NNJMs (BNNJM), which are similar to the NNJM, but use the current target word not as the output, but as the input of the neural network, estimating whether the target word under examination is correct or not, as shown in Figure 1b. Because the BNNJM uses the current target word as input, the information about the current target word can be combined with the context word information and processed in the hidden layers.

The BNNJM learns a simple binary classifier, given the context and target words, therefore it can be trained by MLE very efficiently. "Incorrect" target words for the BNNJM can be generated in the same way as NCE generates noise

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2094–2099,
Lisbon, Portugal, 17-21 September 2015.

for the NNJM. We present a novel noise distribution based on translation probabilities to train the NNJM and the BNNJM efficiently.

2 Neural Network Joint Model

Let $T = t_1^{|T|}$ be a translation of $S = s_1^{|S|}$. The NNJM (Devlin et al., 2014) defines the following probability,

$$P(T|S) = \prod_{i=1}^{|T|} P\left(t_i | s_{a_i-(m-1)/2}^{a_i+(m-1)/2}, t_{i-n+1}^{i-1}\right) \quad (1)$$

where target word t_i is affiliated with source word s_{a_i}. Affiliation a_i is derived from the word alignments using heuristics[1]. To estimate these probabilities, the NNJM uses m source context words and $n-1$ target history words as input to a neural network and performs estimation of unnormalized probabilities $p(t_i|C)$ before normalizing over all words in the target vocabulary V,

$$\begin{aligned} P(t_i|C) &= \frac{p(t_i|C)}{Z(C)} \\ Z(C) &= \sum_{t_i' \in V} p(t_i'|C) \end{aligned} \quad (2)$$

where C stands for source and target context words as in Equation 1.

The NNJM can be trained on a word-aligned parallel corpus using standard MLE, but the cost of normalizing over the entire vocabulary to calculate the denominator in Equation 2 is quite large. Devlin et al. (2014)'s self-normalization technique can avoid normalization cost during decoding, but not during training.

NCE can be used to train NNLM-style models (Vaswani et al., 2013) to reduce training times. NCE creates a noise distribution $q(t_i)$, selects k noise samples $t_{i1}, ..., t_{ik}$ for each t_i and introduces a random variable v which is 1 for training examples and 0 for noise samples,

$$\begin{aligned} P(v=1, t_i|C) &= \frac{1}{1+k} \cdot \frac{p(t_i|C)}{Z(C)} \\ P(v=0, t_i|C) &= \frac{k}{1+k} \cdot q(t_i). \end{aligned}$$

NCE trains the model to distinguish training data from noise by maximize the conditional likelihood,

$$L = \log P(v=1|C, t_i) + \sum_{j=1}^{k} \log P(v=0|C, t_{ik}).$$

The normalization cost can be avoided by using $p(t_i|C)$ as an approximation of $P(t_i|C)$.[2]

[1] If t_i aligns to exactly one source word, a_i is the index of this source word; If t_i aligns to multiple source words, a_i is the index of the aligned word in the middle; If t_i is unaligned, they inherit its affiliation from the closest aligned word.

[2] The theoretical properties of self-normalization techniques, including NCE and Devlin et al. (2014)'s method, are investigated by Andreas and Klein (2015).

3 Binarized NNJM

In this paper, we propose a new framework of the binarized NNJM (BNNJM), which is similar to the NNJM but learns not to predict the next word given the context, but solves a binary classification problem by adding a variable $v \in \{0, 1\}$ that stands for whether the current target word t_i is correctly/wrongly produced in terms of source context words $s_{a_i-(m-1)/2}^{a_i+(m-1)/2}$ and target history words t_{i-n+1}^{i-1},

$$P\left(v | s_{a_i-(m-1)/2}^{a_i+(m-1)/2}, t_{i-n+1}^{i-1}, t_i\right).$$

The BNNJM is learned by a feed-forward neural network with $m+n$ inputs $\left\{s_{a_i-(m-1)/2}^{a_i+(m-1)/2}, t_{i-n+1}^{i-1}, t_i\right\}$ and two outputs for $v = 1/0$.

Because the BNNJM uses the current target word as input, the information about the current target word can be combined with the context word information and processed in the hidden layers. Thus, the hidden layers can be used to learn the difference between correct target words and noise in the BNNJM, while in the NNJM the hidden layers just contain information about context words and only the output layer can be used to discriminate between the training data and noise, giving the BNNJM more power to learn this classification problem.

We can use the BNNJM probability in translation as an approximation for the NNJM as below,

$$\begin{aligned} &P\left(t_i | s_{a_i-(m-1)/2}^{a_i+(m-1)/2}, t_{i-n+1}^{i-1}\right) \\ &\approx P\left(v=1 | s_{a_i-(m-1)/2}^{a_i+(m-1)/2}, t_{i-n+1}^{i-1}, t_i\right). \end{aligned}$$

As a binary classifier, the gradient for a single example in the BNNJM can be calculated efficiently by MLE without it being necessary to calculate the softmax over the full vocabulary. On the other hand, we need to create "positive" and "negative" examples for the classifier. Positive examples can be extracted directly from the word-aligned parallel corpus as $\left\langle s_{a_i-(m-1)/2}^{a_i+(m-1)/2}, t_{i-n+1}^{i-1}, t_i \right\rangle$; Negative examples can be generated for each positive example in the same way that NCE generates noise data as $\left\langle s_{a_i-(m-1)/2}^{a_i+(m-1)/2}, t_{i-n+1}^{i-1}, t_i' \right\rangle$, where $t_i' \in V \setminus \{t_i\}$.

4 Noise Sampling

4.1 Unigram Noise

Vaswani et al. (2013) adopted the unigram probability distribution (UPD) to sample noise for train-

Figure 2: A parallel sentence pair.

ing NNLMs with NCE,

$$q\left(t_i'\right) = \frac{occur(t_i')}{\sum\limits_{t_i'' \in V} occur(t_i'')}$$

where $occur\left(t_i'\right)$ stands for how many times t_i' occurs in the training corpus.

4.2 Translation Model Noise

In this paper, we propose a noise distribution specialized for translation models, such as the NNJM or BNNJM.

Figure 2 gives a Chinese-to-English parallel sentence pair with word alignments to demonstrate the intuition behind our method. Focusing on s_{a_i}="安排", this is translated into t_i ="*arrange*". For this positive example, UPD is allowed to sample any arbitrary noise, such as t_i' = "*banana*". However, in this case, noise t_i' = "*banana*" is not useful for model training, as constraints on possible translations given by the phrase table ensure that "安排" will never be translated into "*banana*". On the other hand, noise t_i' = "*arranges*" and "*arrangement*" are both possible translations of "安排" and therefore useful training data, that we would like our model to penalize.

Based on this intuition, we propose the use of another noise distribution that only uses t_i' that are possible translations of s_{a_i}, i.e., $t_i' \in U\left(s_{a_i}\right) \setminus \{t_i\}$, where $U\left(s_{a_i}\right)$ contains all target words aligned to s_{a_i} in the parallel corpus.

Because $U\left(s_{a_i}\right)$ may be quite large and contain many wrong translations caused by wrong alignments, "*banana*" may actually be included in U("安排"). To mitigate the effect of uncommon examples, we use a translation probability distribution (TPD) to sample noise t_i' from $U\left(s_{a_i}\right) \setminus \{t_i\}$ as follows,

$$q\left(t_i'|s_{a_i}\right) = \frac{align\left(s_{a_i}, t_i'\right)}{\sum_{t_i'' \in U\left(s_{a_i}\right)} align\left(s_{a_i}, t_i''\right)}$$

where $align\left(s_{a_i}, t_i'\right)$ is how many times t_i' is aligned to s_{a_i} in the parallel corpus.

Note that t_i could be unaligned, in which case we assume that it is aligned to a special $null$ word. Noise for unaligned words is sampled according to the TPD of the $null$ word. If several target/source words are aligned to one source/target word, we choose to combine these target/source words as a new target/source word.[3]

5 Experiments

5.1 Setting

We evaluated the effectiveness of the proposed approach for Chinese-to-English (CE), Japanese-to-English (JE) and French-to-English (FE) translation tasks. The datasets officially provided for the patent machine translation task at NTCIR-9 (Goto et al., 2011) were used for the CE and JE tasks. The development and test sets were both provided for the CE task while only the test set was provided for the JE task. Therefore, we used the sentences from the NTCIR-8 JE test set as the development set. Word segmentation was done by BaseSeg (Zhao et al., 2006) for Chinese and Mecab[4] for Japanese. For the FE language pair, we used standard data for the WMT 2014 translation task. The training sets for CE, JE and FE tasks contain 1M, 3M and 2M sentence pairs, respectively.

For each translation task, a recent version of Moses HPB decoder (Koehn et al., 2007) with the training scripts was used as the baseline (Base). We used the default parameters for Moses, and a 5-gram language model was trained on the target side of the training corpus using the IRSTLM Toolkit[5] with improved Kneser-Ney smoothing. Feature weights were tuned by MERT (Och, 2003).

The word-aligned training set was used to learn the NNJM and the BNNJM.[6] For both NNJM and BNNJM, we set $m = 7$ and $n = 5$. The NNJM was trained by NCE using UPD and TPD as noise distributions. The BNNJM was trained by standard MLE using UPD and TPD to generate negative examples.

The number of noise samples for NCE was set to be 100. For the BNNJM, we used only one negative example for each positive example in each training epoch, as the BNNJM needs to calculate

[3]The processing for multiple alignments helps sample more useful negative examples for TPD, and had little effect on the translation performance when UPD was used as the noise distribution for the NNJM and the BNNJM in our preliminary experiments.

[4]http://sourceforge.net/projects/mecab/files/

[5]http://hlt.fbk.eu/en/irstlm

[6]Both the NNJM and the BNNJM had one hidden layer, 100 hidden nodes, input embedding dimension 50, output embedding dimension 50. A small set of training data was used as validation data. The training process was stopped when validation likelihood stopped increasing.

the whole neural network (not just the output layer like the NNJM) for each noise sample and thus noise computation is more expensive. However, for different epochs, we resampled the negative example for each positive example, so the BNNJM can make use of different negative examples.

5.2 Results and Discussion

Table 1 shows how many epochs these two models needed and the training time for each epoch on a 10-core 3.47GHz Xeon X5690 machine.[7] Translation results are shown in Table 2.

We can see that using TPD instead of UPD as a noise distribution for the NNJM trained by NCE can speed up the training process significantly, with a small improvement in performance. But for the BNNJM, using different noise distributions affects translation performance significantly. The BNNJM with UPD does not improve over the baseline system, likely due to the small number of noise samples used in training the BNNJM, while the BNNJM with TPD achieves good performance, even better than the NNJM with TPD on the Chinese-to-English and French-to-English translation tasks.

From Table 2, the NNJM does not improve translation performance significantly on the FE task. Note that the baseline BLEU for the FE task is lower than CE and JE tasks, indicating that learning is harder for the FE task than CE and JE tasks. The validation perplexities of the NNJM with UPD for CE, JE and FE tasks are 4.03, 3.49 and 8.37. Despite these difficult learning circumstances and lack of large gains for the NNJM, the BNNJM improves translations significantly for the FE task, suggesting that the BNNJM is more robust to difficult translation tasks that are hard for the NNJM.

[7]The decoding time for the NNJM and the BNNJM were similar, since the NNJM trained by NCE uses $p(t_i|C)$ as an approximation of $P(t_i|C)$ without normalization and the BNNJM only needs to be normalized over two output neurons.

Table 4: Scores for different translations.

Table 3 gives Chinese-to-English translation examples to demonstrate how the BNNJM (with TPD) helps to improve translations over the NNJM (with TPD). In this case, the BNNJM helps to translate the phrase "该 移动 持续 到" better. Table 4 gives translation scores for these two translations calculated by the NNJM and the BNNJM. Context words are used for predictions but not shown in the table.

As can be seen, the BNNJM prefers T_2 while the NNJM prefers T_1. Among these predictions, the NNJM and the BNNJM predict the translation for "到" most differently. The NNJM clearly predicts that in this case "到" should be translated into "to" more than "until", likely because this example rarely occurs in the training corpus. However, the BNNJM prefers "until" more than "to", which

demonstrates the BNNJM's robustness to less frequent examples.

5.3 Analysis for JE Translation Results

Finally, we examine the translation results to explore why the BNNJM with TPD did not outperform the NNJM with TPD for the JE translation task, as it did for the other translation tasks. We found that using the BNNJM instead of the NNJM on the JE task did improve translation quality significantly for infrequent words, but not for frequent words.

First, we describe how we estimate translation quality for infrequent words. Suppose we have a test set S, a reference set R and a translation set T with I sentences,

$$S_i\,(1 \leq i \leq I)\,, R_i\,(1 \leq i \leq I)\,, T_i\,(1 \leq i \leq I)$$

T_i contains J individual words,

$$W_{ij} \in Words\,(T_i)$$

$T_o\,(W_{ij})$ is how many times W_{ij} occurs in T_i and $R_o\,(W_{ij})$ is how many times W_{ij} occurs in R_i.

The general 1-gram translation accuracy (Papineni et al., 2002) is calculated as,

$$P_g = \frac{\sum_{i=1}^{I}\sum_{j=1}^{J} \min\left(T_o(W_{ij}), R_o(W_{ij})\right)}{\sum_{i=1}^{I}\sum_{j=1}^{J} T_o(W_{ij})}$$

This general 1-gram translation accuracy does not distinguish word frequency.

We use a modified 1-gram translation accuracy that weights infrequent words more heavily,

$$P_c = \frac{\sum_{i=1}^{I}\sum_{j=1}^{J} \min(T_o(W_{ij}), R_o(W_{ij})) \cdot \frac{1}{Occur\left(W_{ij}\right)}}{\sum_{i=1}^{I}\sum_{j=1}^{J} T_o(W_{ij})}$$

where $Occur\,(W_{ij})$ is how many times W_{ij} occurs in the whole reference set. Note P_c will not be 1 even in the case of completely accurate translations, but it can approximately reflect infrequent word translation accuracy, since correct frequent word translations contribute less to P_c.

Table 5 shows P_g and P_c for different translation tasks. It can be seen that the BNNJM improves infrequent word translation quality similarly for all translation tasks, but improves general translation quality less for the JE task than the other translation tasks. We conjecture that the reason why the BNNJM is less useful for frequent word translations on the JE task is the fact that the JE parallel corpus has less accurate function word alignments than other language pairs, as the grammatical features of Japanese and English are quite different.[8] Wrong function word alignments will make noise sampling less effective and therefore lower the BNNJM performance for function word translations. Although wrong word alignments will also make noise sampling less effective for the NNJM, the BNNJM only uses one noise sample for each positive example, so wrong word alignments affect the BNNJM more than the NNJM.

6 Related Work

Xu et al. (2011) proposed a method to use binary classifiers to learn NNLMs. But they also used the current target word in the output, similarly to NCE. The BNNJM uses the current target word as input, so the information about the current target word can be combined with the context word information and processed in hidden layers.

Mauser et al. (2009) presented discriminative lexicon models to predict target words. They train a separate classifier for each target word, as these lexicon models use discrete representations of words and different classifiers do not share features. In contrast, the BNNJM uses real-valued vector representations of words and shares features, so we train one classifier and can use the similarity information between words.

7 Conclusion

This paper proposes an alternative to the NNJM, the BNNJM, which learns a binary classifier that takes both the context and target words as input and combines all useful information in the hidden layers. We also present a novel noise distribution based on translation probabilities to train the BNNJM efficiently. With the improved noise sampling method, the BNNJM can achieve comparable performance with the NNJM and even improve the translation results over the NNJM on Chinese-to-English and French-to-English translations.

[8] Infrequent words are usually content words and frequent words are usually function words.

Abstract

When applying machine learning to problems in NLP, there are many choices to make about how to represent input texts. They can have a big effect on performance, but they are often uninteresting to researchers or practitioners who simply need a module that performs well. We apply sequential model-based optimization over this space of choices and show that it makes standard linear models competitive with more sophisticated, expensive state-of-the-art methods based on latent variables or neural networks on various topic classification and sentiment analysis problems. Our approach is a first step towards black-box NLP systems that work with raw text and do not require manual tuning.

1 Introduction

NLP researchers and practitioners spend a considerable amount of time comparing machine-learned models of text that differ in relatively uninteresting ways. For example, in categorizing texts, should the "bag of words" include bigrams, and is tf-idf weighting a good idea? In learning word embeddings, distributional similarity approaches have been shown to perform competitively with neural network models when the hyperparameters (e.g., context window, subsampling rate, smoothing constant) are carefully tuned (Levy et al., 2015). These choices matter experimentally, often leading to big differences in performance, with little consistency across tasks and datasets in which combination of choices works best. Unfortunately, these differences tell us little about language or the problems that machine learners are supposed to solve.

We propose that these decisions can be automated in a similar way to hyperparameter selection (e.g., choosing the strength of a ridge or lasso regularizer). Given a particular text dataset and classification task, we show a technique for optimizing over the space of representational choices, along with other "nuisances" that interact with these decisions, like hyperparameter selection. For example, using higher-order n-grams means more features and a need for stronger regularization and more training iterations. Generally, these decisions about instance representation are made by humans, heuristically; our work seeks to automate them, not unlike Daelemans et al. (2003), who proposed to use genetic algorithms to optimize representational choices.

Our technique instantiates sequential model-based optimization (SMBO; Hutter et al., 2011). SMBO and other Bayesian optimization approaches have been shown to work well for hyperparameter tuning (Bergstra et al., 2011; Hoffman et al., 2011; Snoek et al., 2012). Though popular in computer vision (Bergstra et al., 2013), these techniques have received little attention in NLP.

We apply it to logistic regression on a range of topic and sentiment classification tasks. Consistently, our method finds representational choices that perform better than linear baselines previously reported in the literature, and that, in some cases, are competitive with more sophisticated non-linear models trained using neural networks.

2 Problem Formulation and Notation

Let the training data consist of a collection of pairs $\boldsymbol{d}_{train} = \langle\langle d.i_1, d.o_1\rangle, \ldots, \langle d.i_n, d.o_n\rangle\rangle$, where each input $d.i \in \mathcal{I}$ is a text document and each output $d.o \in \mathcal{O}$, the output space. The overall training goal is to maximize a performance function f (e.g., classification accuracy, log-likelihood, F_1 score, etc.) of a machine-learned model, on a held-out dataset, $\boldsymbol{d}_{dev} \in (\mathcal{I} \times \mathcal{O})^{n'}$.

Classification proceeds in three steps: first, $\mathbf{x} : \mathcal{I} \rightarrow \mathbb{R}^N$ maps each input to a vector representation. Second, a predictive model (typically, its parameters) is learned from the inputs (now transformed into vectors) and outputs: $L : (\mathbb{R}^N \times \mathcal{O})^n \rightarrow (\mathbb{R}^N \rightarrow \mathcal{O})$. Finally, the resulting classifier $c : \mathcal{I} \rightarrow \mathcal{O}$ is fixed as $L(\boldsymbol{d}_{train}) \circ \mathbf{x}$ (i.e., the composition of the representation function with

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2100–2105,
Lisbon, Portugal, 17-21 September 2015.

the learned mapping).

Here we consider linear classifiers of the form $c(d.i) = \arg\max_{o \in \mathcal{O}} \mathbf{w}_o^\top \mathbf{x}(d.i)$, where the parameters $\mathbf{w}_o \in \mathbb{R}^N$, for each output o, are learned using logistic regression on the training data. We let $\mathbf{w}$ denote the concatenation of all $\mathbf{w}_o$. Hence the parameters can be understood as a function of the training data and the representation function $\mathbf{x}$. The performance function f, in turn, is a function of the held-out data $\boldsymbol{d}_{dev}$ and $\mathbf{x}$—also $\mathbf{w}$ and $\boldsymbol{d}_{train}$, through $\mathbf{x}$. For simplicity, we will write "$f(\mathbf{x})$" when the rest are clear from context.

Typically, $\mathbf{x}$ is fixed by the model designer, perhaps after some experimentation, and learning focuses on selecting the parameters $\mathbf{w}$. For logistic regression and many other linear models, this training step reduces to convex optimization in $N|\mathcal{O}|$ dimensions—a solvable problem that is costly for large datasets and/or large output spaces. In seeking to maximize f with respect to $\mathbf{x}$, we do not wish to carry out training any more times than necessary.

Choosing $\mathbf{x}$ can be understood as a problem of selecting *hyperparameter values*. We therefore turn to Bayesian optimization, a family of techniques that can be used to select hyperparameter values intelligently when solving for parameters ($\mathbf{w}$) is costly.

3 Bayesian Optimization

Our approach is based on sequential model-based optimization (SMBO; Hutter et al., 2011). It iteratively chooses representation functions $\mathbf{x}$. On each round, it makes this choice through a probabilistic model of f, then evaluates f—we call this a "trial." As in any iterative search algorithm, the goal is to balance exploration of options for $\mathbf{x}$ with exploitation of previously-explored options, so that a good choice is found in a small number of trials.

More concretely, in the tth trial, $\mathbf{x}_t$ is selected using an acquisition function $\mathcal{A}$ and a "surrogate" probabilistic model p_t. Second, f is evaluated given $\mathbf{x}_t$—an expensive operation which involves training to learn parameters $\mathbf{w}$ and assessing performance on the held-out data. Third, the surrogate model is updated. See Algorithm 1; details on $\mathcal{A}$ and p_t follow.

Acquisition Function. A good acquisition function returns high values for $\mathbf{x}$ when either the value $f(\mathbf{x})$ is predicted to be high, or the uncertainty about $f(\mathbf{x})$'s value is high; balancing between these is the classic tradeoff between exploitation and exploration. We use a criterion called Expected Improvement (EI; Jones, 2001),[1] which is the expectation (under the current surrogate model p_t) that $f(\mathbf{x}) = y$ will exceed $f(\mathbf{x}^*) = y^*$:

$$\mathcal{A}(\mathbf{x}; p_t, y^*) = \int_{-\infty}^{\infty} \max(y - y^*, 0) p_t(y \mid \mathbf{x}) dy$$

where $\mathbf{x}^*$ is chosen depending on the surrogate model, discussed below. (For now, think of it as a strongly-performing "benchmark" discovered in earlier iterations.) Other options for the acquisition function include maximum probability of improvement (Jones, 2001), minimum conditional entropy (Villemonteix et al., 2009), Gaussian process upper confidence bound (Srinivas et al., 2010), or a combination of them (Hoffman et al., 2011).

Algorithm 1 SMBO algorithm

Input: number of trials T, target function f
$p_1 =$ initial surrogate model
Initialize y^*
for $t = 1$ **to** T **do**
  $\mathbf{x}_t \leftarrow \arg\max_{\mathbf{x}} \mathcal{A}(\mathbf{x}; p_t, y^*)$
  $y_t \leftarrow$ evaluate $f(\mathbf{x}_t)$
  Update y^*
  Estimate p_t given $\mathbf{x}_{1:t}$ and $y_{1:t}$
end for

Surrogate Model. As a surrogate model, we use a tree-structured Parzen estimator (TPE; Bergstra et al., 2011).[2] This is a nonparametric approach to density estimation. We seek to estimate $p_t(y \mid \mathbf{x})$ where $y = f(\mathbf{x})$, the performance function that is expensive to compute exactly. The TPE approach seeks $p_t(y \mid \mathbf{x}) \propto p_t(y) \cdot \begin{cases} p_t^<(\mathbf{x}), & \text{if } y < y^* \\ p_t^\geq(\mathbf{x}), & \text{if } y \geq y^* \end{cases}$, where $p_t^<$ and $p_t^\geq$ are densities estimated using observations from previous trials that are less than and greater than y^*, respectively. In TPE, y^* is defined as some quantile of the observed y from previous trials; we use 15-quantiles.

As shown by Bergstra et al. (2011), the Expected Improvement in TPE can be written as:

[1] EI is the most widely used acquisition function that has been shown to work well on a range of tasks.

[2] Another common approach to the surrogate is the Gaussian process (Rasmussen and Williams, 2006; Hoffman et al., 2011; Snoek et al., 2012). Like Bergstra et al. (2011), our preliminary experiments found the TPE to perform favorably. Further TPE's tree-structured configuration space is advantageous, because it allows nested definitions of hyperparameters, which we exploit in our experiments (e.g., only allows bigrams to be chosen if unigrams are also chosen).

Hyperparameter	Values
n_{min}	$\{1, 2, 3\}$
n_{max}	$\{n_{min}, \ldots, 3\}$
weighting scheme	{tf, tf-idf, binary}
remove stop words?	{True, False}
regularization	$\{\ell_1, \ell_2\}$
regularization strength	$[10^{-5}, 10^{5}]$
convergence tolerance	$[10^{-5}, 10^{-3}]$

Table 1: The set of hyperparameters considered in our experiments. The top half are hyperparameters related to text representation, while the bottom half are logistic regression hyperparameters, which also interact with the chosen representation.

$\mathcal{A}(\mathbf{x}; p_t, y^*) \propto \left(\gamma + \frac{p_t^<(\mathbf{x})}{p_t^>(\mathbf{x})}(1-\gamma)\right)^{-1}$, where $\gamma = p_t(y < y^*)$, fixed at 0.15 by definition of y^* (above). Here, we prefer $\mathbf{x}$ with high probability under $p_t^>(\mathbf{x})$ and low probability under $p_t^<(\mathbf{x})$. To maximize this quantity, we draw many candidates according to $p_t^>(\mathbf{x})$ and evaluate them according to $p_t^<(\mathbf{x})/p_t^>(\mathbf{x})$. Note that $p(y)$ does not need to be given an explicit form. To compute $p_t^<(\mathbf{x})$ and $p_t^>(\mathbf{x})$, we associate each hyperparameter with a node in the graphical model and multiply individual probabilities at every node—see Bergstra et al. (2011) for details.

4 Experiments

We fix L to logistic regression. We optimize text representation based on the types of n-grams used, the type of weighting scheme, and the removal of stopwords; we also optimize the regularizer and training convergence criterion, which interact with the representation. See Table 1 for a complete list.

Note that even with this limited number of options, the number of possible combinations is huge,[3] so exhaustive search is computationally expensive. In all our experiments for all datasets, we limit ourselves to 30 trials per dataset. The only preprocessing we applied was downcasing.

We always use a development set to evaluate $f(\mathbf{x})$ during learning and report the final result on an unseen test set. We summarize the hyperparameters selected by our method, and the accuracies achieved (on test data) in Table 5. We discuss comparisons to baselines for each dataset in turn. For each of our datasets, we select supervised, non-ensemble classification methods from previous literature as baselines. In each case, we emphasize comparisons with the best-published linear method (often an SVM with a linear kernel with representation selected by experts) and the best-published method overall. In the following, "SVM" always means "linear SVM." All methods were trained and evaluated on the same training/testing splits as baselines; in cases where standard development sets were not available, we used a random 20% of the training data as a development set.

Stanford sentiment treebank (Socher et al., 2013)—Table 2. A sentence-level sentiment analysis dataset of rottentomatoes.com movie reviews: http://nlp.stanford.edu/sentiment. We use the binary classification task where the goal is to predict whether a review is positive or negative (no neutral). Our logistic regression model outperforms the baseline SVM reported by Socher et al. (2013), who used only unigrams but did not specify the weighting scheme for their SVM baseline. While our result is still below the state-of-the-art based on the the recursive neural tensor networks (Socher et al., 2013) and the paragraph vector (Le and Mikolov, 2014), we show that logistic regression is comparable with recursive and matrix-vector neural networks (Socher et al., 2011; Socher et al., 2012).

Method	Acc.
Naïve Bayes	81.8
SVM	79.4
Vector average	80.1
Recursive neural networks	82.4
LR (this work)	82.4
Matrix-vector RNN	82.9
Recursive neural tensor networks	85.4
Paragraph vector	87.8

Table 2: Comparisons on the Stanford sentiment treebank dataset. Scores are as reported by Socher et al. (2013) and Le and Mikolov (2014). Test size $= 6,920$.

Amazon electronics (McAuley and Leskovec, 2013)—Table 3. A binary sentiment analysis dataset of Amazon electronics product reviews: http://riejohnson.com/cnn_data.html. The best-performing methods on this dataset are based on convolutional neural networks (Johnson and Zhang, 2015).[4] Our method is on par with the second-best of these, outperforming all of the reported feed-forward neural networks and SVM variants Johnson and Zhang used as baselines. They varied

[3] It is actually infinite since the reg. strength and conv. tolerance are continuous values, but we could discretize them.

[4] These are convolutional neural networks with a rectifier activation function, trained under ℓ_2 regularization with stochastic gradient descent. The authors also consider an extension based on parallel CNN that we do not include here.

the representations, and used log term frequency and normalization to unit vectors as the weighting scheme, after finding that this outperformed term frequency. Our method achieved the best performance with binary weighting, which they did not consider.

IMDB movie reviews (Maas et al., 2011)—Table 3. A binary sentiment analysis dataset of highly polar IMDB movie reviews: http://ai.stanford.edu/~amaas/data/sentiment. The results parallel those for Amazon electronics; our method comes close to convolutional neural networks (Johnson and Zhang, 2015), which are state-of-the-art.[5] It outperforms SVMs and feed-forward neural networks, the restricted Boltzmann machine approach presented by Dahl et al. (2012), and compressive feature learning (Paskov et al., 2013).[6]

Method	Accuracy	
	Amazon	IMDB
SVM-unigrams	88.29	88.64
RBM		89.23
SVM-$\{1,2\}$-grams	90.95	90.26
Compressive feature learning		90.40
SVM-$\{1,2,3\}$-grams	91.29	90.58
LR-$\{1,2,3,4,5\}$-grams		90.60
NN-$\{1,2,3\}$-grams	91.52	90.83
LR (this work)	91.56	90.85
Bag of words CNN	91.61	91.34
Sequential CNN	92.52	91.61

Table 3: Comparisons on the Amazon electronics and IMDB reviews datasets. SVM results are from Wang and Manning (2012), the RBM (restricted Bolzmann machine) result is from Dahl et al. (2012), NN and CNN results are from Johnson and Zhang (2015), and LR-$\{1,2,3,4,5\}$-grams and compressive feature learning results are from Paskov et al. (2013). Test size $= 20,000$ for both datasets.

Congressional vote (Thomas et al., 2006)—Table 4. A dataset of transcripts from the U.S. Congressional debates: http://www.cs.cornell.edu/~ainur/sle-data.html. Similar to previous work (Thomas et al., 2006; Bansal et al., 2008; Yessenalina et al., 2010), we consider the task to predict the vote ("yea" or "nay") for the speaker of each speech segment (speaker-based speech-segment classification). Our method outperforms the best results of Yessenalina et al. (2010), which use a multi-level structured model based on a latent-variable SVM. We show comparisons to two weaker baselines as well.

Method	Acc.
SVM-link	71.28
Min-cut	75.00
SVM-SLE	77.67
LR (this work)	78.59

Table 4: Comparisons on the congress vote dataset. SVM-link exploits link structures (Thomas et al., 2006); the min-cut result is from Bansal et al. (2008); and SVM-SLE result is reported by Yessenalina et al. (2010). Test size $= 1,175$.

20 Newsgroups (Lang, 1995) all topics—Table 6. 20 Newsgroups is a benchmark topic classification dataset: http://qwone.com/~jason/20Newsgroups. There are 20 topics in this dataset. Our method outperforms state-of-the-art methods including the distributed structured output model (Srikumar and Manning, 2014).[7] The strong logistic regression baseline from Paskov et al. (2013) uses all 5-grams, heuristic normalization, and elastic net regularization; our method found that unigrams and bigrams, with binary weighting and ℓ_2 penalty, achieved far better results.

Method	Acc.
Discriminative RBM	76.20
LR-$\{1,2,3,4,5\}$-grams	82.80
Compressive feature learning	83.00
Distributed structured output	84.00
LR (this work)	87.84

Table 6: Comparisons on the 20 Newsgroups dataset for classifying documents into all topics. The disriminative RBM result is from Larochelle and Bengio (2008); compressive feature learning and LR-5-grams results are from Paskov et al. (2013), and the distributed structured output result is from Srikumar and Manning (2014). Test size $= 9,052$.

20 Newsgroups: talk.religion.misc vs. alt.atheism and comp.graphics vs. comp.windows.x. We derived three additional topic classification tasks from the 20N dataset. The first and second tasks are talk.religion.misc vs. alt.atheism (test size $= 686$) and comp.graphics vs. comp.windows.x (test size $= 942$). Wang and Manning (2012) report a bigram naïve Bayes model achieving 85.1% and 91.2% on these tasks, respectively (best single model results).[8] Our

[5] As noted, semi-supervised and ensemble methods are excluded for a fair comparison.

[6] This approach is based on minimum description length, using unlabeled data to select a set of higher-order n-grams to use as features.

[7] This method was designed for structured prediction, but Srikumar and Manning (2014) also applied it to classification. It attempts to learn a distributed representation for features and for labels. The authors used unigrams and did not discuss the weighting scheme.

[8] They also report a naïve Bayes/SVM ensemble achieving 87.9% and 91.2%.

Dataset	Acc.	n_{min}	n_{max}	Weighting	Stopword removal?	Reg.	Strength	Conv.
Stanford sentiment	82.43	1	2	tf-idf	F	ℓ_2	10	0.098
Amazon electronics	91.56	1	3	binary	F	ℓ_2	120	0.022
IMDB reviews	90.85	1	2	binary	F	ℓ_2	147	0.019
Congress vote	78.59	2	2	binary	F	ℓ_2	121	0.012
20N all topics	87.84	1	2	binary	F	ℓ_2	16	0.008
20N all science	95.82	1	2	binary	F	ℓ_2	142	0.007
20N atheist/religion	86.32	1	2	binary	T	ℓ_1	41	0.011
20N x/graphics	92.09	1	1	binary	T	ℓ_2	91	0.014

Table 5: Classification accuracies and the best hyperparameters for each of the datasets in our experiments. "Acc" shows accuracies for our logistic regression model. "Min" and "Max" correspond to the min n-grams and max n-grams respectively. "Reg." is the regularization type, "Strength" is the regularization strength, and "Conv." is the convergence tolerance. For regularization strength, we round it to the nearest integer for readability.

method achieves 86.3% and 92.1% using slightly different representations (see Table 5). The last task is to classify related science documents into four science topics (sci.crypt, sci.electronics, sci.space, sci.med; test size $= 1,899$). We were not able to find previous results that are comparable to ours on this task; we include our result (95.82%) to enable further comparisons in the future.

5 Discussion

Optimized representations. For each task, the chosen representation is different. Out of all possible choices in our experiments (Table 1), each of them is used by at least one of the datsets (Table 5). For example, on the Congress vote dataset, we only need to use bigrams, whereas on the Amazon electronics dataset we need to use $\{1, 2, 3\}$-grams. The binary weighting scheme works well for most of the datasets, except the sentence-level sentiment analysis task, where the tf-idf weighting scheme was selected. ℓ_2 regularization was best in all cases but one. We do not believe that an NLP expert would be likely to make these particular choices, except through the same kind of trial-and-error process our method automates efficiently.

Number of trials. We ran 30 trials for each dataset in our experiments. Figure 1 shows each trial accuracy and the best accuracy on development data as we increase the number of trials for two datasets. We can see that 30 trials are generally enough for the model to obtain good results, although the search space is large.

Transfer learning and multitask setting. We treat each dataset independently and create a separate model for each of them. It is also possible to learn from previous datasets (i.e., transfer learning) or to learn from all datasets simultaneously (i.e., multitask learning) to improve performance. This has the potential to reduce the number of trials required even further. See Bardenet et al. (2013), Swersky et al. (2013), and Yogatama and Mann (2014) for more about how to perform Bayesian optimization in these settings.

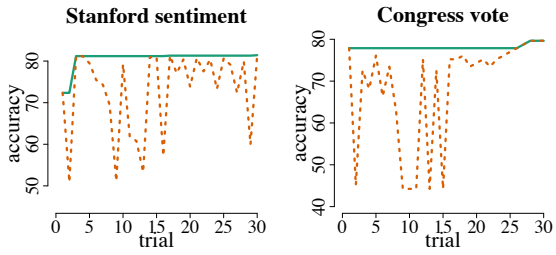

Figure 1: Classification accuracies on development data for Stanford sentiment treebank (left) and congressional vote (right) datasets. In each plot, the green solid line indicates the best accuracy found so far, while the dotted orange line shows accuracy at each trial. We can see that in general the model is able to obtain reasonably good representation in 30 trials.

Beyond supervised learning. Our framework could also be extended to unsupervised and semi-supervised models. For example, in document clustering (e.g., k-means), we also need to construct representations for documents. Log-likelihood might serve as a performance function. A range of random initializations might be considered. Investigation of this approach for nonconvex problems is an exciting area for future work.

6 Conclusion

We used Bayesian optimization to optimize choices about text representations for various categorization problems. Our technique identifies settings for a standard linear model (logistic regression) that are competitive with far more sophisticated methods on topic classification and sentiment analysis.

Abstract

This paper aims to compare different regularization strategies to address a common phenomenon, severe overfitting, in embedding-based neural networks for NLP. We chose two widely studied neural models and tasks as our testbed. We tried several frequently applied or newly proposed regularization strategies, including penalizing weights (embeddings excluded), penalizing embeddings, re-embedding words, and dropout. We also emphasized on incremental hyperparameter tuning, and combining different regularizations. The results provide a picture on tuning hyperparameters for neural NLP models.

1 Introduction

Neural networks have exhibited considerable potential in various fields (Krizhevsky et al., 2012; Graves et al., 2013). In early years on neural NLP research, neural networks were used in language modeling (Bengio et al., 2003; Morin and Bengio, 2005; Mnih and Hinton, 2009); recently, they have been applied to various supervised tasks, such as named entity recognition (Collobert and Weston, 2008), sentiment analysis (Socher et al., 2011; Mou et al., 2015), relation classification (Zeng et al., 2014; Xu et al., 2015), etc. In the field of NLP, neural networks are typically combined with word embeddings, which are usually first pre-trained by unsupervised algorithms like Mikolov et al. (2013); then they are fed forward to standard neural models, fine-tuned during supervised learning. However, embedding-based neural networks usually suffer from severe overfitting because of the high dimensionality of parameters.

A curious question is whether we can regularize embedding-based NLP neural models to improve generalization. Although existing and newly proposed regularization methods might alleviate the problem, their inherent performance in neural NLP models is not clear: the use of embeddings is sparse; the behaviors may be different from those in other scenarios like image recognition. Further, selecting hyperparameters to pursue the best performance by validation is extremely time-consuming, as suggested in Collobert et al. (2011). Therefore, new studies are needed to provide a more complete picture regarding regularization for neural natural language processing. Specifically, we focus on the following research questions in this paper.

RQ 1: How do different regularization strategies typically behave in embedding-based neural networks?

RQ 2: Can regularization coefficients be tuned incrementally during training so as to ease the burden of hyperparameter tuning?

RQ 3: What is the effect of combining different regularization strategies?

In this paper, we systematically and quantitatively compared four different regularization strategies, namely penalizing weights, penalizing embeddings, newly proposed word re-embedding (Labutov and Lipson, 2013), and dropout (Srivastava et al., 2014). We analyzed these regularization methods by two widely studied models and tasks. We also emphasized on incremental hyperparameter tuning and the combination of different regularization methods.

Our experiments provide some interesting results: (1) Regularizations do help generalization, but their effect depends largely on the datasets' size. (2) Penalizing ℓ_2-norm of embeddings helps optimization as well, improving training accuracy unexpectedly. (3) Incremental hyperparameter tuning achieves similar performance, indicat-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2106–2111,
Lisbon, Portugal, 17-21 September 2015.

ing that regularizations mainly serve as a "local" effect. (4) Dropout performs slightly worse than ℓ_2 penalty in our experiments; however, provided very small ℓ_2 penalty, dropping out hidden units and penalizing ℓ_2-norm are generally complementary. (5) The newly proposed re-embedding words method is not effective in our experiments.

2 Tasks, Models, and Setup

Experiment I: Relation extraction. The dataset in this experiment comes from SemEval-2010 Task 8.[1] The goal is to classify the relationship between two marked entities in each sentence. We refer interested readers to recent advances, e.g., Hashimoto et al. (2013), Zeng et al. (2014), and Xu et al. (2015). To make our task and model general, however, we do not consider entity tagging information; we do not distinguish the order of two entities either. In total, there are 10 labels, i.e., 9 different relations plus a default `other`.

Regarding the neural model, we applied Collobert's convolutional neural network (CNN) (Collobert and Weston, 2008) with minor modifications. The model comprises a fixed-window convolutional layer with size equal to 5, **0** padded at the end of each sentence; a max pooling layer; a $\tanh$ hidden layer; and a $\mathrm{softmax}$ output layer.

Experiment II: Sentiment analysis. This is another testbed for neural NLP, aiming to predict the sentiment of a sentence. The dataset is the Stanford sentiment treebank (Socher et al., 2011)[2]; target labels are `strongly/weakly positive/negative`, or `neutral`.

We used the recursive neural network (RNN), which is proposed in Socher et al. (2011), and further developed in Socher et al. (2012); Irsoy and Cardie (2014). RNNs make use of binarized constituency trees, and recursively encode children's information to their parent's; the root vector is finally used for sentiment classification.

Experimental Setup. To setup a fair comparison, we set all layers to be 50-dimensional in advance (rather than by validation). Such setting has been used in previous work like Zhao et al. (2015). Our embeddings are pretrained on the Wikipedia corpus using Collobert and Weston (2008). The learning rate is 0.1 and fixed in Experiment I; for RNN, however, we found learning rate decay helps to prevent parameter blowup (probably due to the recursive, and thus chaotic nature). Therefore, we applied power decay (Senior et al., 2013) with power equal to -1. For each strategy, we tried a large range of regularization coefficients, $10^{-9}, \cdots, 10^{-2}$, extensively from underfitting to no effect with granularity 10x. We ran the model 5 times with different initializations. We used mini-batch stochastic gradient descent; gradients are computed by standard backpropagation. For source code, please refer to our project website.[3]

It needs to be noticed that, the goal of this paper is not to outperform or reproduce state-of-the-art results. Instead, we would like to have a fair comparison. The testbed of our work is two widely studied models and tasks, which were not chosen on purpose. During the experiments, we tried to make the comparison as fair as possible. Therefore, we think that the results of this work can be generalized to similar scenarios.

3 Regularization Strategies

In this section, we describe four regularization strategies used in our experiment.

- Penalizing ℓ_2-norm of weights. Let E be the cross-entropy error for classification, and R be a regularization term. The overall cost function is $J = E + \lambda R$, where λ is the coefficient. In this case, $R = \|W\|^2$, and the coefficient is denoted as λ_W.
- Penalizing ℓ_2-norm of embeddings. Some studies do not distinguish embeddings or connectional weights for regularization (Tai et al., 2015). However, we would like to analyze their effect separately, for embeddings are sparse in use. Let Φ denote embeddings; then we have $R = \|\Phi\|^2$.
- Re-embedding words (Labutov and Lipson, 2013). Suppose Φ_0 denotes the original embeddings trained on a large corpus, and Φ denotes the embeddings fine-tuned during supervised training. We would like to penalize the norm of the difference between Φ_0 and Φ, i.e., $R = \|\Phi_0 - \Phi\|^2$. In the limit of penalty to infinity, the model is mathematically equivalent to "frozen embeddings," where word vectors are used as surface features.
- Dropout (Srivastava et al., 2014). In this strategy, each neural node is set to 0 with a predefined dropout probability p during training; when testing, all nodes are used, with activation multiplied by $1 - p$.

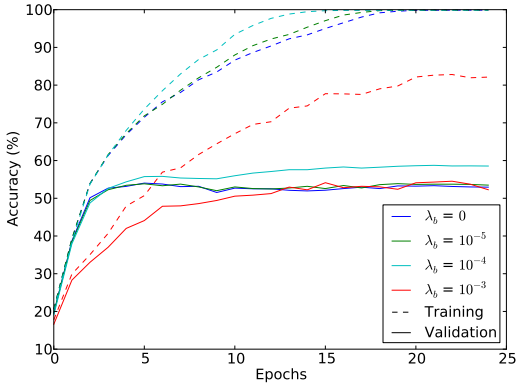
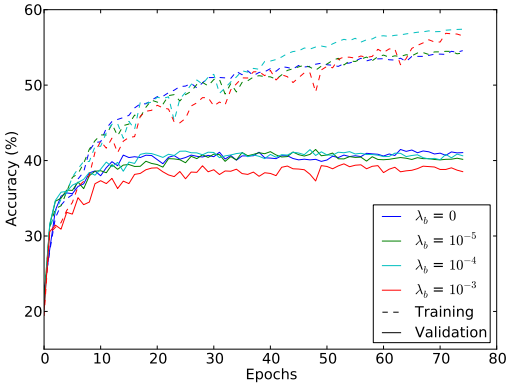
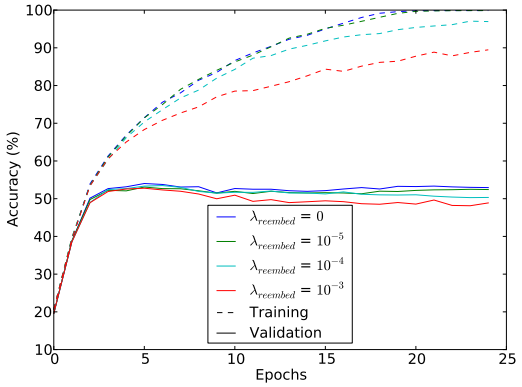
(b) Penalizing weights in Experiment II.



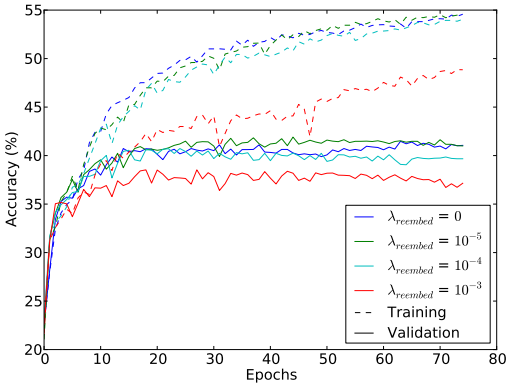
(c) Penalizing embeddings in Experiment I.



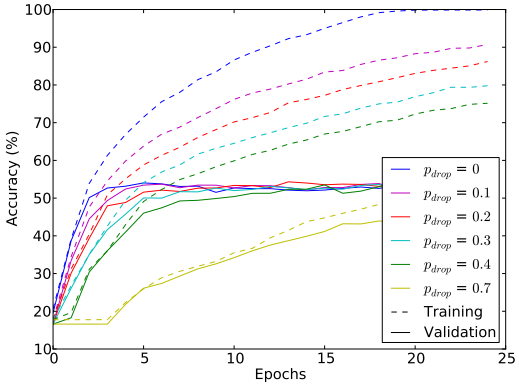
(d) Penalizing embeddings in Experiment II.



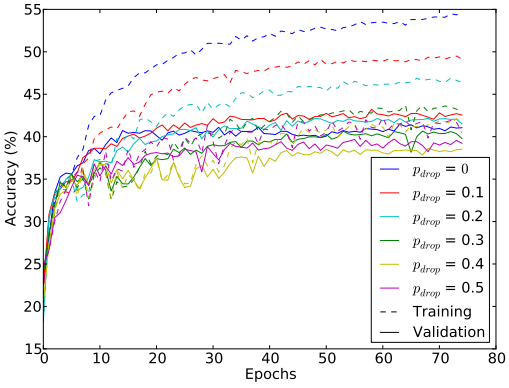
(e) Re-embedding words in Experiment I.



(f) Re-embedding words in Experiment II.



(g) Applying dropout in Experiment I. $p = 0.5, 0.6$ are omitted because they are similar to small values.



(h) Applying dropout in Experiment II.

Figure 1: Averaged learning curves. Left: Experiment I, relation extraction with CNN. Right: Experiment II, sentiment analysis with RNN. From top to bottom, we penalize weights, penalize embeddings, re-embed words, and drop out. Dashed lines refer to training accuracies; solid lines are validation accuracies.

4 Individual Regularization Behaviors

This section compares the behavior of each strategy. We first conducted both experiments without regularization, achieving accuracies of $54.02 \pm 0.84\%$, $41.47 \pm 2.85\%$, respectively. Then we plot in Figure 1 learning curves when each regularization strategy is applied individually. We report training and validation accuracies through out this paper. The main findings are as follows.

- Penalizing ℓ_2-norm of weights helps generalization; the effect depends largely on the size of training set. Experiment I contains 7,000 training samples and the improvement is 6.98%; Experiment II contains more than 150k samples, and the improvement is only 2.07%. Such results are consistent with other machine learning models.

- Penalizing ℓ_2-norm of embeddings unexpectedly helps optimization (improves training accuracy). One plausible explanation is that since embeddings are trained on a large corpus by unsupervised methods, they tend to settle down to large values and may not perfectly agree with the tasks of interest. ℓ_2 penalty pushes the embeddings towards small values and thus helps optimization. Regarding validation accuracy, Experiment I is improved by 6.89%, whereas Experiment II has no significant difference.

- Re-embedding words does not improve generalization. Particularly, in Experiment II, the ultimate accuracy is improved by 0.44, which is not large. Further, too much penalty hurts the models in both experiments. In the limit λ_{reembed} to infinity, re-embedding words is mathematically equivalent to using embeddings as surface features, that is, freezing embeddings. Such strategy is sometimes applied in the literature like Hu et al. (2014), but is not favorable as suggested by the experiment.

- Dropout helps generalization. Under the best settings, the eventual accuracy is improved by 3.12% and 1.76%, respectively. In our experiments, dropout alone is not as useful as ℓ_2 penalty. However, other studies report that dropout is very effective (Irsoy and Cardie, 2014). Our results are not consistent; different dimensionality may contribute to this disagreement, but more experiments are needed to confirm the hypothesis.

5 Incremental Hyperparameter Tuning

The above experiments show that regularization generally helps prevent overfitting. To pursue the best performance, we need to try out different hyperparameters through validation. Unfortunately, training deep neural networks is time-consuming, preventing full grid search from being a practical technique. Things will get easier if we can incrementally tune hyperparameters, that is, to train the model without regularization first, and then add penalty.

In this section, we study whether ℓ_2 penalty of weights and embeddings can be tuned incrementally. We exclude the dropout strategy because its does not make much sense to incrementally drop out hidden units. Besides, from this section, we only focus on Experiment I due to time and space limit.

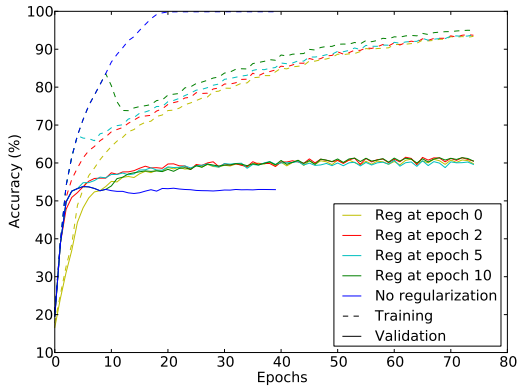
Before continuing, we may envision several possibilities on how regularization works.

- (On initial effects) As ℓ_2-norm prevents parameters from growing large, adding it at early stages may cause parameters settling down to local optima. If this is the case, delayed penalty would help parameters get over local optima, leading to better performance.
- (On eventual effects) ℓ_2 penalty lifts error surface of large weights. Adding such penalty may cause parameters settling down to (a) almost the same catchment basin, or (b) different basins. In case (a), when the penalty is added does not matter much. In case (b), however, it makes difference, because parameters would have already gravitated to catchment basins of larger values before regularization is added, which means incremental hyperparameter tuning would be ineffective.

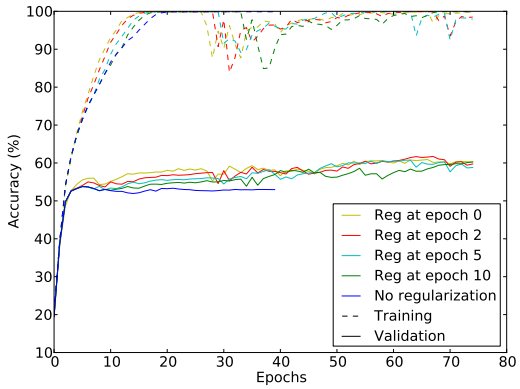
To verify the above conjectures, we design four settings: adding penalty (1) at the beginning, (2) before overfitting at epoch 2, (3) at peak performance (epoch 5), and (4) after overfitting (validation accuracy drops) at epoch 10.

Figure 2 plots the learning curves regarding penalizing weights and embeddings, respectively; baseline (without regularization) is also included.

For both weights and embeddings, all settings yield similar ultimate validation accuracies. This shows ℓ_2 regularization mainly serves as a "local" effect—it changes the error surface, but parameters tend to settle down to a same catchment basin. We notice a recent report also shows local optima



(a) Incrementally penalizing ℓ_2-norm of weights.



(b) Incrementally penalizing ℓ_2-norm of biases.

Figure 2: Tuning hyperparameters incrementally in Experiment I. Penalty is added at epochs 0, 2, 5, 10, respectively. We chose the coefficients yielding the best performance in Figure 1. The controlled trial (no regularization) is early stopped because the accuracy has already decreased.

	λ_{W}			
λ_{embed}	0	10^{-4}	$3{\cdot}10^{-4}$	10^{-3}
0	54.02	57.88	59.96	61.00
10^{-5}	54.94	57.82	60.68	62.05
$3{\cdot}10^{-5}$	55.68	61.02	**64.00**	**63.15**
10^{-4}	60.91	**64.00**	**63.07**	60.56
$3{\cdot}10^{-4}$	58.92	61.33	59.85	42.93
10^{-3}	54.77	56.43	54.05	16.50

Table 1: Accuracy in percentage when we combine ℓ_2-norm of weights and embeddings (Experiment I). Bold numbers are among highest accuracies (greater than peak performance minus 1.5 times standard deviation, i.e., 1.26 in percentage).

	λ_W			λ_{embed}		
p	10^{-4}	$3{\cdot}10^{-4}$	10^{-3}	10^{-5}	$3{\cdot}10^{-5}$	10^{-4}
0	57.88	**59.96**	**61.00**	54.94	55.68	**60.91**
1/6	58.36	59.36	43.42	58.49	59.59	**60.00**
2/6	58.22	**60.00**	16.60	59.34	**60.08**	59.61
3/6	58.63	59.73	16.60	59.59	**59.98**	58.82
4/6	56.43	54.63	16.60	56.76	59.19	56.64
5/6	38.07	16.60	16.60	49.79	53.63	49.75

Table 2: Combining ℓ_2 regularization and dropout. Left: connectional weights. Right: embeddings. (p refers to the dropout rate.)

may not play an important role in training neural networks, if the effect of parameter symmetry is ruled out (Breuel, 2015).

We also observe that regularization helps generalization as soon as it is added (Figure 2a), and that regularizing embeddings helps optimization also right after the penalty is applied (Figure 2b).

6 Combination of Regularizations

We are further curious about the behaviors when different regularization methods are combined.

Table 1 shows that combining ℓ_2-norm of weights and embeddings results in a further accuracy improvement of 3–4 percents from applying either single one of them. In a certain range of coefficients, weights and embeddings are complementary: given one hyperparameter, we can tune the other to achieve a result among highest ones.

Such compensation is also observed in penalizing ℓ_2-norm versus dropout (Table 2)—although the peak performance is obtained by pure ℓ_2 regularization, applying dropout with small ℓ_2 penalty also achieves a similar accuracy. The dropout rate is not very sensitive, provided it is small.

7 Discussion

In this paper, we systematically compared four regularization strategies for embedding-based neural networks in NLP. Based on the experimental results, we answer our research questions as follows. (1) Regularization methods (except re-embedding words) basically help generalization. Penalizing ℓ_2-norm of embeddings unexpectedly helps optimization as well. Regularization performance depends largely on the dataset's size. (2) ℓ_2 penalty mainly acts as a local effect; hyperparameters can be tuned incrementally. (3) Combining ℓ_2-norm of weights and biases (dropout and ℓ_2 penalty) further improves generalization; their coefficients are mostly complementary within a certain range. These empirical results of regularization strategies shed some light on tuning neural models for NLP.

Abstract

Hyper-parameter optimization is an important problem in natural language processing (NLP) and machine learning. Recently, a group of studies has focused on using sequential Bayesian Optimization to solve this problem, which aims to reduce the number of iterations and trials required during the optimization process. In this paper, we explore this problem from a different angle, and propose a multi-stage hyper-parameter optimization that breaks the problem into multiple stages with increasingly amounts of data. Early stage provides fast estimates of good candidates which are used to initialize later stages for better performance and speed. We demonstrate the utility of this new algorithm by evaluating its speed and accuracy against state-of-the-art Bayesian Optimization algorithms on classification and prediction tasks.

1 Introduction

Hyper-parameter optimization has been receiving an increasingly amount of attention in the NLP and machine learning communities (Thornton et al., 2013; Komer et al., 2014; Bergstra et al., 2011; Bardenet et al., 2013; Zheng et al., 2013). The performance of learning algorithms depend on the correct instantiations of their hyper-parameters, ranging from algorithms such as logistic regression and support vector machines, to more complex model families such as boosted regression trees and neural networks. While hyper-parameter settings often make the difference between mediocre and state-of-the-art performance (Hutter et al., 2014), it is typically very time-consuming to find an optimal setting due to the complexity of model classes, *and* the amount of training data available for tuning. The issue is particularly important in large-scale problems where the size of the data can be so large that even a quadratic running time is prohibitively large.

Recently several sequential Bayesian Optimization methods have been proposed for hyper-parameter search (Snoek et al., 2012; Eggensperger et al., 2015; Brochu et al., 2010; Hutter et al., 2011; Eggensperger et al., 2014). The common theme is to perform a set of iterative hyper-parameter optimizations, where in each round, these methods fit a hyper-parameter response surface using a probabilistic regression function such as Gaussian Process (Snoek et al., 2012) or tree-based models (Hutter et al., 2011), where the response surface maps each hyper-parameter setting to an approximated accuracy. The learned regression model is then used as a cheap surrogate of the response surface to quickly explore the search space and identify promising hyper-parameter candidates to evaluate next in order to enhance validation accuracy.

While these methods have enjoyed great success compared to conventional random search (Bergstra et al., 2012; Bengio et al., 2013) and grid search algorithms by significantly reducing the number of iterations and trials required during the process, the focus and starting point of these work have largely been on dealing with many dimensions of hyper-parameters, *rather than* scaling to large amount of data as typical in many NLP tasks, where the efficiency bottleneck stems from the size of the training data in addition to hyper-parameter dimensions. For example, as dataset size grows, even simple models (with few hyper-parameters) such as logistic regression can require more training time per iteration in these algorithms, leading to increased overall time complexity.

In this work, we introduce a multi-stage Bayesian Optimization framework for efficient

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2112–2117,
Lisbon, Portugal, 17-21 September 2015.

hyper-parameter optimization, and empirically study the impact of the multi-stage algorithm on hyper-parameter tuning. Unlike the previous approaches, the multi-stage approach considers hyper-parameter optimization in successive stages with increasingly amounts of training data. The first stage uses a small subset of training data, applies sequential optimization to quickly identify an initial set of promising hyper-parameter settings, and these promising candidates are then used to initialize Bayesian Optimization on later stages with full training dataset to enable the expensive stages operate with better prior knowledge and converge to optimal solution faster.

The key intuition behind the proposed approach is that both dataset size and search space of hyper-parameter can be large, and applying the Bayesian Optimization algorithm on the data can be both expensive and unnecessary, since many evaluated candidates may not even be within range of best final settings. We note our approach is orthogonal and complementary to parallel Bayesian Optimization (Snoek et al., 2012) and multi-task learning (Yogatama et al., 2014; Swersky et al., 2012), because the improved efficiency per iteration, as achieved by our algorithm, is a basic building block of the other algorithms, thus can directly help the efficiency of multiple parallel runs (Snoek et al., 2012), as well as runs across different datasets (Yogatama et al., 2014; Swersky et al., 2012).

2 Methodology

The new multi-stage Bayesian Optimization is a generalization of the standard Bayesian Optimization for hyper-parameter learning (Snoek et al., 2012; Feurer et al., 2015). It is designed to scale standard Bayesian Optimization to large amounts of training data. Before delving into the details, we first describe hyper-parameter optimization and give a quick overview on the standard Bayesian Optimization solution for it.

2.1 Hyper-parameter Optimization

Let $\boldsymbol{\lambda} = \{\lambda_1, \ldots, \lambda_m\}$ denote the hyper-parameters of a machine learning algorithm, and let $\{\Lambda_1, \ldots, \Lambda_m\}$ denote their respective domains. When trained with $\boldsymbol{\lambda}$ on training data T_{train}, the validation accuracy on T_{valid} is denoted as $L(\boldsymbol{\lambda}, \mathrm{T}_{train}, \mathrm{T}_{valid})$. The goal of hyper-parameter optimization is to find a hyper-parameter setting $\boldsymbol{\lambda}^*$ such that the validation accuracy L is maximized. Current state-of-the-art methods have focused on using model-based Bayesian Optimization (Snoek et al., 2012; Hutter et al., 2011) to solve this problem due to its ability to identify good solutions within a small number of iterations as compared to conventional methods such as grid search.

2.2 Bayesian Optimization for Hyper-parameter Learning

Model-based Bayesian Optimization (Brochu et al., 2010) starts with an initial set of hyper-parameter settings $\boldsymbol{\lambda}_1, \ldots \boldsymbol{\lambda}_n$, where each setting denotes a set of assignments to all hyper-parameters. These initial settings are then evaluated on the validation data and their accuracies are recorded. The algorithm then proceeds in rounds to iteratively fit a probabilistic regression model V to the recorded accuracies. A new hyper-parameter configuration is then suggested by the regression model V with the help of acquisition function (Brochu et al., 2010). Then the accuracy of the new setting is evaluated on validation data, which leads to the next iteration. A common acquisition function is the expected improvement, EI (Brochu et al., 2010), over best validation accuracy seen so far L^*:

$$a(\boldsymbol{\lambda}, V) = \int_{-\infty}^{\infty} max(L - L^*, 0) p_V(L|\boldsymbol{\lambda}) d_L$$

where $p_V(L|\boldsymbol{\lambda})$ denotes the probability of accuracy L given configuration $\boldsymbol{\lambda}$, which is encoded by the probabilistic regression model V. The acquisition function is used to identify the next candidate (the one with the highest expected improvement over current best L^*). More details of acquisition functions can be found in (Brochu et al., 2010).

The most common probabilistic regression model V is the Gaussian Process prior (Snoek et al., 2012), which is a convenient and powerful prior distribution on functions. For the purpose of our experiments, we also use Gaussian Process prior as the regression model. However, we would like to note the fact that the proposed multi-stage Bayesian Optimization is agnostic of the regression model used, and can easily handle other instantiations of the regression model.

Algorithm 1: Multi-stage Bayesian Optimization for Hyper-parameter Tuning

Input: Loss function L, number of stages S, iterations per stage $\boldsymbol{Y} = \langle Y_1, \ldots, Y_S \rangle$, training data per stage $T_{train} = \langle T^1_{train}, \ldots, T^S_{train} \rangle$, validation data T_{valid}, initialization $\boldsymbol{\lambda}_{1:k}$

Output: hyper-parameter $\boldsymbol{\lambda}^*$

for *stage s=1 to S* **do**
  for *i=1 to k* **do**
    L_i = Evaluate L($\boldsymbol{\lambda}_i, T^s_{train}, T_{valid}$)
  end
  for *j=k+1 to* Y_s **do**
    V: regression model on $\langle \boldsymbol{\lambda}_i, L_i \rangle_{i=1}^{j-1}$
    $\boldsymbol{\lambda}_j = \arg\max_{\boldsymbol{\lambda} \in \boldsymbol{\Lambda}} a(\boldsymbol{\lambda}, V)$
    L_j = Evaluate L($\boldsymbol{\lambda}_j, T^s_{train}, T_{valid}$)
  end
  reset $\boldsymbol{\lambda}_{1:k}$=best k configs $\in \langle \boldsymbol{\lambda}_1, \ldots \boldsymbol{\lambda}_{Y_s} \rangle$ based on validation accuracy $\boldsymbol{L}$
end
return $\boldsymbol{\lambda}^* = \arg\max_{\boldsymbol{\lambda}_j \in \{\boldsymbol{\lambda}^{Y_1}, \ldots, \boldsymbol{\lambda}^{Y_S}\}} L_j$

2.3 Multi-stage Bayesian Optimization for Hyper-parameter Tuning

The multi-stage algorithm as shown in Algorithm 1 is an extension of the standard Bayesian Optimization (Section 2.2) to enable speed on large-scale datasets. It proceeds in multiple stages of Bayesian Optimization with increasingly amounts of training data $|T^1_{train}| \leq \ldots, \leq |T^S_{train}|$. During each stage s, the k best configurations (based on validation accuracy) passed from the previous stage[1] are first evaluated on the current stage's training data T^s_{train}, and then the standard Bayesian Optimization algorithm are initialized with these k settings and applied for $Y_s - k$ iterations on T^s_{train} (discounting the k evaluations done earlier in the stage), where Y_s is the total number of iterations for stage s. Then the top k configurations based on validation accuracy are used to initialize the next stage's run.

We note after the initial stage, rather than only considering candidates passed from the previous stage, the algorithm expands from these points on larger data. Continued exploration using larger data allows the algorithm to eliminate any potential sensitivity the hyper-parameters may have with respect to dataset size. After running all S stages the algorithm terminates, and outputs the configuration with the highest validation accuracy from all hyper-parameters explored by all stages (including the initialization points explored by the first stage).

[1] A special case is the initial stage. We adopt the convention that a Sobol sequence is used to initialize the first stage (Snoek et al., 2012). The value k for the first stage is the number of points in the Sobol sequence.

	Hyper-parameters
SVM	bias, cost parameter, and regularization parameter
Boosted regression trees	feature sampling rate, data sampling rate, learning rate, # trees, # leaves, and minimum # instance per leaf

Table 1: Hyper-parameters used in SVM and boosted regression trees.

This multi-stage algorithm subsumes the standard Bayesian optimization algorithm as a special case when the total number of stages $S = 1$. In our case, for datasets used at stages $1, \ldots, S-1$, we use random sampling of full training data to get subsets of data required at these initial stages, while stage S has full data. For the number of top configurations k used to initialize each following stage, we know the larger k is, the better results in the next stage since Bayesian Optimization relies on good initial knowledge to fit good regression models (Feurer et al., 2015). However, larger k value also leads to high computation cost at the next stage, since these initial settings will have to be evaluated first. In practice, the number of stages S and the value of k depend on the quantity of the data and the quality of stage-wise model. In our experiments, we empirically choose their values to be $S = 2$ and $k = 3$ which result in a good balance between accuracy and speed on the given datasets.

3 Experiment

We empirically evaluate the algorithm on two tasks: classification and question answering. For classification we use the Yelp dataset (Yelp, 2014) which is a customer review dataset. Each review contains a star/rating (1-5) for a business, and the task is to predict the rating based on the textual information in the review. The training data contains half-million feature vectors, and unique unigrams are used as features (after standard stop-word re-

moval and stemming (Manning et al., 2008)). For question answering (QA), the task is to identify correct answers for a given question. We use a commercial QA dataset containing about 3800 unique training questions and a total of 900,000 feature vectors. Each feature vector corresponds to an answer candidate for a given question, the vector consists of a binary label (1=correct, 0=incorrect) and values from standard unigram/bigram, syntactic, and linguistic features used in typical QA applications (Voorhees et al., 2011). Both QA and Yelp datasets contain independent training, validation, and test data, from which the machine learning models are built, accuracies are evaluated, and test results are reported, respectively.

We evaluate our multi-stage method against two methods: 1) state-of-the-art Bayesian Optimization for hyper-parameter learning (Snoek et al., 2012)), and 2) the same Bayesian Optimization but only applied on a small subset of data for speed. For experiments, we consider learning hyper-parameters for two machine learning algorithms: SVM implementation for classification (Fan et al., 2008) and boosted regression trees for question answering (Ganjisaffar et al., 2011) as shown in Table 1.

3.1 Accuracy vs time

Figures 1 and 2 compare the test accuracy of our proposed multi-stage Bayesian optimization as a function of tuning time for QA and Yelp, respectively. The state-of-the-art Bayesian optimization (Snoek et al., 2012) is applied on full training data, and the fast variant of Bayesian Optimization is applied with 30% of training data (randomly sampled from full dataset). The top-1 and classification accuracies on test data are reported on the y-axis for QA and Yelp, respectively, and the tuning time is reported on the x-axis. For fairness of comparison, the multi-stage method uses the same 30% training data at the initial stage, and full training data at the subsequent stage.

From these figures, while in general both of the comparison methods produce more effective results when given more time, the multi-stage method consistently achieves higher test accuracy than the other two methods across all optimization time values. For example, best test accuracy is achieved by the multi-stage algorithm at time (45 min) for the QA task, while both the full Bayesian Optimization and the subset variant

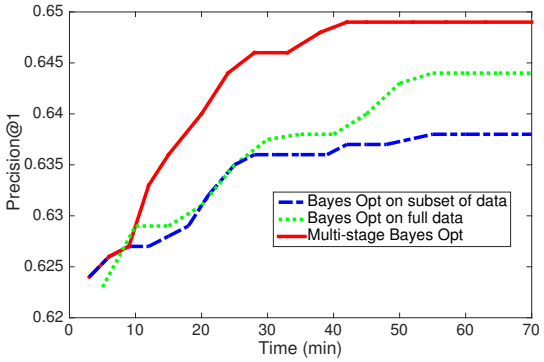

Figure 1: QA task: test accuracy vs tuning time.

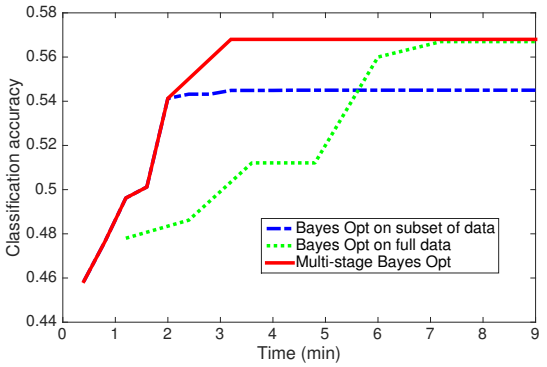

Figure 2: Yelp classification: test accuracy vs tuning time.

can only achieve a fraction of the best value at the same time value. We also note in general the multi-stage algorithm approaches the upper bound more rapidly as more time is given. This shows that the new algorithm is superior across a wide range of time values.

3.2 Expected accuracy and cost per iteration

To investigate the average accuracy and cost per iteration achieved by different methods across different time points, we compare their mean expected accuracy (according to precision@1 for QA and classification accuracy for Yelp) in Table 2, and their average speed in Table 3. In terms of average accuracy, we see that the state-of-the-art Bayesian optimization on full training data and the multi-stage algorithm achieve similar test accuracy, and they both outperform the sub-

	QA	Yelp
Bayes opt on small subset	0.633	0.530
Bayes opt on full data	0.639	0.543
Multi-stage algorithm	0.641	0.542

Table 2: Average test accuracy for QA (precision@1) and Yelp dataset (classif. accuracy).

	QA	Yelp
Bayes opt on small subset	3.2 min	0.4 min
Bayes opt on full data	7.8 min	1.2 min
Multi-stage algorithm	6 min	0.6 min

Table 3: Average time (min) per iteration.

set variant of Bayesian Optimization. However, in terms of time per iteration, the full Bayesian Optimization is the most expensive, taking more than twice amount of time over subset variant algorithm, while the multi-stage is 23% and 50% faster than standard Bayesian Optimization on QA and Yelp (Table 3), respectively, while maintaining the same accuracy as full Bayesian Optimization. This demonstrates the multi-stage approach achieves a good balance between the two baselines and can simultaneously delivers good speedup and accuracy.

4 Conclusion

We introduced a multi-stage optimization algorithm for hyper-parameter optimization. The proposed algorithm breaks the problem into multiple stages with increasingly amounts of data for efficient optimization. We demonstrated its improved performance as compared to the state-of-the-art Bayesian optimization algorithm and fast variants of Bayesian optimization on sentiment classification and QA tasks.

Improved Arabic Dialect Classification with Social Media Data

Fei Huang
Facebook Inc.
Menlo Park, CA
feihuang@fb.com

Abstract

Arabic dialect classification has been an important and challenging problem for Arabic language processing, especially for social media text analysis and machine translation. In this paper we propose an approach to improving Arabic dialect classification with semi-supervised learning: multiple classifiers are trained with weakly supervised, strongly supervised, and unsupervised data. Their combination yields significant and consistent improvement on two different test sets. The dialect classification accuracy is improved by 5% over the strongly supervised classifier and 20% over the weakly supervised classifier. Furthermore, when applying the improved dialect classifier to build a Modern Standard Arabic (MSA) language model (LM), the new model size is reduced by 70% while the English-Arabic translation quality is improved by 0.6 BLEU point.

1 Introduction

As more and more users share increasing amount of information on various social media platforms (Facebook, Twitter, etc.), text analysis for social media language is getting more important and challenging. When people share their stories, opinions, post comments or tweets on social media platforms, they frequently use colloquial languages, which are more similar to spoken languages. In addition to typical natural language processing problems, the informal nature of social media languages presents additional challenges, such as frequent spelling errors, improper casing, internet slang, spontaneity, dis-fluency and ungrammatical utterances (Eisenstein, 2014). Dialect classification and dialect-specific processing are extra challenges for languages such as Arabic and Chinese.

Considering Arabic as an example: there are big differences between MSA and various dialectal Arabic: MSA is the standardized and literary variety of Arabic used in writing and in most formal speech.[1] It is widely used in government proceedings, newspapers and product manuals. Many research and linguistic resources for Arabic natural language processing are based on MSA. For example, most existing Arabic-English bilingual data are MSA-English parallel sentences. The dialect Arabic has more varieties: 5 major dialects are spoken in different regions of the Arab world: *Egyptian, Gulf, Iraqi, Levantine* and *Maghrebi* (Zaidan and Callison-Burch, 2011). These dialects differ in morphologies, grammatical cases, vocabularies and verb conjugations. These differences call for dialect-specific processing and modeling when building Arabic automatic speech recognition (ASR) systems or machine translation (MT) systems. Therefore, identification and classification of Arabic text is fundamental for building social media Arabic speech and language processing systems.

In order to build better MT systems between Arabic and English, we first analyze the distribution of different Arabic dialects appearing on a very large scale social media platform, as well as their effect on Arabic-English machine translation. We propose several methods to improve the dialect classification accuracy by training models with distant supervision: a weakly supervised model is trained with data whose labels are automati-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2118–2126,
Lisbon, Portugal, 17-21 September 2015.

cally assigned based on authors' geographical information. A strongly supervised model is trained with manually annotated data. More importantly, semi-supervised learning on large amount of unlabeled data effectively increases the classification accuracy. We also combine different classifiers to achieve even bigger improvement. When evaluated on two test sets, the widely adopted Arabic Online Commentary (AOC) corpus and a test set created from the social media domain (Facebook), our methods demonstrate an absolute 20% improvement over the weakly supervised classifier, and 5% over the strongly supervised classifier. Furthermore, the improved classifier is applied on large amount of Arabic social media text to filter out non-MSA data. An LM trained with the cleaned data is used for English-Arabic (MSA) translation. Compared with the baseline model trained with the unfiltered data, the MSA LM reduces the training data by 85%, model size by 70%, and it brings 0.6 BLEU point (Papineni et al., 2002) gain in MT.

The rest of the paper is organized as follows: in section 2 we review previous research on this topic. In section 3 we analyze the dialect distribution and its impact on social media data translation. We present the problem formulation in section 4. In section 5 we introduce two supervised classifiers trained with weakly and strongly labeled data. We describe different semi-supervised learning methods in section 6, followed by the combination of multiple classifiers in section 7. In section 8 we show the experimental results on dialect classification as well as machine translation. The paper finishes with discussions and conclusion in section 9.

2 Related Work

Previous research on Arabic dialect identification focused on two problems: spoken dialect classification for speech recognition ((Novotney et al., 2011) and (Lei and Hansen, 2011)), and written text dialect classification mostly for machine translation. (Habash and Rambow, 2006), (Habash et al., 2008), (Diab et al., 2010) and (Elfardy and Diab, 2012) developed annotation guidelines and morphology analyzer for Arabic dialect.

(Zaidan and Callison-Burch, 2011) created the AOC data set by extracting reader commentary from online Arabic newspaper forums. The selected Arabic sentences are manually labeled with one of 4 dialect labels with the help of crowd sourcing: *Egyptian*, *Gulf*, *Iraqi* and *Levantine*. A dialect classifier using unigram features is trained from the labeled data. In the BOLT (Broad Operational Language Translation) project, translation from dialectal Arabic (especially Egyptian Arabic) to English is a main problem. (Elfardy and Diab, 2013) uses the same labeled AOC data to generate token-based features and perplexity-based features for sentence level dialect identification between MSA and Egyptian Arabic. (Tillmann et al., 2014) trained feature-rich linear classifier based on linear SVM then evaluated the classification between MSA and Egyptian Arabic, reporting 1.4% improvement. All these experiments are based on the AOC corpus. The characteristics and distribution of the Arabic dialects could be different for online social media data. (Darwish et al., 2014) selected Twitter data and developed models taking consideration of lexical, morphological, and phonological information from different dialects, then classified Egyptian and MSA Arabic tweets. (Cotterell and Callison-Burch, 2014) collected dialect data covering Iraqi and Maghrebi Arabic from Twitter as well.

When translating Arabic dialect into English, (Sawaf, 2010) and (Salloum and Habash, 2011) normalized dialect words into MSA equivalents considering character- and morpheme-level features, then translated the normalized input with MSA Arabic-English MT system. (Zbib et al., 2012) used crowd sourcing to build Levantine-English and Egyptian-English parallel data. Even with small amount of parallel corpora for each dialect, they obtained significant gains (6-7 BLEU pts) over a baseline MSA-English MT system.

3 Social Media Arabic Dialect Distribution and Translation

The population speaking a dialect does not necessarily reflect its popularity on internet and social media. Many factors, such as a country's social-economic development status, internet access and government policy, play important roles. To understand the distribution of Arabic dialects on social media, we select data from the largest social media platform, Facebook. There are around one billion users sharing content in 60+ languages every day. The Arabic content comes from different regions of the Arabic world, representative enough for our analysis. We randomly select 2700

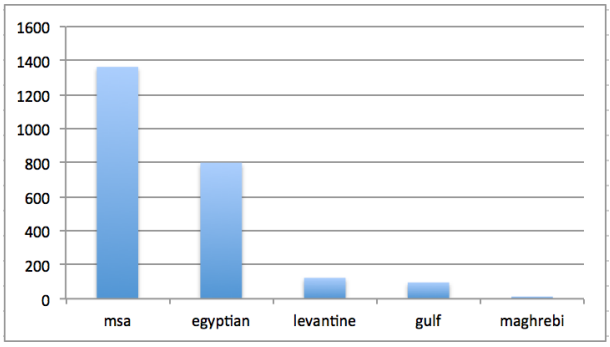

Figure 1: Distribution of various Arabic dialect on the social media platform

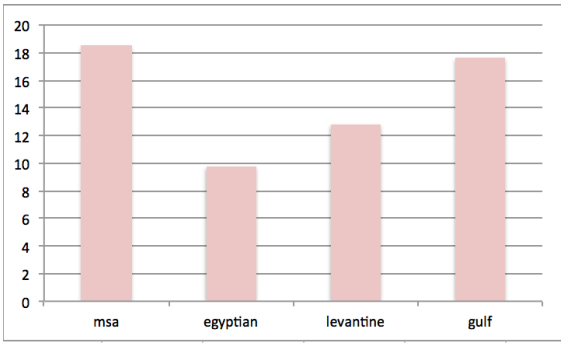

Figure 2: BLEU scores of different Arabic dialects in Arabic-English translation. The MT model is trained with mostly MSA-English parallel data.

sentences from public posts, then ask human annotators to label their dialect types[2]. The result is shown in Figure 1. Not surprisingly, MSA is the most widely used, accounting for 58% of sentences. Besides that, Egyptian Arabic is the most frequent dialect (34%), followed by Levantine and Gulf. Maghrebi is the least frequent. There are other sentences which are not labeled as Arabic dialect, such as classical Arabic, verses from the Quran, foreign words and their transliterations, etc.

We also investigate the effect of different dialects on Arabic-English translation. We ask humans to translate the Arabic sentences into English to create reference translations. We build a phrase-based Arabic-English MT system with 1M sentence pairs selected from MSA Arabic-English parallel corpora (UN corpus, Arabic news corpus, etc.).[3] The training and decoding procedures are similar to those described in (Koehn et al., 2007). More details about the MT system are given in section 8. We group the source Arabic sentences into different subsets based on their dialect labels, then translate them with the MT system. We measure the BLEU score for each subset, as shown in Figure 2. As expected the MSA subset has the highest BLEU scores (18), followed by the Gulf dialect, which is somewhat similar to MSA. The translation of the Egyptian and Levantine dialects is more challenging, with BLEU scores around 10-12, even though they are 40% of the total Arabic data. To improve Arabic-English MT quality, increasing the bilingual data coverage for these two dialects should be most effective, as seen in (Zbib et al., 2012). Because the Maghrebi dialect sample size is too small, we do not report its BLEU score. From these experiments, we further appreciate the importance of accurately identifying Arabic dialect and building dialect-specific translation models.

[2]The data was annotated by a translation service provider under confidentiality agreement.

[3]Because existing Arabic-English bilingual corpora do not include parallel data from social media domain, increasing training data size does not increase the translation quality.

4 Problem Formulation

In this section we present the general framework of dialect classification. Given a sentence $S = \{w_1, w_2, .., w_l\}$ generated by user u, its dialect class label d^* is determined based on the following functions:

$$d^* = \arg\max_i P(d_i|S, u),$$

where the probability function is defined according to the following exponential model:

$$P(d_i|S, u) = \frac{\exp \sum_k \lambda_k f_k(d_i, \cdot)}{\sum_j \exp \sum_k \lambda_k f_k(d_j, \cdot)}$$

$$d^* = \arg\max_i \sum_k \lambda_k f_k(d_i, \cdot).$$

Here $f_k(d_i, \cdot)$ is the k-th feature function. For example. $f(d_i, u)$ models the likelihood of writing dialect d_i by user u given the user's profile information. $f(d_i, S)$ models the likelihood of generating sentence S with d_i's n-gram language model:

$$f(d_i, S) = \log p(S|d_i)$$
$$= \sum_{k=1}^{l} \log p_{d_i}(w_k|w_{k-1}, ..., w_{k-n+1}).$$

This framework allows the incorporation of rich feature functions such as geographical, lexical,

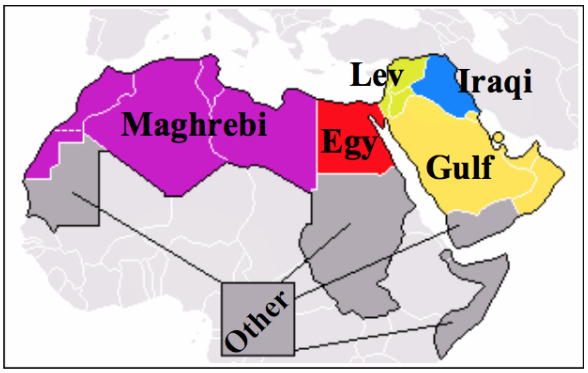

Figure 3: Arabic dialect map, from (Zaidan and Callison-Burch, 2011).

morphological and n-gram information, as seen in previous work ((Zaidan and Callison-Burch, 2011) , (Darwish et al., 2014), (Tillmann et al., 2014) and (Elfardy and Diab, 2013)). However, in this paper we focus on training classifiers with weakly and strongly labeled data, as well as semi-supervised learning methods. So we only choose the geographical and text-based features. Exploration of other features will be reported in another paper.

Previous research (Zaidan and Callison-Burch, 2014) indicated that the unigram model obtains the best accuracy in dialect classification. However, (Tillmann et al., 2014) and (Darwish et al., 2014) exploited more sophisticated text features that lead to better accuracy on selected test set. In our experiments, we find that the unigram model does outperform bigram and trigram models, so we stick to the unigram features.

5 Supervised Learning

5.1 Learning with Weakly Labeled Data

In the chosen social media platform, each user is associated with a unique profile, which includes user-specific information such as the age and gender of the user, the country where s/he is from, etc.. As different Arabic dialects are spoken in different countries, one approach is to classify a post's dialect type based on the author's country, assuming that there is at least a major dialect spoken in each country. This approach is not highly accurate, because the user's country information may be missing or inaccurate; one dialect may be spoken in multiple countries (for example, Egyptian is very popular in different regions of the Arabic world) and multiple dialects may be spoken in the same country; the user can post in MSA instead of dialect Arabic or a mixture of both. However, using data from certain countries as the "approximate" dialect training data, we can train a baseline classifier. As the training data labels are inferred from user profiles instead of manually annotated, such data is called weakly labeled data.

According to the dialect map shown in Fig.3, we group the social media posts into the following 5 dialects according to the author's country:

1. *Egyptian*: Egypt
2. *Gulf*: Saudi Arabia, United Arab Emirate, Qatar, Bahrain, Oman, Yemen
3. *Levantine*: Syrian, Jordan, Palestinian, Lebanese
4. *Iraqi*: Iraq
5. *Maghrebi*: Algeria, Libya, Tunisia, Morocco

Table 1 shows the number of words for each dialect group. Considering the dialect distribution in the social media platform (shown in Figure 1), we focus on the classification of *MSA* (msa) and 3 Arabic dialects: *Egyptian* (egy), *Gulf* (gul) and *Levantine* (lev).

We train an n-gram model for each dialect from the collected data. To train the MSA model, we select sentences from Arabic UN corpus and news collections. All the dialect and MSA models share the same vocabulary, thus perplexity can be compared properly. At classification time, given an input sentence, the classifier computes the perplexity for each dialect type and choose the one with minimum perplexity as the label.

Dialect	Weakly Labeled	Strongly Labeled
egy	22M	0.45M
gul	6M	0.34M
lev	8M	0.45M
msa	27M	1.34M
iraqi	3M	0.01M

Table 1: Corpus size (word count) of weakly and strongly labeled data for supervised learning. The weakly labeled dialect data is from Facebook based on users' country information. The strongly labeled data is manually annotated from the AOC corpus.

5.2 Learning with Strongly Labeled Data

In the AOC corpus, every sentence's dialect type is labeled by human annotators. As these labels

are gold labels, the AOC corpus is strongly labeled data. Because of the high cost of manual annotation, the strongly labeled data is much less than the weakly labeled data, but the higher quality makes it possible to train a better classifier. Table 1 shows the corpus size. Although over 50% data is MSA. Egyptian, Gulf and Levantine dialects still have significant presence while the Iraqi dialect has the least labeled data. Such distribution is consistent with what we observed from the social media data. Using these strongly labeled data, we can train a classifier that significant outperforms the weakly supervised classifier.

6 Semi-supervised Learning

6.1 Self-training

Given the small amount of gold labeled data from the AOC corpus and large amount of unlabeled data from the social media platform, a natural combination is semi-supervised learning. In other words, by applying the strongly supervised classifier on the unlabeled data, we can obtain "automatically labeled" dialect data that could further improve the classification accuracy. From the social media platform we select additional Arabic posts with a total of 646M words. The sizes of the newly created dialect corpora are shown in Table 2. Notice that the MSA data accounts for more than 75% of all the labeled data. We train a new classifier with these additional data. As the new labels are only from the original strong classifier, this is self-training.

6.2 Co-Training

Another approach for automatic labeling is co-training (Blum and Mitchell, 1998). With two classifier C_1 and C_2 classifying the same input sentence S with labels l_1 and l_2, S is labeled as l only if $l_1 = l_2 = l$. In other words, a sentence is labeled and used to train a model only when the two classifiers agree. In our experiment we use both the weakly and strongly supervised classifiers to classify the same unlabeled data. Table 2 lists the sizes of the dialect corpora from co-training. Compared with the self-training approach, the co-training method filters out 25% data.

6.3 Data Filtering

Because of domain mismatch, even the strongly supervised classifier does not achieve very high accuracy on the social media test set, thus there is lots of noise in the automatically labeled data. To filter this noise, we only keep the sentences whose minimum perplexity score (corresponding to the winning dialect label) is smaller than any other perplexity score by a margin. Lower perplexity means higher probability of generating the sentence from the dialect model. In other words, sentence S is assigned with label l and used in model re-training if and only if $perp_l(S) < perp_k(S) \times threshold$, for $k \neq l$. The threshold is selected to optimize the classification accuracy on a tuning set. Table 2 also shows the corpora size after filtering. We can see that the filtered dialect is only a quarter of the self-training data. We will compare the three semi-supervised learning methods and evaluate the gains to dialect classification.

Dialect	Self-training	Co-training	Filter
egy	73M	54M	21M
gul	46M	5.1M	2.7M
lev	34M	11.7M	2.5M
msa	493M	406M	139M
All	646M	476M	165M

Table 2: The size of dialect corpora from semi-supervised learning.

7 Classifier Combination

Now we have 3 types of classifiers:

1. The weakly supervised classifier trained with data whose labels are automatically assigned according to author's country;
2. The strongly supervised classifier trained with human labeled data;
3. The semi-supervised classifier trained with automatically classified data, with different data selection methods.

How should we combine them to further improve the classification accuracy?

One approach is data combination: simply adding all the training data together to train a unified n-gram model for each dialect. This experiment is straightforward but the performance is suboptimal because the classifier will be dominated by the model with the most training data, even though its accuracy may not be the best.

The second approach is model combination: we compute the model scores of the weakly supervised (w), strongly supervised (s) and semi-supervised (e) classifiers, then combines them

with linear interpolation:

$$p(S|d_i) = \sum_{m=\{w,m,e\}} w_m p_m(S|d_i)$$

As the dialect n-gram perplexity is computed separately, the model weights w_m can be tuned. In our experiments we optimize them with a tuning set from all the dialects.

8 Experiment Results

8.1 Dialect Classification

We already described the training data for supervised and semi-supervised classifiers in previous sections. In this section we will compare their dialect classification accuracies. We select two test sets: 9.5K sentences from the AOC corpus as the AOC test set and 2.3K sentences from the Facebook data set as the FB test set[4]. Both test sets have the dialect of each sentence labeled by human. The accuracy is computed as the percentage of sentences whose classified label is the same as the human label. 90% of the AOC labeled data are used for training the strongly supervised classifier, and the remaining 10% data containing 9.5K sentences is for evaluation. We also keep 200 sentences from the AOC corpus as the development set to tune the model combination parameters.

Model	AOC	FB
weakly supervised	68.4%	48.5%
strongly supervised	83.4%	63.1%
semi-supervised	86.2%	67.7%
combination	87.8%	68.2%

Table 3: Arabic dialect classification accuracies with the weakly and strongly supervised classifiers, as well as the semi-supervised model.

In Table 3 we show the overall classification accuracies of different models on both test sets. Notice that the weakly supervised classifier trained with 68M words obtains 68% accuracy on the AOC test set and 48% on the FB test set (row 1), which is not much higher. However, considering this classifier is trained without any human labeled dialect data, the performance is expected and can be improved with better training data and models. The strongly supervised classifier (row 2), which is trained with much less human labeled data (only 2.6M words), outperforms the weak classifier by 15%. Such a difference is consistently observed in both test tests. This confirms the significant benefits from the gold labeled data.

We apply the strong classifier to large amount of unlabeled data, and train several semi-supervised classifiers with these automatically labeled data. The best result is obtained with the co-training strategy, which brings significant improvement over the strongly supervised model: 2.8-4.6% (row 3), as the label noise is effectively reduced among the agreed labels from two supervised classifiers. Finally, combining all three classifiers (row 1, 2 and 3) with model combination achieves the best result: about 5% improvement of the strong baseline and 20% over the weak baseline. These results demonstrate the effectiveness of combining labeled and unlabeled data obtained from social media platform.

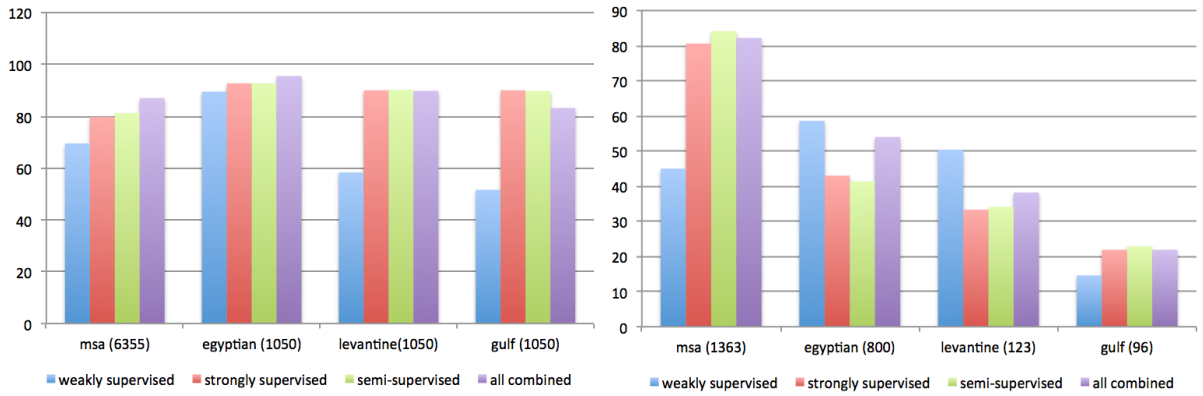
Model	AOC	FB
strongly supervised baseline	83.4%	63.1%
self-training	84.4%	65.5%
co-training	86.2%	67.7%
data filtering	85.2%	64.8%
model interpolation	87.8%	68.2%
data concatenation	82.1%	67.4%

Table 4: Comparison of semi-supervised learning and combination methods.

With semi-supervised learning, we evaluate three data selection methods: self-training, co-training and data filtering. The results are shown in Table 4. Compared with the strong classifier baseline, the self-training method improves by 1% - 2.4%, the co-training method improves by 2.8-4.6%, and the data filtering method improves by 1.7-1.8%. The co-training method is the most effective for both test sets because the information are from two independent classifiers. Data filtering is more effective for the AOC test set (which has the same domain as the baseline model) but less so for the FB test set because valuable in-domain data are filtered out.

In the same table we also compare the results from model and data combination: one from the semi-supervised co-training and the other from the strongly supervised learning. On the AOC test set, the data concatenation method is significantly

[4]The FB test set is available for download at https://www.facebook.com/groups/2419174607/10153205046974608/.



(a) Result on the AOC test set.

(b) Result on the Facebook test set.

Figure 4: Classification precisions by dialect. The number in parenthesis is the number of sentences from each dialect.

worse than the model interpolation method. Its accuracy is even lower than that of the supervised classifier (82.1% vs. 83.4%). However the gap is much smaller on the FB test set. The automatically labeled data is much more than the human labeled data, thus it dominates the combined training data set, which is not a good match for the AOC test data, but is more relevant to the FB test data. In both cases, the model combination obtains better classification accuracies, where the supervised model is assigned higher weights (0.9) and the semi-supervised model is used for smoothing, therefore the combined model is able to improve over the strong classifier.

We further analyze the classification precision for each type of dialect on both test sets in Figure 4. Figure 4a shows the result on the AOC test set. The number after the dialect type (in the parenthesis) is the number of sentences from that dialect. Precisions increase from the weakly supervised to the strongly supervised to the semi-supervised classifier, and the combined classifier generally outperforms all three classifiers, except for the Gulf dialect. However, considering the smaller percentage of the Gulf dialect, we still observe significant improvement overall. Figure 4b shows the result on the FB test set, where the MSA and Egyptian dialects are much more frequent than the Levantine and Gulf dialects. Improving classification on the MSA and Egyptian dialect (especially MSA) will be very helpful. We notice that the supervised classifier improves over the unsupervised classifier by a large margin on the MSA and Gulf dialects, but performs worse on the Egyptian and Levantine dialects. This is different from the result in the AOC test set, where the supervised classifier consistently improves over the unsupervised classifier. One reason is that in the AOC test set, the training and test data are from the same corpus, thus the supervised training from in-domain data is very effective. For the FB test set, the strongly labeled data and the test data mismatch in genre and topics. The automatically labeled data is less similar to the dialect test set, thus it is less effective for the Egyptian and Levantine dialects. This further confirms the necessity of combining information from multiple sources. The combined classifier performs significantly better for the MSA and Gulf dialect, but slightly worse for the Egyptian and Levantine dialects. The overall result is still positive.

We also compare our approach with other dialect classification methods on the AOC corpus, which is commonly used so the results are comparable. Most previous work focus on the classification of MSA vs. EGY dialect, and report the accuracies from 85.3% (Elfardy and Diab, 2013), 87.9% (Zaidan and Callison-Burch, 2014) to 89.1% (Tillmann et al., 2014), adding morphological features, using word-based unigram-model and linear SVM models. Our MSA vs. EGY dialect classification accuracy is 92.0%, the best known result on this test set. We do not use more sophisticated features; the improvement is just from the mined unlabeled data and the combination of different classifiers. On the FB test set, our strongly supervised classifier is the same as (Zaidan and Callison-Burch, 2014), both using word-based unigram model. We see 5% gain with the combined classifiers.

8.2 Machine Translation

The motivation of this research is to handle challenges from Arabic dialects to improve machine translation quality. For example, using the dialect classifier output one can build dialect-specific Arabic-English MT systems. Given an Arabic sentence, the system first identifies its dialect type, then translates with the corresponding MT system. When building English-to-Arabic (MSA) translation systems for social media translation, the target LM trained from in-domain data is very helpful to improve the translation quality. Considering that the Arabic in-domain data contains lots of dialects, an effective dialect classifier helps filter out dialect Arabic and only keep the MSA to train a cleaner LM.

Because of the limited bilingual resources of dialect Arabic-English, we will focus on English-Arabic MT system first. In this experiment, the training data for the English-Arabic MT system is 1M parallel sentences selected from publicly available Arabic-English bilingual data (LDC, OPUS). Because none of the parallel corpora is for social media translation, we select a subset closer to the social media domain by maximizing the n-gram coverage on the test domain. The development and test sets contain 700 and 892 English sentences, respectively. These sentences are translated into MSA by human translators. We apply the standard SMT system building procedures: pre-processing, automatic word alignment, phrase extraction, parameter tuning with MERT, and decoding with a typical phrase-based decoder similar to (Koehn et al., 2007). The LM is trained with the target side of the parallel data, plus 200M in-domain Arabic sentences.

Using the above combined dialect classifier, we label the dialect type of each sentence in the in-domain data, filter out any non-MSA sentences and re-train the target LM. Again to keep the in-domain data clean, we also apply the threshold-based data filtering. As shown in Table 5, the dialect filtering reduces the LM training data by 85%, which corresponds to 70% less memory footprint. Thanks to the cleaner LM, the translation quality is also improved by 0.6 BLEU point.[5]

[5]Due to the challenging nature of social media data, and the lack of in-domain training data, the BLEU score is much lower than the one in news translation.

	All Arabic Data	Filtered MSA data
number of sentences	200M	30M
memory footprint	23G	6.6G
BLEU score (1-reference)	12.52	13.14

Table 5: Cleaned MSA LM after dialect filtering for English-Arabic(MSA) translation.

9 Discussion and Conclusion

Existing Arabic dialect classification methods solely rely on textural features, be they n-gram language model or morphology/POS-based features. This paper utilizes authors' geographical information to train a weakly supervised dialect classifier. Using the weakly and strongly supervised classifiers to classify and filter unlabeled data leads to several improved semi-supervised classifiers. The combination of all three significantly improves the Arabic dialect classification accuracy on both in-domain and out-of-domain test sets: 20% absolute improvement over the weak baseline and 5% absolute over the strong baseline. After applying the proposed classifier to filter out Arabic dialect data, and building a cleaned MSA LM, we observe 70% model size reduction with 0.6 BLEU point gain in English-Arabic translation quality.

In future work, we would like to explore more user-specific information for dialect classification, apply the classifier for Arabic-to-English MT systems, and extend the approach to a larger family of languages and dialects.

Abstract

Analyzing arguments in user-generated Web discourse has recently gained attention in argumentation mining, an evolving field of NLP. Current approaches, which employ fully-supervised machine learning, are usually domain dependent and suffer from the lack of large and diverse annotated corpora. However, annotating arguments in discourse is costly, error-prone, and highly context-dependent. We asked whether leveraging unlabeled data in a semi-supervised manner can boost the performance of argument component identification and to which extent is the approach independent of domain and register. We propose novel features that exploit clustering of unlabeled data from debate portals based on a word embeddings representation. Using these features, we significantly outperform several baselines in the cross-validation, cross-domain, and cross-register evaluation scenarios.

1 Introduction

Argumentation mining, an evolving sub-field of NLP, deals with analyzing argumentation[1] in various genres, such as legal cases (Mochales and Moens, 2011), student essays (Stab and Gurevych, 2014a), and medical and scientific articles (Green, 2014; Teufel and Moens, 2002). Recently, the focus of argumentation mining has also shifted to the Web registers (such as comments to articles, forum posts, or blogs) which is motivated by the need of retrieving and understanding ordinary people's arguments to various contentious topics on the large scale. Applications include passenger rights and protection (Park and Cardie, 2014), hotel reviews (Wachsmuth et al., 2014), and controversies in education (Habernal et al., 2014).

Despite the plethora of existing argumentation theories (van Eemeren et al., 2014), the prevalent view in argumentation mining treats arguments as discourse structures consisting of several argument components, such as *claims* and *premises* (Peldszus and Stede, 2013). Current approaches to automatic analysis of argumentation usually follow the fully supervised machine-learning paradigm (Biran and Rambow, 2011; Stab and Gurevych, 2014b; Park and Cardie, 2014) and rely on manually annotated datasets. Only few publicly available argumentation corpora exist, as annotations are costly, error-prone, and require skilled human annotators (Stab and Gurevych, 2014a; Habernal et al., 2014).

To overcome the limited scope and size of the existing annotated corpora, semi-supervised methods can be adopted, as they gain performance by exploiting large unlabeled datasets (Settles, 2012). However, unlike in other NLP tasks where data can be cheaply labeled using for example distant supervision, employing such methods in argumentation mining is questionable. First, argumentation is an act of persuasion (Nettel and Roque, 2011; Mercier and Sperber, 2011) but not all user-generated texts can be treated as persuasive (Park and Cardie, 2014; Habernal et al., 2014), thus the selection of an appropriate unlabeled dataset represents a problem on its own. Second, argument components (e.g., *claims* or *premises*) are highly context-dependent and cannot be easily labeled in distant data using predefined patterns. So far, semi-supervised methods for argumentation mining remain unexplored.

In this article, we tackle argumentation min-

[1]Argumentation is *a verbal activity for which the goal consists of convincing the listener or reader of the acceptability of a standpoint by means of a constellation of propositions justifying or refuting the proposition expressed in the standpoint* (van Eemeren et al., 2002) or *the art of persuading others to think or act in a definite way, including all writing and speaking which is persuasive in form* (Ketcham, 1917).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2127–2137,
Lisbon, Portugal, 17-21 September 2015.

ing of user-generated Web data by exploiting *debate portals*—semi-structured discussion websites where members pose contentious questions to the community and allow others to pick a side and provide their opinions and arguments in order to 'win' the debate.[2] Our first research question is whether debate portals (which contain noisy user-generated data) can be utilized in a semi-supervised manner for fine-grained identification of argument components. As a second research question, we investigate to what extent our methods are domain independent and evaluate their adaptation across several domains and registers.

Our contribution is three-fold. First, to the best of our knowledge, we present the first successful attempt to semi-supervised argumentation mining in Web data based on exploiting unlabeled external resources. We leverage these resources and derive features in an unsupervised manner by projecting data from debate portals into a latent argument space using unsupervised word embeddings and clustering. Second, our novel features significantly outperform state-of-the-art features in all scenarios, namely in cross-validation, cross-domain evaluation, and cross-register evaluation. Third, to ensure full reproducibility of our experiments, we provide all data and source codes under free licenses.[3]

2 Related work

Analysis of argumentation has been an active topic in numerous research areas, such as philosophy (van Eemeren et al., 2014), communication studies (Mercier and Sperber, 2011), and informal logic (Blair, 2004), among others. In this section, we will focus on the most related works on argumentation mining techniques in NLP in the first part, with an emphasis on Web data in the second part.

Mochales and Moens (2011) based their work on argumentation schemes (Walton et al., 2008) and experimented with Araucaria and ECHR datasets using supervised models to classify argumentative and non-argumentative sentences ($\approx 0.7F_1$) and their structure. Feng and Hirst (2011) classified argument schemes on the Araucaria dataset, reaching 0.6-0.9 accuracy. Experiments on this dataset were also conducted by Rooney et al. (2012), who classified sentences to four categories (*conclusion*, *premise*, *conclusion-premise*, and *none*) and achieved 0.65 accuracy. These approaches assume the text is already segmented into argument components. Stab and Gurevych (2014b) examined argumentation in persuasive essays and classified argument components into four categories (*premise*, *claim*, *major claim*, *non-argumentative*) using SVM and achieved 0.73 macro F_1 score. They further classified argument relations (support and attack) and reached 0.72 macro F_1 score. The best-performing features were structural features (such as the location or length ratios), as persuasive essays usually comply with a certain structure which can be seen as a potential drawback of this approach.

Regarding user-generated Web data, Biran and Rambow (2011) used naive Bayes for classifying justification of subjective claims from blogs and Wikipedia talk pages, relying on features from RST Treebank and manually-processed n-grams. In similar Web registers, Rosenthal and McKeown (2012) automatically determined whether a sentence is a *claim* using logistic regression and various lexical and sentiment-related features and achieved accuracy about 0.66-0.71. Park and Cardie (2014) classified propositions in user comments into three classes (*verifiable experiential*, *verifiable non-experiential*, and *unverifiable*) using SVM and reached 0.69 macro F_1 score. Goudas et al. (2014) identified *premises* in Greek social media texts using BIO encoding and achieved 0.42 F_1 score with Conditional Random Fields. The research gaps in the above-mentioned approaches are the following. First, the argumentation models are simplified to either *claims* or a few types of *premises/propositions*. Second, the segmentation of discourse into argument components is ignored (except the work of Goudas et al. (2014)). Recently, Boltužić and Šnajder (2015) employed hierarchical clustering to cluster arguments in online debates using embeddings projection, but in contrast to our work they performed only intrinsic evaluation of the clusters.

Debate portals have been used in a related body of research, such as classifying support and attack between posts by Cabrio and Villata (2012), or stance detection by Hasan and Ng (2013) or Gottipati et al. (2013). These approaches consider the complete documents (posts) but do not analyze the micro-level argumentation (e.g., *claims* or *premises*).

Doc #2823 (article comment, public-private-schools): [*claim:* I agree - Kids can do great in the public school system and parents DO need to be involved.] The more people leave, the worse its going to become. [*premise:* The public school system lets them deal with real life too, unfortunate that it may be but that is what's out there in college and the work force too.] [*premise:* There are still great teachers in the public schools - lets stand behind them.]

Doc #2224 (forumpost, single-sex-education): [*backing:* I went to an all boys school –] [*claim:* Can't say I particularly liked it, I would of much preferred gone to a co-ed.] [*premise:* It is closer to the 'real world' that way. Kids should grow up in the company of both sexes... They will be more at ease around the opposite sex when they are older and it just makes sense.] If it is purely education you are concerned about (and not so much behaviour), our year (at a private school) went shockingly bad in OP scores. We were the worst in 12 years and were beaten by LOTS of co-ed and public schools... So you can never tell. In saying that my sister really enjoyed going to an all girls school. Her year went really well too. Ask your daughters what they would prefer... [*backing:* Btw, I work at a co-ed school at the moment and the kids there get on just fine.]

Figure 1: Two examples of argument annotation of an article comment and a forum post.

3 Data

As data for training and evaluation of our methods, we use a corpus consisting of 340 English documents (approx. 90k tokens) annotated[4] with argumentation by Habernal et al. (2014). Compared to other corpora mentioned in the related work, this corpus is the largest one to date that covers different domains and spans several registers of user-generated Web content. In particular, the corpus comprises four registers (comments to articles, forum posts, blogs, and argumentative newswire articles) and covers six domains related to educational controversies (homeschooling, private vs. public schools, mainstreaming, single-sex education, prayer in schools, and redshirting).

The argumentation model used in this corpus is based on extended Toulmin's model (Toulmin, 1958). Each document contains usually one argument, where each argument consists of several argument components. There are five different components in this model, namely, the *claim* (the statement about to be established in the argument which conveys author's stance towards the topic), the *premise(s)* (propositions that are intended to give reasons of some kind for the claim), the *backing* (additional information used to back-up the argument), the *rebuttal* (attacks the claim), and the *refutation* (which attacks the rebuttal). Relations between the argument components are encoded implicitly in the function of the particular component type, for instance, premises are always attached to the claim. We made two observations in the data: the *claim* is often implicit (must be inferred by the reader), and some sentences have no argumentative function (thus are not labeled by any argument component).[5]

Figure 1 depicts two example annotations from the corpus. Argument components were annotated on the token level as non-overlapping annotation spans. We therefore represent the argument annotations using BIO encoding. Each token is labeled with one of the 11 categories (5 argument component types $\times$ B or I tag $+$ one O category for non-argumentative text).

4 Method

We cast the task of identifying argument components as a sequence tagging problem and employ SVM^{hmm} (Joachims et al., 2009).[6] For linguistic annotations and feature engineering, we rely on two UIMA-based frameworks – DKProCore (Eckart de Castilho and Gurevych, 2014) and DKProTC (Daxenberger et al., 2014).

Although the argument component annotations in the corpus are aligned to the token boundaries (token-level annotations), the minimal classification unit in our sequence tagging approach is set to the sentence level. First, this allows us to capture rich features that are available for entire sentences as opposed to the token level. Second, by modeling sequences on the token level we would lose the advantage of SVM^{hmm} to estimate dependencies between labels, as the label context is limited due to computational feasibility. On the token level, the label sequences are rather static (long sequences with the same label), as opposed to the sentence level. Before the classification step, we adjust all annotation boundaries (note that we use 11 BIO labels) so that they are aligned to the sentence boundaries and each sentence is then treated as a single classification unit with one label (for example, the first sentence from Figure 1 with token labels *Claim-B, Claim-I, Claim-I, ...* be-

[4] Available at `www.ukp.tu-darmstadt.de/data/argumentation-mining/`

[5] A publication containing a thorough analysis of the dataset is pending.

[6] Keerthi and Sundararajan (2007) conclude that performance of SVM^{hmm} is comparable to another widely used method, Conditional Random Fields (Lafferty et al., 2001)

comes *Claim-B*). After classification, the labels are mapped back to tokens (so that, for example, *Claim-B* sentence label is transformed to *Claim-B, Claim-I, ...* token labels). However, all evaluations are performed on the token level and the performance is always measured against the original token labels. Using this approximation, we lose only about 10% of F_1 performance.[7]

4.1 Baseline features

Lexical baseline (FS0) We encode the presence of unigrams, bigrams, and trigrams in the sentence as 'one-hot' (binary) features.

Structural and syntactic features (FS1) Since the presence of discourse markers has been shown to be helpful in argument component analysis (e.g, "therefore" and "since" for *premises* or "think" and "believe" for *claims*), we encode the first and last three words as binary features. Furthermore, we capture the relative position of the sentence in the paragraph and the document, the number of part of speech 1-3 grams, maximum dependency tree depth, constituency tree production rules, and number of sub-clauses (Stab and Gurevych, 2014b). We used Stanford POS Tagger (Toutanova et al., 2003), Berkeley parser (Petrov et al., 2006), and Malt parser (Nivre, 2009).

Sentiment and topic features (FS2) We assume that claims express sentiment, thus we compute five sentiment categories (from very negative to very positive) using Stanford sentiment analyzer (Socher et al., 2013) and use these values directly as features. Furthermore, in order to help detecting off-topic and non-argument sentences, we employ topic model features. In particular, we use features taken from a vector representation of the sentence obtained by using Gibbs sampling on LDA model (Blei et al., 2003; McCallum, 2002) with topics trained on unlabeled data provided as a part of the corpus.[8]

Semantic and discourse features (FS3) Features based on semantic frames has been introduced in relevant works on stance recognition (Hasan and Ng, 2013). Our features, based on PropBank semantic role labels and obtained from NLP Semantic Role Labeler (Choi, 2012), extract various semantic information (agent, predicate + agent, predicate + agent + patient + (optional) negation, argument type + argument value) and discourse markers. Discourse relations also play an important role in argumentation analysis (Cabrio et al., 2013). We thus employ binary features (such as the presence of the sentence in a chain, the transition type, the distance to previous/next sentences in the chain, or the number of inter-sentence coreference links) obtained from Stanford Coreference Chain Resolver (Lee et al., 2013). Furthermore, we include features resulting from a PTDB-style discourse parser (Li et al., 2012), such as the type of discourse relation (explicit, implicit), the presence of discourse connectives, and attributions.

4.2 Unsupervised features

We enrich the above-mentioned features by utilizing external large unlabeled resources – *debate portals*. They fulfill several criteria, namely (a) they are 'argumentative' (meant as opposed to, for example, prose or encyclopedic genres), (b) they are comprised of user-generated content and (c) and there is at least some overlap with topics from our experimental corpus. On the other hand, they contain noisy texts of questionable quality and they do not provide any specific argumentative structure (in fact, these debates are simple discussions to a topic, where each post is only labeled with a *pro* or *contra* stance). Nevertheless, we assume that the posts from (unlabeled) debate portals contain valuable information that will help us with classifying argument components in labeled data. In order to do so, we employ clustering based on latent semantics, which we now formalize as *argument space* features.

We assume that phrases (sentences or documents) can be projected into a latent vector space, using, typically, a sum or a weighted average of all the word embeddings vectors in the phrase; see for example (Le and Mikolov, 2014). Neighboring vectors in the latent vector space exhibit some interesting properties, such as semantic similarity (thoroughly studied within the distributional semantics area). If the latent vector space is clustered, each n-dimensional vector gets reduced to a single cluster number; such clusters have been used directly as features in many tasks, such as NER (Turian et al., 2010), POS tagging (Owoputi

[7] In only 1% of the sentences there are two or more argument components in it; we arbitrarily choose the largest one.

[8] The number of topics was empirically set to 30, therefore for each sentence the topic distribution results into 30 real-valued features.

et al., 2013), or sentiment analysis (Habernal and Brychcín, 2013).

We build upon the above-mentioned approach (described by Søgaard (2013) as 'clusters-as-features' semi-supervised paradigm) and extend it further. We take both sentences and posts from the unlabeled debate portals, project them into a latent space using word embeddings and cluster them. The motivation is that these clusters will contain similar phrases or (similar 'arguments'). Centroids of these clusters would then represent a 'prototypical argument' (note that the centroids exist only in the latent vector space and thus do not correspond to any existing sentence or post). Then we project each sentence (classification unit) in the labeled data to the latent vector space, compute its distance vector to all the cluster centroids, and encode this distance vector directly as real-valued features. By contrast to the above-mentioned works using a single cluster label as a feature, the distance vector to cluster centroids resembles a soft labeling where each sentence belongs to several clusters with a certain 'weight'. We also use the latent vector space representation of the sentence directly as a feature vector.

As unlabeled data, we use data from two largest debate portals.[9] As a pre-processing step we removed all posts with less than one 'point' earned.[10] The data were then indexed using the Lucene framework and the top 100 debates for each of the 6 domains were retrieved which resulted into 5,759 posts ($\approx$ 35k sentences) in the unlabeled data in total. Our approach is formalized in the following paragraph.

Argument space features (FS4) Let $\vec{e}(w)$ be the embedding vector of word w and $\mathrm{tfidf}(w)$ be the TD-IDF value of w. Sentence $\vec{s} = (w_1, \ldots, w_n)$ is then projected into the embedding space $\mathbb{E}$ as $\vec{s}_e = \sum_{i=1}^{n} \mathrm{tfidf}(w_i)\vec{e}(w_i)n^{-1}$ so $\dim(\vec{s}_e) = \dim(\mathbb{E})$. Analogically to $\vec{s}$, we project the entire post $\vec{a} = (w_1, \ldots, w_m)$ to the same embedding space $\mathbb{E}$ such that $\vec{a}_e = \sum_{i=1}^{m} \mathrm{tfidf}(w_i)\vec{e}(w_i)m^{-1}$.

Let K be the number of *sentence* clusters in $\mathbb{E}$ and $\vec{c}_k$ a centroid vector of cluster $k \in K$. Then $\vec{s}_c$ denotes the distance of sentence $\vec{s}_e$ to the sentence cluster centroids such that $\vec{s}_c = (\cos(\vec{s}_e, \vec{c}_1), \ldots, \cos(\vec{s}_e, \vec{c}_k))$ where $\dim(\vec{s}_c) = K$ and $\cos(\bullet, \bullet)$ denotes cosine similarity. Analogically, let L be the number of *post* clusters in $\mathbb{E}$ and $\vec{a}_l$ a centroid vector of cluster $l \in L$. Then $\vec{s}_a$ denotes the distance of sentence $\vec{s}_e$ to the post cluster centroids such that $\vec{s}_a = (\cos(\vec{s}_e, \vec{a}_1), \ldots, \cos(\vec{s}_e, \vec{a}_l))$. We construct the feature vector by concatenating $\vec{s}_e$, $\vec{s}_c$ and $\vec{s}_a$.

For word embeddings, we use pre-trained skip-gram word vectors[11] produced by Mikolov et al. (2013) ($\dim(\mathbb{E}) = 300$). To create clusters for the argument space features, we used CLUTO software package[12] with Repeated Bisection clustering method (Zhao and Karypis, 2002). We clustered the data using different hyper-parameters K and L (we experimented with $K = \{50, 100, 500, 1000\}$ and $L = \{50, 100, 500, 1000\}$).

5 Results

We investigate three evaluation scenarios. First, we report 10-fold cross validation over all 340 documents, where the data are randomly distributed across the folds regardless of the domain or register. In this scenario, the model can benefit from domain-dependent features for the testing data, such as lexical knowledge (FS0) or domain-relevant argument space features (FS4). Second, we evaluate the cross-domain performance; the model is always trained on five domains and tested on the sixth one. In this settings, we also remove all features that exploit distant data relevant to the test set. For instance, if the test domain is *mainstreaming*, we exclude all debates relevant to this domain before constructing the argument space features (FS4). This evaluates the model's cross-domain performance without any target domain data available. Finally, we test cross-register performance in two set-ups: we train the models using comments and forum posts and test on blogs and newswire articles, and then the other way round. We divided the data into these two parts based on similar properties of blogs/articles and comments/forums, such as the length, or the distribution of argumentative and non-argumentative text.

In the evaluation, we focus on F_1 scores achieved on *claims*, *premises*, *backing*, and non-argumentative text (the 'O' class). Although the

Table 1: F_1 results for the 10-fold cross-validation scenario. Feature set combination (the **FS** column) naming is explained in Section 4.1. Class labels: **B-B/I** = *Backing-B/I*, **C-B/I** = *Claim-B/I*, **O** = *non-argumentative*, **P-B/I** = *Premise-B/I*. Star ($\star$) denotes that the row is significantly better than the previous row; dagger (†) means the row is not significantly better than the previous row, but is significantly better than the previous row minus one; $p < 0.001$ using exact Liddell's test (Liddell, 1983).

classifier is trained and tested on all 11 classes including *rebuttal* and *refutation*, we do not report performance of these two argument components—the results are very poor regardless of the parameters for two reasons. First, these classes are underrepresented in the data (*Rebuttal-B*, *Rebuttal-I*, *Refutation-B* and *Refutation-I* are present in only about 4% of sentences). Second, the inter-annotator agreement reached on these classes were reported to be very low (Habernal et al., 2014).

Cross validation results Table 1 shows results for the cross-validation scenario. The human baseline in the first row is an average score between three original annotators of the dataset. The baseline features (FS0) perform poorly, yet they beat the random assignment and majority vote (< 0.12 F_1). The argument space features (FS4) increase the performance in every combination. The best results for *claims* are achieved when only discourse, sentiment, and argument space features are involved (FS3 and FS4), whereas *premises* and *backing* benefit from the presence of lexical, syntactic, and semantic features (the richest feature set). The overall average best results are obtained from a feature combination with higher level of abstraction, in particular without low-level lexical features from FS0.

After the cross validation experiments, we also fixed the hyperparameters (using grid search) to $K = 1000, L = 100$ for the cluster sizes and $t = 1$ and $e = 0$ for the hyperparameters of SVM^{hmm} .

Cross-domain results For each domain, the cross-domain results are shown in Table 2. On average, the best results are about 0.10 F_1 points worse than in the cross-validation settings (Table 1). In all domains, the best average performance was achieved using only the argument space features (FS4); in four cases this system significantly outperforms all other systems ($p < 0.001$). Moreover, more high-level feature set combinations that also contain argument space features (such as FS2+FS3+F4 or FS3+FS4) yield usually better results for particular argument components in contrast to features based on lexical or syntactic information (FS0 and FS1). For identifying non-argumentative texts, there is no clear winner with respect to feature set abstraction (in three domains the best results are achieved using FS4 but in other three domains the baseline FS0 performs best).

Cross-register results The argument space features (FS4) performs best in average also in the cross-register evaluation (see Table 3). In recognizing *premises*, better results were achieved by a system trained on blogs and articles and tested on comments and forum posts. Recognizing *claims* exhibits similar behavior. On the other hand, recognizing non-argumentative text performs better in the opposite direction. On average, the cross-register results are much worse than cross-validation and slightly worse than cross-domain results.

5.1 Error analysis

First, we quantitatively investigate errors in the cross-validation scenario. The confusion matrix in Table 4 shows that about 50-60% of errors for each argument component were caused by misclassifying it as non-argumentative (the 'O' class). The system tends to prefer the 'O' predictions because of the high presence of non-argumentative sentences in the corpus (about 57%). *Backing* is often confused with *premises*; in particular, *Backing-B* with *Premise-B* in 14%, *Backing-I* with *Premise-I* in 17%. These two argument components have a similar function–to support the claim–so the differences in the discourse (which are sometimes very subtle) confuse the system. Note that despite the confusion between these classes, the *-I* and *-B* tags mostly remain the same (the system correctly predicts whether the argument component begins or not).[13]

We also analyzed the errors of the best-

[13]To provide the complete picture, we also show the previously unreported classes (*rebuttal* and *refutation*). *Rebuttal* is usually misclassified as non-argumentative or *premise*, *refutation* as either non-argumentative, *backing*, or *premise*.

Table 3: F_1 results for the cross-register evaluation scenario ranked by performance. Feature set combination naming (the **FS** column) is explained in Section 4.1. Class labels: **B-B/I** = *Backing-B/I*, **C-B/I** = *Claim-B/I*, **O** = *non-argumentative*, **P-B/I** = *Premise-B/I*. Diamond (◇) in the last (winning) row signals a significant difference between this row and all other rows; $p < 0.001$ using exact Liddell's test (Liddell, 1983).

performing cross-domain system in detail.[14] We randomly sampled 40 documents and manually compared the predicted arguments with the gold data. We found that 11 predicted documents were simply wrong or no argument components were predicted at all (e.g., document #1640, #1658, #1021, #5258). Most of these errors occur in blogs, which seem to convey rather complex argumentation structure (#1666, #1197, #4586, #5258). In 8 documents, we identified that only some premises were (correctly) spotted by the system. This happened mostly in long comments (#452) and blogs (#400, #697, #4583). In 7 investigated documents, we identified errors caused by slightly different boundaries of recognized argument components (#4517, #2447, #2252, #4840) or when multiple segments were merged/split (#1604, #2180, #2310).

By analyzing the predicted output, we also found that in 12 documents the recognized argument components seemed to be valid to some extent, although this was our subjective judge. For instance, in #4285 (see Figure 2), the first *premise* was misclassified as a *claim*. The gold-data argument was annotated as an *enthymeme* (with implicit *claim* that advocates private schools), while in the prediction, the same proposition was identified as the an explicit *claim* supporting private

[14] Available also as PDF at `https://github.com/habernal/emnlp2015`; we use #ID to point to the particular documents.

schools with one *premise* why the education was not satisfying, which might be also another valid interpretation. The second example #2180 in Figure 2 shows that the boundaries of the predicted *premises* are mixed up (two recognized instead of three), but the longer *backing* is also meaningful. These examples demonstrate that argument analysis is in some cases ambiguous and allows for different valid interpretations.

6 Conclusion

In this article, we proposed a semi-supervised model for argumentation mining of user-generated Web content. We developed new unsupervised features for argument component identification that exploit clustering of unlabeled argumentative data from debate portals based on word embeddings representation. With the help of these features we significantly improved performance of the argumentation mining system and outperformed several baselines. While the improvement was decent in cross-validation scenario, we gained almost 100% improvement in cross-domain and cross-register settings.

We evaluated the methods on a publicly available corpus annotated with argumentation that origins from user-generated Web data. By a detailed analysis of the errors, we pointed out the strengths (such as domain adaptability) and weaknesses (such as unsatisfying results for *rebuttal* and *refutation* components), as well as the challenges for the argumentation mining task (such as boundary identification issues or ambiguous arguments). If we put our results into the context of existing works, the most relevant one by (Goudas et al., 2014) achieved 0.42 F_1 score on identifying only premises. We get comparable results in the cross-validation settings (F_1 0.31-0.40) yet with more complex argumentation model (five different components).

Although argumentation mining in user-generated Web discourse has a long way to go (our methods currently achieve only about 50% of human performance), we see a huge potential for various future tasks, such as information seeking for better-informed personal decision making or support for argument quality assessment. To foster the research within the community, we provide all source codes and data required for the experiments under free licenses.

Confounds and Consequences in Geotagged Twitter Data

Abstract

Twitter is often used in quantitative studies that identify geographically-preferred topics, writing styles, and entities. These studies rely on either GPS coordinates attached to individual messages, or on the user-supplied location field in each profile. In this paper, we compare these data acquisition techniques and quantify the biases that they introduce; we also measure their effects on linguistic analysis and text-based geolocation. GPS-tagging and self-reported locations yield measurably different corpora, and these linguistic differences are partially attributable to differences in dataset composition by age and gender. Using a latent variable model to induce age and gender, we show how these demographic variables interact with geography to affect language use. We also show that the accuracy of text-based geolocation varies with population demographics, giving the best results for men above the age of 40.

1 Introduction

Social media data such as Twitter is frequently used to identify the unique characteristics of geographical regions, including topics of interest (Hong et al., 2012), linguistic styles and dialects (Eisenstein et al., 2010; Gonçalves and Sánchez, 2014), political opinions (Caldarelli et al., 2014), and public health (Broniatowski et al., 2013). Social media permits the aggregation of datasets that are orders of magnitude larger than could be assembled via traditional survey techniques, enabling analysis that is simultaneously fine-grained and global in scale. Yet social media is not a representative sample of any "real world" population, aside from social media itself. Using social media as a sample therefore risks introducing both geographic and demographic biases (Mislove et al., 2011; Hecht and Stephens, 2014; Longley et al., 2015; Malik et al., 2015).

This paper examines the effects of these biases on the geo-linguistic inferences that can be drawn from Twitter. We focus on the ten largest metropolitan areas in the United States, and consider three sampling techniques: drawing an equal number of GPS-tagged tweets from each area; drawing a *county-balanced* sample of GPS-tagged messages to correct Twitter's urban skew (Hecht and Stephens, 2014); and drawing a sample of *location-annotated* messages, using the location field in the user profile. Leveraging self-reported first names and census statistics, we show that the age and gender composition of these datasets differ significantly.

Next, we apply standard methods from the literature to identify geo-linguistic differences, and test how the outcomes of these methods depend on the sampling technique and on the underlying demographics. We also test the accuracy of text-based geolocation (Cheng et al., 2010; Eisenstein et al., 2010) in each dataset, to determine whether the accuracies reported in recent work will generalize to more balanced samples.

The paper reports several new findings about geotagged Twitter data:

- In comparison with tweets with self-reported locations, GPS-tagged tweets are written more often by young people and by women.
- There are corresponding linguistic differences between these datasets, with GPS-tagged tweets including more geographically-specific non-standard words.
- Young people use significantly more geographically-specific non-standard words. Men tend to mention more geographically-specific entities than women, but these

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2138–2148,
Lisbon, Portugal, 17-21 September 2015.

differences are significant only for individuals at the age of 30 or older.

- Users who GPS-tag their tweets tend to write more, making them easier to geolocate. Evaluating text-based geolocation on GPS-tagged tweets probably overestimates its accuracy.
- Text-based geolocation is significantly more accurate for men and for older people.

These findings should inform future attempts to generalize from geotagged Twitter data, and may suggest investigations into the demographic properties of other social media sites.

We first describe the basic data collection principles that hold throughout the paper (§ 2). The following three sections tackle demographic biases (§ 3), their linguistic consequences (§ 4), and the impact on text-based geolocation (§ 5); each of these sections begins with a discussion of methods, and then presents results. We then summarize related work and conclude.

2 Dataset

This study is performed on a dataset of tweets gathered from Twitter's streaming API from February 2014 to January 2015. During an initial filtering step we removed retweets, repetitions of previously posted messages which contain the "retweeted_status" metadata or "RT" token which is widely used among Twitter users to indicate a retweet. To eliminate spam and automated accounts (Yardi et al., 2009), we removed tweets containing URLs, user accounts with more than 1000 followers or followees, accounts which have tweeted more than 5000 messages at the time of data collection, and the top 10% of accounts based on number of messages in our dataset. We also removed users who have written more than 10% of their tweets in any language other than English, using Twitter's `lang` metadata field. Exploration of code-switching (Solorio and Liu, 2008) and the role of second-language English speakers (Eleta and Golbeck, 2014) is left for future work.

We consider the ten largest Metropolitan Statistical Areas (MSAs) in the United States, listed in Table 1. MSAs are defined by the U.S. Census Bureau as geographical regions of high population with density organized around a single urban core; they are not legal administrative divisions. MSAs include outlying areas that may be substantially less urban than the core itself. For example, the Atlanta MSA is centered on Fulton County (1750 people per square mile), but extends to Haralson County (100 people per square mile), on the border of Alabama. A per-county analysis of this data therefore enables us to assess the degree to which Twitter's skew towards urban areas biases geo-linguistic analysis.

3 Representativeness of geotagged Twitter data

We first assess potential biases in sampling techniques for obtaining geotagged Twitter data. In particular, we compare two possible techniques for obtaining data: the location field in the user profile (Poblete et al., 2011; Dredze et al., 2013), and the GPS coordinates attached to each message (Cheng et al., 2010; Eisenstein et al., 2010).

3.1 Methods

To build a dataset of GPS-tagged messages, we extracted the GPS latitude and longitude coordinates reported in the tweet, and used GIS-TOOLS[1] reverse geocoding to identify the corresponding counties. This set of geotagged messages will be denoted $\mathcal{D}_G$. Only 1.24% of messages contain geo-coordinates, and it is possible that the individuals willing to share their GPS comprise a skewed population. We therefore also considered the user-reported location field in the Twitter profile, focusing on the two most widely-used patterns: (1) city name, (2) city name and two letter state name (e.g. *Chicago* and *Chicago, IL*). Messages that matched any of the ten largest MSAs were grouped into a second set, $\mathcal{D}_L$.

While the inconsistencies of writing style in the Twitter location field are well-known (Hecht et al., 2011), analysis of the intersection between $\mathcal{D}_G$ and $\mathcal{D}_L$ found that the two data sources agreed the overwhelming majority of the time, suggesting that most self-provided locations are accurate. Of course, there may be many false negatives — profiles that we fail to geolocate due to the use of non-standard toponyms like *Pixburgh* and *ATL*. If so, this would introduce a bias in the population sample in $\mathcal{D}_L$. Such a bias might have linguistic consequences, with datasets based on the location field containing less non-standard language overall.

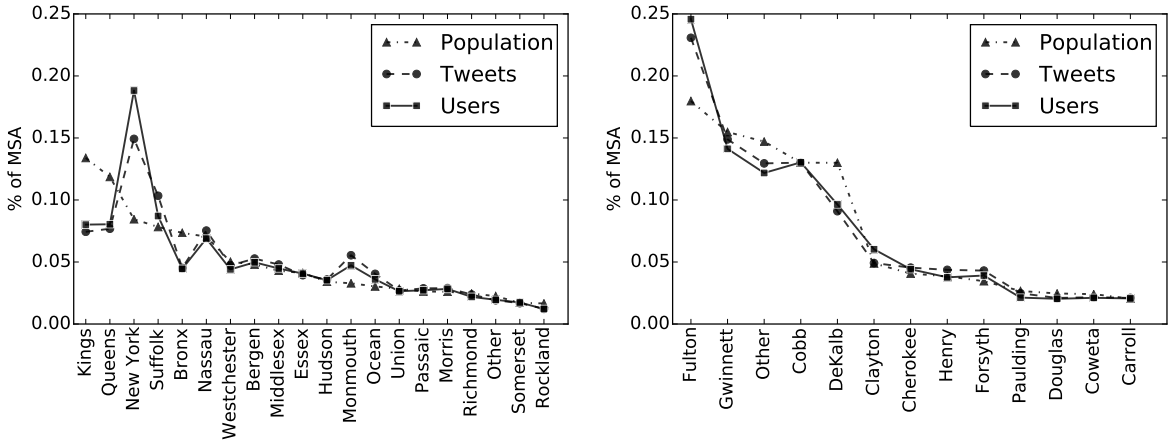

Figure 1: Proportion of census population, Twitter messages, and Twitter user accounts, by county. New York is shown on the left, Atlanta on the right.

3.1.1 Subsampling

The initial samples $\mathcal{D}_G$ and $\mathcal{D}_L$ were then resampled to create the following balanced datasets:

GPS-MSA-BALANCED From $\mathcal{D}_G$, we randomly sampled 25,000 tweets per MSA as the message-balanced sample, and all the tweets from 2,500 users per MSA as the user-balanced sample. Balancing across MSAs ensures that the largest MSAs do not dominate the linguistic analysis.

GPS-COUNTY-BALANCED We resampled $\mathcal{D}_G$ based on county-level population (obtained from the U.S. Census Bureau), and again obtained message-balanced and user-balanced samples. These samples are more geographically representative of the overall population distribution across each MSA.

LOC-MSA-BALANCED From $\mathcal{D}_L$, we randomly sampled 25,000 tweets per MSA as the message-balanced sample, and all the tweets from 2,500 users per MSA as the user-balanced sample. It is not possible to obtain county-level geolocations in $\mathcal{D}_L$, as exact geographical coordinates are unavailable.

3.1.2 Age and gender identification

To estimate the distribution of ages and genders in each sample, we queried statistics from the Social Security Administration, which records the number of individuals born each year with each given name. Using this information, we obtained the probability distribution of age values for each given name. We then matched the names against the first token in the name field of each user's profile, enabling us to induce approximate distributions over ages and genders. Unlike Facebook and Google+, Twitter does not have a "real name" policy, so users are free to give names that are fake, humorous, etc. We eliminate user accounts whose names are not sufficiently common in the social security database (i.e. first names which are at least 100 times more frequent in Twitter than in the social security database), thereby omitting 33% of user accounts, and 34% of tweets. While some individuals will choose names not typically associated with their gender, we assume that this will happen with roughly equal probability in both directions. So, with these caveats in mind, we induce the age distribution for the GPS-MSA-BALANCED sample and the LOC-MSA-BALANCED sample as,

$$p(a \mid \text{name} = n) = \frac{count(\text{name} = n, \text{age} = a)}{\sum_{a'} count(\text{name} = n, \text{age} = a')} \quad (1)$$

$$p_{\mathcal{D}}(a) \propto \sum_{i \in \mathcal{D}} p(a \mid \text{name} = n_i). \quad (2)$$

We induce distributions over author gender in much the same way (Mislove et al., 2011). This method does not incorporate prior information about the ages of Twitter users, and thus assigns too much probability to the extremely young and old, who are unlikely to use the service. While it would be easy to design such a prior — for example, assigning zero prior probability to users under the age of five or above the age of 95 — we see no principled basis for determining these cutoffs. We therefore focus on the *differences* between the estimated $p_{\mathcal{D}}(a)$ for each sample $\mathcal{D}$.

MSA	Num. Counties	L1 Dist. Population vs. Users	L1 Dist. Population vs. Tweets
New York	23	0.2891	0.2825
Los Angeles	2	0.0203	0.0223
Chicago	14	0.0482	0.0535
Dallas	12	0.1437	0.1176
Houston	10	0.0394	0.0472

Atlanta	28	0.1448	0.1730
Boston	7	0.1878	0.2303

Table 1: L1 distance between county-level population and Twitter users and messages

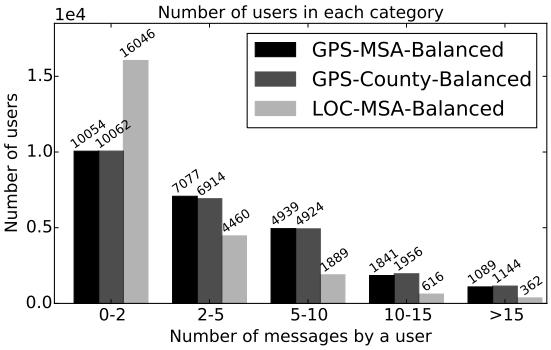

Figure 2: User counts by number of Twitter messages

3.2 Results

Geographical biases in the GPS Sample We first assess the differences between the true population distributions over counties, and the per-tweet and per-user distributions. Because counties vary widely in their degree of urbanization and other demographic characteristics, this measure is a proxy for the representativeness of GPS-based Twitter samples (county information is not available for the LOC-MSA-BALANCED sample). Population distributions for New York and Atlanta are shown in Figure 1. In Atlanta, Fulton County is the most populous and most urban, and is over-represented in both geotagged tweets and user accounts; most of the remaining counties are correspondingly underrepresented. This coheres with the urban bias noted earlier by Hecht and Stephens (2014). In New York, Kings County (Brooklyn) is the most populous, but is underrepresented in both the number of geotagged tweets and user accounts, at the expense of New York County (Manhattan). Manhattan is the commercial and entertainment center of the New York MSA, so residents of outlying counties may be tweeting from their jobs or social activities.

To quantify the representativeness of each sample, we use the L1 distance $||\mathbf{x} - \mathbf{y}||_1 = \sum_c |p_c - t_c|$, where p_c is the proportion of the MSA population residing in county c and t_c is the proportion of tweets (Table 1). County boundaries are determined by states, and their density varies: for example, the Los Angeles MSA covers only two counties, while the smaller Atlanta MSA is spread over 28 counties. The table shows that while New York is the most extreme example, most MSAs feature an asymmetry between county population and Twitter adoption.

Usage Next, we turn to differences between the GPS-based and profile-based techniques for obtaining ground truth data. As shown in Figure 2, the LOC-MSA-BALANCED sample contains more low-volume users than either the GPS-MSA-BALANCED or GPS-COUNTY-BALANCED samples. We can therefore conclude that the county-level geographical bias in the GPS-based data does not impact usage rate, but that the difference between GPS-based and profile-based sampling does; the linguistic consequences of this difference will be explored in the following sections.

Demographics Table 2 shows the expected age and gender for each dataset, with bootstrap confidence intervals. Users in the LOC-MSA-BALANCED dataset are on average two years older than in the GPS-MSA-BALANCED and GPS-COUNTY-BALANCED datasets, which are statistically indistinguishable. Focusing on the difference between GPS-MSA-BALANCED and LOC-MSA-BALANCED, we plot the difference in age probabilities in Figure 3, showing that GPS-MSA-BALANCED includes many more teens and people in their early twenties, while LOC-MSA-BALANCED includes more people at middle age and older. Young people are especially likely to use social media on cellphones (Lenhart, 2015), where location tagging would be more relevant than when Twitter is accessed via a personal computer. Social media users in the age brackets 18-29 and 30-49 are also more likely to tag their locations in social media posts than social media users in the age brackets 50-64 and 65+ (Zickuhr, 2013), with women and men tagging at roughly equal rates. Table 2 shows that the GPS-MSA-BALANCED and GPS-COUNTY-BALANCED samples contain significantly more women than LOC-

Sample	Expected Age	95% CI	% Female	95% CI
GPS-MSA-BALANCED	36.17	[36.07 – 36.27]	51.5	[51.3 – 51.8]
GPS-COUNTY-BALANCED	36.25	[36.16 – 36.30]	51.3	[51.1 – 51.6]
LOC-MSA-BALANCED	38.35	[38.25 – 38.44]	49.3	[49.1 – 49.6]

Table 2: Demographic statistics for each dataset

Figure 3: Difference in age probability distributions between GPS-MSA-BALANCED and LOC-MSA-BALANCED.

MSA-BALANCED, though all three samples are close to 50%.

4 Impact on linguistic generalizations

Many papers use Twitter data to draw conclusions about the relationship between language and geography. What role do the demographic differences identified in the previous section have on the linguistic conclusions that emerge? We measure the differences between the linguistic corpora obtained by each data acquisition approach. Since the GPS-MSA-BALANCED and GPS-COUNTY-BALANCED methods have nearly identical patterns of usage and demographics, we focus on the difference between GPS-MSA-BALANCED and LOC-MSA-BALANCED. These datasets differ in age and gender, so we also directly measure the impact of these demographic factors on the use of geographically-specific linguistic variables.

4.1 Methods

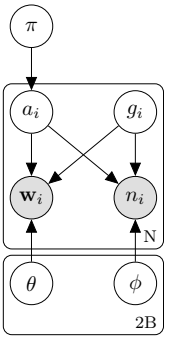
Discovering geographical linguistic variables We focus on lexical variation, which is relatively easy to identify in text corpora. Monroe et al. (2008) survey a range of alternative statistics for finding lexical variables, demonstrating that a regularized log-odds ratio strikes a good balance between distinctiveness and robustness. A similar approach is implemented in SAGE (Eisenstein et al., 2011a)[2], which we use here. For each sample — GPS-MSA-BALANCED and LOC-MSA-BALANCED — we apply SAGE to identify the twenty-five most salient lexical items for each metropolitan area.

Keyword annotation Previous research has identified two main types of geographical lexical variables. The first are non-standard words and spellings, such as *hella* and *yinz*, which have been found to be very frequent in social media (Eisenstein, 2015). Other researchers have focused on the "long tail" of entity names (Roller et al., 2012). A key question is the relative importance of these two variable types, since this would decide whether geo-linguistic differences are primarily topic-based or stylistic. It is therefore important to know whether the frequency of these two variable types depends on properties of the sample. To test this, we take the lexical items identified by SAGE (25 per MSA, for both the GPS-MSA-BALANCED and LOC-MSA-BALANCED samples), and annotate them as NONSTANDARD-WORD, ENTITY-NAME, or OTHER. Annotation for ambiguous cases is based on the majority sense in randomly-selected examples. Overall, we identify 24 NONSTANDARD-WORDS and 185 ENTITY-NAMES.

Inferring author demographics As described in § 3.1.2, we can obtain an approximate distribution over author age and gender by linking self-reported first names with aggregate statistics from the United States Census. To sharpen these estimates, we now consider the text as well, building a simple latent variable model in which both the name and the word counts are drawn from distributions associated with the latent age and gender (Chang et al., 2010). The model is shown in Figure 4, and involves the following generative process:

For each user $i \in \{1...N\}$,
(a) draw the age, $a_i \sim \text{Categorical}(\pi)$
(b) draw the gender, $g_i \sim \text{Categorical}(0.5)$

[2] https://github.com/jacobeisenstein/jos-gender-2014



a_i	Age (bin) for author i
g_i	Gender of author i
$\mathbf{w}_i$	Word counts for author i
n_i	First name of author i
π	Prior distribution over age bins
$\theta_{a,g}$	Word distribution for age a and gender g
$\phi_{a,g}$	First name distribution for age a and gender g

Figure 4: Plate diagram for latent variable model of age and gender

(c) draw the author's given name, $n_i \sim \text{Categorical}(\phi_{a_i,g_i})$

(d) draw the word counts, $w_i \sim \text{Multinomial}(\theta_{a_i,g_i})$,

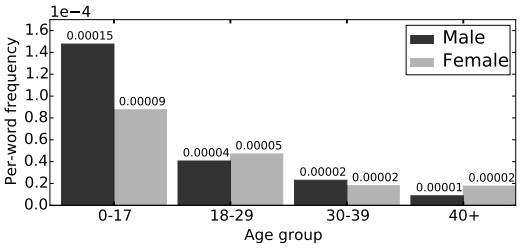
where we elide the second parameter of the multinomial distribution, the total word count. We use expectation-maximization to perform inference in this model, binning the latent age variable into four groups: 0-17, 18-29, 30-39, above 40.[3] Because the distribution of names given demographics is available from the Social Security data, we clamp the value of ϕ throughout the EM procedure. Other work in the domain of demographic prediction often involves more complex methods (Nguyen et al., 2014; Volkova and Durme, 2015), but since it is not the focus of our research, we take a relatively simple approach here, assuming no labeled data for demographic attributes.

4.2 Results

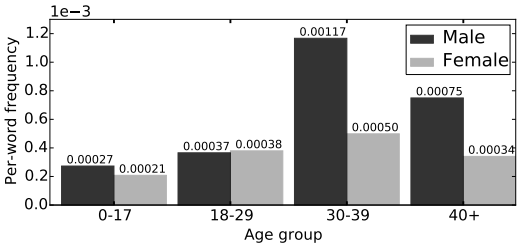
Linguistic differences by dataset We first consider the impact of the data acquisition technique on the lexical features associated with each city. The keywords identified in GPS-MSA-BALANCED dataset feature more geographically-specific non-standard words, which occur at a rate of 3.9×10^{-4} in GPS-MSA-BALANCED, versus 2.6×10^{-4} in LOC-MSA-BALANCED; this difference is statistically significant ($p < .05, t = 3.2$).[4]

[3] Binning is often employed in work on text-based age prediction (Garera and Yarowsky, 2009; Rao et al., 2010; Rosenthal and McKeown, 2011); it enables word and name counts to be shared over multiple ages, and avoids the complexity inherent in regressing a high-dimensional textual predictors against a numerical variable.

[4] We employ a paired t-test, comparing the difference in frequency for each word across the two datasets. Since we cannot test the complete set of entity names or non-standard words, this quantifies whether the observed difference is robust across the subset of the vocabulary that we have selected.



(a) non-standard words



(b) entity names

Figure 5: Aggregate statistics for geographically-specific non-standard words and entity names across imputed demographic groups, from the GPS-MSA-BALANCED sample.

For entity names, the difference between datasets was not significant, with a rate of 4.0×10^{-3} for GPS-MSA-BALANCED, and 3.7×10^{-3} for LOC-MSA-BALANCED. Note that these rates include only the non-standard words and entity names detected by SAGE as among the top 25 most distinctive for one of the ten largest cities in the US; of course there are many other relevant terms that are below this threshold.

In a pilot study of the GPS-COUNTY-BALANCED data, we found few linguistic differences from GPS-MSA-BALANCED, in either the aggregate word-group frequencies or the SAGE word lists — despite the geographical imbalances shown in Table 1 and Figure 1. Informal examination of specific counties shows some expected differences: for example, Clayton County, which hosts Atlanta's Hartsfield-Jackson airport, includes terms related to air travel, and other counties include mentions of local cities and business districts. But the aggregate statistics for under-represented counties are not substantially different from those of overrepresented counties, and are largely unaffected by county-based resampling.

Demographics Aggregate linguistic statistics for demographic groups are shown in Figure 5. Men use significantly more geographically-specific entity names than women ($p \ll .01, t =$

Age	Sex	New York	Dallas
0-17	F	*niall, ilysm, hemmings, stalk, ily*	*fanuary, idol, lmbo, lowkey, jonas*
	M	*ight, technique, kisses, lesbian, dicks*	*homies, daniels, oomf, teenager, brah*
18-29	F	*roses, castle, hmmmm, chem, sinking*	*socially, coma, hubby, bra, swimming*
	M	*drunken, manhattan, spoiler, guardians, gonna*	*harden, watt, astros, rockets, mavs*
30-39	F	*suite, nyc, colleagues, york, portugal*	*astros, sophia, recommendations, houston, prepping*
	M	*mets, effectively, cruz, founder, knicks*	*texans, rockets, embarrassment, tcu, mississippi*
40+	F	*cultural, affected, encouraged, proverb, unhappy*	*determine, islam, rejoice, psalm, responsibility*
	M	*reuters, investors, shares, lawsuit, theaters*	*mph, wazers, houston, tx, harris*

Table 3: Most characteristic words for demographic subsets of each city, as compared with the overall average word distribution

8.0), but gender differences for geographically-specific non-standard words are not significant ($p \approx .2$).[5] Younger people use significantly more geographically-specific non-standard words than older people (ages 0–29 versus 30+, $p \ll .01, t = 7.8$), and older people mention significantly more geographically-specific entity names ($p \ll .01, t = 5.1$). Of particular interest is the intersection of age and gender: the use of geographically-specific non-standard words decreases with age much more profoundly for men than for women; conversely, the frequency of mentioning geographically-specific entity names increases dramatically with age for men, but to a much lesser extent for women. The observation that high-level patterns of geographically-oriented language are more age-dependent for men than for women suggests an intriguing site for future research on the intersectional construction of linguistic identity.

For a more detailed view, we apply SAGE to identify the most salient lexical items for each MSA, subgrouped by age and gender. Table 3 shows word lists for New York (the largest MSA) and Dallas (the 5th-largest MSA), using the GPS-MSA-BALANCED sample. Non-standard words tend to be used by the youngest authors: *ilysm* ('I love you so much'), *ight* ('alright'), *oomf* ('one of my followers'). Older authors write more about local entities (*manhattan, nyc, houston*), with men focusing on sports-related entities (*harden, watt, astros, mets, texans*), and women above the age of 40 emphasizing religiously-oriented terms (*proverb, islam, rejoice, psalm*).

[5]But see Bamman et al. (2014) for a much more detailed discussion of gender and standardness.

5 Impact on text-based geolocation

A major application of geotagged social media is to predict the geolocation of individuals based on their text (Eisenstein et al., 2010; Cheng et al., 2010; Wing and Baldridge, 2011; Hong et al., 2012; Han et al., 2014). Text-based geolocation has obvious commercial implications for location-based marketing and opinion analysis; it is also potentially useful for researchers who want to measure geographical phenomena in social media, and wish to access a larger set of individuals than those who provide their locations explicitly.

Previous research has obtained impressive accuracies for text-based geolocation: for example, Hong et al. (2012) report a median error of 120 km, which is roughly the distance from Los Angeles to San Diego, in a prediction space over the entire continental United States. These accuracies are computed on test sets that were acquired through the same procedures as the training data, so if the acquisition procedures have geographic and demographic biases, then the resulting accuracy estimates will be biased too. Consequently, they may be overly optimistic (or pessimistic!) for some types of authors. In this section, we explore where these text-based geolocation methods are most and least accurate.

5.1 Methods

Our data is drawn from the ten largest metropolitan areas in the United States, and we formulate text-based geolocation as a ten-way classification problem, similar to Han et al. (2014).[6] Using our

[6]Many previous papers have attempted to identify the precise latitude and longitude coordinates of individual authors, but obtaining high accuracy on this task involves much more complex methods, such as latent variable models (Eisenstein et al., 2010; Hong et al., 2012), or multilevel grid structures (Cheng et al., 2010; Roller et al., 2012). Tuning such

user-balanced samples, we apply ten-fold cross validation, and tune the regularization parameter on a development fold, using the vocabulary of the sample as features.

5.2 Results

Many author-attribute prediction tasks become substantially easier as more data is available (Burger et al., 2011), and text-based geolocation is no exception. Since GPS-MSA-BALANCED and LOC-MSA-BALANCED have very different usage rates (Figure 2), perceived differences in accuracy may be purely attributable to the amount of data available per user, rather than to users in one group being inherently harder to classify than another. For this reason, we bin users by the number of messages in our sample of their timeline, and report results separately for each bin. All errorbars represent 95% confidence intervals.

GPS versus location As seen in Figure 6a, there is little difference in accuracy across sampling techniques: the location-based sample is slightly easier to geolocate at each usage bin, but the difference is not statistically significant. However, due to the higher average usage rate in GPS-MSA-BALANCED(see Figure 2), the overall accuracy for a sample of users will appear to be higher on this data.

Demographics Next, we measure classification accuracy by gender and age, using the posterior distribution from the expectation-maximization algorithm to predict the gender of each user (broadly similar results are obtained by using the prior distribution). For this experiment, we focus on the GPS-MSA-BALANCED sample. As shown in Figure 6b, text-based geolocation is consistently more accurate for male authors, across almost the entire spectrum of usage rates. As shown in Figure 6c, older users also tend to be easier to geolocate: at each usage level, the highest accuracy goes to one of the two older groups, and the difference is significant in almost every case. As discussed in § 4, older male users tend to mention many entities, particularly sports-related terms; these terms are apparently more predictive than the non-standard spellings and slang favored by younger authors.

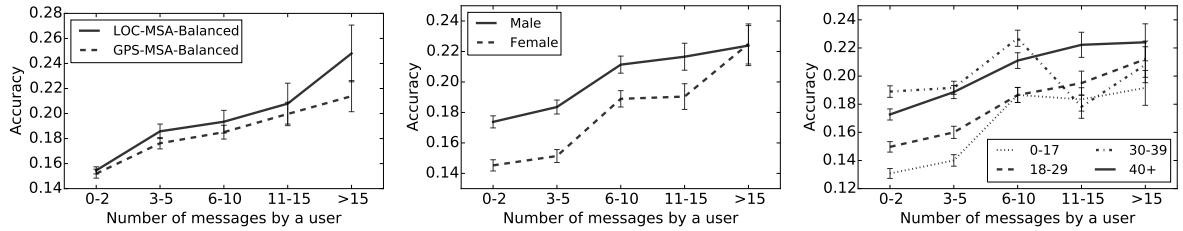
models can be challenging, and the resulting accuracies might be affected by initial conditions or hyperparameters. We therefore focus on classification, employing the familiar and well-understood method of logistic regression.

6 Related Work

Several researchers have studied how adoption of Internet technology varies with factors such as socioeconomic status, age, gender, and living conditions (Zillien and Hargittai, 2009). Hargittai and Litt (2011) use a longitudinal survey methodology to compare the effects of gender, race, and topics of interest on Twitter usage among young adults. Geographic variation in Twitter adoption has been considered both internationally (Kulshrestha et al., 2012) and within the United States, using both the Twitter location field (Mislove et al., 2011) and per-message GPS coordinates (Hecht and Stephens, 2014). Aggregate demographic statistics of Twitter users' geographic census blocks were computed by O'Connor et al. (2010) and Eisenstein et al. (2011b); Malik et al. (2015) use census demographics in spatial error model. These papers draw similar conclusions, showing that the the distribution of geotagged tweets over the US population is not random, and that higher usage is correlated with urban areas, high income, more ethnic minorities, and more young people. However, this prior work did not consider the biases introduced by relying on geotagged messages, nor the consequences for geo-linguistic analysis.

Twitter has often been used to study the geographical distribution of linguistic information, and of particular relevance are Twitter-based studies of regional dialect differences (Eisenstein et al., 2010; Doyle, 2014; Gonçalves and Sánchez, 2014; Eisenstein, 2015) and text-based geolocation (Cheng et al., 2010; Hong et al., 2012; Han et al., 2014). This prior work rarely considers the impact of the demographic confounds, or of the geographical biases mentioned in § 3. Recent research shows that accuracies of core language technology tasks such as part-of-speech tagging are correlated with author demographics such as author age (Hovy and Søgaard, 2015); our results on location prediction are in accord with these findings. Hovy (2015) show that including author demographics can improve text classification, a similar approach might improve text-based geolocation as well.

We address the question about the impact of geographical biases and demographic confounds by measuring differences between three sampling techniques, in both language use and in the accuracy of text-based geolocation. Recent unpublished work proposes reweighting Twitter data to



(a) Classification accuracy by sampling technique

(b) Classification accuracy by user gender

(c) Classification accuracy by imputed age

Figure 6: Classification accuracies

correct biases in political analysis (Choy et al., 2012) and public health (Culotta, 2014). Our results suggest that the linguistic differences between user-supplied profile locations and per-message geotags are more significant, and that accounting for the geographical biases among geotagged messages is not sufficient to offer a representative sample of Twitter users.

7 Discussion

Geotagged Twitter data offers an invaluable resource for studying the interaction of language and geography, and is helping to usher in a new generation of location-aware language technology. This makes critical investigation of the nature of this data source particularly important. This paper uncovers demographic confounds in the linguistic analysis of geo-located Twitter data, but is limited to demographics that can be readily induced from given names. A key task for future work is to quantify the representativeness of geotagged Twitter data with respect to factors such as race and socioeconomic status, while holding geography constant. However, these features may be more difficult to impute from names alone. Another crucial task is to expand this investigation beyond the United States, as the varying patterns of use for social media across countries (Pew Research Center, 2012) implies that the findings here cannot be expected to generalize to every international context.

Abstract

We present novel experiments in modeling the rise and fall of story characteristics within narrative, leading up to the *Most Reportable Event* (MRE), the compelling event that is the nucleus of the story. We construct a corpus of personal narratives from the bulletin board website Reddit, using the organization of Reddit content into topic-specific communities to automatically identify narratives. Leveraging the structure of Reddit comment threads, we automatically label a large dataset of narratives. We present a change-based model of narrative that tracks changes in formality, affect, and other characteristics over the course of a story, and we use this model in distant supervision and self-training experiments that achieve significant improvements over the baselines at the task of identifying MREs.

1 Introduction

What is a narrative? In one of the early linguistic analyses of storytelling, Prince (1973) defines a story as describing an event that causes a change of state. Prince's minimal story has three parts: the starting state, the ending state, and the event that transforms the stating state into the ending state. An example of a minimal story is as follows:

> A man was unhappy, then he fell in love, then as a result, he was happy.

Polanyi (1976) notes that minimal stories are toy examples that would never hold an audience's interest. So what makes a story interesting?

Labov (1967; 1997) defines a well-formed narrative as a series of actions leading to a *Most Reportable Event* (MRE). The MRE is the point of the story – the most unusual event that has the greatest emotional impact on the narrator and the audience. For a story to be interesting, Prince's change-of-state event should be an MRE.

The following is an example of a narrative from the corpus we create in this work, with the sentence containing the MRE emphasized:

> This isn't exactly creepy, but it's one of the scariest things that's ever happened to me. I was driving down the motorway with my boyfriend in the passenger seat, and my dad in the seat behind my own. My dad is an epileptic and his fits are extremely sporadic. Sometimes he goes extremely stiff and other times he will try to get out of places or grab and punch people. *Mid-conversation I felt his hands wrap around my throat as I was driving, pulling my head back and making it increasingly difficult to drive.* My boyfriend managed to help steer the car into the hard shoulder but it was one of the scariest experiences in my life.

The MRE is the shortest possible summary of a story; it is what we would say about the story if we could only say one thing. If we could identify the MRE of a narrative, we could automatically generate summaries or headline-style titles for online stories. Detecting MREs could also allow us to explore how storytellers build emotional impact as they lead up to the climaxes of their stories.

In this work, we present a novel approach to modeling narrative in order to automatically identify the MRE. The MRE is a real world event underlying the story and thus is difficult to infer; instead, we identify sentences that describe or refer to it. We incorporate Prince's change-of-state formalization as well as Labov's definition of the MRE by modeling changes in story characteristics suggested by Prince, Polanyi, and Labov, such as measures of syntactic complexity and emotional

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2149–2158,
Lisbon, Portugal, 17-21 September 2015.

content. If Prince and Labov are both correct, we should find the MRE at a point of change in the story and in our story characteristics.

We create a corpus of thousands of personal narratives collected from Reddit, a social bulletin board website organized into topic-specific 'subreddit' communities. We automatically label most of this data using heuristics based on the comment-thread structure of Reddit content. Using this corpus, we conduct two experiments in classifying sentences of a story as containing the MRE or not: the first using distant supervision, and the second using self-training.

In Section 2, we discuss prior work on automatically identifying personal narratives, as well as related experiments using Labov's theory of narrative analysis. Section 3 discusses data collection and labeling. Sections 4-5 present our change-based model of narrative and our experiments. Finally, Section 6 discusses our experimental results and proposes directions for future work.

2 Related Work

Prior work using Labov's theory of narrative has focused on classifying clauses by their function.

Rahimtoroghi et al. (2013)worked on 20 of Aesop's fables. The 315 clauses were manually annotated with the three labels of Labov and Waltezky (1967), Orientation (background information), Action (events), and Evaluation (author's perspective), which we discuss in Section 4. Rahimtoroghi et al. used two annotators with high agreement and achieved accuracy and precision around 0.9 on all three labels, as well as recall above 0.9 on all but Orientation. They noted that their data set was very clean: interannotator agreement was nearly perfect, the language was simple, and each clause served a clear narrative purpose.

Ouyang and McKeown (2014) explored identifying the Action chain of the oral narratives in Labov (2013). They used a dataset of 49 narratives (1,277 clauses), transcribed from recordings of speech and annotated by Labov and achieved 0.72 f-score on classifying clauses as Action or not. This task is easier than our proposed task of identifying sentences containing MREs. Actions account for nearly half the clauses in the Labov (2013) dataset, while there are only and average of 2.5 MRE sentences per story. Additionally, identifying Labov's Actions is a problem of detecting causal and temporal relations among events; identifying the MRE is a problem of measuring how impactful and shocking an event is.

Swanson et al. (2014) used 50 stories, which were annotated with an extended label set by three annotators, and each of the 1,602 clauses was assigned the label given by the majority of annotators. The extended label set was then mapped to Labov and Waletzky's three labels. Nearly half of the clauses in this dataset are Evaluations, and Orientations and Actions each make up nearly one quarter of the dataset. Swanson et al. achieved 0.69 overall f-score on three-way classification of clauses. Again, this task is less difficult than our proposed task. The three labels, Orientation, Action, and Evaluation have distinct functions that are reflected in tense, mood, and a clause's position in the narrative. The MRE is not a sentence or clause but an event that may be described or referred to by any sentence in a narrative; it is distinguished from the other events only by its surprisingness and emotional impact, dimensions that are difficult to model computationally without a deep semantic understanding of the story.

The stories that Swanson et al. used were drawn from a corpus drawn from weblog posts (Gordon and Swanson, 2009). Gordon and Swanson used unigram features to classify posts as either stories or not, achieving 75% precision. They note that only about 17% of weblog text consists of stories.

In contrast to the relatively small datasets used by Rahimtoroghi et al., Ouyang and McKeown, and Swanson et al., we use a larger dataset automatically collected from Reddit. Our collection method achieved 94% precision in identifying narratives. A number of researchers have characterized the structure and use of Reddit, currently the 26th most popular website in the world[1]. Weninger et al. (2013) described the structure of Reddit comment threads. Gilbert (2013) measured user participation in the voting process that ranks Reddit content. Singer et al. (2014) conducted a longitudinal study of the Reddit user community, finding a trend favoring original, user-generated content.

3 Data

3.1 Collection

We collected data from the AskReddit subreddit, where users post questions for other members of the community, who reply with comments answering the questions. Table 1 shows some examples

[1] http://www.alexa.com/siteinfo/reddit.com

of these posts, and we can see some of the wide variety of story topics found on AskReddit.

Post Title
Whats your creepiest (REAL LIFE) story?
Your best "Accidentally Racist" story?
What are your stories of petty revenge?

Table 1: Examples of AskReddit posts.

Using PRAW[2], we scraped the top 50 AskReddit posts containing the keyword 'story.' Of these posts, 10 were tagged as NSFW ('not safe for work'), indicating they contained adult content; we did not use these posts in this work, as we felt the language would be too different from that used in posts without the tag. Another 3 posts did not contain personal narratives, and instead were about fictional stories in movies or music.

With the 37 remaining posts, we treated each top-level comment (those that replied directly to the posted question) as a story. The example given in Section 1 is one such story. We collected 6,000 top-level comments and discarded those without comment threads replying to them. As we discuss in Section 3.2, we use comment threads to automatically label our training data. We tokenized the top-level comments by sentence (Bird et al., 2009) and removed all sentences following any variation of the word 'EDIT', as these were usually responses to readers' comments. We discarded texts with fewer than three sentences, based on Prince's definition of a minimal story as consisting of a starting state, an event, and an ending state. We are left with 4,896 stories, with an average length of 16 sentences and a maxiumum of 198.

3.2 Labeling

We partitioned our data into development, seed, and tuning sets of 100 stories each; a testing set of 200 stories; and a training set of 4,178 stories. The development, seed, tuning, and testing sets were manually annotated by a native English speaker (not one of the authors), who was instructed to label all sentences that contained or referred to the MRE. For convenience, from here on, we will use the term 'MRE' to refer to both the Most Reportable Event itself (of which there can only be one per narrative) and to sentences that contain or refer to it (of which there can be more than one).

To measure interannotator agreement, we also had a second annotator (also a native English speaker and not one of the authors) label MREs in the 100 narratives in our development set. We found substantial agreement (Cohen's $\kappa = 0.729$); the two classes, MRE and not-MRE, are highly unbalanced, so percent agreement between the two annotators was extremely high (95%).

In addition to labeling the MREs, our first annotator identified and discarded 31 texts that were not true stories, but rather Reddit-specific inside jokes or comments on how cool the stories in the thread were. From this, we can see that the precision of our story collection method is very high. Gordon et al. (2007) found that stories were 17% of the weblog text that they collected; of the 500 texts given to our annotators, 94% were stories.

Using the development set, we experimented with seven heuristics, defined below, for automatically labeling the training set. Each predicts a sentence index s_h to be the index of an MRE. We measured the performance of each heuristic using root-mean-square error (RMSE), which measures the standard deviation of how far the heuristic's predictions fall from a true MRE.

$$\text{Let } N = \text{number of narratives}$$
$$s_{MRE} = \text{index of a true MRE}$$
$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(s_{MRE_i} - s_{h_i})^2}$$

We used a linear combination of three heuristics with the lowest RMSE to label our training set.

Similarity to comment. The bag-of-words cosine similarity between a sentence and comments replying to the story. We expect comments to refer to the MRE because of its shocking nature and importance to the story. This heuristic achieved RMSE of 5.5 sentences on the development set.

Similarity to tl;dr. The latent semantic similarity between a sentence and the *tl;dr*. The tl;dr (too long; didn't read) is a very short paraphrase of a post given by its author. They are relatively rare – 663 stories, or 14% of our data, had tl;drs. Since the MRE is the central event of the story, we expect it to be included in the tl;dr. We calculated the similarity using the weighted matrix factorization algorithm described by Guo and Diab (2012). This heuristic achieved RMSE of 5.8 sentences.

[2]https://praw.readthedocs.org/en/v2.1.20/, Python Reddit API Wrapper

In contrast, bag-of-words cosine similarity to the tl;dr performed poorly (RMSE of 13.2). This is due to the tl;dr being both short and a paraphrase of its story. There are few words in the tl;dr, and those words are often synonyms of, but not the same as, words in the story. Guo and Diab's latent semantic similarity score addresses this word sparsity problem by modeling words that are not present in the input text. We also experimented with latent semantic similarity for the similarity-to-comment and similarity-to-prompt heuristics, but in these two cases, it did not perform as well as the bag-of-words cosine similarity.

Similarity to prompt. The bag-of-words cosine similarity between a sentence and the AskReddit post that prompted the story. The story should be relevant to the prompt, so we expect the MRE to be similar to the prompt text. This heuristic achieved RMSE of 6.3 sentences.

We used the heuristic with the fourth lowest RMSE as one of the baselines in our experiments:

Last sentence. The last sentence in the story. Since the events of a story build up to the MRE, the MRE should occur near the end of the story. This heuristic achieved RMSE of 6.9 sentences.

Other heuristics. We also tried the following:

- Single-sentence paragraph (RMSE of 8.7). This heuristic was meant to capture emphasis, as an MRE might be placed in its own, separate paragraph to draw attention to it.
- First sentence (RMSE of 13.7). Narratives occasionally open with a brief introductory paragraph that summarizes the events to come. This heuristic was meant to capture a reference to the MRE in this introduction.

The training set was automatically labeled using a linear combination of the three best-performing heuristics: similarity to comment, similarity to tl;dr, and similarity to prompt.

$$h_{\text{label}} = 0.2 * h_{\text{comment}} + 0.5 * h_{\text{tldr}} + 0.3 * h_{\text{prompt}}$$

This outperformed each of the three alone, achieving an RMSE of 5.1 sentences. The weights for each heuristic were tuned on the development set. For stories without a tl;dr, that heuristic was set to 0. The sentence in the story with the highest heuristic score was selected as the MRE.

In 52 of the 99 stories in the development set, we found that multiple, consecutive sentences were labeled by our annotator as MREs. The average number of consecutive MREs was 2.5 sentences. To reflect this, we labeled our training set in three-sentence blocks. The sentence selected by our labeling heuristic, along with the immediately preceding and following sentences, were all labeled as MREs. The result was the weakly-labeled training set in Table 2.

		Number of Sentences	
Data Set	Stories	MRE	Total
dev*	99	169	1528
seed*	82	184	958
tuning*	95	212	1301
testing*	193	444	2771
training	4178	11205	67954

4 Modeling Narrative

Our approach to modeling narrative is based on both Labov (2013) and Prince (1973). We claim that Labov's MRE is Prince's change of state with the added requirement of reportability or interestingness – in fact, all three components of Prince's minimal story have equivalences in Labov.

Labov and Waletzky (1967) proposed three components of narrative: the Orientation, which we equate with Prince's starting state; the Action, the chain of events culminating in the MRE; and the Evaluation, the author's perspective on the story. Labov (2013) adds three more components: the Resolution, equivalent to Prince's ending state, and the Abstract and Coda, where the author introduces and concludes the story.

We focus on Prince's claim that stories are about change. Polanyi (1985) observes that the turning point of a story is marked by a change in style, formality of language, or emphasis in the telling of the story. Labov (2013) likewise observes that a change in verb tense often accompanies MREs. We hypothesize that the MRE should be found at a point of change in the story.

We score each sentence according to three views of narrative: syntax, semantics, and affect.

Syntax. We model Polanyi's claim that a change in formality marks the changing point by including metrics of sentential syntax; we use the syntactic complexity of a sentence as an approximation for formality. The complexity of a sentence also reflects emphasis – short, staccato sentences bear more emphasis than long, complicated ones. We use the length of the sen-

tence, the length of its verb phrase, and the ratio of these two lengths; the depth of the sentence's parse tree (Klein and Manning, 2003), the depth of its verb phrase's subtree, and the ratio of these two depths. We also use the average word length for the sentence and the syntactic complexity formula proposed by Botel and Granowsky (1972), which scores sentences on specific structures, such as passives, appositives, and clausal subjects. Finally, we use the formality and complexity dictionaries described in Pavlick and Nenkova (2015), which provide human formality judgments for 7,794 words and short phrases and complexity judgments for 5,699 words and phrases. We score each sentence by averaging across all words and phrases in the sentence.

Semantics. As the MRE is surprising and shocking, we expect it to be dissimilar from the surrounding sentences; we use semantic similarity to surrounding sentences as a measure of shock. Our semantic scores are the bag-of-words cosine and the latent semantic similarity scores for adjacent sentences (Guo and Diab, 2012).

Affect. A change in affect reflects a change in style, and we expect the MRE to occur at an emotional peak. We use the Dictionary of Affect in Language (DAL) (Whissell, 1989), augmented with WordNet for coverage (Miller, 1995). The DAL represents lexical affect with three scores: evaluation (*ee*, hereafter 'pleasantness' to avoid confusion with Labov's Evaluation), activation (*aa*, activeness), and imagery (*ii*, concreteness). We also use a fourth score, the activation-evaluation (AE) norm, a measure of subjectivity defined by Agarwal et al. (2009):

$$norm = \frac{\sqrt{ee^2 + aa^2}}{ii}$$

For each of these four word-level scores, we calculate a sentence-level score by averaging across the words in the sentence using the finite state machine described by Agarwal et al. We expect the sentences surrounding an MRE to be more subjective and emotional as the impact of the MRE becomes clear. We also expect a build-up in activeness and intensity, peaking at the MRE.

To model change over the course of a narrative, we look for changes in the syntactic, semantic, and affectual scores. To illustrate this, Figure 1 shows the activeness and pleasantness DAL scores for the example narrative given in Section 1. We can see how the MRE is the most exciting sentence in the story – global maximum in activation – as well as the most horrifying – global minimum in pleasantness. The overall shape of the activeness scores reflects Prince's three components of a minimal story: low initial activation (starting state) and low final activation (ending state) with a build up to a peak at the MRE (change in state) between them.

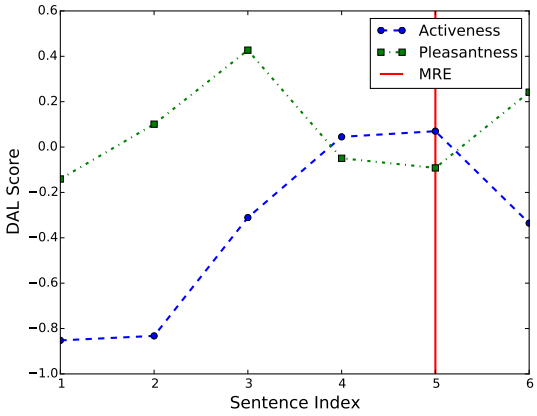

Figure 1: Activeness and pleasantness scores.

5 Experiments

Using our Reddit dataset and change-based model of narrative, we conducted two experiments on automatically identifying MREs. We compare our results with three baselines: random, our labeling heuristic, and the last sentence of the story (best-performing heuristic not used in labeling).

As described in Section 3.2, we labeled our training set in blocks of three consecutive MREs, centered on the sentence from each narrative that was selected by our heuristics. To account for this, in our experiments and baselines, we predicted the presence of an MRE in a three-sentence block. In testing, we considered a predicted block to be correct if it contained at least one gold-label MRE.

5.1 Features

Change-based Features. For each of the fifteen metrics in Section 4, shown in Table 3, we first smooth the scores by applying a Gaussian filter. We also tried weighted and exponential moving averages, as well as a Hamming window, but the Gaussian performed best in experiments on our tuning set. We then generate 11 features for each sentence: the metric score at the sentence; whether or not the sentence is a local maximum or minimum; the sentence's distance from the global

Type	Metric Names
Syntactic	sentlength, vplength, lengthratio, sentdepth, vpdepth, depthratio wordlength, structcomplexity, wordformality, wordcomplexity
Semantic	cossimilarity, lssimilarity
Affectual	pleasantness, activation, imagery, subjectivity

Table 3: The fifteen metrics for change.

maximum and minimum; the difference in score between the sentence and the preceding sentence, the difference between the sentence and the following sentence, and the average of these differences (approximating the incoming, outgoing, and self- slopes for the metric); and the incoming, outgoing, and self- differences of differences (approximating the second derivative).

Other Features.

- The tense of the main verb and whether or not there is a shift from the previous sentence. Labov (2013) suggests a shift between the past and the historical present near the MRE.
- The position of the sentence in the narrative.
- The bag-of-words cosine similarity and latent semantic similarity between the sentence and the first and second sentences in the narrative. The MRE usually appears near the end of a story, but Labov (2013) notes that the Abstract, a short introduction that occurs in some narratives, often refers to the MRE.

5.2 Distant Supervision

Our first experiment used a distant supervision approach with our automatically-labeled training set. Distant supervision has previously been applied to NLP problems such as sentiment analysis (Go et al., 2009; Purver and Battersby, 2012; Suttles and Ide, 2013) and relation extraction (Mintz et al., 2009; Yao et al., 2010; Hoffmann et al., 2011; Nguyen and Moschitti, 2011; Krause et al., 2012; Min et al., 2013; Xu et al., 2013).

We classify blocks of three sentences as containing the MRE or not. The two classes, *MRE* and *not-MRE*, were weighted inversely to their frequencies in the weakly-labeled set, and all features were normalized to the range $[0, 1]$. We trained an SVM with margin $C = 1$ and an RBF kernel with $\gamma = 0.001$, chosen using grid search on our tuning set (Pedregosa et al., 2011).

Trial	Precision	Recall	F-Score
Last sent. baseline	0.208	0.112	0.146
Heuristic baseline	0.107	0.333	0.162
No change*	0.146	0.378	0.211
Random baseline	0.185	0.586	0.281
Change only*	0.351	0.685	0.466
All features*	**0.398**	**0.745**	**0.519**

Table 4: Distant supervision results (*$p < 0.01$).

The results of the distant supervision experiment are shown in Table 4. Our best results use all features, but, notably, using the change-based features alone achieves significant improvement over the three baselines ($p < 0.00005$). The 'no change' trial used the metric scores themselves and the 'other' features but none of the change-based features, such as slopes and proximity to global extremes. This feature set was outperformed by the random baseline ($p < 0.0024$), supporting our hypothesis that it is change in a metric, rather than the score itself, that predicts MREs.

Because we used an non-linear kernel, we were not able to examine feature weights directly. Instead, Table 5 shows the results of a logistic regression model trained on our features. The 10 best features are shown, along with their weights and 95% confidence intervals. From feature 8, we see that the MRE is found in sentences near the narrative's global minimum in imagery (the Evaluation), but feature 1 indicates that sentences containing the MRE show a sharp increase in imagery compared to the previous sentences. The MRE is described in a burst of vivid language, followed by more abstract author opinions .

Features 2 and 9 indicate that the MRE tends to be described using informal language – a textual echo to Labov's observation that the subjects of his sociolinguistic interviews spoke less formally and more colloquially as they relived the climaxes of their stories (Labov, 2013). Feature 3 suggests that sentences containing the MRE are similar to the surrounding sentences. While we expected MRE sentences to be different from their neighbors due to the unusual and shocking nature of the MRE, this feature seems instead to reinforce the idea that MREs tend to described over the course of multiple, consecutive sentences, rather than in a single

	Feature Name	Weight	Confidence Interval
1.	incomingd2_imagery	4.174	(4.062, 4.287)
2.	distancefrommin_wordformality_neg	4.109	(3.952, 4.265)
3.	cossimilarity_adjacent	3.618	(3.425, 3.812)
4.	distancefrommin_activeness	3.377	(2.855, 3.298)
5.	sentdepth	3.364	(3.138, 3.590)
6.	distancefrommin_wordlength_neg	3.321	(3.018, 3.624)
7.	distancefrommin_vpdepth	3.034	(2.823, 3.247)
8.	distancefrommin_imagery_neg	2.790	(2.524, 3.056)
9.	wordformality_neg	2.329	(2.226, 2.432)
10.	incomingd2_vplen	2.128	(1.938, 2.318)

Table 5: Top 10 features.

sentence. From feature 4, we see, as expected, that the MRE is far from the narrative's global minimum in activeness, as it is the end of a chain of events, far away from the stative Orientation.

Finally, features 5 and 10 suggest that MRE sentences are not only long, but much longer than the preceding sentences, and feature 6 indicates that MRE sentences are close to the global minimum in average word length. Shorter average word length is expected, as an indicator of both informal word choice and emphasis. Long sentences, however, suggest a domain difference between our work on text and Labov's work on transcribed speech. Looking over our development set, we find that many authors combine the description of the MRE with evaluative material in a single sentence, resulting in a longer and more syntactically complex MRE sentence than is found in Labov's data.

5.3 Self-Training

Our second experiment used a self-training approach, where a classifier uses a small, labeled seed set to label a larger training set. Self-training has been applied to parsing (McClosky et al., 2006; Reichart and Rappoport, 2007; McClosky and Charniak, 2008; Huang and Harper, 2009; Sagae, 2010) and word sense disambiguation (Mihalcea, 2004). With the same parameters as in the distant supervision experiment, we trained an SVM on our hand-labeled seed set of 958 sentences. We used this initial model to relabel the training set. All sentences where this labeling agreed with our automatically-generated heuristic labels were added to the seed set and used to train a new model, which was in turn used to label the remaining sentences, and so on until none of the current model's labels agreed with any of the remaining heuristic labels. Figure 2 shows the learning curve for the self-training experiment, along with the growth of the self-training set.

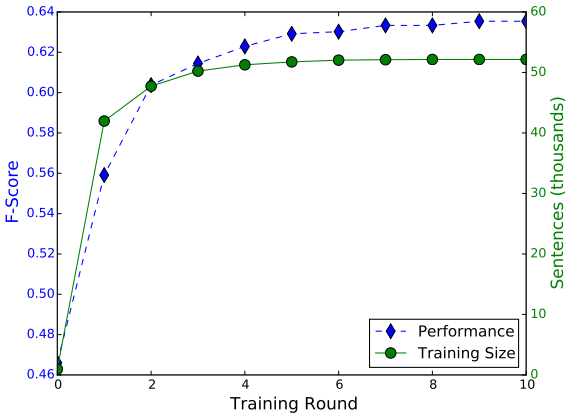

Figure 2: Learning and training set size curves.

The results of the self-training experiment are shown in Table 6. We achieve the best performance, f1 = 0.635, after 9 rounds of self-training. Self-training terminated after 10 rounds, but the 10th round had no effect on performance.

Trial	Precision	Recall	F-Score
Random baseline	0.185	0.586	0.281
Seed only*	0.374	0.617	0.466
Dist. supervision*	0.398	0.745	0.519
Self-training*	**0.478**	**0.946**	**0.635**

Table 6: Best self-training results (*$p < 0.01$).

The initial model, trained only on the seed set, performed nearly as well as our distant supervi-

sion experiment. This illustrates that quantity of data does not overcome the use of accurate manual labels on a small dataset. As described in Section 3.2, the distant supervision labels were based on a linear combination of three heuristics that achieved at best an RMSE of 5.1 sentences. However, with self-training, we can exploit the noisy heuristic labels by using only those labels that agree with the seed-trained model, thus reducing the amount of noise. 52,147 of the 67,954 weakly-labeled sentences were used in self-training.

6 Discussion and Future Work

Identifying MREs is a hard problem. A human annotator can rely on world knowledge to find the most shocking and impactful event in a story, but we do not have access to that knowledge. Additionally, MREs are rare, comprising 15% of the sentences in our hand-annotated datasets. MREs comprise just over 16% of our weakly-labeled training set, but as we discuss below, there is too much noise in the automatically-generated labels.

Despite the difficulty of the task, our experiments show that our change-based model of narrative is effective for identifying MREs, and this model provides evidence supporting the change-in-state view of narrative suggested by Prince (1973), Polanyi (1985), and Labov (1997). We achieve high recall with self-training (95%), but precision is low across the board. This suggests that, while MREs do occur at extremes in syntactic complexity, semantic similarity, and emotional activation, there may be many non-MRE local extremes throughout a narrative.

Examining our results, we find a few common sources of error. False positive sentences tend to have high imagery and activeness. In Table 5, we saw that imagery and activeness alone do not indicate the presence of the MRE. An MRE sentence is not just active; it is separated from the stative introduction by the other events of the story. Nor is it enough for a sentence to have high imagery; the MRE is more vividly described than the preceding events – we see again the importance of change in our model of narrative. False negatives tend to have high scores in syntactic complexity and formality. As low formality was one of our stronger predictors of MRE sentences, we may need to adjust these features in future work.

We also hope to refine our automatically-generated labels in future work. Our self-training experiment showed that 27% of our automatically-generated labels were too noisy to use. We also hope to improve our filters for automatically discarding non-story text. We currently reject texts shorter than three sentences, based on Prince's three-part definition of a story. In spite of this filtering, 7% of our 500 manually-labeled texts were identified as non-stories by our annotator. Extrapolating to our training set, we suspect that over 300 of our training 'narratives' are not narratives at all.

Finally, we hope to explore other theories of narrative analysis that could suggest new ways to quantify change in narrative. Prince, Polanyi, and Labov propose a high-level view of personal narrative: stories are centered around reportable events that cause a change in state for the author. This work tested fifteen surface-level features that reflect this change in state. Are there others? Or is a deeper semantic understanding of the starting and ending states of stories required?

7 Conclusion

We have described a new model of narrative based on Prince (1973), Polanyi (1985), and Labov (1997). Our model tracks story characterstics over the course of a narrative, capturing change in complexity, meaning, and emotion.

We have created a corpus of 4,896 personal narratives, taking advantage of AskReddit, a community where members often prompt each other for stories. Our experiments on this corpus show that our change-based model is able to identify MREs. They also demonstrate that large quantities of hand-labeled data are not required for this task. Our distant supervision and self-training approaches successfully use data weakly labeled using heuristic rules that leverage the comment thread structure of Reddit content. We believe these Reddit stories are representative of the short, personal narratives found online in blogs or discussion forums, and so this work should be useful for finding MREs in a variety of online personal narratives. The one difference between this data and stories from other online sources is the prompt. A personal narrative posted to someone's personal blog is unlikely to have a prompt. We use the prompt for our heuristic labeling, so our automatic labels on non-Reddit data may be noisier, but many blog posts also have titles or tags that may be just as useful.

Identifying MREs is a hard problem that has not

previously been addressed in work on computational narrative. We have shown that the high-level view proposed by linguistic theories of narrative – that stories are about change – holds true. Measuring change over the course of a narrative yields better results than other features and baselines.

Why do we care about MREs? Polanyi (1976) asserts that "one does not produce a narrative text for no reason at all." The Most Reportable Event is that reason. It is the point of the story; the shortest possible summary; the answer to the question, "So what?". It could be used to generate titles or summaries to be used in organizing stories for readers to browse, or it could be used in recommendation systems to help readers find related stories. In future work we hope to be able to generate a text description the full MRE, which would be better suited to summarization or generating headlines, rather than identifying sentences that refer to it. We hope this work will encourage others to further investigate the Most Reportable Event.

Towards the Extraction of Customer-to-Customer Suggestions from Reviews

Abstract

State of the art in opinion mining mainly focuses on positive and negative sentiment summarisation of online customer reviews. We observe that reviewers tend to provide advice, recommendations and tips to the fellow customers on a variety of points of interest. In this work, we target the automatic detection of suggestion expressing sentences in customer reviews. This is a novel problem, and therefore to begin with, requires a well formed problem definition and benchmark dataset. This work provides a 3- fold contribution, namely, problem definition, benchmark dataset, and an approach for detection of suggestions for the customers. The problem is framed as a sentence classification problem, and a set of linguistically motivated features are proposed. Analysis of the nature of suggestions, and classification errors, highlight challenges and research opportunities associated with this problem.

1 Introduction

Opinion mining mainly deals with the summarisation of opinions on the basis of their sentiment polarities (Liu, 2012). However, on a closer observation of such opinionated text, we can discover other facets of opinions. For example, a hotel review sentence like, *Make sure you bring plenty of sun tan lotion-very expensive in the gift shop*, would be labeled as a neutral sentiment in current opinion mining methodologies, since it would only be interested in collecting opinions about the hotel. In the case of aspect based sentiment analysis, the sentence does not comprise of hotel related aspects, and thus will again be labeled as neutral/objective. While such sentences are generally ignored in sentiment based opinion summarisation, these can be very useful information to extract from the reviews. In hotel reviews, such suggestions range from tips and advice on the reviewed entity, to suggestions and recommendations about the neighbourhood, transportation, and things to do. Similarly, in product reviews suggestions can be about how to make a better use the product, accessories which go with them, or availability of better deals. We refer to such sentences as customer-to-customer suggestions (CTC).

Another type of suggestions, which can appear in the reviews, are the ones aiming at manufacturers or service providers, suggesting new features and improvements in products or services. For example, *An electric kettle in the room would have been a useful addition*. Recently, there have been some works on extracting the suggestions for improvements from reviews (section 3), but they did not focus on CTC suggestions. Also, suggestions for improvement discuss only about the reviewed entity and its aspects, unlike suggestions to customers, which might also include other topics of interest.

Suggestion mining and retrieval can be a potential new research area emerging from this kind of research. Industrial importance of suggestions to customers can be validated from the sections like 'Room Tips' (Figure 1) on TripAdvisor[1]. Similarly, Yelp also features 'tips' [2] (Figure 2) related to a business, and defines it as 'key information'. Such tips are often suggestions, or some important information, a user wants to convey to others. These tips are manually entered by the users, in addition to the reviews. We note that using suggestion mining, such information can be automatically extracted from a large number of already ex-

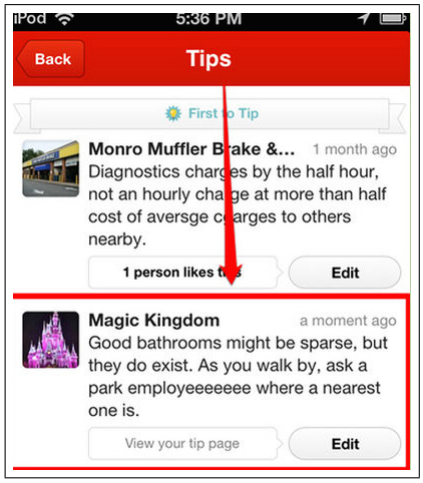

Figure 2: Tips on Yelp

isting reviews. The recommendation type of suggestions are of great importance in the case, when there is no dedicated reviews available for small shops, cafe, restaurants etc. in the vicinity of a hotel/business. Suggestions extracted from a large number of reviews, can also be seen as a kind of summarisation, an alternative or complementary to sentiment summarisation over the reviews.

In order to perform suggestion mining, expressions of suggestions should to be detected in a given text. The presence of a variety of linguistic strategies in the suggestion expressing sentences makes this task interesting from a computational linguistics perspective. Section 2 discusses this in more detail. The detection of suggestions in text goes beyond the scope of sentiment polarity detection, and opens up new problems and challenges in the areas of subjectivity analysis, social media analysis, and extra-propositional semantics.

Our main contributions through this work can be listed as:

- Proposition of the task of detection of CTC suggestions.
- A well formed problem definition and scope.
- Preparation of benchmark dataset for two domains of reviews, hotel and electronics.
- An approach to automatically detect CTC suggestions from review texts.

2 Task Definition

Since suggestion mining is a young problem, there is a need for problem analysis and definition. As indicated in the previous section, the tasks under suggestion mining may vary. Below, we propose three parameters whose value would help define such tasks, and the values for these parameters in the context of the current task of detection of CTC suggestions.

- **Who is the suggestion aimed at?**
  As we explained in section 1, suggestions can be aimed at one of the two kinds of stakeholders, customers and service providers. In this work, we perform the detection of suggestions for customers only.

- **What should be the textual unit of suggestion?**
  The previous works on extraction of suggestions for product improvement considered sentences as the unit of suggestions. In this work, we also consider sentences as units of suggestion. However, we observe that sentences might miss the context, or refer to something mentioned in the previous sentence. Furthermore, punctuation marks are often erroneously used in social media text, so automatic sentence split does not work well with such text. The approach used in this work aims at the detection of expressions of suggestions, regardless of the presence or absence of context in the same sentence. Therefore, we currently ignore the problems associated with using sentences as a unit for suggestions. The datasets used in this work are sentiment analysis review datasets from other works, in which reviews are already split into sentences. For future works, we assume that context can be determined by the neighbouring text once the expression of suggestion is successfully detected.

- **What kind of text should be considered as a suggestion?**
  Oxford dictionary defines suggestion as, *An idea or plan put forward for consideration*. Some of the listed synonyms of suggestions are *proposal, proposition, recommendation, advice, hint, tip, clue*. In a general scenario, this defini-

Sentence	Category	% Annotators	Suggestion Expression
Concierge is not available 24 hours	Inform	70	Implicit
We did not have breakfast at the hotel but opted to grab breads/pastries/coffee from the many food-outlets in the main stations.	Tell	80	Implicit
Room was very quiet despite being close to the elevator.	Remark	50	Implicit
The staff was nice and friendly	Praise	60	Implicit
Double bed quite narrow and not as comfortable as expected.	Disappoint	60	Implicit
The view from the 7th floor was amazing.	Fascinate	50	Implicit
If you do end up here, be sure to specify a room at the back of the hotel.	Suggest	100	Explicit
I recommend going for a Trabi Safari	Recommend	90	Explicit

Table 1: Sentences Which Were Perceived as CTC Suggestions by Laymen

tion of suggestion easily distinguishes suggestions from other kind of text. However, when suggestions are required to be identified in the space of customer reviews, there seems to be a tendency to consider most of the sentences as suggestions to other customers. This observation is based on a preliminary data annotation task, which was meant for data analysis and development of annotation guidelines. Asher et. al (2009) define 20 types of opinion expressions, including suggestions and recommendations, which appear in opinionated text. In order to form a representative sample, we chose 20 sentences from reviews, corresponding to each of these types, and asked 10 people (layman) to decide if these sentences are CTC suggestions or not. Table 1 shows sentences for which 5 or more people agreed of CTC Suggestion label. Asher et. al. (2009) observe that these types are not uniformly distributed in the reviews. According to them, suggestions and recommendations constitute about 10% of the statements, while judgements (blame, praise) and sentiments (love, fascinate, hate, disappoint, sad) constitute about 80%. Later, when we annotate the review datasets for CTC sugggestions, they also shows a smaller percentage of suggestions (see table 2).

Except the *suggest* and *recommend* categories, suggestions in rest of the categories are in an implicit form and need to be inferred. Since human beings can inherently infer suggestions, the layman annotators considered both implicit and explicit form of suggestions as suggestions. However, in a real case scenario, humans cannot go through the large amount of reviews and infer suggestions from all of them. In this work, we aim to automatically detect and extract the explicit expressions of suggestions, rather than inferring them.

For the ease of defining the scope of our work, we propose two form of suggestions:
Explicit: Directly suggests/recommends an entity or action,
Implicit: Only provides the information from which a suggestion can be inferred, but do not authoritatively suggest anything.

Lastly, we frame the problem of CTC suggestion detection problem as a sentence classification problem:
Given a set S of statements $\{s_1, s_2, s_3, ..., s_n\}$*, predict a label* l_i *for each of statement in S, where* $l_i \in \{$*CTC suggestion, non CTC suggestion*$\}$*, where CTC suggestion should be explicitly expressed.*

3 Related Work

Only a few attempts have been made to study suggestion mining, and there is an unavailability of benchmark datasets. Therefore, suggestion mining still remains a young area of study.

- **Suggestion Mining from Customer Reviews**
  As mentioned in section 1, there have been some attempts to extract suggestions for improvements in products from customer reviews. Ramanand et. al. (2010) used manually formulated patterns to extract wishes regarding improvements in products. Brun and Hagege (2013) also used manually formulated rules to extract suggestions for improvements from the product reviews. Negi and Buitelaar (2015) studied linguistic nature of suggestions and wishes for improvements and performed experiments in order to assert that these contain subjunctive mood. These works do not acknowledge the fact that reviews can also contain suggestions for other customers. One major drawback of previous works on customer reviews is the public unavailability of evaluation datasets.

- **Other Domains**
  Two other lines of work extracted suggestions from domains other than reviews. Dong et. al. (2013) performed detection of suggestions for product improvement using tweets. They used a statistical classifier, with features comprising of bag of words, automatically extracted suggestion templates using sequential pattern mining and hashtags. (Wicaksono and Myaeng, 2012; Wicaksono and Myaeng, 2013) extracted advice from discussion threads. They also used a supervised classification approach, where some of the features were domain dependent, like the similarity between original query post and a given sentence. They do not make any distinction between implicit and explicit advice, since there is less ambiguity in the domain of discussion forum.

None of the previous works study the complex and interesting nature of suggestions in opinionated text, and the relationship between suggestions and sentiments. Also, there is an unavailability of benchmark datasets of suggestions customer reviews.

4 Data

Since there is no available dataset of suggestions for customers, we prepare new datasets for this task. We consider two kinds of reviews for this task, hotel reviews and electronic product reviews.
Hotel: Wachsmuth et al. (2014) provide a large dataset of TripAdvisor hotel reviews, where reviews are segmented into statement so that each statement has only one sentiment label. Statements have been manually tagged with positive, negative, conflict and neutral sentiments. We take a smaller subset of these reviews, where each statement is an instance of our dataset. Each statement also bears a unique identity no., which is constituted of hotel identity no., statement number and review identity no. Therefore, the reviews belonging to same hotel, and the statements of the same review can be identified.
Electronics: Hu et. al.(2004) provide a dataset consisting of reviews of electronic products, which is also already split into sentences, and the corresponding sentiment for each sentence is manually tagged.
In the next section, we further annotate the sentences from these two datasets, for the current task.

Agreement	**Hotel(8050 sentences)**	**Electronics(3782 sentences)**
Phase 1		
Confidence	CTC Sugg.	CTC Sugg.
>= 0.6	3220	1488
>= 0.7	1046	604
>= 0.8	1024	562
>= 0.9	1020	558
1	1019	553
Phase 2		
kappa	CTC Sugg.(Explicit)	CTC Sugg.(Explicit)
0.86	407	273

Table 2: Statistics of Phase 1 and Phase 2 Annotations

4.1 Dataset Preparation

We performed a two phase annotation using both crowdsourced and expert annotations. This reduced the number of statements to be annotated by experts.
Phase 1 - Crowdsourced Annotations: The Crowdflower[3] platform was used for crowdsourced annotations. The platform provides a set of management and analytics tools for quality management, as well as for interaction with the annotators. In order to qualify for the annotation task, a Crowdflower worker was required to obtain a score of $7/10$ out of 10 test statements. The annotators were asked to choose one label out of 'Suggestion to Customers' or 'Other Statement' for each sentence. The definition of suggestion was left entirely to the understanding of the annotators. For each sentence, Crowdflower selects the answer with the highest confidence score[4]. We set the system not to seek more than 3 annotations for a statement if one of the labels attained a confidence score of 0.6 or more. At least 3, and at most 5 annotators labeled each statement. Confidence score for each label is the weighted sum of the trust scores of annotators who chose that label[5]. Trust score is determined by annotator's score in the test questions. Table 2 shows the variation in the number of statements tagged as suggestions with the corresponding confidence scores. These suggestions are a mixture of both implicit and explicit types, since the definition of suggestions was not restricted for the annotators. We observed that with the increase of confidence score, the ratio of explicit suggestions among the tagged suggestions increases.

[3] http://www.crowdflower.com/

[4] https://success.crowdflower.com/hc/en-us/articles/201855939-Get-Results-How-to-Calculate-a-Confidence-Score

[5] https://success.crowdflower.com/hc/en-us/articles/202703305-Getting-Started-Glossary-of-Terms

Phase 2 - Expert Annotations: Since we target the extraction of explicitly expressed suggestions, two expert annotators further classified the sentences which were finally labelled as 'Suggestion to Customers' by the Crowdflower platform, as explicit CTC suggestions and implicit CTC suggestions. Therefore, the number of sentences which experts annotated was much smaller than the total number of sentences in the two datasets. The key points of annotation guidelines for identifying the explicit suggestions are:

1. The intention of giving a suggestion and the suggested action or recommended entity should be explicitly stated in the sentence. For example:
   $[[\text{Try}]_{intention}[\text{the cup cakes at the bakery next door}]_{entity}]_{action}$.
   Other explicit forms of this suggestion could be: *I recommend the cup cakes at the bakery next door*, or, *You should definitely taste the cup cakes from the bakery next door*. Implicit form could be, *The cup cakes from the bakery next door were delicious.*

2. The suggestion should have the intention of benefiting the customers, and should not be mere sarcasm or joke. For example, *If the player doesn't work now, you can run it over with your car*.

A kappa value of 0.86 was calculated between the annotations performed by the expert annotators. The datasets from both phase 1 and phase 2 annotations are freely available for research. The final dataset has 3 kinds of labels, Implicit CTC, Explicit CTC, and others. Therefore, this dataset is also usable by the works which intend to extract implicit suggestions as well.

5 Suggestion Detection

We frame the task of CTC suggestion detection as a text classification problem. Our approach performs binary classification in a supervised fashion. Explicit CTC suggestions belong to the positive class, and rest of the sentences to the negative class.

Heuristic Features: A general notion about the task is that suggestions contain some distinctive keywords like, *suggest, recommend* etc, and should be easily detectable using them. Therefore, we use a set of manually selected features in order to test this notion.

- **Suggestion keywords:** These include the verbs: *suggestion, advise, request, ask, warn, recommend, do, do not*; their corresponding nouns: *suggestion, advice, request, warning, tip, recommendation*, and the synonyms of these words obtained from WordNet. Suggestion keywords constitute a single feature, which is binary in nature, and its value is determined by the presence of any of the suggestion keywords in the sentence.
- **POS tag *VB*:** Base form of Verb (VB) appears to be frequently used in the predicates of CTC suggestions.

Generic Features: Standard uni, bi, tri-grams, and uni, bi, tri-grams of Part of Speech tags (Penn Tree bank tagset). We consider the best performing set of Heuristics and generic feature types as the baseline for this task (see Table 3).

5.1 Special Features

We suggest a set of complementary features, which are motivated by the linguistic analysis of explicit CTC suggestions.

1. **Imperative Mood Sequential Patterns:** Imperative mood expressions are often present in explicit suggestions. Wicaksono et. al. (2013) also observed the presence of imperative mood in advice sentences. They used an imperative mood detector, based on a set of handmade rules to determine whether a sentence is imperative.
   In our case, the statements often contain more than one clause, and more than one mood expression. This feature aims to detect if any part of a given statement bears atleast one expression of imperative mood. We aim to identify sequential patterns of linguistic elements (POS tags in our case) which mark the imperative mood, and check if these patterns are present in a given statement. We automatically extract these features (patterns) using sequential pattern mining. We prepare a small dataset of 200 example sentences of imperative mood. These sentences were short sentence of lengths between 3-8 words, and are manually collected from websites related to English grammar, and linguistic research papers on mood and modality.
   Sequential Pattern Mining - Background: State of the art sequential pattern mining algorithms require the dataset to be converted into

0.60	$< VB >< PRP >$
0.54	$< VB >< VB >< NN >$
0.51	$< RB >< VB >$
0.70	$< MD >< VB >$

Table 4: Sequential POS Patterns obtained from Imperative Mood Dataset

an ordered list of *events*. An event is a non-empty unordered collection of *items*, which in turn is the smallest unit of sequences. The output of these algorithms are sequential patterns, which comprise of sequences of items, and is defined to be frequent if its support (a measure of frequency) is equal or more than a user-defined threshold. $(a_1, a_2, ..., a_q)$ is a sequence, where a_i is an event. A sequence $(a_1, a_2, ..., a_n)$, is a subsequence of another sequence $(b_1, b_2, ...b_m)$, if there exist integers $i_1 < i_2 < ... < i_n$ such that $a_1 \subseteq b_{i1}$, $a_2 \subseteq b_{i2}, ..., a_n \subseteq b_{in}$. For example, given a sequence (AB,E,ACD), where B is an item and AB, E and ACD are events. (B,AC) is a subsequence, since B $\subseteq$ AB and AC $\subseteq$ ACD and the order of events is preserved. (AB,E) is not a subsequence of the sequence (ABE). In our case, each POS tag is an event, and all the events are of length 1 item.

We use Clospan (Yan et al., 2003) algorithm to obtain the patterns of POS tags appearing in imperative mood sentences. Closed pattern mining algorithms produce a significantly less number of sequences than the older methods, while preserving the same expressive power. We use 2-3 length sequences with a relative support greater than 0.5, where maximum relative support is 1 (see Table 4).

Sequential patterns and n-grams: Sequential patterns are different from continuous n-grams in the sense that these are similar to the templates with place-holders, or skip n-grams, where the items in a pattern are ordered but should not necessarily be immediate to each other.

The part of speech tags avoid sparse nature of word based patterns, and at the same time captures the language usage model of imperative sentences. However, the pos tags tend to repeat in longer texts, therefore we limit the number of placeholders which could appear between two items of a pattern to 2. Each pattern is treated as a separate feature, whose feature value is binary depending on its presence or absence in a given sentence.

2. **Sentiment Features:** Given that suggestions are being extracted from customer reviews, which are otherwise mostly used for sentiment analysis, a relation between sentiments and suggestions can be suspected. It can be observed From the Figure 3, 4 suggestions do not seem to always carry one particular sentiment, but different sentiments at different instances. We compare three types of sentiment related features:
a) Manually tagged sentiments: These annotations were provided with the used sentiment analysis datasets.
b) Sentiwordnet score summation: SentiWordNet (Esuli and Sebastiani, 2006) sentiment score summation of all the words in a sentence. No sense disambiguation is performed, and all synset scores are summed up for each word.
c) Normalised sentiwordnet score summation: These scores are the sum of all the sentiment scores of the words in a given sentence, normalised over the number of words carrying non-neutral sentiment score.

3. **Information about the subject/s of a statement:** This feature captures the presence of nsubj dependency (Marneffe and Manning,

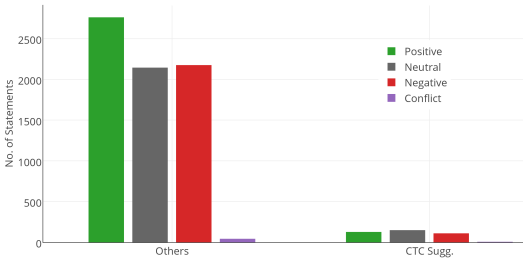

Figure 4: Manually labelled Sentiment Distribution of Hotel Dataset

2008), and if present, the pair of POS tags of the arguments of this dependency. Often a reviewer addresses the reader when giving a suggestion. For the sentence, *If you do end up here, be sure to specify a room at the back of the hotel*, the nsubj dependency is nsubj(do, you). The feature value would be *VBP-PRP* in this case. On the other hand, this suggestion could also have been, *Be sure to specify a room at the back of the hotel.*. In this case the feature value would be *null*. If more than one nsubj dependency is present, the POS pair of each of them will be included in the feature value.

Experimental Setup: We use the Stanford Parser (Toutanova et al., 2003) for obtaining part of speech and dependency information. Stemming did not effect the results. Stopwords were used using a customised stopword list. We employ the LibSVM library (Chang and Lin, 2011) for Support Vector Machine classifiers (SVM), as implemented in Weka machine learning toolkit (Hall et al., 2009). The parameter values of SVM classifiers are: SVM type = C-SVC, Kernel Function = Radial Basis Function. A 10 fold cross validation is performed in order to evaluate the classifier model. Features are ranked using the feature selection algorithm InfoGain (Mitchell, 1997). The other attribute selection algorithms provided with the Weka toolkit were also experimented with, but InfoGain consistently performed best in all the runs. Only the features which posses a positive information gain value are retained. The best performing run has a feature vector of size 300. The problem of having a imbalanced dataset is handled by using a higher class weight of 5:1 (Akbani et al., 2004) for positive class.

6 Results and Discussion

We evaluate the proposed features using 10-fold cross validation. As indicated in section 5, we consider best performing set of generic features as the baseline, which is: uni, bi grams and unigrams of pos tags. Table 5 summarises the classifier performance with the addition of special features, measured in Precision, Recall, F1 score, and ROC Area Under Curve. The results indicate that special features improve the F score in both the domains. However, some of the generic features produced better precision and recall values (Table 3). Imperative patterns improve the baseline results for electronics dataset, but not for the hotel dataset. Also, the special features produce better improvement over baseline for electronics dataset. We attribute this to the smaller size of electronics dataset.

Table 7 shows how the top ranked features change on addition of special features. Heuristic features tend to appear as some of the top ranked generic features. On the addition of special features, some of the special features replace the top general features. This validates the importance of proposed special features. Normalised sentiment

#	Sentence	Classifier	Human
1	Buy this for the storage and price , avoid it if you know nothing about computers.	1	1
2	whichever camera you buy, add upto about 200 dollars for an additional memory card i bought a 256 mb card, usb card reader,camera bag and the warranty.	0	1
3	Looks sort of like picasa software (google it if you dont know) in the interface and is as easy to install and operate as g2	0	1
4	If you cant make an Italian meal don't advertise you can.	1	0
5	It would have been better to have some sort of window on the carrying case , so you could see the display without opening it	1	0
6	If you have a lot of money to waste, make sure you book this hotel	1	0

	Elec.	you, VB, $< VB, NN >$, recommend, if you, nsubj, buy, suggest, $< VB, PRP >$, norm. sentiment score

Table 7: Some of the Top Ranked Features in Different Runs

score prove to be better features than the other two types of sentiment features including the manually labelled sentiments. This indicates that this method of sentiment calculation is capturing some universally used phrasing for suggestions, where real sentiment of the sentence fails to capture it.

Observed Challenges: Table 6 shows some instances of Type 1 and Type 2 errors in the best performing feature set. Our error analysis reveals the challenges associated with this task.

1. Non-CTC Suggestions: Example #4 gives a suggestion for the improvement of the hotel restaurant. Similarly, #5 is a suggestion to the product manufacturer instead of fellow customers. These kind of suggestions at times possess features similar to CTC suggestions.
2. Complex sentences: Often, suggestion is only expressed in one part of a very long sentence (#2,#3,). This might generate erroneous rank for features; also part of speech taggers tend to perform poorly for such sentences.
3. Sarcasm: The surface form of #6 is a suggestion, but it is a sarcasm.
4. Biased Datasets: Explicit CTC suggestion expressing sentences occur sparsely, which is unfavourable for supervised learning approaches because of increased cost of data annotation task, and imbalanced class representation.

A general observation is that the text in the form of suggestions may not always be a suggestion, and vice versa. Therefore, syntactic and lexical features seem to be ineffective in many cases.

7 Conclusion

This work serves as an introduction and analysis of the problem of the extraction of customer-to-customer suggestions from reviews. The task is useful for a number of practical applications. We observed that the layman perception of *suggestion* is very wide, especially in the case of reviews. Therefore, we defined and limited the scope of our work to explicit suggestions. Following this, we prepared a well-investigated benchmark dataset, which is freely available for research purposes.

A pilot approach to the problem is presented, which analyses the performance of standard text classification features, and tests a set of complementary/special features. The special features improved the baseline results for both service and product reviews.

Analysis of classification errors highlighted the challenges associated with the task. The classification results have scope for improvement, and therefore the task calls for advanced semantic features and dedicated models, which will be our future direction. Furthermore, the relation between sentiments and suggestions seem to be worth investigating.

Abstract

A microblog repost tree provides strong clues on how an event described therein develops. To help social media users capture the main clues of events on microblogging sites, we propose a novel repost tree summarization framework by effectively differentiating two kinds of messages on repost trees called leaders and followers, which are derived from content-level structure information, i.e., contents of messages and the reposting relations. To this end, Conditional Random Fields (CRF) model is used to detect leaders across repost tree paths. We then present a variant of random-walk-based summarization model to rank and select salient messages based on the result of leader detection. To reduce the error propagation cascaded from leader detection, we improve the framework by enhancing the random walk with adjustment steps for sampling from leader probabilities given all the reposting messages. For evaluation, we construct two annotated corpora, one for leader detection, and the other for repost tree summarization. Experimental results confirm the effectiveness of our method.

1 Introduction

Microblogging platforms have become the center for reporting, discussing, and disseminating real-life issues, on which users usually *repost* to share microblog messages with their following users. Also, users can *repost with commentary* for not only further broadcasting but also extending the original microblog post content. Because an individual post is generally too short to cover the main clues of an event, microblogging users cannot easily capture the key information from received posts due to the lack of context. And reposting messages, namely reposts, can provide valuable context information to the previous posts including their background, development, public opinions and so on. However, a popular post usually attracts a large number of reposts. It is impractical for users to read them all and fully understand their contents.

The task of microblog context summarization aims to produce succinct summaries to help users better understand the main clues by extracting salient information among massive reposts of the original posts. An intuitive approach is to directly apply existing extractive summarizers based on the unstructured, plain microblog contents. But such short and informal reposts render the lack of structures in each individual message, and it is difficult for conventional extractive summarizersto identify salient messages. Chang et al. (2013) proposed to summarize Twitter context trees by focusing on modeling user influence. However, the reposts of influential users might not be salient summary candidates necessarily. For instance, celebrities might simply repost with nothing important. Also, modeling user influence accurately needs tremendous historical user interaction data external to the tree being summarized while such kind of information cannot be utilized directly for summarizing the messages on the tree.

In this paper, we propose a novel microblog context summarization framework based on content-level structures, i.e., message contents and reposting relations, rather than user-level influence signals. The reposting relations connect the reposting messages and form a cohesive body as a tree structure named *repost tree*. The root represents the original post and the edges denote re-

Lisbon, Portugal, 17-21 September 2015.

posting relations. Our idea is to exploit the structure of repost tree together with content of messages to help distinguish two different *messages* on repost tree, i.e., leaders and followers. Specifically, **leader** is referred to as a *message* on repost tree covering salient new information, which can lead further comments or discussions in its descendant reposts; **follower** is referred to as a *message* that contains no comment, simply repeats or naively responds to its ancestor leader message, thus providing no important information. The example below illustrates a repost tree path, where we use $[O]$ and $[R_i]$ to indicate the original post and the i-th repost, respectively:

$[O]$ @MAS: Malaysia Airlines has lost contact of MH17 from Amsterdam. The last known position was over Ukrainian airspace.

$[R_1]$ @Hanna: OMG... Poor on MH17... Preying...

$[R_2]$ @Victoria: OMG that's horrible!!! I'm sorry to hear that. God will bless u poor guys. Wish world can be peaceful. And no one will get hurt.

$[R_3]$ @Dr.Dr: Six top HIV scientists are on MH17. They go for AIDS and would NEVER come back!!!

$[R_4]$ @TomyBlack: 6 experts died?! Terrible loss to HIV research :(

$[O]$ reports the news about MH17 missing, which brings about further comments in $[R_1]$ and $[R_2]$. $[R_3]$ does not continue commenting on that but offers some new information and triggers shocking reaction in $[R_4]$. So $[O]$ and $[R_3]$ act as leaders; $[R_1]$, $[R_2]$ and $[R_4]$ are followers.

Intuitively, leaders would be more important than followers from the summarization's perspective since leaders are supposed to capture the main clues or aspects of event evolvement. The first step of our summarization system is to distinguish leaders and followers effectively. Leaders are detected across repost tree paths which provide rich context information owing to the tree structure. We utilize sequence tagging model Conditional Random Fields (CRF) to infer how likely it is each repost being a leader or follower. Then we incorporate leader detection result into an unsupervised summarization model based on random walk. Our model uses content similarities between messages and consider their possibilities of being leaders to rank and select salient reposting messages that form summaries. Furthermore, we improve the framework by enhancing the random walk to reduce the impact of errors cascaded from the leader detection module. Compared to the state-of-the-art baselines, the experimental results confirm the effectiveness of our proposed framework.

Our contributions are given as follows:

- We propose a novel microblog context summarization framework, in which given reposting messages organized as a repost tree (obtaining repost tree is trivial using public microblogging toolkit (Ren et al., 2014)), we summarize the repost trees based on content information and reposting relations of messages.
- We identify a novel problem of leader detection for summarization, which aims to reduce noise on repost trees, and present a CRF-based method for effectively detecting leaders by utilizing the tree structure and message contents.
- We incorporate the leader detection result into an unsupervised summarization model based on random walk and substantially enhance the model to reduce the impact of leader detection errors on summarization.

2 Related Work

The goal of text summarization is to automatically produce a succinct summary for one or more documents that preserves important information (Radev et al., 2002). Generally, text summarization techniques can be categorized into extractive and abstractive methods (Das and Martins, 2007). Extractive approaches focus on how to identify and distill salient contents from original texts whereas abstractive approaches aim at producing grammatical summaries by text generation.

Recently, the development of social media has made microblog summarization a hot topic. Most prior works are on event-level or topic-level summarization. Typically, the first step is to cluster posts into sub-events (Chakrabarti and Punera, 2011; Duan et al., 2012; Shen et al., 2013) or subtopics (Long et al., 2011; Rosa et al., 2011; Meng et al., 2012), and then the second step generates summary for each cluster.

Some works tried to apply conventional extractive summarization models directly, e.g., LexRank (Erkan and Radev, 2004), MEAD (Radev et al., 2004), TF-IDF (Inouye and Kalita, 2011), Integer Linear Programming (Liu et al., 2011; Takamura et al., 2011), etc. Sharif et al. (2010) modeled the problem as optimal path finding on a phrase reinforcement graph. However, these general summarizers were found not suitable for microblog posts, which are informal and noisy (Chang et al., 2013). Researchers

then considered social signals like user following relations and retweet count (Duan et al., 2012; Liu et al., 2012), and reported such features useful to help summarize microblog posts. Our work studies repost tree summarization by leveraging content-level structure to enrich context of messages, which is a different kind of signal.

Chang et al. (2013) proposed a task to summarize Twitter context trees consisting of an original tweet and all its reposts (i.e., replies and retweets). They combined user influence signals into a supervised summarization framework. Our work is different from theirs: 1) They simply treat a context tree as a tweets stream while we consider repost tree structures in summarization; 2) They rely on user interactions to calculate *user influence* for extracting salient messages while we focus on how to utilize contents and repost tree structures to differentiate *leader and follower messages* for summarization; 3) Our summarization module is unsupervised, thus no need of ground-truth summaries.

3 Leader Detection Model

This section deals with how to differentiate leader and follower messages on a repost tree. Intuitively, identifying leaders effectively makes one step closer to obtaining a good summary.

Figure 1 illustrates an example of a repost tree[1]. As shown in the figure, a leader message contains contents that brings essential information increase, such as a new clue about MH17 reported in $[R_6]$, and potentially triggers a new round of information propagation by attracting follower messages to focus on the raised clue, like $[R_7]$, $[R_8]$ and $[R_9]$. As the repost tree grows, it also happens that some new reposts join in, following the clue raised by one of their ancestors, but further extend it by mentioning something new, thus some of these messages may evolve into new leaders, such as $[R_{10}]$.

A simple way to detect leaders on repost tree is to directly apply a binary classifier like SVM on each individual message. However, these models assume reposts are independent without effectively leveraging abundant context along the repost tree paths, such as the reposting relations among different reposts on a path. For instance, $[R_2]$ covering rich content may be misclassified as a leader if not leveraging context information. But

[1]The example in Section 1 actually denotes the left-most path extracted from this tree

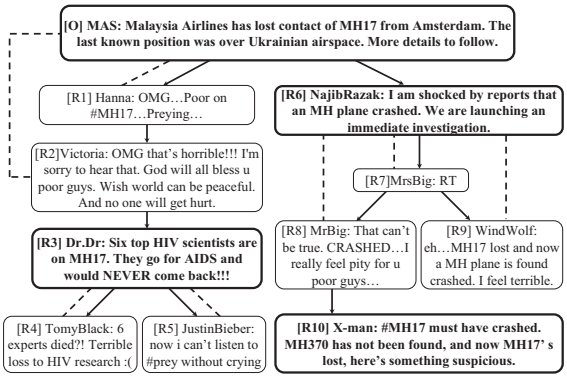

Figure 1: An example of repost tree. $[O]$: the original post; $[R_i]$: the i-th repost; Solid arrow lines: reposting relationship; Dotted lines: hidden leader-follower relationship; Dark boxes: leaders to be detected.

if we look into its context, we can find that $[R_2]$ talks about similar things as $[R_1]$, then $[R_1]$ classified as a follower indicates the higher chance of $[R_2]$ being a follower rather than a leader. Therefore, context information is important for indicating the messages being leaders or followers.

We extract all root-to-leaf paths within a repost tree structure and detect leaders across each path. We formulate leader detection on repost tree paths as a sequence tagging problem by utilizing a state-of-the-art sequence learning model CRF (Lafferty et al., 2001), and taking advantage of its power in maximizing the likelihood of global label sequences. We adopt CRF rather than other competitive context sensitive model like SVM^{hmm} (Altun et al., 2003) due to its probabilistic nature. The probability of prediction by CRF can provide critical chances for the following summarization procedure to reduce the impact of errors made by leader detection model on summarization (see Section 4.2).

We map a repost tree path with n microblogs $(m_1, m_2, \cdots, m_n)$ to a training instance (X, Y). Let $X = (x_1, x_2, \cdots, x_n)$ represents observed sequence, where x_i denotes the observed feature vector extracted from the i-th microblog m_i, and $Y = (y_1, y_2, \cdots, y_n)$ where y_i is the label indicating whether m_i is a leader or not. CRF defines the discriminative function as a joint distribution over Y given X as follows:

$$P(Y|X;\theta) \propto \exp\left(\sum_{i,j}\lambda_j f_j(y_i, y_{i-1}, X) + \sum_{i,k}\mu_k g_k(y_i, X)\right)$$

where f_j and g_k are the fixed feature functions,

Feature category	Feature name	Feature description
Lexical	# of terms	The number of terms in m_i
	POS	The part-of-speech of each term in m_i
	Type of sentence	Whether m_i contains a question mark or an exclamation
Microblog-specific	# of emoticons	The number of emoticons in m_i
	# of hashtags	The number of hashtags in m_i
	# of urls	The number of URLs in m_i
	# of mentions	The number of mentions, or @UserName, in m_i
Path-specific	Similarity to neighbors	Cosine similarity between m_i and m_{i+d} where $d \in \{\pm 1, \pm 2, \pm 3\}$
	Similarity to root	Cosine similarity to the root microblog in repost tree path

Table 1: Features used for leader detection

$\theta = (\lambda_1, \lambda_2, ...; \mu_1, \mu_2, ...)$ are the parameters indicating the weights of features that can be estimated by maximum likelihood procedure in training process. The prediction is done based on dynamic programming. More details can be found in (Lafferty et al., 2001). Table 1 lists the features we use for leader detection.

CRF can utilize both historical and future information for prediction so as to maximize the likelihood of the global label sequences. But we would encounter the problem of label conflict, i.e., the predictions for the same repost in context of different paths might be different. For this reason, we determine a repost as a leader if its average marginal probabilities being a leader in context of different paths exceeds 50%.

4 LeadSum Summarization Model

Let $T = (V, E)$ represent a repost tree to be summarized, where V is a set of nodes corresponding to microblog messages, and $E = \{(u, v)|v \text{ is the repost of } u\}$ is the edge set denoting reposting relations. This section describes how to rank nodes in V to produce repost tree summaries. Enlightened by the general random-walk-based ranking algorithm DivRank (Mei et al., 2010), we propose an unsupervised summarization model called LeadSum that aims to select true and salient leaders into summaries utilizing a variant of random walk based on content similarities and reposting relations of messages. We first present a basic LeadSum model, which assumes leader detection is perfect. Then, we enhance it to become a soft LeadSum model that reduces the impact of leader detection errors on the summarization.

4.1 Basic-LeadSum Model

Due to the nature of leaders, they generally cover more important contents than follows do. Thus our first summarizer selects contents only from detected leaders. For the leaders detected in a repost tree T, we build a similarity graph among leaders denoted as $G_L = (V_L, E_L)$, where $V_L = \{v \in V|v \text{ is a detected leader}\}$ is the vertex set and $E_L = \{(u, v)|u \in V_L, v \in V_L, \text{ and } u \neq v\}$ is the edge set. The weight for any edge (u, v) represents the content similarity between u and v, for which we use cosine similarity.

DivRank (Mei et al., 2010) is a generic graph ranking model that aims to balance high information coverage and low redundancy in top ranking vertices, which are also two key requirements for choosing salient summarization sentences (Li et al., 2009; Liu et al., 2015). Based on that, we present a model to rank and select salient messages from leader set V_L to form a summary. Since this model simply assumes perfect leader detection, it is therefore named Basic-LeadSum.

Similar as DivRank (Mei et al., 2010), the transition probability at the t-th iteration of random walk is given as follows:

$$p_t(u \to v) = (1-\mu) \cdot p_0(v) + \mu \cdot \frac{p_0(u \to v) N_{t-1}(v)}{Z(u)} \quad (1)$$

and $Z(u)$ is the normalizing factor:

$$Z(u) = \sum_{w \in V_L} p_0(u \to w) N_{t-1}(w) \quad (2)$$

where $p_0(u \to v)$ is the organic transition probability which represents the content similarity between u and v; $N_{t-1}(v)$ denotes the times vertex v is visited up to the $(t-1)$-th iteration; $p_0(v) = \frac{1}{|V_L|}$ denotes random jumping probability similar to that in PageRank; and μ is the damping weight set as 0.85 following most PageRank-based models. The probability of traveling to leader v can accumulate as its weight increases during random walk, and leaders already having high weight can "absorb" weights from other leaders with high similarity to it, thus avoids redundancy.

For any $v \in V_L$, the update function for its ranking score at the t-th iteration $R_t(v)$ is formulated as:

$$R_t(v) = \sum_{u \in V_L} p_t(u \to v) R_{t-1}(u) \tag{3}$$

It has been proved that the Markov chain is ergodic, thus can converge to a stationary distribution (Mei et al., 2010), which determines the final rankings for leaders.

4.2 Soft-LeadSum Model

As a two-step summarization system, the performance of LeadSum relies on the leader detection, which might be error-prone. Followers misidentified as leaders participating in leader ranking brings risks to extract real followers into summary. Also, leaders misclassified as followers may leave out strong summary candidates. To reduce such error propagation, we enhance Basic-LeadSum by using an even-length random walk with adjustment steps that sample from leader probabilities given all the reposting messages, which is referred to as Soft-LeadSum.

Different from Basic-LeadSum, every message on repost tree T, no matter detected as a leader or a follower, participates in ranking process of Soft-LeadSum. In other words, in the random walk, visitor wanders on a complete graph $G = (V, E')$ whose vertex set V is identical to repost tree T, and $E' = \{(u, v) | u \in V, v \in V, \text{ and } u \neq v\}$ represents the edge set. Therefore, this makes it possible to include true leaders misclassified as followers by leader detection module into summary.

However, allowing all messages to participate in ranking also increases the risk of selecting real followers. To avoid this problem, Soft-LeadSum is composed of two types of walks on G, namely WALK-1 and WALK-2. In WALK-1, visitor moves based on content similarities between messages, which follows transition probabilities similar to equation (1), but is specifically given as:

$$p_t(u \to v) = (1 - \mu) \cdot \frac{1}{|V|} + \mu \cdot \frac{p_0(u \to v) N_{t-1}(v)}{Z(u)} \tag{4}$$

where $u, v \in V$, $p_0(u \to v)$ is proportional to content similarity between u and v similar to Basic-LeadSum, and $Z(u)$ is the normalizing factor.

WALK-2 attempts to avoid selecting true followers by adopting a sampling process, whose result determines the next vertex on G to be visited. Suppose the current vertex being visited is u, then we sample from $p_L(u)$, i.e., the probability of u being a leader. Practically, $p_L(u)$ can be estimated with the average of u's marginal probabilities as a leader over all root-to-leaf paths passing u on T output by the leader detection module. If u is sampled to be a leader, we claim that leader detection is correct and the visitor stays; otherwise, u is sampled as a follower, indicating that leader detection module misclassifies u, so the visitor should go to u's leader. Here we assume that a follower u's leader is its nearest ancestor leader on T as shown by the dotted lines in Figure 1. Based on such simplification, we let the visitor trace back one by one along the path on T from u to root and sample from their leader probabilities until a node v is sampled as a leader and then we determine v as u's leader.

So for any u's ancestor v, the probability of v being u's leader is:

$$\begin{aligned} &Pr\{v \text{ is } u\text{'s leader}\} \\ &= p_L(v)(1 - p_L(u) - \sum_{w \in \mathcal{P}(v,u)} Pr\{w \text{ is } u\text{'s leader}\}) \\ &= p_L(v) \prod_{w \in \mathcal{P}(v,u) \bigcup \{u\}} (1 - p_L(w)) \end{aligned} \tag{5}$$

where $\mathcal{P}(v, u)$ is the set of nodes between v and u on v-to-u path of repost tree, i.e., $\mathcal{P}(v, u) = \{w \in V | w \text{ is } v\text{'s descendant and } u\text{'s ancestor on } T\}$. In particular, we assume that $p_L(r) = 1$ so as to stop the sampling process when the visitor arrives at root r.

Therefore, WALK-2's transition probabilities can be calculated as follows:

$$q(u \to v) = \begin{cases} p_L(v) & \text{if } v = u; \\ Pr\{v \text{ is } u\text{'s leader}\} & \text{if } v \text{ is } u\text{'s ancestor}; \\ 0 & \text{otherwise} \end{cases} \tag{6}$$

Algorithm 1 shows the ranking process of Soft-LeadSum, during which the visitor walks on G following WALK-1 and WALK-2 alternately. The fact that WALK-1 is ergodic ensures the ergodicity and convergency of the algorithm. In implementation, we set max iteration N=1000 empirically which is large enough to ensure convergence, or stop random walk process in advance when the condition of convergence is met, i.e., the change of Euclidean difference of ranking scores for three consecutive iterations are all less than 1e-6.

Soft-LeadSum can reduce the impact of errors made by leader detection on summarization due to the following two reasons: 1) It allows all messages to participate in ranking process, thus permits those leaders leaving out by leader detection module to be selected into summary; 2) With

Algorithm 1 Algorithm of Soft-LeadSum

Input: T, G, μ=0.85, max iteration N, length cut-off n
Output: Summary with n microblog messages

For all $v \in V$, initialize $R_0(v) = p_0(v) = \frac{1}{|V|}$
Initialize WALK-1's transition probabilities $p_0(u \rightarrow v)$ with normalized cosine similarity between u and v.
Calculate WALK-2's transition probabilities $q(u \rightarrow v)$ by equation (5) and (6).
Initialize current_walk="WALK-1"

  for all $v \in V$ **do**
    if current_walk=="WALK-1" **then**
      Update $p_t(u \rightarrow v)$ by equation (4)
      Update $R_t(v)$ as follows:
        $R_t(v) = \sum_{u \in V} R_{t-1}(u) \cdot p_t(u \rightarrow v)$
      Set current_walk="WALK-2"
    end if
    if current_walk=="WALK-2" **then**
      Update $R_v(v)$ as follows:
        $R_t(v) = \sum_{u \in V} R_{t-1}(u) \cdot q(u \rightarrow v)$
      Set current_walk="WALK-1"
    end if
  end for
end for
Sort all $v \in V$ by $R_N(v)$ in descending order
Pick the top-n messages as summary

WALK-2 sampling from leader probabilities, it also reduces the risk of including real followers into summary.

5 Experiments and Results

To evaluate the two modules in our repost tree summarization system, i.e., CRF-based model for leader detection and LeadSum model for summarization, we conducted two sets of experiments based on microblog posts data collected from Sina Weibo, which has a similar market penetration as Twitter (Rapoza, 2011)[2]. Microblog messages on Sina Weibo are in Chinese and we use FudanNLP (Qiu et al., 2013) for text preprocessing including word segmentation and POS tagging.

5.1 Experiment for Leader Detection

In this experiment, we evaluated the performance of CRF model for leader detection task.

5.1.1 Data Collection and Setup

We first crawled 1,300 different repost trees using the public PKUVIS toolkit (Ren et al., 2014). Given an original microblog post, the toolkit can automatically crawl its complete repost tree. For each tree, we randomly selected one path and further formed a set with 1,300 repost tree paths, which ensures that paths have different roots and the dataset can cover a wide variety of context information.

Then three annotators were invited to label each repost as a leader or a follower in the context of its repost tree path independently. The average Cohen's Kappa of each two of the three annotators was 0.52, which is considered good agreement (Fleiss et al., 2013). Then, we used the labels agreed by at least two annotators as the ground truth. The training and test of the leader detection models were conducted on this corpus.

We compared the performance of CRF-based leader detection model with four baselines: Random Classifier (RC) as a weak baseline; two state-of-the-art point-wise supervised models Logistic Regression (LR) and Support Vector Machine (SVM); and an effective context sensitive model SVM^{hmm}. We applied LibLinear toolkit (Fan et al., 2008) to implement LR and SVM with linear kernel. SVM^{hmm} was implemented by SVM^{struct} toolkit (Joachims et al., 2009). And CRF's implementation was based on CRF++[3]. For all the baselines, we used features listed in Table 1. The hyper-parameters of all leader detection models were tuned to the same extent based on 5-fold cross validation (with 1 fold as development set). The evaluation metrics were precision, recall and F1 score for the detected leaders.

	Cross-validation			Held-out		
	Prec	Rec	F1	Prec	Rec	F1
Random	29.8	49.5	37.3	31.6	49.6	38.6
LR	70.5	66.3	68.4	70.4	66.2	68.2
SVM	70.9	66.9	68.8	68.9	66.2	67.5
SVM^{hmm}	74.8	65.5	69.8	69.3	70.1	69.7
CRF	**75.5**	**72.0**	**73.7**	**71.1**	**70.7**	**70.9**

Table 2: The performance of leader detection (%)

5.1.2 Results

Table 2 shows the comparison result of 5-fold cross validation on 1,000 repost tree paths and held-out experiment on 300 complete fresh paths.

Among all baselines, SVM^{hmm} performed the best, which indicates the effectiveness of incorporating structure information for leader detection. And among context-sensitive models, both SVM^{hmm} and CRF were competitive. CRF outperformed SVM^{hmm} slightly with 5.6% and 1.7% improved F1 score in cross validation and held-out

[2]The datasets are available at http://www1.se.cuhk.edu.hk/~lijing/data/repost_tree_summ.zip

[3]http://taku910.github.io/crfpp/

experiments, respectively. In spite of their comparable performance, our framework applies CRF instead of SVM^{hmm} for leader detection because of its probabilistic nature, which can be exploited by the sampling process in Soft-LeadSum to reduce the propagation of classification error to the summarization stage. Section 5.2.2 shows the relevant experiment.

5.2 Experiment for Summarization

In this experiment, we evaluated end-to-end performance of our basic and soft LeadSum summarization models by comparing them with state-of-the-art microblog summarizers.

5.2.1 Data Collection and Evaluation Metrics

There is no public editorial repost tree dataset. Therefore, we manually selected 10 hot events taking place during January 2nd – July 28th 2014, and then used the PKUVIS toolkit (Ren et al., 2014) to crawl the complete repost trees for all the events given the corresponding original posts. Table 3 shows the details about the repost tree corpus[4]. Note that this repost tree corpus has no overlap with the repost tree path dataset for learning leader detection models in Section 5.1.1.

After that, we invited three experienced editors to write summaries for each repost tree. To ensure the quality of reference summaries, we first extracted a list of frequent nouns from each repost tree and generalized 7 to 10 topics based on the nouns list, which provided a high-level overview of a repost tree to editors. Then, our guideline required editors to read all repost microblogs ordered sequentially on a repost tree. For every message, its entire repost tree path was also provided as supplementary context information. When finished reading, editors wrote down one or two sentences to summarize each topic in the list.

We utilized ROUGE-N metric (Lin, 2004) for benchmark, which is a standard for evaluating automatic summaries based on N-gram overlapping between a generated summary and a reference. Specifically, ROUGE-1 and ROUGE-2 F1-measure were used as our evaluation metrics. Lin et al. (2004) has demonstrated that ROUGE-2 correlates well with humans in summarizing formal texts. And ROUGE-1 is a better alternative in evaluating summaries for short and informal microblog messages (Inouye and Kalita, 2011; Chang et al., 2013).

In our human-generated summaries, the average inter-annotator-agreement by ROUGE-1 is 0.431, which means each pair of manual summaries have no more than 50% words overlap on average even written under topic constraints. This indicates that microblog repost tree summarization is generally a difficult task. The reason is that repost trees have complex structure, and editors could hardly reconstruct the repost trees even though they went through all the microblogs. Therefore, in evaluation for each tree, we computed the average ROUGE F1 score between the model-generated summary and the three human-generated summaries.

5.2.2 Results

In each automatic summarizer, we selected the top-10 ranked reposts to form a summary. We compared the end-to-end performance with the following baseline systems:

- **RandSum:** RandSum is a weak baseline that randomly selects reposts into summaries.
- **RepSum:** RepSum ranks and selects messages simply by their reposts count, i.e., the size of their subtrees, based on reposting relations.
- **UserRankSum:** UserRankSum ranks and selects reposts by their authors' follower count based on user following relations.
- **LeadProSum:** LeadProSum ranks and selects reposting messages by their marginal probabilities as leaders determined by our CRF-based leader detection model.
- **SVDSum:** SVDSum adopts the Singular Value Decomposition (SVD) to discover hidden sub-topics for summarization (Gong and Liu, 2001). Reposting messages are ranked according to latent semantic analysis with SVD on term-message matrix.
- **DivRankSum:** DivRankSum directly applies DivRank (Mei et al., 2010) algorithm to rank all messages unaware of leaders and followers. A similar model is also reported in Yan et al. (2011). Following their work, we set damping weight as 0.85.
- **UserInfSum:** Chang et al. (2013) ranks messages utilizing Gradient Boosted Decision Tree (GBDT) algorithm with text, popularity, temporal and user influence signals to summarize Twitter context tree. In particular, without the interaction data with external users, we utilize users' fol-

– Significantly different with S-LS+CRF: † ($p < 0.1$); ‡ ($p < 0.05$)

Table 4: Comparison of different summarizers

lower count to approximate user influence. GBDT implementation is based on RankLib[5], and as a supervised method, UserInfSum is evaluated with 10-fold cross validation.

In addition, we observed that SVM^{hmm} is a competitive baseline for leader detection (see Table 2). So we also study its impact on the Basic-LeadSum model. Note that SVM^{hmm} cannot be combined with Soft-LeadSum since it is not probabilistic.

Table 4 shows the result of overall comparisons. We have the following observations:

• RepSum utilized trivial structure information, i.e., the size of sub-tree, and its performance was poor, which was even worse than RandSum on ROUGE-2. This implies that messages with a lot of reposts may not be good candidates as other reasons may lead to their popularity, e.g., a good posting time or sense of humor.

• UserRankSum performed the best on ROUGE-1&2 among all baseline summarizers, which confirms that user following relations can indeed be a strong signal in microblog summarization. UserRankSum is even slightly better than Basic-LeadSum on ROUGE-2. But, it does not perform consistently well for all repost trees, evidenced as the large standard deviation on ROUGE-1&2. This suggests that the user following relations cannot always effectively indicate salient candidates. It may not work for repost trees where authors have similar number of following users, or reposts of influential users contain nothing salient.

• LeadProSum achieved the second best performance among all unsupervised baselines, which indicates that the marginal probabilities as leaders can signal good summary candidates. This also confirms that leaders contain salient contents and should be distinguished from followers in summarization.

• Utilizing either SVM^{hmm} or CRF as leader detection model to filter out followers, Basic-LeadSum almost doubled the ROUGE-1 and tripled the ROUGE-2 scores compared to DivRankSum's performance. This indicates that differentiating leaders and followers is very helpful to summarization.

• Basic-LeadSum performed better than all baselines on ROUGE-1&2 except for a marginal drop compared to UserRankSum on ROUGE-2. But the differences with UserRankSum, LeadProSum and UserInfSum are not statistically significant. This may be ascribed to the error propagated from leader detection module to summarization process.

• Soft-LeadSum outperformed all the baselines with a large margin on ROUGE-1&2, including supervised summarizer UserInfSum. The one-tailed pairwise t-test indicates that all the improvements over baselines are significant at the 95% confidence level except for UserRankSum with 90% confidence level on ROUGE-2. This confirms the effectiveness of our framework for producing high-quality repost tree summaries.

• The supervised model UserInfSum did not

[5] http://sourceforge.net/p/lemur/wiki/RankLib/

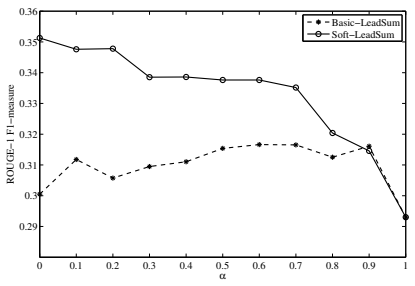

Figure 2: The impact of α on the ROUGE-1 F1-measure of combined models

perform quite well. The reason is that the model needs large amount of user interaction data external to the tree which are not readily available, and also it might be overfitting to the limited number of training instances.

• Basic-LeadSum with CRF and SVM^{hmm} had very close ROUGE-1&2 scores. Basic-LeadSum+SVM^{hmm} is even slightly better than Basic-LeadSum+CRF. Though SVM^{hmm} was marginally worse in leader detection experiment (Table 2), we can conclude that SVM^{hmm} is a comparable alternative as the leader detection module for Basic-LeadSum.

• Among our models, Soft-LeadSum significantly outperformed both Basic-LeadSum with CRF and that with SVM^{hmm}. This implies that sampling steps in the enhanced random walk of Soft-LeadSum is effective in reducing the impact of leader detection error on summarization.

5.3 Discussion

From Table 4, we observed that user following relations used by UserRankSum is a strong signal for microblog summarization. A natural question is: "Can the user following relations commonly used for modeling user influence be complementary to the content-level structure information used in our summariztaion models?"

We thus linearly combine the normalized ranking scores of LeadSum and UserRankSum using the formula $\alpha * \mathbf{u} + (1-\alpha) * \mathbf{l}$, where $\mathbf{u}$ and $\mathbf{l}$ denote the UserRankSum and LeadSum ranking scores, respectively. Figure 2 demonstrates the impact of α on our basic and soft LeadSum model with CRF.

Clearly, Basic-LeadSum can benefit from user influence information by incorporating UserRankSum scores into it. From the incremental trend of summarization performance with the increase of α for $\alpha \in [0, 0.9]$, we can conclude that user influence is helpful to it. This is because Basic-LeadSum is not sufficiently robust to the errors cascaded from leader detection module, thus user-level structures can have the chance to compensate these errors for content-level structures.

Incorporating the same information into Soft-LeadSum cannot improve its performance regardless of the value of α. This implies that content-level structures, i.e., message content and reposting relations together, are better indicative of good summary candidates. When these features are appropriately modeled by Soft-LeadSum, user influence, a traditionally well-known strong signal, cannot provide extra benefit at all.

6 Conclusion and Future Work

This work presents a study for microblog repost tree summarization, whose output can provide important clues for event analysis on microblogging platforms. Conventional works considering only plain text streams is insufficient to summarize noisy repost trees. We propose a novel summarization system by effectively differentiating leader and follower messages on repost tree based on content-level structure information. Firstly, a leader detection model categorizes each repost on repost tree path as a leader or a follower. Then, a random-walk variant summarization model called LeadSum is proposed to rank and select salient microblog messages on the basis of leader detection result. To reduce errors cascaded from leader detection, we enhance LeadSum based on an even-length random walk by sampling from leader probabilities for improving summarization. Based on real-world microblog post dataset, the experimental results confirm that our proposed framework is effective for repost tree summarization by the end-to-end comparison with the state-of-the-art baselines.

Constrained by the amount of annotation, we adopt this two-step framework and an unsupervised summarization algorithm. With the development of our corpora, we plan to explore the usefulness of supervised structure learning approaches, such as tree-structured CRF (Tang et al., 2006; Mensink et al., 2013), to integrate leader detection and summarization into a unified framework, and make global inference for important leaders by capturing various non-linear dependencies.

Intra-sentential Zero Anaphora Resolution using Subject Sharing Recognition

Ryu Iida Kentaro Torisawa Chikara Hashimoto

Abstract

In this work, we improve the performance of intra-sentential zero anaphora resolution in Japanese using a novel method of recognizing subject sharing relations. In Japanese, a large portion of intra-sentential zero anaphora can be regarded as subject sharing relations between predicates, that is, the subject of some predicate is also the unrealized subject of other predicates. We develop an accurate recognizer of subject sharing relations for pairs of predicates in a single sentence, and then construct a *subject shared predicate network*, which is a set of predicates that are linked by the subject sharing relations recognized by our recognizer. We finally combine our zero anaphora resolution method exploiting the subject shared predicate network and a state-of-the-art ILP-based zero anaphora resolution method. Our combined method achieved a significant improvement over the the ILP-based method alone on intra-sentential zero anaphora resolution in Japanese. To the best of our knowledge, this is the first work to explicitly use an independent subject sharing recognizer in zero anaphora resolution.

1 Introduction

In 'pro-dropped' languages such as Japanese, Chinese and Italian, pronouns are often unrealized in text. For example, the subject of *nomu* (take) is omitted in example (1).

(1) *Tom$_i$-wa* *infuruenza-ni* *natta-node* ,
Tom-TOP flu-IOBJ had-since punc
(ϕ_i-ga) *kusuri-o* ***non-da*** .
he$_i$-SUBJ medicine-OBJ took period
Since Tom$_i$ had the flu, (he$_i$) took medicine.

Such unrealized pronouns are regarded as *zero anaphors*, which are indicated using ϕ in literature, like ϕ_i-ga in example (1). Zero anaphor refers to its antecedent somewhere. This phenomenon of the reference is called *zero anaphora*. In Japanese, about 60% of subjects appear as zero anaphors in newspaper articles (Iida et al., 2007b), and thus zero anaphora resolution is an essential task for developing highly accurate machine translation and information extraction systems.

In this paper, we propose a novel method of resolving intra-sentential zero anaphora, in which a subject zero anaphor refers to its antecedent inside *a single sentence*. This work does not address inter-sentential zero anaphora, in which a zero anaphor in a sentence refers to its antecedent in *another sentence*. The novelty of our method is in the use of *subject sharing relations*, which are relations between two predicates that share a subject by (zero) anaphora or coreference. For example, in example (2), there are two subject sharing relations for predicate pairs, *advance-plan* and *plan-dispatch*, as illustrated in Figure 1.

(2) *seifu$_i$-wa* *(ϕ_i-ga)* *hisaichi-ni*
government$_i$-TOP it$_i$-SUBJ disaster site-IOBJ
50 nin-o ***hakensuru*** *koto-o* *(ϕ_i-ga)*
50 people-OBJ dispatch COMP-OBJ it$_i$-SUBJ
keikakusi *junbisagyo-o* ***susumeru*** .
plan preparation-OBJ advance period
The government$_i$ plans that (it$_i$) will dispatch 50 people to the disaster site and (it$_i$) is advancing its preparations.

The most straightforward method to recognize subject sharing relations is to apply a (zero) anaphora resolution system to a sentence and detect such relations by recognizing (zero) anaphora, like the relations represented by *seifu$_i$* and two zero anaphors ϕ_i in Figure 1. However, to our surprise, we found that a simple supervised classifier that exploits the local contexts surrounding

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2179–2189,
Lisbon, Portugal, 17-21 September 2015.

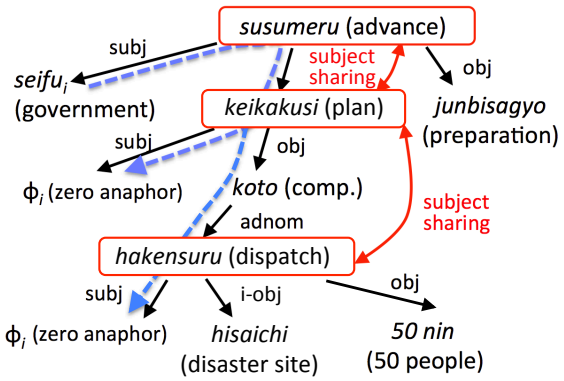

Figure 1: Example of subject shared predicate network

predicates achieved a higher accuracy than that of the straightforward method. This suggests that just *propagating* the realized subject of a predicate to the subject zero anaphor of other predicates through recognized subject sharing relations (e.g., propagating subject *government* of *advance* to the subject positions of *plan* and *dispatch* in Figure 1) might lead to a higher accuracy in zero anaphora resolution than the existing zero anaphora resolution methods. In addition, a large portion of zero anaphora can be regarded as subject sharing relations (e.g., 39% of the intra-sentential zero anaphora in the NAIST Text Corpus (Iida et al., 2007b) are such cases). Hence, just by combining our subject zero anaphora method with an existing general anaphora resolution method that covers other types of anaphora, significant improvement of accuracy over all types of anaphora might be achieved. This paper empirically shows that this is actually the case through a series of experiments in which we combine our method with an existing ILP-based zero anaphora resolution method (Iida and Poesio, 2011).

Our subject zero anaphora resolution method constructs a *subject shared predicate network (SSPN)*, which is a network of predicates in which subject sharing predicates are linked, from the results of our accurate *pairwise subject sharing recognizer*, which detects the predicate pairs that share a subject. Zero anaphora resolution is done by propagating the realized subject of a predicate to the subject zero anaphor of other predicates in the SSPN. An important point here is that SSPN was introduced to solve the issue related to our pairwise subject sharing recognizer. Our recognizer is applied only to the restricted pairs of predicates in a sentence, such as predicates that have a *direct* dependency relation between them. This is because our current recognizer cannot achieve high accuracy for *any* pair of predicates. In Figure 1, for instance, our recognizer can detect a subject sharing relation between *advance* and *plan* and another between *plan* and *dispatch*, but it cannot detect one between *advance* and *dispatch*. However, in the SSPN, the undetected relations can be derived by connecting the two detected ones, and in the zero anaphora resolution subject *government* of *advance* can be successfully propagated to the subject position of *dispatch*.

The rest of our paper is organized as follows. In Section 2, we briefly overview previous work on zero anaphora resolution. In Section 3, we overview the procedure of our zero anaphora resolution method. We explain the three types of subject sharing relations on which we focus and propose a method of pairwise subject sharing recognition for the three types in Section 4. We evaluate how effectively our method recognizes subject sharing relations for these types in Section 5. After that, we investigate the impact of explicitly introducing SSPNs in Section 6 and compare our zero anaphora resolution method with a state-of-the-art ILP-based method on the task of intra-sentential subject zero anaphora resolution in Section 7. Finally, in Section 8 we summarize this work and discuss future directions.

2 Related work

Traditional approaches to zero anaphora resolution are based on manually created heuristic rules (Kameyama, 1986; Walker et al., 1994; Okumura and Tamura, 1996; Nakaiwa and Shirai, 1996), which are mainly motivated by the rules and preferences introduced in Centering Theory (Grosz et al., 1995). However, the research trend of zero anaphora resolution has shifted from such rule-based approaches to machine learning-based approaches because in machine learning we can easily integrate many different types of information, such as morpho-syntactic, semantic and discourse-related information. Researchers have developed methods of zero anaphora resolution for Chinese (Zhao and Ng, 2007; Chen and Ng, 2013), Japanese (Seki et al., 2002; Isozaki and Hirao, 2003; Iida et al., 2007a; Taira et al., 2008; Sasano et al., 2008; Sasano et al., 2009; Imamura

et al., 2009; Watanabe et al., 2010; Hayashibe et al., 2011; Iida and Poesio, 2011; Yoshikawa et al., 2011; Hangyo et al., 2013; Yoshino et al., 2013) and Italian (Iida and Poesio, 2011). One critical issue in zero anaphora resolution is optimizing the outputs of sub-problems (e.g., zero anaphor detection and antecedent identification). Recent works by Watanabe et al. (2010), Iida and Poesio (2011) and Yoshikawa et al. (2011) revealed that joint inference improves the overall performance of zero anaphora resolution. We employed one of these works as a baseline in Section 6.

Concerning subject sharing recognition, related methods have been explored for pronominal anaphora (Yang et al., 2005) or coreference resolution (Bean and Riloff, 2004; Bansal and Klein, 2012). In these methods, the semantic compatibility between the contexts surrounding an anaphor and its antecedent (e.g., the compatibility of verbs *kidnap* and *release* given some arguments) was automatically extracted from raw texts in an unsupervised manner and used as features in a machine learning-based approach. However, because the automatically acquired semantic compatibility is not always true or applicable in the context of any pair of an anaphor and its antecedent, the effectiveness of the compatibility features might be weakened. In contrast, we accurately recognize the explicit subject sharing relations and directly use them for propagating the subject of some predicate to the empty subject position of other predicates instead of indirectly using the relations as features.

3 Zero anaphora resolution using subject shared predicate network

In this section, we first give an overview of the procedure of our zero anaphora resolution method. Intra-sentential zero anaphora resolution in our method is performed in the following five steps, as depicted in Figure 2.

Step 1 The pairwise subject sharing relations between two predicates in a sentence are recognized by our subject sharing recognizer.

Step 2 A subject shared predicate network (SSPN) is constructed based on the results of pairwise subject sharing recognition.

Step 3 For each predicate in the set of the subject shared predicates in the SSPN, a subject is detected by our subject detector, if one exists.

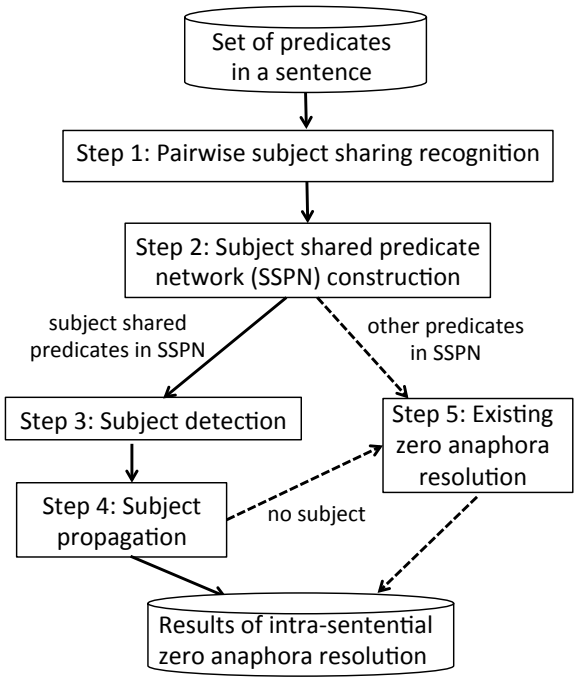

Figure 2: Procedure of our zero anaphora resolution method

Step 4 If a subject is detected, it is propagated to the empty subject position of each predicate in the subject shared predicates in the SSPN.

Step 5 For resolving the potential zero anaphora that were not resolved until Step 4, we apply the existing ILP-based method (Iida and Poesio, 2011).

We define subject sharing relations as follows. Two predicates have a subject sharing relation if and only if they share the same subject that is referred to by (zero) anaphora or coreference. Note that the shared subject does not need to be realized in the text; it can appear as inter-sentential zero anaphora or exophora. In Step 1, the pairwise subject sharing relations between two predicates are recognized, but recognizing the relations between any two predicates in a sentence remains difficult. We thus focus on some typical types of predicate pairs. The details of the predicate pair types will be explained in Section 4.1.

Given the results of pairwise subject sharing recognition, we construct an SSPN in Step 2. In an SSPN, every predicate in a sentence is a node and only the predicate pairs that were judged to be subject sharing are connected by a link. The major advantage of explicitly constructing an SSPN is that it enables us to resolve zero anaphora even

if a predicate with a subject zero anaphor does not have any direct subject sharing relation with a predicate with a subject, like predicates *susumeru* (advance) and *hakensuru* (dispatch) in Figure 1. By traversing the paths of the subject sharing relations in the SSPN, such predicates can be connected to successfully propagate the subject. The effect of introducing SSPNs is empirically evaluated in Section 6.

For use in Step 3, we create a subject detector, which judges whether an argument to a predicate is its subject using SVM^{light} [1], an implementation of Support Vector Machine (Vapnik, 1998), with a polynomial kernel of 2nd degree. The training instances of the subject detector are extracted from the predicate-argument relations[2] in the NAIST Text Corpus. The numbers of positive and negative instances are 35,304 and 104,250 respectively. As features, we used the morpho-syntactic information about the lemmas of the predicate and its argument and the functional words following the predicate and its argument. The results of subject detection with 5-fold cross-validation demonstrate that our subject detector accurately detects subjects with performances of 0.949 in recall, 0.855 in precision, and 0.899 in F-score.

Note that our subject detector checks whether each predicate in an SSPN has a syntactic subject among its arguments. An SSPN can include more than one predicate, and each predicate may have its own subject[3]. In this step, if two or more distinct subjects are detected for predicates in an SSPN, we use the most likely subject (i.e., the subject with the highest SVM score outputted by our subject detector) for subject propagation. Note that subject propagation is not performed if the subject position of a predicate is already filled.

Up to this point, the zero anaphora of the following three cases cannot be resolved: (i) no subject was detected for any predicate in a group linked by the subject sharing relations in the SSPN, (ii) no subject sharing relation was recognized for a predicate in the SSPN and (iii) non-

[1] http://svmlight.joachims.org/

[2] Note that if a predicate appears in a relative clause and a noun modified by the clause is the *semantic* subject of the predicate, the noun is not regarded as subject by our subject detector.

[3] The subject sharing recognizer is likely to regard two predicates, each of which has its own subject, as non-subject sharing predicate pairs, but it is still logically possible that they are judged as subject sharing predicate pairs hence as a part of an SSPN.

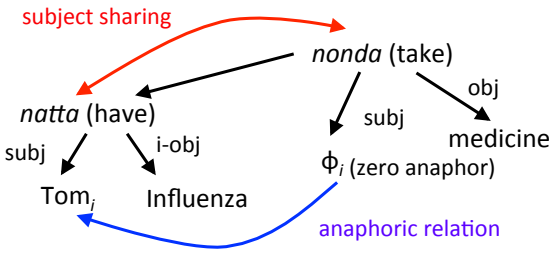

Figure 3: Example of DEP type

subject arguments were omitted as zero anaphors. To resolve zero anaphora in these cases, we apply a state-of-the-art ILP-based zero anaphora resolution method (Iida and Poesio, 2011) in Step 5. This method determines zero anaphor and its antecedent by joint inference using the results of subject detection, zero anaphor detection and intra- and inter-sentential antecedent identification. In the original method by Iida and Poesio (2011), the inter-sentential zero anaphora was resolved, but in this work we focus on intra-sentential zero anaphora. To adapt their method for our problem setting, we simply removed the inter-sentential antecedent identification model from their method.

4 Pairwise subject sharing recognition

A key component in our zero anaphora resolution method is pairwise subject sharing recognition. In this work, we focus on three types of subject sharing relations (DEP, ADJ and PNP types) as a first step because the instances belonging to the three types occupy 62% of intra-sentential zero anaphora that can be regarded as subject sharing. We developed a method that recognizes each subject sharing type and evaluate it.

4.1 Three types of subject sharing relations

We first describe the three types of subject sharing relations we focus on.

DEP A typical type of subject sharing relation is one between two predicates that have a syntactical dependency relation. The relation between two predicates, *natta* (have) and *nonda* (take), in example (1) in Section 1 is classified as this type because the two predicates have the same subject *Tom*$_i$ (ϕ_i), as illustrated in Figure 3. We call this type of subject sharing the DEP type.

ADJ This type is a subject sharing relation between two *adjacent* predicates, i.e., a predicate

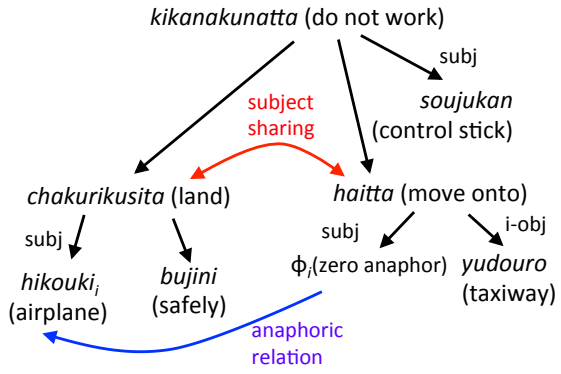

Figure 4: Example of ADJ type

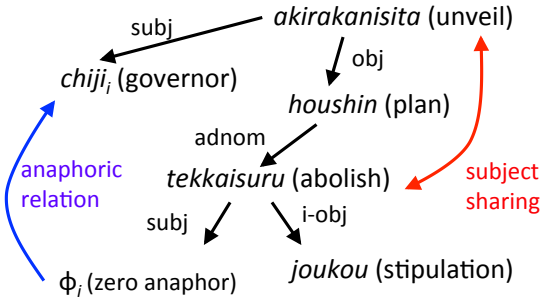

Figure 5: Example of PNP type

pairs that do not have any other predicate between them in the surface order of a sentence. Although two adjacent predicates in a sentence tend to share the same subject, they sometimes cannot be captured as the DEP type due to a long-distance dependency between predicates. For example, in example (3), two adjacent predicates, *land* and *move onto*, have the same subject but not a direct dependency relation, as illustrated in Figure 4.

(3) *hikouki-wa* *bujini* ***chakurikusi-ta-ga***
airplane-TOP safely land-PAST-but

(ϕ$_i$-ga) *yudouro-ni* ***hait-ta-atoni***
it$_i$-SUBJ taxiway-IOBJ move onto-PAST-after

soujukan-ga *kikanakunat-ta* .
control stick-SUBJ do not work-PAST period
The airplane safely landed, but its control stick did not work after (it$_i$) moved onto the taxiway.

To cover such cases, we also take into account the subject sharing relations of the ADJ type in which two predicates appear adjacently in the surface order.

PNP In addition to the above two types of relations, in Japanese predicate pairs often have a subject sharing relation when one of the predicates syntactically depends on a noun (or noun phrase) that in turn syntactically depends on the other predicate. Example (4) is classified as such a type because noun *houshin* (plan) is placed between two predicates, *akirakanisita* (unveil) and *tekkaisuru* (abolish), in the dependency path and predicates share subject *chiji* (governor), as illustrated in Figure 5.

(4) *chiji$_i$-wa* *(ϕ$_i$-ga)* *joukou-o*
governor-TOP he$_i$-SUBJ stipulation-OBJ

tekkaisuru *houshin-o* ***akirakanisi-ta*** .
abolish plan-TOP unveil-PAST period
The governor$_i$ unveiled his plan under which (he$_i$) will abolish the stipulation.

We call this type of subject sharing relation the PNP type.

In this work, we solve the problem of subject sharing recognition as a binary classification problem in which we classify whether two predicates share the same subject. We solve this problem using a supervised approach. We independently extract the training instances for each type from a corpus to which (zero) anaphora, coreference and subjects were annotated. The binary labels of the training instances are classified into the positive class if the subject of the two predicates in an instance is shared by coreference or (zero) anaphora, and negative otherwise. To create a classifier, we use SVM^{light} and experiment with both a linear kernel and a polynomial kernel of 2nd degree.

As features, we use the feature set shown in Table 1. Even though these features look simple, we expect them to work well to capture the characteristics of each subject sharing type. For example, as shown in example (5), the (subject) case marker of the argument (mother-SUBJ) between two predicates *natta* (have) and *katta* (buy) is a good indicator of non-subject sharing.

(5) *Tom$_i$-ga* *infuruenza-ni* ***natta-node*** ,
Tom-SUBJ flu-IOBJ had-since punc

haha-ga *kusuri-o* ***katta*** .
mother-SUBJ medicine-OBJ buy-PAST period
Since Tom had the flu, his mother bought medicine.

For recognizing the PNP type of subject sharing relations, whether certain nouns appear between two predicates is an important clue, e.g., *koto* (complementizer) in example (6) and *nouryoku* (ability) in example (7).

Name	Description
PoS_i (PoS_j)	PoS of p_i (p_j)
lemma_i (lemma_j)	lemma of p_i (p_j)
func_w_i (func_w_j)	function words following p_i (p_j)
case_i (case_j)	case marker of arguments of p_i (p_j)
btw_case	case marker of arguments that appeared between p_i and p_j
NpPoS*	PoS of *np*
Np_lemma*	lemma of *np*
func_w_{np}*	function words following *np*
case_{np}*	case marker of dependents of *np*
n_class*	noun class of *np* based on Kazama and Torisawa (2008)

p_i and p_j stand for the left and right predicates in predicate pairs. *np* is the noun phrase between p_i and p_j. b_i (b_j) stands for the *bunsetsu*-unit[4] including p_i (p_j). The features marked with * are only used for PNP type.

Table 1: Features of subject sharing recognition

(6) *seifu$_i$-wa* *(ϕ_i-ga)* *sono isetsu-o*
government-TOP it_i-SUBJ the relocation-OBJ
mitomeru ***koto-o*** *kime-ta* .
admit COMP-OBJ decide-PAST period
The government$_i$ decided that (it_i) admits the relocation.

(7) *sono fune-wa* *(ϕ_i-ga)* *hayaku*
the ship-TOP it_i-SUBJ fast
hashiru ***nouryoku-o*** *motteiru* .
run ability-OBJ have period
The ship$_i$ has an ability that (it_i) runs fast.

To robustly capture this characteristic, we use as features the discrete classes created by the noun clustering algorithm proposed by Kazama and Torisawa (2008). It follows the distributional hypothesis, which states that semantically similar words tend to appear in similar contexts (Harris, 1954). By treating the syntactic dependency relations between words as 'contexts,' the clustering method defines a probabilistic model of noun-verb dependencies with hidden classes:

$$p(n, \langle v, r \rangle) = \sum_c p(n|c)p(\langle v, r \rangle|c)p(c)$$

where n is a noun, v is a verb or noun on which n depends by grammatical relation r (post-positions in Japanese), and c is a hidden class. The dependency relation frequencies were obtained from a 600-million page web corpus, and model parameters $p(n|c)$, $p(\langle v, r \rangle|c)$ and $p(c)$ were estimated using the EM algorithm (Hofmann, 1999). We clustered one million nouns into 500 discrete classes by assigning noun n to class c when the model parameter $p(c|n) > \theta$ ($\theta = 0.2$).

[4]A bunsetsu-unit is a Japanese base phrase consisting of at least one content word optionally followed by functional words.

5 Experiment 1: pairwise subject sharing recognition

We first empirically evaluate the performance of our pairwise subject sharing recognition for the DEP, ADJ and PNP types.

5.1 Experimental setting

The training data for the subject sharing recognizer were generated from the NAIST Text Corpus 1.4 (Iida et al., 2007b), in which (zero) anaphora, coreference and subjects were manually annotated. We automatically extracted pairs of predicates from the corpus. Since the original NAIST Text Corpus has a wide variety of annotation noise, we cleaned it up by the following strategy. According to the annotation scheme in the NAIST Text Corpus, predicate-argument relations were annotated for the 'bare predicates' even if the predicates appear in passive or causative sentences. In such cases, the annotation was difficult and caused inconsistencies because the annotators needed to imagine the predicate-argument relations for predicates that are not explicitly written, considering case alternation caused by changes of voice and so on. As such, to achieve a higher level of consistency, we modified the annotation scheme for predicate-argument relations by considering 'surface predicates' and re-annotated predicate-argument relations in passive and causative cases, thus reducing the risk of inconsistent annotations caused by case alternation.

type	method	Recall	Precision	F-score
DEP	baseline	0.161	0.505	0.244
	proposed (linear)	0.545	0.719	0.620
	proposed (poly-2d)	0.578	0.732	**0.646**
ADJ	baseline	0.143	0.414	0.212
	proposed (linear)	0.011	0.604	0.021
	proposed (poly-2d)	0.285	0.713	**0.407**
PNP	baseline	0.154	0.329	0.210
	proposed (linear)	0.028	0.844	0.053
	proposed (poly-2d)	0.159	0.723	**0.260**

Table 2: Results of subject sharing recognition

Another important point is that in the NAIST Text Corpus, if the antecedent of a zero anaphor is not explicitly written in the corpus, it is simply annotated as 'exophoric', and the subject sharing relations between two predicates whose subject was annotated as exophoric cannot be captured. In contrast, in our cleaning procedure, the annotators additionally annotated such 'exophoric' subject sharing relations to take into account all subject sharing relations in the corpus.

The predicates in the corpus and their dependency relations were detected based on the outputs of a Japanese dependency parser, J.DepP[5] (Yoshinaga and Kitsuregawa, 2009). We obtained 49,313 predicate pairs for the DEP type, 86,728 for the ADJ type, and 27,117 for the PNP types. The numbers of positive instances of DEP, ADJ and PNP types are 9,524, 13,104, and 2,363 respectively. To evaluate the subject sharing recognition, we conducted 5-fold cross-validation using these predicate pairs and measured the performance using recall, precision and F-score.

Note that we also evaluated a baseline method that recognizes subject sharing relations using the results of the state-of-the-art zero anaphora resolution method (Iida and Poesio, 2011) and the subject detector at Step 3 in Section 3.

5.2 Results: subject sharing recognition

We measured the performances of the baseline and our subject sharing recognition method using recall, precision and F-score for each of the three types of subject sharing relations, which are shown in Table 2. The results demonstrate that all of the proposed classifiers solved the problems with high precision. In particular, for each type, the classifier using a polynomial kernel achieved more than 70% precision. We thus used the classifiers with a polynomial kernel for evaluations in Section 6. The results also show that the classifier using a polynomial kernel for each type outperformed the baseline method based on the state-of-the-art zero anaphora resolution method. That is, the direct subject sharing recognition using our classifiers has the potential to lead to a significant improvement in zero anaphora resolution, which we confirm through the experiments in Section 7.

Table 2 also shows that the classifier for the DEP type outperformed those for all of the other types in F-score. The difference reflects the wider variations of the problems in both ADJ and PNP compared to the case of DEP. For example, to recognize the PNP type of subject sharing relation, our classifier needs to appropriately learn the complicated relationship between two predicates and the noun that intervenes between them, a problem we do not need to consider for the DEP type.

6 Experiment 2: intra-sentential zero anaphora resolution between subjects

We next investigate the effect of introducing SSPNs. In this experiment, we evaluated the performance of intra-sentential zero anaphora resolution only between subjects, i.e., the positive instances used in this experiment were limited to the cases where the antecedent of a zero anaphor is the realized subject of a predicate. We evaluated a method of zero anaphora resolution using only SSPNs, where intra-sentential zero anaphora is resolved by the first four steps (Steps 1 to 4) in Section 3. We compared it to a baseline that only used the results of pairwise subject sharing recognition without SSPNs: if the subject sharing relation between two predicates is recognized by our pairwise subject sharing recognizer and a

Table 3: Results of intra-sentential zero anaphora resolution between subjects

single subject is detected by our subject detector for one of the two predicates, then the subject fills the empty subject position of the other predicate. Note that in this baseline method, *transitive* subject propagation through more than one subject sharing relation is not performed. Also, if multiple subjects are detected for a predicate, we used the most likely subject to fill the subject position of the predicate, as in our method.

We conducted 5-fold cross-validation using the modified version of the NAIST Text Corpus presented in Section 5.1. In this evaluation, we used the 8,473 subject zero anaphors that refer to the *subject* antecedents (46% of all the *intra-sentential subject zero anaphora*, in which a subject zero anaphor refers to the antecedent that are not limited to subject) in the corpus. We measured the performance using recall, precision and F-score for each of the three types of subject sharing relations and their combinations. When combining more than one subject sharing recognizer in our method, we construct the SSPN using the subject sharing relations recognized by at least one of those recognizers for transitive subject propagation. On the other hand, in the baseline method, the SSPN was not constructed and zero anaphoric relations were identified using only the outputs of our subject detector and one of those recognizers.

The experimental results shown in Table 3 clearly demonstrate that the method with SSPNs for each type or a combination of the three types consistently outperformed that without SSPNs except for the PNP type. This result suggests that multi-step propagation of subjects through more than one subject sharing relation, as done in SSPNs, is an effective way to propagate a subject to a subject position that cannot be reached by a single subject sharing relation. Our results also show that the F-score is improved by combining different types of subject sharing relations, and the best F-score, 0.456, was achieved when we used all types of relations, i.e., in the case of DEP+ADJ+PNP with SSPNs.

7 Experiment 3: intra-sentential subject zero anaphora resolution

Finally, we evaluate the performance of intra-sentential subject zero anaphora resolution. In the previous section, we evaluated just a part of our method, i.e., from Step 1 to Step 4 presented in Section 3. In this section, we evaluate the whole method, i.e., from Step 1 to Step 5, against 18,324 subject zero anaphors, which are all subject zero anaphors annotated in our modified version of the NAIST Text Corpus. As a baseline, we employed Iida and Poesio (2011)'s method that was tuned for intra-sentential zero anaphora resolution. The baseline method solves the problems by applying only Step 5 in Section 3 to all the predicates.

Our results in Table 4 show that all the methods using either each type or a combination of the three types significantly outperformed the baseline[6]. The best performing method was DEP+PNP, which achieved 0.380 in F-score, which is 3.6%

[6]The significance was tested using McNemar's testing ($p < 0.01$).

	Recall	Precision	F-score
Baseline (Step 5)	0.345	0.344	0.344
+DEP with SSPN	0.388	0.363	0.375
+ADJ with SSPN	0.374	0.347	0.360
+PNP with SSPN	0.351	0.347	0.349
+DEP+ADJ with SSPN	0.399	0.355	0.376
+DEP+PNP with SSPN	0.394	0.366	**0.380**

DEP+PNP with SSPN	0.150	0.749	0.250
ADJ+PNP with SSPN	0.094	0.566	0.161
DEP+ADJ+PNP with SSPN	0.169	0.607	0.264

Table 5: Results of intra-sentential subject zero anaphora resolution (Steps 1 to 4 vs. Step 5)

higher than the baseline. This suggests that our method exploiting subject sharing relations and SSPNs has a positive impact on accuracy of *general* intra-sentential zero anaphora resolution methods because about 84% of zero anaphors of general intra-sentential zero anaphora appear as subject zero anaphor in our corpus.

We also estimate how accurately the method using only the SSPNs evaluated in Section 6 resolves intra-sentential subject zero anaphora in comparison to the baseline method. The results are shown in Table 5 and demonstrate that the performance of all the methods without Step 5 does not reach that of the baseline method in F-score. However, they retain high precision that ranges from 60% to 75%, preserving more than 10% of the recall on the DEP, DEP+ADJ, DEP+PNP and DEP+ADJ+PNP methods. Actually, in some of the potential applications of zero anaphora resolution, such as information extraction, methods with high precision and low recall are preferable to ones with low precision and high recall. Our methods with SSPNs alone might be usable in such applications because of their high precision.

8 Conclusion

In this paper, we introduced a subject shared predicate network (SSPN), which is a network of predicates that are linked by subject sharing relations for resolving typical intra-sentential zero anaphora. In our zero anaphora resolution method, zero anaphoric relations are identified by propagating a subject through subject sharing *paths* in the SSPN. To construct SSPNs, we developed a novel method of pairwise subject sharing recognition using the local contexts that surround two predicates and demonstrated that it can accurately recognize subject sharing relations. We combined our method of intra-sentential zero anaphora resolution with Iida and Poesio (2011)'s method and achieved significantly better F-score than Iida and Poesio (2011)'s method alone.

As future work, we are planning to use commonsense knowledge, such as causality (Hashimoto et al., 2014) and script-like knowledge (Sano et al., 2014), that has been automatically acquired from big data for accurate subject sharing recognition to improve inter-sentential zero anaphora resolution for cases not focused on in this work.

Abstract

For annotation tasks involving independent judgments, probabilistic models have been used to infer ground truth labels from data where a crowd of many annotators labels the same items. Such models have been shown to produce results superior to taking the majority vote, but have not been applied to sequential data. We present two methods to infer ground truth labels from sequential annotations where we assume judgments are not independent, based on the observation that an annotator's segments all tend to be several utterances long. The data consists of crowd labels for annotation of discourse segment boundaries. The new methods extend Hidden Markov Models to relax the independence assumption. The two methods are distinct, so positive labels proposed by both are taken to be ground truth. In addition, results of the models are checked using metrics that test whether an annotator's accuracy relative to a given model remains consistent across different conversations.

1 Introduction

A single, spontaneous, spoken interaction can consist of multiple activities, such as to plan a future event, to complain about a past situation, or to carry out a transaction that might consist of subtasks. Speakers shift from one activity to the next with more or less awareness and explicit demarcation. To treat such conversational activities as a sequence of discrete units is a convenient oversimplification that is often resorted to (Bokaei et al., 2015; Galley et al., 2003; Passonneau and Litman, 1997). Systems that provide automated access to spoken language data often rely on segmentation of spoken discourse into sequential units for summarization (Wang and Cardie, 2012; Dielmann and Renals, 2005) or information retrieval (Ward et al., 2015). Research on the organization of spoken discourse also relies directly or indirectly on identification of such units to detect agreement among participants (Hillard et al., 2003; Somasundaran et al., 2007; Germesin and Wilson, 2009), multiparty meeting action items (Purver et al., 2007), decisions (Fernández et al., 2008), or answers to questions (Sun and Chai, 2007; Bosma, 2005). To support such research, there is a need for annotation methods to segment conversational interaction into sequential, multi-utterance units. We present and compare two methods to derive such data from crowdsourced annotations.

Crowdsourced annotation, where each item is labeled by a crowd of many independent annotators, is becoming more common in natural language processing. Examples include word sense (Bruce and Wiebe, 1999; Snow et al., 2008; Passonneau and Carpenter, 2014), named entities (Finin et al., 2010), and several other tasks in (Snow et al., 2008), including textual entailment. Three advantages to corpus annotation through application of a probabilistic model to crowdsourced labels, rather than reliance on interannotator agreement computed for a small number of trained annotators, are higher quality, lower cost, and a posterior probability for each ground truth label (Sheng et al., 2008; Snow et al., 2008; Passonneau and Carpenter, 2014). The latter serves as a confidence measure, which contrasts with interannotator agreement measures and with majority-voted labels, neither of which provides quality information for the ground truth labels on individual items. Previous work has demonstrated that model estimation of ground truth labels from crowd labels produces results superior to the crowd's majority vote, due to differences among annotators in the quality of their labels (Dawid and Skene, 1979; Snow et al., 2008; Passonneau and Carpenter, 2014). No previous work, however, provides model-based estimation of labels for sequential annotation from crowd labels.

For the discourse segmentation data presented here, annotators were presented with audio files of conversations and corresponding transcriptions into utterances. The annotation task was to identify each utterance that completes a discourse segment spanning one or more utterances, based on the speakers' conversational activities or intentions, as in (Passonneau and Litman, 1997). The annotations from y annotators for a conversation with x utterances can be represented as a $y \times x$ matrix, with cell values $n_{ij} \in \{0, 1\}$ to represent the binary segment boundary label assigned by annotator y_i at utterance x_j. Figure 1 illustrates part of such a matrix. The eight annotators for this conversation are on the y-axis and utterances 80 through 180 are on the

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2190–2200,
Lisbon, Portugal, 17-21 September 2015.

x-axis. Colored bars represent positive labels, and each color represents a distinct annotator. The label distribution shown here is typical of our dataset: an annotator's positive labels are typically separated by several utterances, and annotators agree much more often on non-boundaries than on boundaries. Full consensus on a positive label is rare, but does occur. Here, all eight annotators assigned a positive label at utterance 120, six at utterance 178, and five at utterance 140.

Our work assumes that unobserved true labels condition the annotators' observed labels, and can be modeled as hidden states in a Markov-type process. Because an annotator rarely assigns positive labels for adjacent utterances, we assume that neither the true labels nor the observations are conditionally independent, and therefore are not generated by a simple Markov process. Our first model adapts the Double Chain Markov Model (Berchtold, 1999), designed to account for such cases. We then propose a second model that assumes that each annotator's labels are drawn from a Bernoulli distribution, that annotator performance is a parameter of the model, and that the state transitions are conditioned by an empirical distribution of discourse segment lengths. The two methods are quite distinct. Each thus serves as an evaluation of the other. The segment boundaries proposed by both models include all the majority vote cases, and in addition, cases voted on by a minority of relatively accurate annotators. We take segment boundaries proposed by both methods as ground truth. To further assess the results of the models, we assume that an annotator's accuracies should be consistent across the conversations she annotates.

2 Related Work

Previous work on annotation of discourse into linear segments has used a variety of methods to derive ground truth segment boundaries. In (Passonneau and Litman, 1997), seven annotators annotated narrative monologues for segments based on speaker intention. Agreement levels for ground truth boundaries were based on statistical significance using Cochran's Q. In (Galley et al., 2003), three annotators segmented the ICSI meeting corpus into topical units, and majority agreement was taken as ground truth. A functional segmentation of meetings from the AMI multiparty meeting corpus based on involved participants was segmented by one annotator and finalized by a second annotator (Bokaei et al., 2015). Task-based segmentation of patron-librarian interactions (Passonneau et al., 2011) measured agreement among two annotators using Krippendorff's Alpha at an average of 0.77 (Krippendorff, 1980). The annotation task here mostly closely resembles (Passonneau and Litman, 1997), and uses a similar number of annotators. No prior work, however, applies a probabilistic model to crowd labels for discourse segmentation.

Estimation of ground truth from crowd labels has been applied to many tasks, but is especially useful where judgments are subjective, making ground truth difficult to arrive at. Application areas include disease prevalence estimation (Albert and Dodd, 2008), identification of craters in images of Venus (Smyth et al., 1995), curation of biological data (Rzhetsky et al., 2009), computer vision (Whitehill et al., 2009), patient history (Dawid and Skene, 1979), and clinical reports (2010). Smyth et al. (1995), Rogers et al., and (2010) and Raykar et al. (2010) discuss the advantages of probabilistically annotated corpora over majority vote. Much of this work is motivated by the observation that annotators have different accuracies, and the fact that when annotators have known accuracies it can be shown that a majority of inaccurate annotators can be wrong (Raykar et al., 2010; Passonneau and Carpenter, 2014). Equally important, information from inaccurate annotators informs the model inference. For example, an inaccurate annotator might be biased towards label m whenever the true label is z.

Dawid and Skene (1979) present a joint model of true labels, observed labels, and annotator performance. Perhaps its first application to NLP data was the Bruce and Wiebe (1999) investigation of word sense. It has also been applied to more fine-grained word sense with a direct comparison to trained annotator labels in (Passonneau and Carpenter, 2014). Snow et al. (2008) showed that application of the same model to noisy crowd annotations produced data of equal quality to five distinct published gold standards. Hovy et al. (2013) apply a simple and effective model to identify untrustworthy annotators and test it on the same datasets used in (Snow et al., 2008). As they point out, when ties occur among an even number of annotators, it's necessary to resort to a tie-breaking procedure, e.g., for utterance 155 in Figure 1 where four annotators assign a positive label and four do not.

In experiments on an existing dataset of word sense annotation, Dligach et al. (2010) compare singly annotated data with doubly annotated adjudicated data, using trained annotators. They find that with the same amount of data, machine learning performance improves with the doubly annotated adjudicated data by

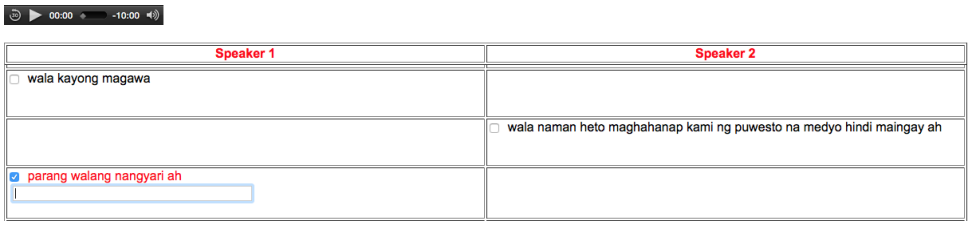

Figure 2: The annotation interface presented the audio control button on the upper left and the transcript below, with a scroll bar (not shown). Utterances from the two speakers are on the right and left sides, respectively. Each utterance had a checkbox; when selected, a textbox appeared to allow annotators to enter their segment descriptions.

a small amount, but that investing in more singly annotated labels leads to greater improvements. Their results on trained annotators, however, would not apply to our use case involving untrained annotators. In previous work, we found the cost per ground truth label of singly annotated data with trained annotators to be more than twice that for multiply annotated data with twenty untrained annotators (Passonneau and Carpenter, 2014). Half that many would have been sufficient for the Dawid & Skene model used there, which would reduce the cost by half again as much.[1]

3 Data and Annotation Task

The data consists of digital recordings and transcripts of fifty telephone calls between family members and friends who were native speakers of Tagalog. These were collected for the Babel program, sponsored by the Intelligence Advanced Research Projects Activity (IARPA). The calls ranged in length from about seven to ten minutes (μ = 9.67 minutes, σ=0.68 minutes). Transcripts provided by IARPA had an average of 364.66 utterances (min=239; max=475; σ=60.80).

The annotations were collected using Amazon Mechanical Turk. The task name and instructions were in English. The instructions were provided through a short video and text. Proficiency in Tagalog was assessed through a vocabulary test. Those who passed the vocabulary test were paid to do an initial annotation so we could ensure they understood the task. The initial task was based on a short Tagalog conversation that had been translated, annotated by a bilingual speaker of Tagalog and English, and verified by Passonneau. Annotators who understood the task and whose labels and descriptions seemed reasonable were admitted into the pool of annotators. A pool of nine annotators completed the qualifications. Each conversation was annotated by at least five annotators. Altogether, annotators assigned 5,567 labels to 164,097 utterances. Annotators' segments had a mean length of 21.85 utterances with a high standard deviation (σ = 19.32).

The interface designed for the annotation task is shown in Figure 2. Through the interface, annotators could read the transcript of a recorded conversation, and could play, pause or stop the audio. Each utterance had a checkbox for assigning a positive label if the annotator judged it to be the end of a segment. As shown, selection of a checkbox opened a text box for the annotator to enter a brief description of the segment. Table 1 in section 8 illustrates the descriptions assigned by six annotators to several segments.

4 Assumptions

Given the many labels from annotators, our goal is to estimate a ground truth label for each utterance position, where the label values represent a binary classification of segment boundaries. Our two models each assume there is a hidden *true* label that conditions an annotator's observed labels, and that can be estimated from the observed labels. How well the estimated ground truth fits the data thus depends on how well the model assumptions accord with the phenomenon of interest. The models do not account for annotator differences in the level of granularity they apply; cf. the contrast between lumpers and splitters in taxonomic classification of the natural world (Branch, 2014). Further, neither model takes linguistic features into account that annotators consider in deciding on segments, such as speaker attitude towards utterance content or speaker role in the conversational activity (Niekrasz and Moore, 2009). We find, however, much agreement between the two models on the proposed segment boundaries, and leave for future work the question of whether more complex models could accoount for differences in granularity or utterance features.

As discussed in section 2, we assume that annotators are not equally accurate, and that a probabilistic model based on the distribution of observed labels can do better than majority vote. Inspired by the type of probabilistic model proposed in (Dawid and Skene, 1979) and extended in (Bruce and Wiebe, 1999; Passonneau and Carpenter, 2014), annotator accuracy is a parameter of our second model. As described in detail in subsequent sections, the two models proposed here rely on distinct assumptions and inference methods. They nevertheless propose many of the same labels. We take each model to provide independent evidence for the ground truth labels, thus the final labels are those voted on by both models.

[1] Twenty labels per item were collected in order to provide tight estimates for item difficulty. This, however, requires a model with a parameter for item difficulty, which had not yet been implemented for this data.

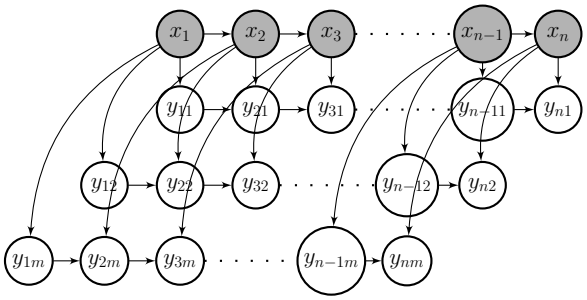

Figure 3: Graphical model of Double Chain Dynamic Hidden Markov Model for a conversation with m annotators and n utterances. The x_t are the hidden states, and the y_{jl} are the observed labels from annotator l at utterance j.

In addition, we assume that annotators' accuracies should be relatively consistent across conversations, and we measure how well each model's results support this assumption. We base the assumption on the observation that the annotation task is the same for all conversations, and an annotator's relative ability to do the task should not change significantly. The annotators all had the same initial training, and did about the same number of conversations. The conversations all had similar conditions of collection, similar participants, and similarly mundane topics and conversational activities that most annotators would be familiar with. The subjects that were discussed included parties, watching tv, siblings, money, jobs, spouses, medical issues, birthdays, and so on.

5 Double Chain Dynamic Hidden Markov Model

The first model we propose combines the Double Chain Markov Model (Berchtold, 1999) and dynamic Bayesian networks (Martinez and Sucar, 2008). The double chaining involves the dependence of observations on immediately prior observations. Figure 3 shows that for all $y_{tl}, t \geq 2$, observation y_{tl} depends on observation $y_{(t-1)l}$. The emission matrix at the first utterance x_1 is thus a 2×2 matrix, while all subsequent emission matrices are $2 \times 2 \times 2$. As in (Martinez and Sucar, 2008), the observed states can be regarded as a composition of m independent chains, where m is the number of annotators for the conversation. Also, the l^{th} annotator's observation at the t^{th} utterance depends not only on the same hidden state x_t, but also on the last observation $y_{(t-1)l}$.

Assume in a conversation, there are m annotators and n utterances. The model $\Theta = \{\pi, \gamma, A, B\}$ can be described as follows:

- a set of hidden states, i.e the true labels: $x_t \in \{0, 1\}$, $t \in \{1, 2, \ldots, n\}$. $x_t = 1$ represents the t^{th} utterance is a true boundary and 0 otherwise;
- a set of observed variables: $y_{tl} \in \{0, 1\}$, $l \in \{1, 2, \ldots, m\}$ annotators, $t \in \{1, 2, \ldots, n\}$ utterances. $y_{tl} = 1$ represents that the l^{th} annotator annotates t^{th} utterance to a true boundary and 0 otherwise;
- Θ is a vector of parameters. To be more specific, the elements are:
  - the probability of the initial hidden state: $\pi_{x_1}, x_1 \in \{0, 1\}$. Note $\pi_0 + \pi_1 = 1$.
  - the probabilities of the initial emission matrix. Note that the initial emission matrix is a 2×2 matrix: $\gamma_l \in \{c_{x_1, y_{1l}}\}$, $x_1, y_{1l} \in \{0, 1\}, l \in \{1, 2, \ldots, m\}$. For annotator l, $c_{x_1, y_{1l}}$ is the probability of emitting from x_1 to y_{1l}.
  - the transition matrix between hidden states, $A \in \{a_{x_{t-1}, x_t}\}$, $x_{t-1}, x_t \in \{0, 1\}$, $t \in \{2, 3, \ldots, n\}$. a_{x_{t-1}, x_t} is the probability of transitioning from x_{t-1} to x_t.
  - the emission matrices, $B_l \in \{b_{x_t, y_{(t-1)l}, y_{tl}}\}$, $x_t, y_{(t-1)l}, y_{tl} \in \{0, 1\}, l \in \{1, 2, \ldots, m\}$, $t \in \{2, 3, \ldots, n\}$. Note that the emission matrix is a $2 \times 2 \times 2$ matrix as each observed state depends on current hidden state as well as the previous observation, i.e., $b_{x_t, y_{(t-1)l}, y_{tl}}$ is the probability of emitting from x_t to y_{tl} and transitioning from $y_{(t-1)l}$ to y_{tl}.

A graphical sketch of the DCD HMM model is shown in Figure 3. The target function $F = P(x, y|\Theta)$ is:

$$F = \pi_{x_1} \prod_{l=1}^{m} c_{x_1, y_{1l}} \prod_{t=2}^{n} a_{x_{t-1}, x_t} \prod_{l=1}^{m} \prod_{t=2}^{n} b_{x_t, y_{(t-1)l}, y_{tl}}$$

We can derive a marginal distribution over y and have the *likelihood* as:

$$L(\Theta) = P(y|\Theta) = \sum_{x} P(x, y|\Theta)$$

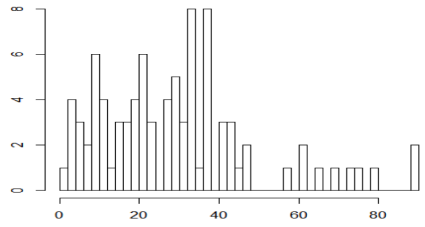
Our goal is to find the parameters (Θ) that maximize the above function. Bayes Net Toolbox for Matlab (Murphy, 2001) is used for the inference. Expectation-Maximization (EM) with Junction Tree inference for the E-step is used for learning the parameters. The Junction Tree Algorithm is a method to calculate marginals by propagation on the graph. It runs as follows: 1) Initialize: Pick a proper root and initialize all variables; 2) Collect: Pass message from each child of a node through separators to the parent node and update the node with collected evidence; 3) Distribute: Send back message to each child of the node through separators and update the child with distributed evidence; 4) Normalize: Normalize cliques connected by a separator so they agree with each other: e.g., for {AB} and {BC}, if we have $\sum_A \{AB\} = \sum_C \{AB\}$, propagation is complete.

After convergence from EM, junction tree propagation is again used for inference, and the model produces

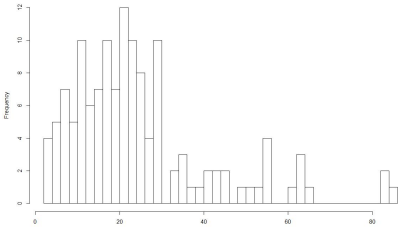
a probability for each ground truth label. We take the label to be positive if the posterior probability is greater than 0.5; as shown in section 8, probabilities tend to be very high or very low.

6 Interval-dependent HMM

The second model, Interval-dependent HMM, imposes a constraint on the state transitions between two positive labels based on the empirical distribution of intervals between observed labels. Initially, we examined known distributions. The Poisson, for example, represents the probability of events in an interval as an average rate. The model based on the Poisson did not perform particularly well. Histograms of interval sizes from different conversations have similar shapes, however, as illustrated in Figure 4. Although more of the probability is towards 20 to 40 utterances in Figure 4a, and between 15 and 35 utterances in Figure 4b, we assume these small differences in the two distributions are mainly due to sampling variation. As discussed in preceding sections, the model we present here assumes that the probability of a true label at time t_i is a function of the interval length $t_i - t_j$, where t_j is the most recent time of a true label. The observed data for all annotators on all conversations provides a set of time intervals to construct the empirical distribution.



(a) First sample conversation



(b) Second sample conversation

Figure 4: Histograms of interval lengths between all observed labels for two conversations.

To assess whether we have sufficient data to reliably construct the empirical distribution, we performed fifty iterations of random divisions of the data into two samples. For each pair of samples, we measured the maximum distance between pairs of cumulative distribution function (CDF) curves, and used the two-sample Kolmogorov-Smirnov test to measure the goodness of fit of the two curves. Figure 5 shows an example comparison of two CDF curves which have a maximum gap

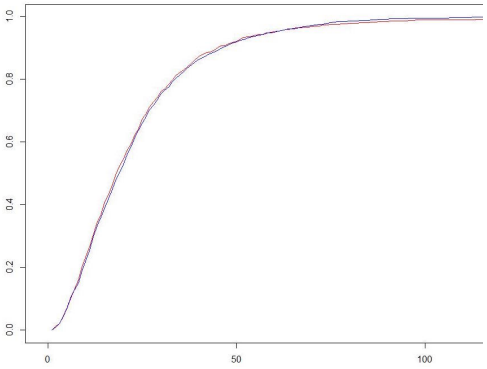


Figure 5: A plot of two CDF curves for a random split of the data. The curves are almost identical; the maximum gap is 0.0175. A two sample K-S test has a p-value of 0.79.

of 0.0175 and a K-S p-value of 0.7866. The mean maximum distance between pairs of curves was 0.014, with a standard deviation of 0.009, both of which are quite small. The p-values for the K-S test ranged from 0.4 to 0.96, which fail to reject the hypothesis that the pairs of samples are from the same distribution. While the two measures are not conclusive evidence that we have sufficient data to construct the empirical distribution, they are supportive. Further, reliance on estimates of the empirical distribution are preferable to a known distribution that does not fit the data, such as the Poisson.

The model can be described as follows:

- the observations $Y_{ij} \in 0, 1, i \in 1, 2, \cdots, N, j \in 1, 2, \cdots, J$;
- the true labels $Z_i \in 0, 1, i \in 1, 2, \cdots, N$;
- the 2×2 annotator performance matrices B_j;
- the initial state probability π

Given N utterances, J annotators, the initial state probability π and four cells in each annotator's performance matrix B_j, where B_{j11} represents the true positives (the probability that given a ground truth positive label, annotator a_j assigns a positive label), B_{j10} represents false negatives, B_{j01} represents false positives, and B_{j00} represents true negatives. $\pi = 1$ is the probability that the first hidden state is a boundary and $\pi = 2$ means it is not. Our objective is to find the parameter vector $\theta = (\pi, B)$ that maximize the likelihood $P(Y|\theta)$, and to use this θ to estimate the true labels Z.

To solve:

$$\underset{\theta}{\text{Argmax}} \log\left[P(Y|\theta)\right] = \underset{\theta}{\text{Argmax}} \log\left[\sum_{Z} P(Y, Z|\theta)\right]$$

we use expectation-maximization (EM).

E step First, we should find the lower bound of our optimization object: $\underset{\theta}{\text{Argmax}} \log\left[\sum_{Z} P(Y, Z|\theta)\right]$; by

Jensen's inequality, we have:

$$\log\left[\sum_Z P(Y,Z|\theta)\right] = \log\left[\sum_Z \frac{P(Y,Z|\theta)}{Q_\theta(Z)} Q_\theta(Z)\right] \geq \sum_Z Q_\theta(Z)\log\left[\frac{P(Y,Z|\theta)}{Q_\theta(Z)}\right]$$

$Q_\theta(Z)$ is a function of θ which satisfies that $\sum_Z Q_\theta(Z) = 1$. The equality holds if and only if

$$\frac{P(Y,Z|\theta)}{Q_\theta(Z)} = c \qquad \text{for all Z}$$

Note that c is a constant. In the E step we need to calculate the Q function to maintain the equality. By straightforward algebra, we get $Q_\theta = P(Z|Y,\theta)$.

M step In this part, we should maximize our lower bound:

$$\underset{\theta}{\text{Argmax}} \sum_Z Q_{\theta^{(n)}}(Z)\log\left[\frac{P(Y,Z|\theta)}{Q_{\theta^{(n)}}(Z)}\right]$$

Since $\log[Q_\theta(Z)]$ is a term not related to θ, $P(Z|Y,\theta) \propto P(Z,Y|\theta)$. Our problem becomes:

$$\underset{\theta}{\text{Argmax}} \sum_Z P(Y,Z|\theta^{(n)})\log[P(Y,Z|\theta)]$$

$\theta^{(n)}$ is the parameter we get from the last iteration, and the Q function is fixed in this M step. We cannot use the forward-backward algorithm to optimize, because the first order Markov property does not hold: $P(Z_i = 1)$ is a function of the last positive label $Z_j = 1$ at time j such that $j < i$, and for all k such that $j < k < i$, $Z_k = 0$. To make use of the Markov property, we rely on a hidden variable U_i to save the interval length between i and j. The hidden parameter space is then expanded to $X_t = (Z_t, U_t)$, where U_t denotes the size of the interval between the current position t_i and the most recent t_j with a positive label. If the true label $Z_{t_i} = 0$, then $U_{t_i} = t_i - t_j$, and if $Z_{t_i} = 1$, then $U_{t_i} = 0$. This gives $t+1$ possible states for each t: the t states for $Z_t = 0$, and one state for $Z_t = 1$.

In this problem, given a length N conversation, there are $N+1$ hidden states at each moment. $X_t = 1$ means $(Z_t = 1, U_t = 0)$, $X_t = 2$ means $(Z_t = 0, U_t = 1)$, $X_t = 3$ means $(Z_t = 0, U_t = 2)$, and so on.

The transition matrix at each t for the cases represented by $P(X_t = k|X_{t-1} = l)$, which is with size $(t+1)\times(t+2)$, will necessarily be very sparse. For example, given an empirical function $f(n) = P(x = n|x \geq n)$, the transition matrix from $t = 4$ to $t = 5$ can be written:

$$\begin{pmatrix} f(1) & 1-f(1) & 0 & 0 & 0 & 0 \\ f(2) & 0 & 1-f(2) & 0 & 0 & 0 \\ f(3) & 0 & 0 & 1-f(3) & 0 & 0 \\ f(4) & 0 & 0 & 0 & 1-f(4) & 0 \\ f(5) & 0 & 0 & 0 & 0 & 1-f(5) \end{pmatrix}$$

After this transformation, X_{t+1} is independent to all X_k for any $k < t$ provided that X_t is given. With X as the new hidden state, we can estimate the HMM parameter by adding some constraints. Replacing the Z in the object function with X, we can rewrite the object function as:

$$\begin{aligned}
&\sum_X P(Y,X|\theta^{(n)})\log[P(Y,X|\theta)] \\
=&\sum_X P(Y,X|\theta^{(n)})\left[\text{Log}P(X_1) + \sum_{t=1}^{N-1}\log P(X_{t+1}|X_t) + \sum_{t=1}^{N}\log P(Y_t|X_t)\right] \\
=&\sum_X P(Y,X|\theta^{(n)})\left[\log[\pi_{X_1}] + \sum_{t=1}^{N-1}\log\left[A_{X_t,X_{t+1}}\right] + \sum_{t=1}^{N}\log[B_{X_t,Y_t}]\right]
\end{aligned}$$

The object is split into three independent parts: the first part is for the initial state distribution π, the second for the transition probability matrix A, and the third is the emission matrix B. For the first term, because in the moment $t = 1$, X_t can just be 1 or 2, we have the optimization problem:

$$\begin{aligned}
&\underset{\pi}{\text{Argmax}} \sum_{i=1}^{2} P(Y, X_1 = i|\theta^{(n)})\log[\pi_i] \\
&\text{s.t} \qquad \pi_1 + \pi_2 = 1 \\
&\qquad \pi_3 = \pi_4 = ... = \pi_{N+1} = 0
\end{aligned}$$

We can easily solve this optimization problem by the Lagrange multiplier: we have the update formula:

$$\pi_1^{(n+1)} = P(X_1 = 1|Y,\theta^{(n)})$$

$$\pi_2^{(n+1)} = P(X_1 = 2|Y,\theta^{(n)})$$

$$\pi_i^{(n+1)} = 0 \qquad \text{for} \quad i > 2$$

Both can be solved by the traditional forward-backward algorithm after this transformation. $\theta^{(n)}$ is the parameter set we get from the last iteration.

The second term can be ignored, since we use the known empirical distribution as the transition matrix; it is therefore a constant term.

The third term can be rewritten as:

$$\begin{aligned}
&\sum_{t=1}^{N} P(Y,X|\theta^{(n)})\log[B_{X_t,Y_t}] \\
=&\sum_{t=1}^{N}\sum_{i=1}^{N+1}\sum_{j=1}^{J}\sum_{k=0}^{1} I(Y_{t,j} = k)P(X_t = i, Y|\theta^{(n)}) \\
&\log[B_{j,i,k}]
\end{aligned}$$

So our problem is:

$$\underset{B}{\text{Argmax}} \sum_{t=1}^{N} \sum_{j=1}^{J} \sum_{i=1}^{N+1} \sum_{k=0}^{1} I(Y_{t,j} = k)$$
$$P(X_t = i, Y|\theta^{(n)}) \log B_{j,i,k}$$
$$\text{s.t} \quad \sum_{k=0}^{1} B_{j,i,k} = 1 \qquad \text{For all i, j}$$
$$B_{j,i_1,k} = B_{j,i_2,k} \qquad \text{For all j, k and } i_1, i_2 \geq 2$$

The second constraint here means that, if this is not a true boundary, a given annotator j will have the same emission matrix no matter what U is. This optimization can also be solved by Lagrange multiplier, where the update formula is as follows. For $i = 1$:

$$B_{j,i=1,k}^{(n+1)} = \frac{\sum_{t=1}^{N} P(Y, Z_t = 1|\theta^{(n)}) I(Y_{t,j} = k)}{\sum_{t=1}^{N} P(Y, Z_t = 1|\theta^{(n)})}$$

For any $i \neq 1$, the matrix B is the same given j:

$$B_{j,i\neq 1,k}^{(n+1)} = \frac{\sum_{t=1}^{N} P(Y, Z_t \neq 1|\theta^{(n)}) I(Y_{t,j} = k)}{\sum_{t=1}^{N} P(Y, Z_t \neq 1|\theta^{(n)})}$$

Now we have the update function for θ. After convergence, we will have π and B. It is straightforward to transfer these parameters for the new space to our original HMM problem. This completes the M step.

7 Model Checking

No ground truth labels are available to evaluate our models. We check the model results, however, in three ways. One, we consider labels proposed by both models to be stronger evidence than labels proposed only by one. Two, we measure the consistency of annotators on the assumption that the same annotator should have relatively consistent performance across conversations, relative to the same model. The third way we can check the models is to examine the descriptive labels that annotators assign to segments to determine whether descriptions for the same segment from different annotators are consistent. In this section, we describe the two consistency metrics.

We measure how consistently the label quality from annotator a_i surpasses that for $a_j, i \neq j$, for all pairs of annotators using a metric to measure inconsistency and strength of inconsistency (I&SI) (de Vries, 1998). We also apply a variant we refer to as Directional Consistency (DC), which takes into account how often annotator a_i surpasses annotator a_j. To measure annotators' performance relative to the inferred true labels, we use F-score, the harmonic mean of recall and precision. Recall is the ratio of true positives to the sum of true positives and false negatives; precision is the ratio of true positives to the sum of true positives and false positives. A square matrix of annotator *dominance* is first constructed to give a count of how many conversations there are where a_i has a higher F measure than $a_j, i \neq j$. A linear dominance ordering $>$ of all annotators has an inconsistency score I that is incremented by 1 for each pair of annotators where $a_i > a_j$ in the linear ordering and $(a_i, a_j) \neq (a_j, a_i)$ in the matrix. I is minimal if no other ordering has fewer inconsistencies. The strength of the inconsistency IS for a linear ordering is incremented by the difference in rank between a_i and a_j for every inconsistent pair in the linear ordering. The I&SI method finds an ordering that minimizes I and SI. To check the results of our models, we compare the I&SI value of the dominance matrix associated with the model results against a simulated random matrix. If the model results are significantly more consistent than the simulation, the model produces a consistent ranking of annotators.

We propose a Directional Consistency index ($DC \in [0, 1]$) which considers the number of times a_i has a higher F measure than a_j (Leiva et al., 2008). Where X is the dominance matrix:

$$DC = \frac{\sum_{i=1}^{n} \sum_{j=i+1}^{n} |x_{ij} - x_{ji}|}{N}$$
$$N = \sum_{i=1}^{n} \sum_{j=1, j\neq i}^{n} x_{ij}$$

DC values closer to zero indicate less consistency in differences among annotators, and the converse for values closer to 1. High DC values for the results of our models thus indicates better performance of the model in predicting consistent annotator behavior.

8 Results and Model Checking

The results consist of the true labels assigned by each model to each conversation, and estimates of the annotators' performance relative to the model's ground truth labels. Note that as the conversation is not a parameter of either model, after estimation of the empirical distribution of segment lengths, the data for each conversation is treated separately.

To provide a concrete illustration, we first review the data for a typical conversation. Table 1 presents the segments derived from both models for an extract from conversation 945, which had six annotators, and the annotator's segment descriptions. We selected a conversation with an even number of annotators to illustrate that an arbitrary choice must be made, given a 50/50 vote split. We take ties as true positives to provide a more conservative baseline. We first discuss this example conversation in detail to explain the kinds of cases where the models differ from majority voting. Then we present summary results on the fifty conversations for majority voting compared with the two models.

In Table 1 a description at n gives the annotator's interpretation of the kind of conversational activity that ends with n. When annotators agree on a positive label that ends a segment, they might not agree on the utterance that starts the segment, so their descriptions will not necessarily be about the same segments. From

Utt	Description
191	C: S1 and S2 are talking about the status of their children's studies I: S1 and S2 are talking about their children's education
216	A: S1 and S2 spoke about their children's studies E: S2 then shared that he's going to Laguna-Muntinlupa tomorrow. S1 said that S2 has many orders. S2 shared that he's striving hard in order for her kids to graduate college. . . . The two laughed at each other about S1's children not getting traits from S1 I: S1 and S2 are talking about who their children took after
217	C: S1 and S2 are joking about the traits their children got from them D: They are talking about S1s daughter that she is good at academics and that she got her being smart from her mom and nothing from S1. S1 said even if she got nothing from him as long as she will just study hard its okay
241	A: S1 and S2 spoke about their time of sleeeping C: S1 and S2 tell each other what time they usually go to sleep D: They are talking about the time that they go to sleep. S2 said sometimes by ten, eleven or twelve midnight. S1 said sometimes he goes out one in the morning. Sometimes he goes to sleep at ten or eleven in the evening too

Table 1: Annotator descriptions for conversation 945 for a sequence of four segment boundaries hypothesized by both models. A description from annotator a_i at utterance n indicates a_i assigned a positive label, and gives the annotator's interpretation of the kind of interaction that ended at utterance n. Underlined utterance numbers indicate cases where at least six annotators assigned a positive label.

the table, however, we see a a pattern that is consistent for most of the data: abstracting over the descriptions gives a good indication of what's going on in the segments that are defined by the positive labels assigned by both models. The descriptions from C and I at 191, for example, describe the first segment as the speakers talking about their children's education. A's similar description at 216 indicates that A ended the segment later than C and I. E and I describe the second segment as being about the children, including who they take after. C's description about who the children take after occurs at a later utterance. The third segment goes into detail about the children's traits, and the fourth is about what time the speakers go to sleep.

Across all fifty conversations, ID HMM assigns more positive labels than the majority, and DCD HMM assigns more than ID HMM. Totals for each labeling

Method	Total
Majority	683
ID HMM	991
DCD HMM	1324

Table 2: Total positive labels assigned by each method.

Utt	Annotators	DCD HMM	ID HMM
11	2 (A,I)	1.00	0.99
42	3 (B,E,I)	1.00	1.00
43	3 (A,C,D)	1.00	1.00
67	6 (A,B,C,D,E,I)	1.00	1.00
114	2 (A,C)	1.00	0.98
126	2 (D,E)	1.00	1.00
127	1 (C)	**0.63**	*0.02*
144	2 (A,D)	1.00	0.98
147	2 (C,I)	0.90	0.65
191	2 (C,I)	0.90	0.73
216	3 (A,E,I)	1.00	1.00
217	2 (C,D)	1.00	0.66
241	3 (A,C,D)	1.00	1.00
276	3 (B,C,D)	1.00	1.00
282	1 (A)	**1.00**	*0.29*
300	*5* (A,B,D,E,I)	1.00	1.00
356	2 (C,I)	**0.98**	*0.27*
357	4 (A,B,D,E)	1.00	1.00

Table 3: Comparison of positive predictions from majority voting (N=8, underlined; ties are taken as positive), DDC HMM (N=18), and the ID HMM (N=15) for conversation 945. Probabilities in bold are for boundaries proposed by only one model; italics are for probabilities below the 0.5 threshold to be considered true boundaries.

method are in Table 2. Wherever the majority vote predicts a true label, both models always do. If ID HMM posits a boundary at an utterance, DCD HMM also does, but DCD HMM predicts additional ones. Because all the ID HMM labels are also identified by DCD HMM, these are the final labels we propose.

Table 3 shows the positive labels predicted for conversation 945 by majority vote, and by our two models. Column one is the utterance number, and again, underlining indicates cases where the voted baseline would assign a positive label. Column two lists the annotators who assigned a positive label, and columns three and four show the posteriors assigned by the two models; for all utterances not listed in the table, the posteriors are below 0.5. Low posteriors for ID HMM where DCD HMM proposed a boundary are in italics.

Ann	Maj	DCD HMM	ID HMM
A	0.68	0.71	0.68
B	0.57	0.36	0.38
C	0.40	0.63	0.46
D	0.59	0.56	0.55
E	0.73	0.50	0.52
I	0.43	0.55	0.49

Table 4: F-measure for annotators in conversation 945 for majority vote labels and both models; recall that the true labels for each model are different, and that DCD HMM hypothesizes more true labels than ID HMM.

For each model, the annotator can be ranked by the F-scores relative to the model predictions. When one of the models agrees with a minority of annotators,

Model	I&SI	DC
Majority	I=1, SI=3, p=0.008	p=0.0600
DCD HMM	I=2, SI=5, p=0.02	p=0.0014
ID HMM	I=0, SI=0, p=0	p=0.0001

Table 5: Consistency of annotators

the minority consists of the annotators considered by the model to have higher performance, as given by F-measure. The three sets of F-scores for the six annotators in 945 are shown in Table 4. Annotator performance given the two models is very similar; the Pearson correlation is 0.80. F-scores based on the majority baseline, however, do not correlate well with DCD ($\rho = -0.5$) or ID ($\rho = 0.49$). In eight cases where DCD posits a true label for conversation 945, and only 2 annotators voted positive, the pair never includes B, the least accurate annotator by DCD (see Table 4), and always includes one of the top three annotators (A,C,D). In the two cases where only one annotator voted positive, it was A or C, one of the two top DCD HMM annotators. Both models consider A to be the best annotator. C is relatively good in the DCD HMM model and relatively poor in the ID HMM model.

I&SI tests whether there exists a linear ordering of the annotators such that their relative performance across conversations is consistent. DC tests whether an ordering $a_i > a_j$ is based on relatively more frequent dominance of a_i over a_j. Table 5 shows that majority vote and the two models produce results that lead to high I&SI consistency, based on the statistically significant p-values. The majority vote p-value for DC, however, is not statistically significant. By the more stringent DC measure, the labels from the two HMM variants are superior to the majority vote labels.

The list of descriptions from annotators at utterance n represents the semantics of the hypothesized segment ending at n. Semantic consistency for a given segment serves as another check on the output of the model, because the human descriptions of the activity within the segment do not conflict. In general, this is the case for both models, but less so for DCD HMM. For conversation 945 illustrated in Table 3, there are three positive labels proposed by DCD HMM that are missing from the ID HMM predictions. These are at 127 where only annotator C had a positive label, 282 where only annotator A had a positive label, and 356 where annotators C and I had a positive label. Annotators B, C and D, for example, describe a segment ending at utterance 276 as the speakers discussing Facebook, whereas annotator A locates the end of the Facebook segment at utterance 282. The DCD HMM model posits a true label at 276 but not at 282, in contast to ID HMM.

9 Discussion

The two models for estimating ground truth labels from crowd labels advance previous work on probabilistic models for annotation by handling sequential data. We have argued that for our data, the Markov assumption must be relaxed. The two models handle this in distinct ways. The first model assumes that each state can be decomposed into multiple aspects, and that states and observations are conditionally dependent on the previous point in time. The second model builds in a parameter for annotator performance, as in previous work that adopts the Dawid and Skene (1979) model. Both assign more ground truth labels than majority voting, and avoid the problem with the majority vote method of ties where there are an even number of annotators. The results of the two models are very similar, but DCD HMM hypothesizes more boundaries, and therefore ranks some annotators differently.

Here we check the models by comparing them to each other, through analysis of each annotator's consistency across multiple conversations, and through inspection of the semantics of annotators' descriptions. Our future work will use the models generatively to predict a subset of the data for a given annotator, based on a model fit to all but the held out data. To do so, we would extend the models with an additional parameter for the conversation, to account for the observation that while all conversations seem to fit the same empirical distribution, there are differences across conversations.

10 Conclusion

Annotation and machine learning of discourse segmentation covers several types of units, including topical segments (Galley et al., 2003), meeting units in which action items are identified or decisions made (Purver et al., 2007; Fernández et al., 2008), transaction subtasks for ordering library books (Passonneau et al., 2014), or speaker involvement (Bokaei et al., 2015). This work relies on manual transcription, and draws on many sources of knowledge for machine learned models, including turn-taking, prosody, and linguistic features. The segmentation annotation can be linear (Galley et al., 2003; Bokaei et al., 2015; Passonneau and Litman, 1997; Passonneau et al., 2014) or hierarchical (Purver et al., 2007; Fernández et al., 2008; Passonneau et al., 2011). The differences in methods and results across this body of work, points to a need for more datasets for research on the organization of discourse into activity units. The results presented here support this research agenda by providing a reliable and cost-effective method to estimate ground truth discourse segment labels from crowd labels.

Acknowledgments

The authors thank Bob Carpenter for discussions during the early stages of the data analysis, and for helpful feedback on the paper. We thank the IARPA Babel program manager, Mary Harper, for giving us permission to annotate the Babel data.

Abstract

This paper presents a detailed comparative framework for assessing the usefulness of unsupervised word representations for identifying so-called implicit discourse relations. Specifically, we compare standard one-hot word pair representations against low-dimensional ones based on Brown clusters and word embeddings. We also consider various word vector combination schemes for deriving discourse segment representations from word vectors, and compare representations based either on all words or limited to head words. Our main finding is that denser representations systematically outperform sparser ones and give state-of-the-art performance or above without the need for additional hand-crafted features.

1 Introduction

Identifying discourse relations is an important task, either to build a discourse parser or to help other NLP systems such as text summarization or question-answering. This task is relatively straightforward when a discourse connective, such as but or because, is used (Pitler and Nenkova, 2009). The identification becomes much more challenging when such an overt marker is lacking, and the relation needs to be inferred through other means. In (1), the presence of the pair of verbs (rose,tumbled) triggers a *Contrast* relation. Such relations are extremely pervasive in real text corpora: they account for about 50% of all relations in the Penn Discourse Treebank (Prasad et al., 2008).

(1) [Quarterly revenue **rose** 4.5%, to $2.3 billion from $2.2 billion]$_{arg1}$ [For the year, net income **tumbled** 61% to $86 million, or $1.55 a share]$_{arg2}$

Automatically classifying implicit relations is difficult in large part because it relies on numerous factors, ranging from syntax, and tense and aspect, to lexical semantics and even world knowledge (Asher and Lascarides, 2003). Consequently, a lot of previous work on this problem have attempted to incorporate some of these information into their systems. These assume the existence of syntactic parsers and lexical databases of various kinds, which are available but for a few languages, and they often involve heavy feature engineering (Pitler et al., 2009; Park and Cardie, 2012). While acknowledging this knowledge bottleneck, this paper focuses on trying to predict implicit relations based on easily accessible lexical features, targeting in particular simple word-based features, such as pairs like (rose,tumbled) in (1).

Most previous studies on implicit relations, going back to (Marcu and Echihabi, 2002), incorporate word-based information in the form of word pair features defined across the pair of text segments to be related. Such word pairs are often encoded in a *one-hot* representation, in which each possible word pair corresponds to a single component of a very high-dimensional vector. From a machine learning perspective, this type of sparse representation makes parameter estimation extremely difficult and prone to overfitting. It also makes it difficult to achieve any interesting semantic generalization. To see this, consider the distance (e.g., Euclidean or cosine) induced by such representation. Assuming for simplicity that one characterizes each pair of discourse segments via their main verbs, the corresponding one-hot encoding for the pair (rose,tumbled) would be at equal distance from the synonymic pair (went_up,lost) and the antonymic pair (went_down,gained), as all three vectors are orthogonal to each others.

Various attempts have been made at reducing sparsity of lexical features. Recently, Ruther-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2201–2211,
Lisbon, Portugal, 17-21 September 2015.

ford and Xue (2014) proposed to use Brown clusters (Brown et al., 1992) for this task, in effect replacing each token by its cluster binary code. These authors conclude that these denser, cluster-derived representations significantly improve the identification of implicit discourse relations and report the best performance to date using also additional features. Unfortunately, their claim is somewhat weakened by the fact that they fail to compare the use of their cluster word pairs against other types of word representations, including one-hot encodings of word pairs or other low-dimensional word representations. This work also leaves other important questions open. In particular, it is unclear whether all word pairs constructed over the two discourse segments are truly informative and should be included in the model. Given that word embeddings capture latent syntactic and semantic information, yet another important question is to which extent the use of these representations dispenses us from using additional hand-crafted syntactic and semantic features.

This paper fills these gaps and significantly extends the work of (Rutherford and Xue, 2014) by explicitly comparing various types of word representations and vector composition methods. Specifically, we investigate three well-known word embeddings, namely Collobert and Weston (Collobert and Weston, 2008), hierarchical log-bilinear model (Mnih and Hinton, 2007) and Hellinger Principal Component Analysis (Lebret and Collobert, 2014), in addition to Brown cluster-based and standard one-hot representations. All these word representations are publicly available for English and can be easily acquired for other languages just using raw text data, thus alleviating the need for hand-crafted lexical databases. This makes our approach easily extendable to resource-poor languages. In addition, we also investigate the issue of which specific words need to be fed to the model, by comparing using just pairs of verbs against all pairs of words, and how word representations should be combined over discourse segments, comparing component-wise product against simple vector concatenation.

2 Word Representations

A word representation associates a word to a mathematical object, typically a high-dimensional vector in $\{0,1\}^{|\mathcal{V}|}$ or $\mathbb{R}^{|\mathcal{V}|}$, where $\mathcal{V}$ is a base vocabulary. Each dimension of this vector corresponds to a feature which might have a syntactic or semantic interpretation. In the following, we review different types of word representations used in NLP.

2.1 One-hot Word Representations

Given a particular NLP problem, the crudest and yet most common type of word representation consists in mapping each word into a one-hot vector, wherein each observed word corresponds to a distinct vector component. More formally, let $\mathcal{V}$ denote the set of all words found in the texts and w a particular word in $\mathcal{V}$. The one-hot representation of w is the d-dimensional indicator vector, noted $\mathbb{1}_w$, such that $d = |\mathcal{V}|$: that is, all of this vector's components are 0's but for one 1 component corresponding to the word's index in $\mathcal{V}$. It is easy to see that this representation is extremely sparse, and makes learning difficult as it mechanically blows up the parameter space of the model.

2.2 Clustering-based Word Representations

An alternative to these very sparse representations consists in learning word representations in an unsupervised fashion using clustering. An example of this approach are the so-called *Brown clusters* induced using the Brown hierarchical clustering algorithm (Brown et al., 1992) with the goal of maximizing the mutual information of bigrams. As a result, each word is associated to a binary code corresponding to the cluster it belongs to. Given the hierarchical nature of the algorithm, one can create word classes of different levels of granularity, corresponding to bit codes of different sizes. The less clusters, the less fine-grained the distinctions between words but the less sparsity. Note that this kind of representations also yields one-hot encodings but on a much smaller vocabulary size (i.e., the number of clusters). Brown clusters have been used for several NLP tasks, including NER, chunking (Turian et al., 2010), parsing (Koo et al., 2008) and implicit discourse relation classification (Rutherford and Xue, 2014).

2.3 Dense Real-Valued Representations

Another approach to induce word representations from raw text is to learn *distributed* word representations (aka word embeddings), which are dense, low-dimensional, and real-valued vectors. These are typically learned using neural language models (Bengio et al., 2003). Each dimension corresponding to a latent feature of the word that captures paradigmatic information. An example of such

embeddings are the so-called Collobert and Weston embeddings (Collobert and Weston, 2008). The embeddings are learned discriminatively by minimizing a loss between the current n-gram and a corrupted n-gram whose last word comes from the same vocabulary but is different from the last word of the original n-gram. Another example are the Hierarchical log-bilinear embeddings (Mnih and Hinton, 2007) induced using a probabilistic and linear neural model, with a hierarchical principle used to speed up the model evaluation. The embeddings are obtained by concatenating the embeddings of the $n-1$ words of a n-gram and learning the embedding of the last word.

A final approach is based on the assumption that words occurring in similar contexts tend to have similar meanings. Building word *distributional* representations is done by computing the raw cooccurrence frequencies between each word and the $|\mathcal{D}|$ words that serve as context, with $\mathcal{D}$ generally smaller than the overall vocabulary, then applying some transformation (e.g. TF-IDF). As $|\mathcal{D}|$ is generally too large to form a tractable representation, a dimensionality reduction algorithm is used to end up with $p \ll |\mathcal{D}|$ dimensions. Like for distributed representations, we end up with a dense low-dimensional real-valued vector for each word. A recent example of such approach is the Hellinger PCA embeddings of (Lebret and Collobert, 2014) which were built using Principal Component Analysis based on Hellinger distance as dimensionality reduction algorithm. An important appeal of these representations is that they are much less time-consuming to train than the ones based on neural language models while allowing similar performance (Lebret and Collobert, 2014).

3 Segment Pair Representations

We now turn to the issue of combining the word representations as described in section 2 into composite vectors corresponding to implicit discourse classification instances. Schematically, the representations employed for pairs of discourse segments differ along three main dimensions. First, we compare the use of a single word per segment (roughly, the two main verbs) against that of all the words contained in the two segments. Second, we compare the use of sparse (i.e., one-hot) vs. dense representations for words. As discussed, Brown cluster bit representations are a special (i.e., low-dimensional) version of one-hot encoding. Third, we use two different types of combinations of word vectors to yield segment vector representations: concatenation and Kronecker product. The proposed framework is therefore much more general than the one given in previous work such as (Rutherford and Xue, 2014).

3.1 Notation

Our classification inputs are pairs of text segments, the two arguments of the relation to be predicted. Let $S_1 = \{w_{1_1}, \ldots, w_{1_n}\}$ denote the n words that make up the first segment and $S_2 = \{w_{2_1}, \ldots, w_{2_m}\}$ the m words in the second segment. That is, we regard segments as bags of words. Let $\mathcal{V}$ again denote the word vocabulary, that is the set of all words found in the segments. Sometimes, we will find it useful to refer to a particular subset of $\mathcal{V}$. Let $\mathrm{head}(\cdot)$ refer to the function that extracts the head word of segment S,[1] and $\mathcal{V}_h \subseteq \mathcal{V}$ the set of head words. As our goal is to compare different feature representations, we define Φ as a generic feature function mapping pairs of segments to a d-dimensional real vector:

$$\begin{aligned}\Phi: \ & \mathcal{V}^n \times \mathcal{V}^m \rightarrow \mathbb{R}^d \\ & (S_1, S_2) \mapsto \Phi(S_1, S_2)\end{aligned}$$

The goal of learning is to acquire for each relation a linear classification function $f_{\boldsymbol{w}}(\cdot)$, parametrized by $\boldsymbol{w} \in \mathbb{R}^d$, mapping $\Phi(S_1, S_2)$ into $\{-1, +1\}$.

Recall that $\mathbb{1}_w$ refers to the d-dimensional one-hot encoding for word $w \in \mathcal{V}$. Let us also denote by $\oplus$ and $\otimes$ the vector concatenation operator and the Kronecker product, respectively. Note that doing a Kronecker product on two vectors $\boldsymbol{u} \in \mathbb{R}^m$ and $\boldsymbol{v} \in \mathbb{R}^n$ is equivalent to doing the outer product $\boldsymbol{u}\boldsymbol{v}^\top \in \mathbb{R}^{m \times n}$. Finally, the $\mathrm{vec}(\cdot)$ operator converts a $m \times n$ matrix into an $mn \times 1$ column vector by stacking its columns.

3.2 Representations based on head words

One of the simplest representation one can construct for a pair of segments (S_1, S_2) is to consider only their head words: $h_1 = \mathrm{head}(S_1)$ and $h_2 = \mathrm{head}(S_2)$. In this simple scenario, two main questions that remain are: (i) which vector representations do we use for h_1 and h_2, and (ii) how do we combine these representations. An important criterion for word vector combination is that they retain text ordering information between text segments which really matters for this task.

[1] Head extraction will be detailed in section 4.1.

Thus, inverting the order between two main verbs (e.g., push and fall) will often lead to distinct discourse relation being inferred, as some relations are asymmetric (e.g., *Result* or *Explanation*).

One-hot representations Starting again with the simplest case, one can use the one-hot encodings corresponding to the two head words, $\mathbb{1}_{h_1}$ and $\mathbb{1}_{h_2}$ respectively, and combine them using either concatenation or product, leading to our two first feature mappings:

$$\Phi_{h,\mathbb{1},\oplus}(S_1, S_2) = \mathbb{1}_{h_1} \oplus \mathbb{1}_{h_2}$$
$$\Phi_{h,\mathbb{1},\otimes}(S_1, S_2) = \text{vec}(\mathbb{1}_{h_1} \otimes \mathbb{1}_{h_2})$$

Note that $\Phi_{h,\mathbb{1},\oplus}(S_1, S_2)$ lives in $\{0,1\}^{2|\mathcal{V}_h|}$ and $\Phi_{h,\mathbb{1},\otimes}$ in $\{0,1\}^{|\mathcal{V}_h|^2}$. The latter representation amounts to assigning one 1 component for each pair of words in $\mathcal{V}_h \times \mathcal{V}_h$, and is the sparsest representation one can construct from head words alone. In some sense, it is also the most expressive in that we learn one parameter for each word pair, hence capturing interaction between words across segments. By contrast, $\Phi_{h,\mathbb{1},\oplus}(S_1, S_2)$ doesn't explicitly model word interaction across discourse segments, treating each word in a given segment (left or right) as a separate dimension.

Dense representations Alternatively, one can represent head words through their real low-dimensional embeddings. Let $\boldsymbol{M}$ denote a $n \times p$ real matrix, wherein the i^{th} row corresponds to the p-dimensional embedding of the i^{th} word of $\mathcal{V}_h$, with $p \ll |\mathcal{V}_h|$.[2] Using this notation, one can derive the word embeddings of the head words h_1 and h_2 from their one-hot representations using simple matrix multiplication: $\boldsymbol{M}^\top \mathbb{1}_{h_1}$ and $\boldsymbol{M}^\top \mathbb{1}_{h_2}$, respectively. Concatenation and product yield two new feature mappings, respectively:

$$\Phi_{h,\boldsymbol{M},\oplus}(S_1, S_2) = \boldsymbol{M}^\top \mathbb{1}_{h_1} \oplus \boldsymbol{M}^\top \mathbb{1}_{h_2}$$
$$\Phi_{h,\boldsymbol{M},\otimes}(S_1, S_2) = \text{vec}(\boldsymbol{M}^\top \mathbb{1}_{h_1} \otimes \boldsymbol{M}^\top \mathbb{1}_{h_2})$$

These new representations live in a much lower dimensional real spaces: $\Phi_{h,\boldsymbol{M},\oplus}(S_1, S_2)$ lives in $\mathbb{R}^{2p}$ and $\Phi_{h,\boldsymbol{M},\otimes}(S_1, S_2)$ in $\mathbb{R}^{p^2}$.

3.3 Representations based on all words

The various segment-pair representations that we derived from pairs of head words can be generalized to the case in which we keep all the words in each segment. The additional issue in this context is in the combination of the different word vector representations within and across the two segments, and that of normalizing the segment vectors thus obtained. For simplicity, we assume that the representation for each segment is computed by summing over the pairs of words vectors composing the segments.

One-hot representations Following this approach and recalling that S_1 contains n words, while S_2 has m words, one can construct one-hot encodings for segment pairs as follows:

$$\Phi_{all,\mathbb{1},\oplus}(S_1, S_2) = \sum_i^n \sum_j^m \mathbb{1}_{w_{1_i}} \oplus \mathbb{1}_{w_{2_j}}$$
$$\Phi_{all,\mathbb{1},\otimes}(S_1, S_2) = \sum_i^n \sum_j^m \text{vec}(\mathbb{1}_{w_{1_i}} \otimes \mathbb{1}_{w_{2_j}})$$

If used without any type of frequency thresholding, these mappings result in very high-dimensional feature representations living in $\mathbb{Z}_{\geq 0}^{2|\mathcal{V}|}$ and $\mathbb{Z}_{\geq 0}^{|\mathcal{V}|^2}$, respectively. Interestingly, note that the feature mapping $\Phi_{all,\mathbb{1},\otimes}(S_1, S_2)$ corresponds to the standard segment-pair representation used in many previous work, as (Marcu and Echihabi, 2002; Park and Cardie, 2012).

Dense representations We can apply the same composition operations to denser representations, yielding two new mappings:

$$\Phi_{all,\boldsymbol{M},\oplus}(S_1, S_2) = \sum_{i,j}^{n,m} \boldsymbol{M}^\top \mathbb{1}_{w_{1_i}} \oplus \boldsymbol{M}^\top \mathbb{1}_{w_{2_j}}$$
$$\Phi_{all,\boldsymbol{M},\otimes}(S_1, S_2) = \sum_{i,j}^{n,m} \text{vec}(\boldsymbol{M}^\top \mathbb{1}_{w_{1_i}} \otimes \boldsymbol{M}^\top \mathbb{1}_{w_{2_j}})$$

Like their head word versions, these vectors live in $\mathbb{R}^{2p}$ and $\mathbb{R}^{p^2}$, respectively.

Vector Normalization Normalization is important as unnormalized composite vectors are sensitive to the number of words present in the segments. The first type of normalization we consider is to simply convert our vector representation into vectors on the unit hypersphere: this is achieved by dividing each vector by its L_2 norm.

Another type of normalization is obtained by inverting the order of summation and concatenation in the construction of composite vectors. Instead

[2] For now, we assume that $n = \mathcal{V}_h$ which is unrealistic. See section 4.1 for a discussion of unknown words.

of summing over concatenated pairs of word vectors across the two segments, one can first sum individual word vectors within each segment, then concatenate the two segment vectors. One can thus use mapping $\Phi'_{all,\mathbb{1},\oplus}$ in lieu of $\Phi_{all,\mathbb{1},\oplus}$:

$$\Phi'_{all,\mathbb{1},\oplus}(S_1, S_2) = \sum_i^n \mathbb{1}_{w_{1_i}} \oplus \sum_j^m \mathbb{1}_{w_{2_j}}$$

It should be clear that $\Phi'_{all,\mathbb{1},\oplus}$ provides a normalized version of $\Phi_{all,\mathbb{1},\oplus}$ as this latter mapping amounts to weighted versions of the former:

$$\Phi_{all,\mathbb{1},\oplus}(S_1, S_2) = m \sum_i^n \mathbb{1}_{w_{1_i}} \oplus n \sum_j^m \mathbb{1}_{w_{2_j}}$$

4 Experiment Settings

Through the comparative framework described in section 3, our objective is to assess the usefulness of different vectorial representations for pairs of discourse segments. Specifically, we want to establish whether dense representations are better than sparse ones, and whether certain word pairs are more relevant than others, which resource and which combination schemes are more adapted to the task, and, finally, whether standard features derived from external databases are still relevant in the presence of dense representations.

4.1 Feature Set

Our main features are primarily lexical in nature and based on surface word forms. These are defined either on *all* words used in the relation arguments or only on their heads.

Head Extraction Heads of discourse segments are first extracted using Collins syntactic head rules[3]. In order to retrieve the semantic predicate, we define a heuristic which looks for the past participle of auxiliaries, the adjectival or nominal attribute of copula, the infinitive complementing "have to" forms and the first head of coordination conjunctions. In case of multiple subtrees, we look for the head of the first independent clause, or, failing that, of the first phrase.

Word Representations We use either one-hot encodings or use word embeddings to build denser representations as described in section 3. The Brown clusters (*Brown*), Collobert-Weston (*CnW*) representations, and the hierarchical log-bilinear (*HLBL*) embeddings correspond to the versions implemented in (Turian et al., 2010)[4]. They have been built on Reuters English newswire with case left intact. We test versions with 100, 320, 1000 and 3,200 clusters for *Brown*, with 25, 50, 100 and 200 dimensions for *CnW* and with 50 and 100 dimensions for *HLBL*. The Hellinger PCA (*H-PCA*) embeddings come from (Lebret and Collobert, 2014)[5] and have been built over the entire English Wikipedia, the Reuters corpus and the Wall Street Journal with all words in lower case. The vocabulary corresponds to the words that appear at least 100 times and normalized frequency is computed with the 10,000 most frequent words as context words. We test versions with 50, 100 and 200 dimensions for *H-PCA*. The coverage of each resource is presented in table 1.

	# words	# missing words	
		All words	Head words
HLBL	246,122	5,439	171
CnW	268,810	5,638	171
Brown	247,339	5,413	171
H-PCA	178,080	7,042	190

Table 1: Word embeddings and Brown clusters lexicon coverage.

When presenting our results, we distinguish between systems based on one-hot encoding built from raw tokens (*one-hot*) or Brown clusters (*Brown*). We group the systems that use embeddings under *Embed.* When relevant, we indicate the number of dimensions (e.g. *Brown 3,200* is the system using Brown clusters with 3,200 clusters). We use the symbols defined in section 3 to represent the operation linking the arguments representations (e.g. *one-hot* $\oplus$ corresponds to the transformation defined by $\Phi_{h,\mathbb{1},\oplus}$ when using heads and by $\Phi_{all,\mathbb{1},\oplus}$ when using all words).

Vocabulary Sizes For one-hot encoding, the case is left intact. We ignore the unknown words when using the Brown clusters following (Rutherford and Xue, 2014). For the word embeddings, we use the mean of the vectors of all words.

In order to give an idea of the sparsity of the one-hot encodings, note that we have $|\mathcal{V}| = 33,649$ different tokens considering all implicit examples without filtering. The Brown clusters

[3] https://github.com/jkkummerfeld/nlp-util

[4] http://metaoptimize.com/projects/wordreprs/

[5] http://lebret.ch/words/

merge these tokens into $3,190$ codes (for $3,200$ clusters), 393 ($1,000$ clusters), 59 (320 clusters) or 16 (100 clusters). For heads, we count $5,615$ different tokens which correspond to $1,988$ codes for $3,200$ clusters and roughly the same number for the others. For the dense representations, the vocabulary size is twice the number of dimensions of the embedding, thus from 50 to 400, or the square of this number, thus from 625 to $40,000$.

Other Features We experiment with additional features commonly used for this task: productions rules, average verb phrases length, Levin verb classes, modality, polarity, General Inquirer tags, number, first last and first three words. These feature templates are well described in (Pitler et al., 2009; Park and Cardie, 2012). They all correspond to a one-hot encoding, except average verb phrases length which is continuous. We thus concatenate these features to the lexical ones.

4.2 Model

We use the same classification algorithm for comparing all the described feature configurations. Specifically, we train a Maximum Entropy (ME) classifier (aka, logistic regression).[6] As in previous studies, we build one binary classifier for each relation. In order to deal with class imbalance, we use a sample weighting scheme: each sample receives a weight inversely proportional to the frequency of its class in the training set. We optimize the hyper-parameters of the algorithm (i.e., the regularization norm: L_1 or L_2, and its strength) and a filter on the features on the development set, based on the F1 score. Note that filtering is pointless for purely dense representations. We test statistical significancy of the results using t-test and Wilcoxon test on a split of the test set in 20 folds.

Previous studies have tested several algorithms generally concluding that Naive Bayes (NB) gives the best performance (Pitler et al., 2009; Rutherford and Xue, 2014). We found that, when the hyper-parameters of ME are well tuned, the performance are comparable to NB if not better. Note that NB cannot be used with word embeddings representations as it does not handle negative value. Concerning the class imbalance issue, the downsampling scheme is the most spread since (Pitler et al., 2009) but it has been shown that oversampling and instance weighting lead to better performance (Li and Nenkova, 2014a).

[6] We use the implementation provided in Scikit-Learn (Pedregosa et al., 2011), available at: `http://scikit-learn.org/dev/index.html`.

Relation	Train	Dev	Test
Temporal	665	93	68
Contingency	3,281	628	276
Comparison	1,894	401	146
Expansion	6,792	1,253	556
Total	12,632	2,375	1,046

Table 2: Number of examples in train, dev, test.

4.3 Penn Discourse Treebank

We use the Penn Discourse Treebank (Prasad et al., 2008), a corpus annotated at the discourse level upon the Penn Treebank, giving access to a gold syntactic annotation, and composed of articles from the Wall Street Journal. Five types of examples are distinguished: implicit, explicit, alternative lexicalizations, entity relations, and no relation. Each example could carry multiple relations, up to four for implicit ones, and the relations are organized into a three-level hierarchy.

We keep only true implicit examples and only the first annotation. We focus on the top level relations which correspond to general categories included in most discursive frameworks. Finally, in order to make comparison easier, we choose the most spread split of the data, used in (Pitler et al., 2009; Park and Cardie, 2012; Rutherford and Xue, 2014) among others. The amount of data for training (sections $2-21$), development ($00, 01, 23, 24$) and evaluation ($21, 22$) is summarized in table 2.

5 Results

We first discuss the models that use only lexical features, defined either over all the words that appear in the arguments or only the head words. We then compare our best performing lexical configurations with the ones that also integrate additional standard features, and to state-of-the-art systems.

5.1 Word Pairs over the Arguments

Our first finding in this setting is that feature configurations that employ unsupervised word representations almost systematically outperform those that use raw tokens. This is shown in the left part of table 3. Although the optimal word representation differs from one relation to another, it is always a dense representation that achieves the

	All words				Head words only

Table 3: F1 score for systems using all words and only heads for *Temporal* (*Temp.*), *Contingency* (*Cont.*), *Comparison* (*Compa.*) and *Expansion* (*Exp.*). * $p \leq 0.1$, ** $p \leq 0.05$ compared to *One-hot* $\otimes$ with t-test and Wilcoxon ; for head words, all the improvements observed against *One-hot* $\otimes$ are significant.

best F1 score. Our baselines correspond to multiplicative and additive one-hot encodings, noted *One-hot* $\otimes$ and *One-hot* $\oplus$, the former being the most commonly used in previous work. These are strong baselines in the sense they have been obtained after optimizing a frequency cut-off. Our best systems based on dense representations correspond to significant improvements in terms of F1 of about 8 points for *Expansion*, 7 points for *Temporal* and 3.5 for *Contingency*. The gains for *Comparison* are not statistically significant. All these results are obtained using the normalization to unit vectors possibly combined to the concatenation-specific normalization described in §3.3.

Comparing Dense Representations The best results are obtained using the Brown clusters (*Brown*) showing that this resource merges words in a way that is relevant to the task. Strikingly, the Brown configuration used in (Rutherford and Xue, 2014) (*One-hot Brown* $3,200$ $\otimes$) does not do better than the raw word pair baselines, except for *Expansion*. Recall that these authors did not explicitly provide this comparison. While doing a little worse, word embeddings (*Embed.*) also yield significant improvements for *Temporal* and *Contingency*, and smaller improvements for the others. This suggests that, even if they were not built based on discursive criteria, the latent dimensions encode word properties that are relevant to their rhetorical function. The superiority of Brown clusters over word embeddings is in line with the conclusions in (Turian et al., 2010) for two rather different NLP tasks (i.e., NER and chunking).

Turian et al. (2010) showed that the optimal word embedding is task dependent. Our experiments suggest that it is relation dependent: the best scores are obtained with *HLBL* for *Temporal*, *CnW* for *Contingency*, *H-PCA* for *Expansion* and *CnW* (Best *Embed.* $\otimes$) and *HPCA* (Best *Embed.* $\oplus$) for *Comparison*. This again demonstrates that these four relations have to be considered as four distinct tasks. Identifying temporal or causal links is indeed sensitive to very different factors, the former relying more on temporal expressions and temporal ordering of events whereas the latter relies on lexical and encyclopaedic knowledge on events. We think that this also explains that the behavior of the F1 against the optimal number of clusters for *Expansion* really differs from what we observed for the other relations: only 100 clusters for the best concatenated system and 320 for the best multiplicative one. *Expansion* is the least semantically marked relation and thus takes less advantage of fine-grained semantic groupings.

Comparing Word Combinations Comparing concatenated configurations ($\oplus$ systems) against multiplicative ones ($\otimes$ systems), we first note that for raw tokens the concatenated form (*one-hot* $\oplus$) yields results that are comparable, and sometimes better, than the standard multiplicative system (*one-hot* $\otimes$), while failing to explicitly model word pair interactions. With Brown clusters, the concatenated form *Best Brown* $\oplus$ lead to better F1 scores than *Best Brown* $\otimes$ except for *Contingency*.

When comparing performance on dev set, we found that the differences between concatenated and multiplicative forms for *Brown* (excluding *Expansion* for now) depend on the number of clusters used. Turian et al. (2010) found that the more clusters, the better the performance. This is also the case here with concatenated forms, but not with multiplicative forms. In that case, F1 increases un-

til $1,000$ clusters and then decreases. There is indeed a trade-off between expressivity and sparsity: having too few clusters means that we loose important distinctions, but having too many clusters leads to a loss in generalization. A similar trend is also found with word embeddings.

5.2 Head Words Only

Considering the right part of table 3, the first finding is that performance of systems that use only head words decrease compared to those using all words, but much more so with the baseline *One-hot* $\otimes$ than with other representations. *One-hot* $\otimes$ has very poor performance for most relations, losing between 7 and 17 points in F_1 score. The performance loss is much less striking with *One-hot* $\oplus$ and with denser representations, which are again the best performing. The only exception is *Expansion* whose precision however increases. As said, this relation is the less semantically marked, making it less likely to take advantage of the use of word representations. The best performance in this setting are obtained with word embeddings (not *Brown*) with significant gain from 8 to 13 points in F1 for most relations. Moreover, the best systems are all based on the multiplicative form confirming that this is a better way of representing pairs than simple concatenation when the number of initial dimensions is not too large.

5.3 Adding Other Features

Finally, we would like to assess how much improvement can still be obtained by adding other standard features, such as those in §4.1, to word-based features. Conversely, we want to evaluate how far we are from state-of-the-art performance by just using word representations. We compare our results with those presented in (Rutherford and Xue, 2014) and in (Ji and Eisenstein, 2014), both systems deal with sparsity either by using Brown clusters or by learning task-dependent representations. To make comparison easier we reproduce the experiments in (Rutherford and Xue, 2014) with Naive Bayes (NB)[7] and Maximum Entropy (ME) but without their coreference features and using gold syntactic parse. These correspond to the "repr." lines in table 4. We attribute the small differences observed with NB by the lack of coreference features and/or the use of different filtering thresholds. Concerning the difference between NB and ME, the only obvious issue is the low F1 score for *Expansion*: the system built using NB predicts all examples as positive thus leading to a high F1 score whereas the other one produces more balanced predictions, meaning neither systems is truly satisfactory. Finally, we give results using the traditional one-encoding based on word pairs plus additional features (*One-hot* $\otimes$ + additional features). These results are summarized in table 4, also including the best results of our experiments without additional features ("only").

Our first finding is that the addition of extra features to our previous word-based only configuration appears to outperform state-of-the art results for *Temporal* and *Contingency*, thus giving the best performance to date on these relations. These improvements are significant compared to our reproduced systems. Note that we also outperform the task-dependent embeddings of Ji and Eisenstein (2014), except for *Expansion*. Our tentative explanation for this is that these authors included Entity relations and coreference features. Note that our system corresponding to a reproduction of (Rutherford and Xue, 2014) gives results similar to the baseline using raw word pairs (*One-hot* $\otimes$ + additional features) showing that their improvements were due to other factors, the optimized filter threshold and the coreference features.

Overall, the addition of these hand-crafted features to our best systems do not provide improvements as high as one might have hoped. While improvements are significant compared to our reproduced systems, they are not with respect to the best systems given in table 3. When using all words, we only have a tendency toward significant improvement for *Contingency*[8]. These very small differences demonstrate that semantic and syntactic properties encoded in these features are already taken into account into the unsupervised word representations.

6 Related Work

Automatically identifying implicit relations is challenging due to the complex nature of the predictors. Previous studies have thus used many features relying on several external resources (Pitler et al., 2009; Park and Cardie, 2012; Biran and McKeown, 2013) as the MPQA lexicon (Wilson et al., 2005) or the General Inquirer lexicon (Stone and Hunt, 1963), or on constituent or dependency

[7] Implemented in Scikit-Learn, we optimized the hyper-parameter corresponding to the smoothing.

[8] $p = 0.135$ with ttest and $p = 0.061$ with Wilcoxon.

	Temporal	*Contingency*	*Comparison*	*Expansion*
System	F1	F1	F1	F1

Table 4: Systems using additional features ("+ add.features"), state-of-the art results either reported or reproduced ("repr.") using Naive Bayes ("NB") or logistic regression ("ME") and best system from previous table ("only").

parsers (Li and Nenkova, 2014b; Lin et al., 2009). Feature selection methods have been proved necessary to handle all of these features (Park and Cardie, 2012; Lin et al., 2009). Interestingly, Park and Cardie (2012) conclude on the worthlessness of word pair features, given the existence of such resources. We showed that provided unsupervised word representations, the opposite was in fact true, as dense word representations capture a lot of syntactic and semantic information.

The major problem of standard word pair representations is their sparsity. A line of work is to deal with this issue by adding automatically annotated data from explicit examples (Marcu and Echihabi, 2002), possibly using some kind of filtering or adaptation methods (Pitler et al., 2009; Biran and McKeown, 2013; Braud and Denis, 2014). Another line of work propose to make use of dense representations as Brown clusters in (Rutherford and Xue, 2014). These authors claim that this resource provides word representations that are relevant to the task, a conclusion that we considerably refined. Ji and Eisenstein (2014) propose to learn a distributed representation from the syntactic trees representing each argument in way that is more directly related to the task. Although this is an attractive idea, the score on top level PDTB relations are mostly below those reported by (Rutherford and Xue, 2014), possibly because their representations are learned on a rather small corpus, the PDTB itself, whereas building this kind of representation requires massive amount of data.

Our work also relates to studies comparing unsupervised representations for other NLP tasks such as name entity recognition, chunking (Turian et al., 2010), sentiment analysis (Lebret and Collobert, 2014) or POS tagging (Stratos and Collins, 2005). In particular, we found some similarities between our conclusions and those in (Turian et al., 2010). Our comparison is slightly richer in that it includes different methods of vector compositions and add an extra distributional representation to our comparison (namely, H-PCA).

7 Conclusions and Future Work

In this paper, we show that one can reach state-of-the-art results for implicit discourse relation identification using only shallow lexical features and existing unsupervised word representations thus contradicting previous conclusions on the worthlessness of these features. We carefully assess the usefulness of word representations for discourse by comparing various formulations and combination schemes, demonstrating the inadequacy of the previously proposed strategy based on Brown clusters and the distinctive relevance of head words, and by establishing that the created dense representations already provide most of the semantic and syntactic information relevant to the task thus alleviating the need for traditional external resources.

In future work, we first plan to extend our comparative framework to a larger set of relations and to other languages. We also want to explore methods for learning embeddings that are directly related to the task of discourse relation classification, potentially using existing embeddings as initialization (Labutov and Lipson, 2013). It is also clear that seeing discourse segments as bag of words is too simplistic, we would like to investigate ways of learning adequate segment-wide embeddings.

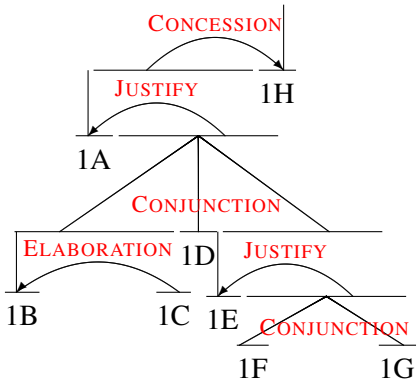
Abstract

Discourse structure is the hidden link between surface features and document-level properties, such as sentiment polarity. We show that the discourse analyses produced by Rhetorical Structure Theory (RST) parsers can improve document-level sentiment analysis, via composition of local information up the discourse tree. First, we show that reweighting discourse units according to their position in a dependency representation of the rhetorical structure can yield substantial improvements on lexicon-based sentiment analysis. Next, we present a recursive neural network over the RST structure, which offers significant improvements over classification-based methods.

1 Introduction

Sentiment analysis and opinion mining are among the most widely-used applications of language technology, impacting both industry and a variety of other academic disciplines (Feldman, 2013; Liu, 2012; Pang and Lee, 2008). Yet sentiment analysis is still dominated by bag-of-words approaches, and attempts to include additional linguistic context typically stop at the sentence level (Socher et al., 2013). Since document-level opinion mining inherently involves multi-sentence texts, it seems that analysis of document-level structure should have a role to play.

A classic example of the potential relevance of discourse to sentiment analysis is shown in Figure 1. In this review of the film *The Last Samurai*, the positive sentiment words far outnumber the negative sentiment words. But the discourse structure — indicated here with Rhetorical Structure Theory (RST; Mann and Thompson, 1988) — clearly favors the final sentence, whose polarity is negative. This example is illustrative in more than one way: it was originally identified by Voll and Taboada (2007), who found that *manually-annotated* RST parse trees improved lexicon-based sentiment analysis, but that automatically-generated parses from the SPADE parser (Soricut and Marcu, 2003), which was then state-of-the-art, did not.



[It could have been a great movie]^{1A} [It does have beautiful scenery,]^{1B} [some of the best since Lord of the Rings.]^{1C} [The acting is well done,]^{1D} [and I really liked the son of the leader of the Samurai.]^{1E} [He was a likable chap,]^{1F} [and I hated to see him die.]^{1G} [But, other than all that, this movie is nothing more than hidden rip-offs.]^{1H}

Figure 1: Example adapted from Voll and Taboada (2007).

Since this time, RST discourse parsing has improved considerably, with the best systems now yielding 5-10% greater raw accuracy than SPADE, depending on the metric. The time is therefore right to reconsider the effectiveness of RST for document-level sentiment analysis. In this paper, we present two different ways of combining RST discourse parses with sentiment analysis. The methods are both relatively simple, and

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2212–2218,
Lisbon, Portugal, 17-21 September 2015.

can be used in combination with an "off the shelf" discourse parser. We consider the following two architectures:

- Reweighting the contribution of each discourse unit, based on its position in a dependency-like representation of the discourse structure. Such weights can be defined using a simple function, or learned from a small of data.

- Recursively propagating sentiment up through the RST parse, in an architecture inspired by recursive neural networks (Smolensky, 1990; Socher et al., 2011).

Both architectures can be used in combination with either a lexicon-based sentiment analyzer, or a trained classifier. Indeed, for users whose starting point is a lexicon-based approach, a simple RST-based reweighting function can offer significant improvements. For those who are willing to train a sentiment classifier, the recursive model yields further gains.

2 Background

2.1 Rhetorical Structure Theory

RST is a compositional model of discourse structure, in which elementary discourse units (EDUs) are combined intro progressively larger discourse units, ultimately covering the entire document. Discourse relations may involve a *nucleus* and a *satellite*, or they may be *multinuclear*. In the example in Figure 1, the unit $1C$ is the satellite of a relationship with its nucleus $1B$; together they form a larger discourse unit, which is involved in a multinuclear CONJUNCTION relation.

The nuclearity structure of RST trees suggests a natural approach to evaluating the importance of segments of text: satellites tend to be less important, and nucleii tend to be more important (Marcu, 1999). This idea has been leveraged extensively in document summarization (Gerani et al., 2014; Uzêda et al., 2010; Yoshida et al., 2014), and was the inspiration for Voll and Taboada (2007), who examined intra-sentential relations, eliminating all words except those in the top-most nucleus within each sentence. More recent work focuses on reweighting each discourse unit depending on the relations in which it participates (Heerschop et al., 2011; Hogenboom et al., 2015). We consider such an approach, and compare it with a compositional method, in which sentiment polarity is propagated up the discourse tree.

Marcu (1997) provides the seminal work on automatic RST parsing, but there has been a recent spike of interest in this task, with contemporary approaches employing discriminative learning (Hernault et al., 2010), rich features (Feng and Hirst, 2012), structured prediction (Joty et al., 2015), and representation learning (Ji and Eisenstein, 2014; Li et al., 2014). With many strong systems to choose from, we employ the publicly-available DPLP parser (Ji and Eisenstein, 2014),[1]. To our knowledge, this system currently gives the best F-measure on relation identification, the most difficult subtask of RST parsing. DPLP is a shift-reduce parser (Sagae, 2009), and its time complexity is linear in the length of the document.

2.2 Sentiment analysis

There is a huge literature on sentiment analysis (Pang and Lee, 2008; Liu, 2012), with particular interest in determining the overall sentiment polarity (positive or negative) of a document. Bag-of-words models are widely used for this task, as they offer accuracy that is often very competitive with more complex approaches. Given labeled data, supervised learning can be applied to obtain sentiment weights for each word. However, the effectiveness of supervised sentiment analysis depends on having training data in the same domain as the target, and this is not always possible. Moreover, in social science applications, the desired labels may not correspond directly to positive or negative sentiment, but may focus on other categories, such as politeness (Danescu-Niculescu-Mizil et al., 2013), narrative frames (Jurafsky et al., 2014), or a multidimensional spectrum of emotions (Kim et al., 2012). In these cases, labeled documents may not be available, so users often employ a simpler method: counting matches against lists of words associated with each category. Such lists may be built manually from introspection, as in LIWC (Tausczik and Pennebaker, 2010) and the General Inquirer (Stone, 1966). Alternatively, they may be induced by bootstrapping from a seed set of words (Hatzivassiloglou and McKeown, 1997; Taboada et al., 2011). While lexicon-based methods may be less accurate than supervised classifiers, they are easier to apply to

[1] https://github.com/jiyfeng/DPLP

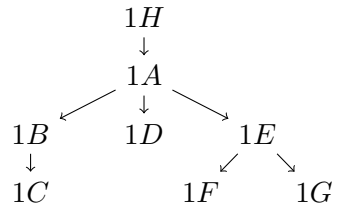

Figure 2: Dependency-based discourse tree representation of the discourse in Figure 1

new domains and problem settings. Our proposed approach can be used in combination with either method for sentiment analysis, and in principle, could be directly applied to other document-level categories, such as politeness.

2.3 Datasets

We evaluate on two review datasets. In both cases, the goal is to correctly classify the opinion polarity as positive or negative. The first dataset is comprised of 2000 movie reviews, gathered by Pang and Lee (2004). We perform ten-fold cross-validation on this data. The second dataset is larger, consisting of 50,000 movie reviews, gathered by Socher et al. (2013), with a predefined 50/50 split into training and test sets. Documents are scored on a 1-10 scale, and we treat scores ≤ 4 as negative, ≥ 7 as positive, and ignore scores of 5-6 as neutral — although in principle nothing prevents extension of our approaches to more than two sentiment classes.

3 Discourse depth reweighting

Our first approach to incorporating discourse information into sentiment analysis is based on quantifying the importance of each unit of text in terms of its discourse depth. To do this, we employ the *dependency-based discourse tree (DEP-DT)* formulation from prior work on summarization (Hirao et al., 2013). The DEP-DT formalism converts the constituent-like RST tree into a directed graph over elementary discourse units (EDUs), in a process that is a close analogue of the transformation of a headed syntactic constituent parse to a syntactic dependency graph (Kübler et al., 2009).

The DEP-DT representation of the discourse in Figure 1 in shown in Figure 2. The graph is constructed by propagating "head" information up the RST tree; if the elementary discourse unit e_i is the satellite in a discourse relation headed by e_j, then there is an edge from e_j to e_i. Thus, the "depth" of each EDU is the number of times in which it is embedded in the satellite of a discourse relation. The exact algorithm for constructing DEP-DTs is given by Hirao et al. (2013).

Given this representation, we construct a simple linear function for weighting the contribution of the EDU at depth d_i:

$$\lambda_i = \max(0.5, 1 - d_i/6). \quad (1)$$

Thus, at $d_i = 0$, we have $\lambda_i = 1$, and at $d_i \geq 3$, we have $\lambda_i = 0.5$. Now assume each elementary discourse unit contributes a prediction $\psi_i = \boldsymbol{\theta}^\top \boldsymbol{w}_i$, where $\boldsymbol{w}_i$ is the bag-of-words vector, and θ is a vector of weights, which may be either learned or specified by a sentiment lexicon. Then the overall prediction for a document is given by,

$$\Psi = \sum_i \lambda_i(\boldsymbol{\theta}^\top \boldsymbol{w}_i) = \boldsymbol{\theta}^\top(\sum_i \lambda_i \boldsymbol{w}_i). \quad (2)$$

Evaluation We apply this approach in combination with both lexicon-based and classification-based sentiment analysis. We use the lexicon of Wilson et al. (2005), and set $\theta_j = 1$ for words marked "positive", and $\theta_j = -1$ for words marked negative. For classification-based analysis, we set $\boldsymbol{\theta}$ equal to the weights obtained by training a logistic regression classifier, tuning the regularization coefficient on held-out data.

Results are shown in Table 1. As seen in the comparison between lines B1 and D1, discourse depth weighting offers substantial improvements over the bag-of-words approach for lexicon-based sentiment analysis, with raw improvements of $4-5\%$. Given the simplicity of this approach — which requires only a sentiment lexicon and a discourse parser — we strongly recommend the application of discourse depth weighting for lexicon-based sentiment analysis at the document level. However, the improvements for the classification-based models are considerably smaller, less than 1% in both datasets.

4 Rhetorical Recursive Neural Networks

Discourse-depth reweighting offers significant improvements for lexicon-based sentiment analysis, but the improvements over the more accurate classification-based method are meager. We therefore turn to a data-driven approach for combining sentiment analysis with rhetorical structure theory, based on recursive neural networks (Socher et al.,

	Pang & Lee	Socher et al.

Rhetorical recursive neural network		
R1. No relations	83.4	85.5
R2. With relations	84.1	85.6

Table 1: Sentiment classification accuracies on two movie review datasets (Pang and Lee, 2004; Socher et al., 2013), described in Section 2.3.

2011). The idea is simple: recursively propagate sentiment scores up the RST tree, until the root of the document is reached. For nucleus-satellite discourse relations, we have:

$$\Psi_i = \tanh(K_n^{(r_i)}\Psi_{n(i)} + K_s^{(r_i)}\Psi_{s(i)}), \quad (3)$$

where i indexes a discourse unit composed from relation r_i, $n(i)$ indicates its nucleus, and $s(i)$ indicates its satellite. Returning to the example in Figure 1, the sentiment score for the discourse unit obtained by combining $1B$ and $1C$ is obtained from $\tanh(K_n^{(\text{elaboration})}\Psi_{1B} + K_s^{(\text{elaboration})}\Psi_{1C})$. Similarly, for multinuclear relations, we have,

$$\Psi_i = \tanh(\sum_{j \in n(i)} K_n^{(r_i)}\Psi_j). \quad (4)$$

In the base case, each elementary discourse unit's sentiment is constructed from its bag-of-words, $\Psi_i = \boldsymbol{\theta}^\top \boldsymbol{w}_i$. Because the structure of each document is different, the network architecture varies in each example; nonetheless, the parameters can be reused across all instances.

This approach, which we call a Rhetorical Recursive Neural Network (R2N2), is reminiscent of the compositional model proposed by Socher et al. (2013), where composition is over the constituents of the syntactic parse of a sentence, rather than the units of a discourse. However, a crucial difference is that in R2N2s, the elements Ψ and K are *scalars*: we do not attempt to learn a latent distributed representation of the sub-document units. This is because discourse units typically comprise multiple words, so that accurate analysis of the sentiment for elementary discourse units is not so difficult as accurate analysis of individual words. The scores for individual discourse units can be computed from a bag-of-words classifier, or, in future work, from a more complex model such as a recursive or recurrent neural network.

While this neural network structure captures the idea of compositionality over the RST tree, the most deeply embedded discourse units can be heavily down-weighted by the recursive composition (assuming $K_s < K_n$): in the most extreme case of a right-branching or left-branching structure, the recursive operator may be applied N times to the most deeply embedded EDU. In contrast, discourse depth reweighting applies a uniform weight of 0.5 to all discourse units with depth ≥ 3. In the spirit of this approach, we add an additional component to the network architecture, capturing the bag-of-words for the entire document. Thus, at the root node we have:

$$\Psi_{\text{doc}} = \gamma\boldsymbol{\theta}^\top(\sum_i \boldsymbol{w}_i) + \Psi_{\text{rst-root}}, \quad (5)$$

with $\Psi_{\text{rst-root}}$ defined recursively from Equations 3 and 4, $\boldsymbol{\theta}$ indicating the vector of per-word weights, and the scalar γ controlling the tradeoff between these two components.

Learning R2N2 is trained by backpropagating from a hinge loss objective; assuming $y_t \in \{-1, 1\}$ for each document t, we have the loss $L_t = (1 - y_t\Psi_{\text{doc},t})_+$. From this loss, we use backpropagation through structure to obtain gradients on the parameters (Goller and Kuchler, 1996). Training is performed using stochastic gradient descent. For simplicity, we follow Zirn et al. (2011) and focus on the distinction between contrastive and non-contrastive relations. The set of contrastive relations includes CONTRAST, COMPARISON, ANTITHESIS, ANTITHESIS-E, CONSEQUENCE-S, CONCESSION, and PROBLEM-SOLUTION.

Evaluation Results for this approach are shown in lines R1 and R2 of Table 1. Even without distinguishing between discourse relations, we get an improvement of more than 3% accuracy on the Stanford data, and 0.5% on the smaller Pang & Lee dataset. Adding sensitivity to discourse relations (distinguishing $K^{(r)}$ for contrastive and non-contrastive relations) offers further improvements on the Pang & Lee data, outperforming the baseline classifier (D2) by 1.3%.

The accuracy of discourse relation detection is only 60% for even the best systems (Ji and Eisen-

stein, 2014), which may help to explain why relations do not offer a more substantial boost. An anonymous reviewer recommended evaluating on gold RST parse trees to determine the extent to which improvements in RST parsing might transfer to downstream document analysis. Such an evaluation would seem to require a large corpus of texts with both gold RST parse trees and sentiment polarity labels; the SFU Review Corpus (Taboada, 2008) of 30 review texts offers a starting point, but is probably too small to train a competitive sentiment analysis system.

5 Related Work

Section 2 mentions some especially relevant prior work. Other efforts to incorporate RST into sentiment analysis have often focused on intra-sentential discourse relations (Heerschop et al., 2011; Zhou et al., 2011; Chenlo et al., 2014), rather than relations over the entire document. Wang et al. (2012) address sentiment analysis in Chinese. Lacking a discourse parser, they focus on explicit connectives, using a strategy that is related to our discourse depth reweighting. Wang and Wu (2013) use manually-annotated discourse parses in combination with a sentiment lexicon, which is automatically updated based on the discourse structure. Zirn et al. (2011) use an RST parser in a Markov Logic Network, with the goal of making polarity predictions at the sub-sentence level, rather than improving document-level prediction. None of the prior work considers the sort of recurrent compositional model presented here.

An alternative to RST is to incorporate "shallow" discourse structure, such as the relations from the Penn Discourse Treebank (PDTB). PDTB relations were shown to improve sentence-level sentiment analysis by Somasundaran et al. (2009), and were incorporated in a model of sentiment flow by Wachsmuth et al. (2014). PDTB relations are often signaled with explicit discourse connectives, and these may be used as a feature (Trivedi and Eisenstein, 2013; Lazaridou et al., 2013) or as posterior constraints (Yang and Cardie, 2014). This prior work on discourse relations within sentences and between adjacent sentences can be viewed as complementary to our focus on higher-level discourse relations across the entire document.

There are unfortunately few possibilities for direct comparison of our approach against prior work. Heerschop et al. (2011) and Wachsmuth et al. (2014) also employ the Pang and Lee (2004) dataset, but neither of their results are directly comparable: Heerschop et al. (2011) exclude documents that SPADE fails to parse, and Wachsmuth et al. (2014) evaluates only on individual sentences rather than entire documents. The only possible direct comparison is with very recent work from Hogenboom et al. (2015), who employ a weighting scheme that is similar to the approach described in Section 3. They evaluate on the Pang and Lee data, and consider only lexicon-based sentiment analysis, obtaining document-level accuracies between 65% (for the baseline) and 72% (for their best discourse-augmented system). Table 1 shows that fully supervised methods give much stronger performance on this dataset, with accuracies more than 10% higher.

6 Conclusion

Sentiment polarity analysis has typically relied on a "preponderance of evidence" strategy, hoping that the words or sentences representing the overall polarity will outweigh those representing counterpoints or rhetorical concessions. However, with the availability of off-the-shelf RST discourse parsers, it is now easy to include document-level structure in sentiment analysis. We show that a simple reweighting approach offers robust advantages in lexicon-based sentiment analysis, and that a recursive neural network can substantially outperform a bag-of-words classifier. Future work will focus on combining models of discourse structure with richer models at the sentence level.

Acknowledgments Thanks to the anonymous reviewers for their helpful suggestions on how to improve the paper. Closing the Gap: Domain Adaptation from Explicit to Implicit Discourse Relations

Abstract

Many discourse relations are explicitly marked with discourse connectives, and these examples could potentially serve as a plentiful source of training data for recognizing implicit discourse relations. However, there are important linguistic differences between explicit and implicit discourse relations, which limit the accuracy of such an approach. We account for these differences by applying techniques from domain adaptation, treating implicitly and explicitly-marked discourse relations as separate domains. The distribution of surface features varies across these two domains, so we apply a marginalized denoising autoencoder to induce a dense, domain-general representation. The label distribution is also domain-specific, so we apply a resampling technique that is similar to instance weighting. In combination with a set of automatically-labeled data, these improvements eliminate more than 80% of the transfer loss incurred by training an implicit discourse relation classifier on explicitly-marked discourse relations.

1 Introduction

Discourse relations reveal the structural organization of text, potentially supporting applications such as summarization (Louis et al., 2010; Yoshida et al., 2014), sentiment analysis (Somasundaran et al., 2009), and coherence evaluation (Lin et al., 2011). While some relations are signaled **explicitly** with connectives such as *however* (Pitler et al., 2008), many more are **implicit**. Expert-annotated datasets of implicit discourse relations are expensive to produce, so it would be preferable to use weak supervision, by automatically labeling instances with explicit connectives (Marcu and Echihabi, 2003).

However, Sporleder and Lascarides (2008) show that models trained on explicitly marked examples generalize poorly to implicit relation identification. They argued that explicit and implicit examples may be linguistically dissimilar, as writers tend to avoid discourse connectives if the discourse relation could be inferred from context (Grice, 1975). Similar observations are made by Rutherford and Xue (2015), who attempt to add automatically-labeled instances to improve supervised classification of implicit discourse relations.

In this paper, we approach this problem from the perspective of domain adaptation. Specifically, we argue that the reason that automatically-labeled examples generalize poorly is due to domain mismatch from the explicit relations (**source** domain) to the implicit relations (**target** domain). We propose to close the gap by using two simple methods from domain adaptation: (1) feature representation learning: mapping the source domain and target domain to a shared latent feature space; (2) resampling: modifying the relation distribution in the explicit relations to match the distribution over implicit relations. Our results on the Penn Discourse Treebank (Prasad et al., 2008) show that these two methods improve the performance on unsupervised discourse relation identification by more than 8.4% on average F_1 score across all relation types, an 82% reduction on the transfer loss incurred by training on explicitly-marked discourse relations.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2219–2224,
Lisbon, Portugal, 17-21 September 2015.

explicitly-marked examples in the rhetorical structure theory (RST) treebank, where the relations are automatically labeled by their discourse connectives: for example, labeling the relation as CONTRAST if the connective is *but*. However, Sporleder and Lascarides (2008) argue that explicitly marked relations are too different from implicit relations to serve as an adequate supervision signal, obtaining negative results in segmented discourse representation theory (SDRT) relations.

More recent work has focused on the Penn Discourse Treebank (PDTB), using explicitly-marked relations to supplement, rather than replace, a labeled corpus of implicit relations. For example, Biran and McKeown (2013) collect word pairs from arguments of explicit examples to help the supervised learning on implicit relation identification. Lan et al. (2013) present a multi-task learning framework, using explicit relation identification as auxiliary tasks to help main task on implicit relation identification. Rutherford and Xue (2015) explore several selection heuristics for adding automatically-labeled examples from Gigaword to their system for implicit relation detection, obtaining a 2% improvement in Macro-F_1. Our work differs from these previous efforts in that we focus exclusively on training from automatically-labeled explicit instances, rather than supplementing a training set of manually-labeled implicit examples.

Learning good feature representations (Ben-David et al., 2007) and reducing mismatched label distributions (Joshi et al., 2012) are two main ways to make a domain adaptation task successful. Structural correspondence learning is an early example of representation learning for domain adaptation (Blitzer et al., 2006); we build on the more computationally tractable approach of marginalized denoising autoencoders (Chen et al., 2012). Instance weighting is an approach for correcting label distribution mismatch (Jiang and Zhai, 2007); we apply a simpler approach of resampling the source domain according to an estimate of the target domain label distribution.

3 Domain Adaptation for Implicit Relation Identification

We employ two domain adaptation techniques: learning feature representations, and resampling to match the target label distribution.

3.1 Learning feature representation: Marginalized denoising autoencoders

The goal of feature representation learning is to obtain dense features that capture feature correlations between the source and target domains. Denoising autoencoders (Glorot et al., 2011) do this by first "corrupting" the original data, $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$ into $\tilde{\boldsymbol{x}}_1, \ldots, \tilde{\boldsymbol{x}}_n$, either by adding Gaussian noise (in the case of real-valued data) or by randomly zeroing out features (in the case of binary data). We can then learn a function to reconstruct the original data, thereby capturing feature correlations and improving resilience to domain shift.

Chen et al. (2012) propose a particularly simple and elegant form of denoising autencoder, by marginalizing over the noising process. Their single-layer marginalized denoising autoencoder (mDA) solves the following problem:

$$\min_{\mathbf{W}} E_{\tilde{\boldsymbol{x}}_i|\boldsymbol{x}_i}[\|\boldsymbol{x}_i - \mathbf{W}\tilde{\boldsymbol{x}}_i\|^2] \quad (1)$$

where the parameter $\mathbf{W} \in \mathbb{R}^{d\times d}$ is a projection matrix. After learning the projection matrix, we use $\tanh(\mathbf{W}\boldsymbol{x})$ as the representation for our relation identification task.

Usually, $\boldsymbol{x}_i \in \mathbb{R}^d$ is a sparse vector with more than 10^5 dimensions. Solving the optimization problem defined in equation 1 will produce a $d \times d$ dense matrix $\mathbf{W}$, and is prohibitively expensive. We employ the trick proposed by Blitzer et al. (2006) to select κ *pivot* features to be reconstructed. We then split all features into non-overlapping subsets of size $\leq K$. Then, a set of projection matrices are learned, so as to transform each feature subset to the pivot feature set. The final projection matrix $\mathbf{W}$ is the stack of all projection matrices learned from the feature subsets.

3.2 Handling mismatched label distributions: Resampling with minimal supervision

There is a notable mismatch between the relation distributions for implicit and explicitly-marked discourse relations in the Penn Discourse Treebank: as shown in Figure 1, the EXPANSION and CONTINGENCY relations comprise a greater share of the implicit relations, while the TEMPORAL and COMPARISON relations comprise a greater share of the explicitly-marked discourse relations. Such label distribution mismatches can be a major source of transfer loss across domains, and therefore, reducing this mismatch can be an easy

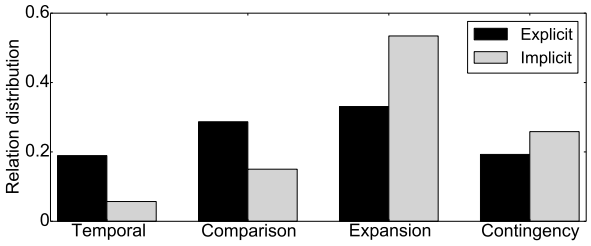

Figure 1: The relation distributions of training examples from the source domain (explicitly-marked relations) and target domain (implicit relations) in the PDTB.

way to obtain performance gains in domain adaptation (Joshi et al., 2012). Specifically, our goal is to modify the relation distribution in the source domain (explicitly-marked relations) and make it as similar as possible to the target domain (implicit relations). Given the label distribution from the target domain, we resample training examples from the source domain with replacement, in order to match the label distribution in the target domain. As this requires the label distribution from the target domain, it is no longer purely unsupervised domain adaptation; instead, we call it *resampling with minimal supervision*.

It may also be desirable to ensure that the source and target training instances are similar in terms of their observed features; this is the idea behind the *instance weighting* approach to domain adaptation (Jiang and Zhai, 2007). Motivated by this idea, we require that sampled instances from the source domain have a cosine similarity of at least τ with at least one target domain instance (Rutherford and Xue, 2015).

4 Experiments

Our experiments test the utility of the two domain adaptation methods, using the Penn Discourse Treebank (Prasad et al., 2008) and some extra-training data collected from a external resource.

4.1 Experimental setup

Datasets The test examples are implicit relation instances from section 21-22 in the PDTB. For the domain adaptation setting, the training set consists of the explicitly-marked examples extracted from sections 02-20 and 23-24, and the development set consists of the explicit relations from sections 21-22. All relations in the explicit examples are automatically labeled by using the connective-to-relation mapping from Table 2 in (Prasad et al., 2007), where we only keep the majority relation type for every connective. For each identified connective, we use its annotated arguments in the PDTB. As an upper bound, we also train a supervised discourse relation classifier, using the implicit examples in sections 02-20 and 23-24 as the training set, and using sections 00-01 as the development set. Following prior work (Pitler et al., 2009; Park and Cardie, 2012; Biran and McKeown, 2013), we consider the first-level discourse relations in the PDTB — Temporal (TEMP.), Comparison (COMP.), Expansion (EXP.) and Contingency (CONT.). We train binary classifiers and report F_1 score on each binary classification task. Extension of this approach to multi-class classification is important, but since this is not the setting considered in most of the prior research, we leave it for future work.

The true power of learning from automatically labeled examples is that we could leverage much larger datasets than hand-annotated corpora such as the Penn Discourse Treebank. To test this idea, we collected 1,000 news articles from CNN.com as extra training data. Explicitly-marked discourse relations from this data are automatically extracted by matching the PDTB discourse connectives (Prasad et al., 2007). For this data, we also need to extract the arguments of the identified connectives: for every identified connective, the sentence following this connective is labeled as Arg2 and the preceding sentence is labeled as Arg1, as suggested by Biran and McKeown (2013). In a pilot study we found that larger amounts of additional training data yielded no further improvements, which is consistent with the recent results of Rutherford and Xue (2015).

Model selection We use a linear support vector machine (Fan et al., 2008) as the classification model. Our model includes five tunable parameters: the number of pivot features κ, the size of the feature subset K, the noise level for the denoising autoencoder q, the cosine similarity threshold for resampling τ, and the penalty parameter C for the SVM classifier. We consider $\kappa \in \{1000, 2000, 3000\}$ for pivot features and $C \in \{0.001, 0.01, 0.1, 1.0, 10.0\}$ for penalty parameters, $q \in \{0.90, 0.95, 0.99\}$ for noise levels. To reduce the free parameters, we set $K = 5\kappa$ and simply fix the cosine similarity threshold $\tau =$

Table 1: Performance of cross-domain learning for implicit discourse relation identification.

0.85; pilot studies found that results are not sensitive to the value of τ across a range of values.

Features All features are motivated by prior work on implicit discourse relation classification: from each training example with two arguments, we extract (1) Lexical features, including word pairs, the first and last words from both arguments (Pitler et al., 2009); (2) Syntactic features, including production rules from each argument, and the shared production rules between two arguments (Lin et al., 2009); (3) Other features, including modality, Inquirer tags, Levin verb classes, and argument polarity (Park and Cardie, 2012). We re-implement these features as closely as possible to the cited works, using the Stanford CoreNLP Toolkit to obtain syntactic annotations (Manning et al., 2014).

The FULL feature set for domain adaptation is constructed by collecting all features from the training set, and then removing features that occur fewer than ten times. The PIVOT feature set includes κ high-frequency features from the FULL feature set. To focus on testing the domain adaptation techniques, we use the same FULL and PIVOT set for all four relations, and leave feature set optimization for each relation as a future work (Park and Cardie, 2012). To obtain the upper bound, we employ the same feature categories and frequency threshold to extract features from the in-domain data, hand-annotated implicit discourse relations. To include the representations from the marginalized denoising autoencoder for relation identification, we concatenate them with the original surface feature representations of the same examples.

4.2 Experimental results

In experiments, we start with surface feature representations as baselines, then incorporate the two domain adaptation techniques incrementally. As shown in line 2 of Table 1, the performance is poor if directly applying a model trained on the explicit examples with the FULL feature set, which is consistent with the observations of Sporleder and Lascarides (2008): there is a 10.28% absolute reduction on average F_1 score from the upper bound obtained with in-domain supervision (line 1). With mDA, the overall performance increases by 0.86% (line 4); resampling gives a further 4.16% improvement mainly because of the performance gain on the EXP. relation (line 5). The resampling method itself (line 3) also gives a better overall performance then mDA (line 4). However, the F_1 scores on the TEMP. and CONT. are even worse than the baseline (line 2).

Surface representations with the FULL feature set were found to cause serious overfitting in the experiments. To deal with this problem, we propose to use only κ pivot features, which gives a stronger baseline of the cross-domain relation identification, as shown in line 6. Then, by incorporating resampling and feature representation

learning individually, the average F_1 increases from 32.74% to 35.44% (line 7) and 36.69% (line 8) respectively. The combination of these two domain adaptation techniques boosts the average F_1 further to 38.62% (line 9). The additional CNN training data further improves performance to 39.46% (line 10). This represents an 8.42% improvement of average F_1 from the original result (line 2), for more than 80% reduction on the transfer loss incurred by training on explicit discourse relations.

An additional experiment is to use automatic argument extraction in both the PDTB and the CNN data, which would correspond to more truly unsupervised domain adaptation. (Recall that in the CNN data, we used adjacent sentences as argument spans, while in the PDTB data, we use expert annotations.) When using adjacent sentences as argument spans in both datasets, the average F_1 is 38.52% for the combination of representation learning and resampling. Compared to line 10, this is a 0.94% performance drop, indicating the importance of argument identification in the PDTB data. In future work we may consider better heuristics for argument extraction, such as obtaining automatically-labeled examples only from those connectors for whom the arguments usually are the adjacent sentences; for example, the connector *nonetheless* usually connects adjacent spans (e.g., *Bob was hungry. Nonetheless he gave Tina the burger.*), while the connector *even though* may connect two spans that follow the connector in the same sentence (e.g., *Even though Bob was hungry, he gave Tina the burger.*).

5 Conclusion

We have presented two methods — feature representation learning and resampling — from domain adaptation to close the gap of using explicit examples for unsupervised implicit discourse relation identification. Experiments on the PDTB show the combination of these two methods eliminates more than 80% of the transfer loss caused by training on explicit examples, increasing average F_1 from 31% to 39.5%, against a supervised upper bound of 41.3%. Future work will explore the combination of this approach with more sophisticated techniques for instance selection (Rutherford and Xue, 2015) and feature selection (Park and Cardie, 2012; Biran and McKeown, 2013), while also tackling the more difficult problems of multi-class relation classification and fine-grained level-2 discourse relations.

Abstract

While most previous work on Wikification has focused on written texts, this paper presents a Wikification approach for spoken dialogues. A set of analyzers are proposed to learn dialogue-specific properties along with domain knowledge of conversations from Wikipedia. Then, the analyzed properties are used as constraints for generating candidates, and the candidates are ranked to find the appropriate links. The experimental results show that our proposed approach can significantly improve the performances of the task in human-human dialogues.

1 Introduction

Linking mentions in natural language to the relevant concepts in knowledge-bases plays a key role in better understanding the meanings of expressions as well as further populating knowledge-bases with less human effort. Especially, Wikipedia has been widely used as a major target resource for linking. Most previous work on this Wikipedia-based linking task called Wikification (Mihalcea and Csomai, 2007) has focused on resolving ambiguities and variabilities of the expressions in written texts including newswire collections (McNamee and Dang, 2009; Ji et al., 2010; Ji et al., 2014) or microblog posts (Genc et al., 2011; Cassidy et al., 2012; Guo et al., 2013; Huang et al., 2014).

But writing and reading are not the only ways for exchange of information, since many communications between people in real life are performed through spoken dialogues also. Thus, we could expect to improve the understanding capabilities of applications based on Wikification and broaden the coverage of the contents in knowledge-bases, if Wikification is successfully performed also for human-human spoken conversations.

In this work, we focus on the following differences between spoken dialogues and written texts as sources for Wikification. Firstly, at least two speakers are engaged in a dialogue session, while the texts in newswire or microblogs are mostly written by a single author. Thus, the viewpoint of each speaker should be considered separately or jointly depending on the situation. Secondly, the correspondence between mentions and concepts in spoken dialogues tends to be dependent not only on the contexts explicitly mentioned in a given dialogue, but also on other information inferred by speakers based on their background knowledge. The other difference is that spoken utterances are more likely to be informal and noisy than written sentences, which makes expressions more ambiguous and variable.

To solve these issues, we propose a three step approach for Wikification on spoken dialogues. At the first step, a set of classifiers are used for analyzing the dialogue-specific aspects of a given mention. According to the analyzed results, the criteria in selecting concept candidates is determined, and then a ranking is performed on the filtered candidates to identify the concept that is the most relevant to the mention.

While many researchers have worked on linking named-entities (Bunescu and Pasca, 2006; Cucerzan, 2007; McNamee and Dang, 2009; Han and Sun, 2011; Han et al., 2011; Ji et al., 2014) or other types of concept mentions (Mihalcea and Csomai, 2007; Milne and Witten, 2008; Ferragina and Scaiella, 2010; Ratinov et al., 2011; Mendes et al., 2011; Cheng and Roth, 2013) to the relevant articles in Wikipedia, all the noun phrases including not only named entities or base noun phrases, but also complex or recursive noun phrases in a dialogue are considered as instances to be linked in this work. For the concept candidates, we divide every article into sub-sections and consider each section as a unit along with article-level concepts.

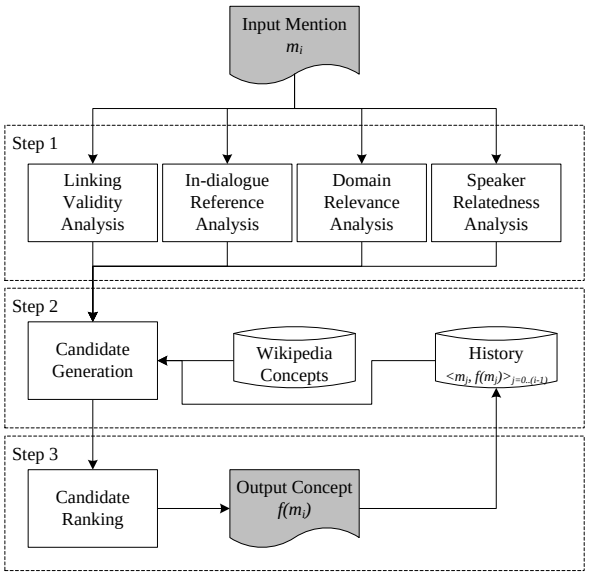

Figure 1: Overall architecture of three-step approach for Wikification on spoken dialogues

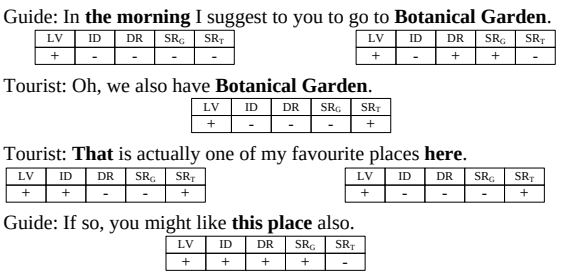

Figure 2: Examples of annotations for mention analysis: SR_G and SR_T denote guide and tourist relatedness, respectively.

2 Method

2.1 Mention Analysis

The first step in our proposed approach (Figure 1) is analyzing the following four types of binary properties of a given mention: linking validity (LV), in-dialogue reference (ID), domain relevance (DR), and speaker relatedness (SR).

Linking validity of the mention is determined by the decision whether it is matched with any Wikipedia concept or not. Since only the mentions assigned with positive validity values are proceeded to the further processes, this classification can be considered as a joint task for target mention identification and NIL detection.

Another type of analysis focuses on the references between the mention and the linking history. If the mention is matched with one in the set of concepts for the previous mentions in the same session, it has a positive value for the in-dialogue reference property.

The other two types of properties are defined for indicating the relevances of the mention to the contents that are specific to the target domain or the profiles of each speaker in the conversation. For these analyses, the whole Wikipedia collection is partitioned into subsets according to the domain or speaker-relevances. In this work, the concepts in these subsets are automatically collected with no manual effort by utilizing the domain knowledge also from Wikipedia. First, we retrieve the 'List' or 'Index' pages in Wikipedia that are related to the topic or the profile of a speaker. Then, all the articles listed on these seed pages are collected and considered as the related concepts in the corresponding sets.

Since every property has a positive or a negative value as a result, each analysis can be considered as a binary classification problem. In this work, we train support vector machines (SVM) (Cortes and Vapnik, 1995) from the dialogues annotated with the corresponding labels as shown in Figure 2 based on the features listed in Table 1.

2.2 Candidate Generation

After analyzing the above property values of a given mention, a set of concepts to be disambiguated are selected from Wikipedia. These candidates are retrieved from a Lucene [1] index on the whole Wikipedia collection with the fields of article title, section title, redirection, category, and body texts. Each query to the search engine is prepared with the combination of the mention phrase and its analyzed properties as constraints for filtering. If the value for in-dialogue reference is positive, the searching is restricted to the set of concepts linked with the previous mentions in the same session. Similarly, the domain relevance and speaker relatedness values provide the filtering condition within the corresponding subsets introduced in Section 2.1.

One practical issue on this candidate generation step is how to combine the multiple constraints when we have more than one positive properties for a given mention. The simplest way is taking the intersection of the corresponding constraints. However, we should consider the fact that the properties assigned automatically can be erroneous, since none of the analyzer is perfect.

[1] http://lucene.apache.org/

Level	Name	Description
Mention	SP	the speaker who spoke that mention
	WM	word n-grams within the mention
	LM	lemma n-grams within the mention
	PM	POS n-grams within the mention
	NE	named entities within the mention
	NP	base noun phrases within the mention
Utterance	BW	the words before the mention
	AW	the words after the mention
	BL	the lemmas before the mention
	AL	the lemmas after the mention
	BP	the POS tags before the mention
	AP	the POS tags after the mention
	IU	whether the mention previously occurs in the same utterance
Dialogue	EO	whether the phrase is previously mentioned in the dialogue history
	EOS	whether the phrase is previously mentioned by the same speaker in the history
Wikipedia	IW	whether the phrase is a title of an entry in Wikipedia
	IWD	whether the phrase is a title of an entry in the set of domain-relevant concepts
	IWS_k	whether the phrase is a title of an entry in the set of k-th speaker-relevant concepts

Table 1: List of features for training the models for mention analysis

For the noisy cases, the intersection-based filtering could be risky, because the errors are also jointly accumulated. To circumvent the impact of errors from the previous step, we also try to use the union of the constraints and compare it with the intersection case later in Section 3.

2.3 Candidate Ranking

In this work, linking a given mention to its most relevant concept is determined by ranking SVM (Joachims, 2002) which is a pairwise ranking algorithm learned from the ranked lists. For each pair of a mention m in the training data and its candidate concept c, the ranking score $s(m, c)$ is assigned as follows:

$$s(m,c) = \begin{cases} 4 & \text{if } c \text{ is the exactly same as } f(m), \\ 3 & \text{if } c \text{ is the parent article of } f(m), \\ 2 & \text{if } c \text{ belongs to the same article} \\ & \text{but different section of } f(m), \\ 1 & \text{otherwise.} \end{cases}$$

where $f(m)$ is the annotation of m in the training dataset. The list of candidates assigned with their scores provides the relative orders for a given mention, and it can be converted into a set of pairwise constraints which are trained by ranking SVM with the features in Table 2.

Name	Description
SP	the speaker who spoke that mention
WM	word n-grams within the surface of m
WT	word n-grams within the title of c
EMT	whether the surface of m is same as the title of c
EMR	whether the surface of m is same as one of re-directions to c
MIT	whether the surface of m is a sub-string of the title of c
TIM	whether the title of c is a sub-string of the m's surface form
MIR	whether the surface of m is a sub-string of a re-directed title to c
RIM	whether a re-directed title to c is a sub-string of the m's surface form
PMT	similarity score based on edit distance between the surface of m and the title of c
PMR	maximum similarity score between the surface of m and the redirected titles to c
OC	whether c previously occurred in the full dialogue history
OC_w	whether c occurred within w previous turns with $w \in \{1, 3, 5, 10\}$

Table 2: List of features for training the ranking SVM model

3 Evaluation

3.1 Data

To demonstrate the effectiveness of our approach to Wikification on spoken dialogues, we performed experiments on a dialogue corpus which consists of 35 sessions collected from human-human conversations in English about tourism in Singapore between actual tour guides in Singapore and tourists from the Philippines. All the recorded dialogues with the total length of 21 hours were manually transcribed, then the 31,034 utterance were pre-processed by Stanford CoreNLP toolkit [2]. Each noun phrase in the constituent trees provided by the parser is considered as an instance for Wikification and manually annotated with the corresponding concept in Wikipedia. 34,949 mentions have been linked to the concepts in Wikipedia.

As a pool for candidate generation, we built a Lucene index based on Wikipedia database dump as of January 2015 which has 4,797,927 articles and 25,577,464 sections in total. From this collection, 11,128 and 27,186 articles have been considered as Singapore-related and Philippines-related concepts, respectively, for the filtering based on domain and speaker relevances.

Features	LV	ID	SR_G	SR_T
M	86.29	69.15	**71.10**	**72.94**
M+U	**86.90**	70.43	70.43	68.85
M+D	86.17	71.09	70.56	71.52
M+W	86.21	68.96	70.66	71.86
M+U+D	86.82	**72.37**	70.12	68.30
M+U+W	86.84	70.13	70.19	68.78
M+U+D+W	86.77	72.20	69.94	68.10

Table 3: Comparisons of the performances in F-measure of mention analyzers with different combinations of features: M,U,D,W denotes mention-level, utterance-level, dialogue-level, and Wikipedia features, respectively

3.2 Mention Analysis

Based on the annotated dialogues, we built four mention analyzers for LV, ID, SR_G, and SR_T, where SR_G is for the guides and SR_T is for the tourists in the conversations. In this work, only the information where each speaker is from was considered as a profile to analyze the speaker-related properties. Since all the guides participated in the data collection are from Singapore and the main topic of the conversations is also about Singapore, we omitted DR which should have the same results as SR_G in the experiments.

For each analyzer, we trained the SVM models using SVM^{light} [3] with the features in Table 1. All the evaluations were performed in five-fold cross validation to the manual annotations with precision, recall, and F-measure.

Table 3 compares the performances of the seven combinations of feature sets for each analyzer. Based on these results, we selected the model that achieved the best performance for each analyzer to process the mentions for the further steps.

3.3 Candidate Generation

For each mention in the corpus, we prepared four sets of candidates with different filtering constraints. While the first baseline set was retrieved with no filtering, the others were generated according to the procedure described in Section 2.2. When more than one positive values were provided from mention analyzers, intersection and union operators were applied for combining multiple constraints. In the last set, the property values manually annotated in the training data were considered as the correct constraints, which is intended for comparing with the others to investigate the influence of errors in mention analysis. For every set, we retrieved top 100 candidates satisfying the given constraints from the Lucene index with Wikipedia collection and added one more special candidate for NIL detection.

Method	P	R	F
No filtering	26.85	22.52	21.24
Intersection	44.37	27.35	33.84
Union	38.04	31.97	34.74
Manual (Oracle)	39.90	34.72	37.13

Table 4: Comparisons of the performances of Wikification on spoken dialogues

3.4 Candidate Ranking

For each set of candidates, we trained a ranking function using SVM^{rank}[4] with the features in Table 2. Both training and testing the ranking models were performed also based on five-fold cross validation with the same divisions as the former evaluation. After getting the ranking results, we took the top-ranked candidate for each list and considered it as a result of Wikification for the corresponding mention.

Table 4 compares the final performances of Wikification obtained by ranking on the candidates generated with different sets of constraints. Both approaches, intersection and union, outperformed the baseline by 12.60 and 13.50 in F-measure, respectively. While the intersection strategy contributed to produce more precise outputs than the others even including the case with manual filtering, the other proposed approach with union achieved more gain in recall with slightly better F-measure than the former one.

4 Conclusions

This paper presented a Wikification approach for spoken dialogues. In this approach, a set of dialogue-specific properties were analyzed for generating concept candidates. Then, supervised ranking was performed on these candidates to identify the relevant concepts. Experimental results show that the proposed constraints help to improve the performances of the task on spoken dialogues.

Abstract

Implicit discourse relation recognition remains a serious challenge due to the absence of discourse connectives. In this paper, we propose a Shallow Convolutional Neural Network (SCNN) for implicit discourse relation recognition, which contains only one hidden layer but is effective in relation recognition. The shallow structure alleviates the overfitting problem, while the convolution and nonlinear operations help preserve the recognition and generalization ability of our model. Experiments on the benchmark data set show that our model achieves comparable and even better performance when comparing against current state-of-the-art systems.

1 Introduction

As a crucial task for discourse analysis, discourse relation recognition (DRR) aims to automatically identify the internal structure and logical relationship of coherent text (e.g., TEMPORAL, CONTINGENCY, EXPANSION, etc). It provides important information to many other natural language processing systems, such as question answering (Verberne et al., 2007), information extraction (Cimiano et al., 2005), machine translation (Guzmán et al., 2014) and so on. Despite great progress in explicit DRR where the discourse connectives (e.g., "*because*", "*but*" et al.) explicitly exist in the text (Miltsakaki et al., 2005; Pitler et al., 2008), implicit DRR remains a serious challenge because of the absence of discourse connectives (Prasad et al., 2008).

Conventional methods for implicit DRR directly rely on feature engineering, wherein researchers generally exploit various hand-crafted features, such as words, part-of-speech tags and production rules (Pitler et al., 2009; Lin et al., 2009; Louis et al., 2010; Wang et al., 2012; Park and Cardie, 2012; McKeown and Biran, 2013; Lan et al., 2013; Versley, 2013; Braud and Denis, 2014; Rutherford and Xue, 2014). Although these methods have proven successful, these manual features are labor-intensive and weak to capture intentional, semantic and syntactic aspects that govern discourse coherence (Li et al., 2014), thus limiting the effectiveness of these methods.

Recently, deep learning models have achieved remarkable results in natural language processing (Bengio et al., 2003; Bengio et al., 2006; Socher et al., 2011b; Socher et al., 2011a; Socher et al., 2013; Li et al., 2013; Kim, 2014). However, to the best of our knowledge, there is little deep learning work specifically for implicit DRR. The neglect of this important domain may be due to the following two reasons: (1) discourse relation distribution is rather unbalanced, where the generalization of deep models is relatively insufficient despite their powerful studying ability; (2) training dataset in implicit DRR is relatively small, where overfitting problems become more prominent.

In this paper, we propose a Shallow Convolutional Neural Network (SCNN) for implicit DRR, with only one simple convolution layer on the top of word vectors. On one hand, the network structure is simple, thereby overfitting issue can be alleviated; on the other hand, the convolution operation and nonlinear transformation help preserve the recognition ability of SCNN. This makes our model able to generalize better on the test dataset. We performed evaluation for English implicit DRR on the PDTB-style corpus. Experimental results show that the proposed method can obtain comparable even better performance when compares against several baselines.

2 Model

In Penn Discourse Treebank (PDTB) (Prasad et al., 2008), implicit discourse relations are anno-

Lisbon, Portugal, 17-21 September 2015.

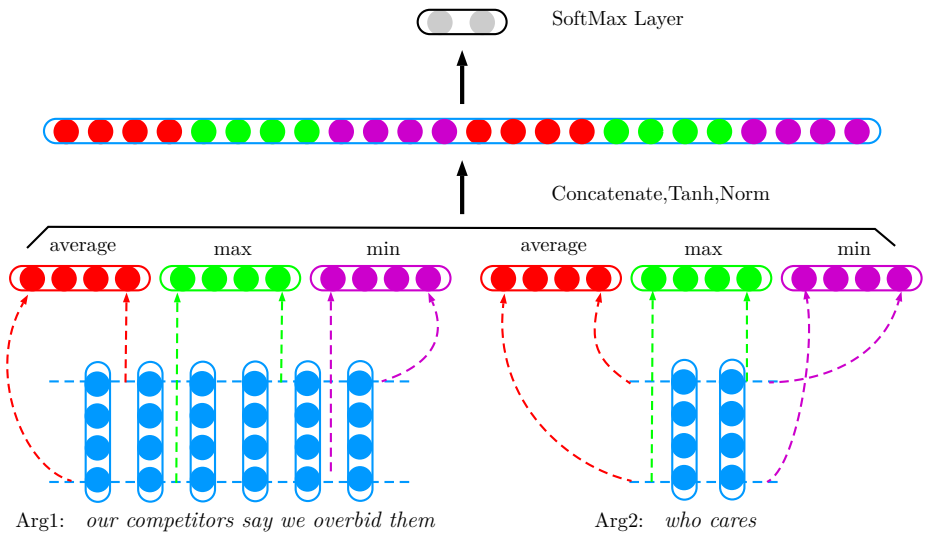

Figure 1: SCNN model architecture visualized with an instance.

tated with connective expressions that best convey implicit relations between two neighboring arguments, e.g.

Arg1: (But) *our competitions say we overbid them*

Arg2: *who cares*

the connective "*But*", which is annotated manually, is used to express the inferred COMPARISON relation.

We learn a classifier for implicit DRR based on convonlutional neural network. The overall model architecture is illustrated in Figure 1.[1] In our model, each word in vocabulary V corresponds to a d-dimensional dense, real-valued vector, and all words are stacked into a word embedding matrix $L \in \mathbb{R}^{d \times |V|}$, where $|V|$ is the vocabulary size.

Given an ordered list of n words in an argument, we retrieve the i-th word representation $x_{v_i} \in \mathbb{R}^d$ from L with its corresponding vocabulary index v_i. All word vectors in the argument produce the following output matrix:

$$\mathrm{X} = (x_{v_1}, x_{v_2}, \ldots, x_{v_n}) \quad (1)$$

Following previous work (Collobert et al., 2011; Socher et al., 2011a), for each row r in X, we explore three convolutional operations to obtain three convolution features *average*, *min* and *max* as follows:

$$c_r^{avg} = \frac{1}{n} \sum_i^n X_{r,i} \quad (2)$$

$$c_r^{min} = \min\left(X_{r,1}, X_{r,2}, \ldots, X_{r,n}\right) \quad (3)$$

$$c_r^{max} = \max\left(X_{r,1}, X_{r,2}, \ldots, X_{r,n}\right) \quad (4)$$

In this way, SCNN is able to capture almost all important information inside X (one with the highest, lowest and average values). Besides, each convolution operation naturally deals with variable argument lengths (Note that $c \in \mathbb{R}^d$). Back to Figure 1, we present c^{avg}, c^{min} and c^{max} with red, purple and green color respectively.

After obtaining the features of both arguments, we concatenate all of them into one vector, and then apply $tanh$ transformation and length normalization successively to generate the hidden layers:

$$a = \left[c_{Arg1}^{avg}; c_{Arg1}^{min}; c_{Arg1}^{max}; c_{Arg2}^{avg}; c_{Arg2}^{min}; c_{Arg2}^{max}\right] \quad (5)$$

$$h = \frac{\tanh(a)}{\|\tanh(a)\|} \quad (6)$$

where $h \in \mathbb{R}^{6d}$ is the hidden layer representation. The normalization operation scales the components of a feature vector to unit length. This, to some extent, eliminates the manifold differences among different features.

Upon the hidden layer, we stack a Softmax layer for relation recognition,

$$y = f(Wh + b) \quad (7)$$

where f is the softmax function, $W \in \mathbb{R}^{l \times 6d}$ is the parameter matrix, $b \in \mathbb{R}^l$ is the bias term, and l is the relation number.

To assess how well the predicted relation y represents the real relation, we supervise it with the

[1] For better illustration, we assume that the dimension of word vectors is 4 throughout this paper.

gold relation g in the annotated training corpus using the traditional cross-entropy error,

$$E(y, g) = -\sum_{j}^{l} g_j \times \log(y_j) \quad (8)$$

Combined with the regularization error, the joint training objective function is

$$J(\theta) = \frac{1}{m}\sum_{t=1}^{m} E(y_t, g_t) + \frac{\lambda}{2}\|\theta\|^2 \quad (9)$$

where m is the number of training instances, y_t is the t-th predicted distribution, λ is the regularization coefficient and θ is parameters, including L, W and b.[2]

To train SCNN, we first employ the toolkit *Word2Vec*[3] (Mikolov et al., 2013) to initialize the word embedding matrix L using a large-scale unlabeled data. Then, L-BFGS algorithm is applied to fine-tune the parameters θ.

3 Experiments

We conducted a series of experiments on English implicit DRR task. After a brief description of the experimental setup and the baseline systems, we further investigated the effectiveness of our method with deep analysis.

3.1 Setup

For comparison with other systems, we formulated the task as four separate one-against-all binary classification problems: one for each top level sense of implicit discourse relations (Pitler et al., 2009).

We used the *PDTB 2.0* corpus[4] (Prasad et al., 2008) for evaluation. The PDTB corpus contains discourse annotations over 2,312 Wall Street Journal articles, and is organized in different sections. Following Pitler et al. (2009), we used sections 2-20 as training set, sections 21-22 as test set, and sections 0-1 as development set for parameter optimization. For each relation, we randomly extracted the same number of positive and negative instances as training data, while all instances in sections 21 and 22 are used as our test set. The statistics of various data sets is listed in Table 1.

We tokenized PDTB corpus using *Stanford NLP Tool*[5]. For all experiments, we empirically set

[2]The bias terms b is not regularized. We preserve it in the equation just for clarity.

d=128 and λ=$1e^{-4}$. Besides, the unlabeled data for word embedding initialization contains 1.02M sentences with 33.5M words.

3.2 Baselines

We compared our model against the following baseline methods:

- **SVM:** This method learns a support vector machine (SVM) classifier with the labeled data.
- **TSVM:** This method learns a transductive SVM (TSVM) classifiers given the labeled data and unlabeled data. We extracted unlabeled data from above-mentioned 1.02M sentences. After filtering the noise ones, we finally obtained 0.11M unlabeled instances, each of which contains only two clauses.
- **RAE:** This method learns a recursive autoencoder (RAE) classifier with the labeled data. We first utilized standard RAEs to represent arguments, and then stacked a Softmax layer upon them. The hyperparameters were set as follows: word dimension 64, balance factor for reconstruction error 0.10282 and regularization factor $1e^{-5}$. Word embeddings are initialized via Word2Vec.

Rutherford and Xue (2014) show that Brown cluster pair feature is very impactful in implicit DRR (Rutherford and Xue, 2014). This feature is superior to one-hot representation for the interactions between two arguments, such as cross-argument word pair features in our baseline methods. We therefore conducted two additional experiments for comparison:

- **Add-Bro:** This method learns an SVM classifier using baseline system features along with the Brown cluster pair feature.
- **No-Cro:** This method learns an SVM classifier on Add-Bro's features without cross-

Table 2: Performance comparison of different systems on the test set.

argument word pair features.

In addition, to further verify the effectiveness of normalization, we also compared against SCNN model without normalization (**SCNN-No-Norm**).

Throughout our experiments, we used the toolkit *SVM-light*[6] (Joachims, 1999) in all the SVM-related experiments. Following previous work (Pitler et al., 2009; Lin et al., 2009), we adopted the following features for baseline methods:

Bag of Words: Three binary features that check whether a word occurs in *A*rg1, *A*rg2 and both arguments.

Cross-Argument Word Pairs: We group all words from *A*rg1 and *A*rg2 into two sets W_1,W_2 respectively, then extract any possible word pair $(w_i, w_j)(w_i \in W_1, w_j \in W_2)$ as features.

Polarity: The count of positive, negated positive, negative and neutral words in *A*rg1 and *A*rg2 according to the MPQA corpus (English). Their cross products are used as features.

First-Last, First3: The first and last words of each argument, the pair of the first words in two arguments, the pair of the last words in two arguments, and the first three words of each argument are used as features.

Production Rules: We extract all production rules from syntactic trees of arguments. We defined three binary features for each rule to check whether this rule appear in *A*rg1, *A*rg2 and both arguments.

Dependency Rules: We also extracted all dependency rules from dependency trees of arguments. Similarly, we defined three binary features for each rule to check whether this rule appear in *A*rg1, *A*rg2 and both arguments.

In order to collect bag of words, production rules, dependency rules, and cross-argument word pairs, we used a frequency cutoff of 5 to remove rare features, following Lin et al. (2009).

3.3 Results and Analysis

All models are evaluated by assessing the accuracy and F1 scores on account of the imbalance in test set. Besides, for better analysis, we also provided the precision and recall results.

Table 2 summarizes the performance of different models. On the whole, the F1 scores for implicit DRR are relatively low on average: COMP., CONT., EXP. and TEMP. about 32%, 50%, 65% and 28% respectively. This illustrates the difficulty in implicit DRR. Although we ex-

[6]http://svmlight.joachims.org/

pected unlabeled data could obtain improvement, we observed negative results appeared in **TSVM**: COMP. and CONT. dropped 1.14% and 0.79% respectively[7]. The F1 scores of TEMP. and EXP. are improved (1.27% and 0.63% respectively). The main reason may be that our unlabeled data is not strictly from the discourse corpus.

Incorporating Brown cluster pair features enhances the recognition of COMP. and CONT.. Particllarly, **No-Cro** achieves the best result in COMP. 34.22%. But we found no consistent improvement in EXP. and TEMP.: **No-Cro** loses 2.74% in TEMP.; **Add-Bro** loses 0.88% and 2.12% in EXP. and TEMP. respectively. This result is inconsistent with the finding of Rutherford and Xue (2014). The reason may lie in the training strategy, where we used sampling to solve the problem of unbalanced dataset while they reweighted training samples.

Compared with SVM-based models, **RAE** performs poorly in three relations, except EXP. which has the largest training dataset. Maybe **RAE** needs more labeled training data for better results. However, SCNN models perform remarkably well, producing comparable and even better results. Without normalization, **SCNN-No-Norm** gains 0.57%, 2.98% and 3.1% F1 scores for CONT., EXP. and TEMP. respectively, but loses 2.11% for COMP.. We obtain further improvement using **SCNN** with normalization: 0.71%, 2.17%, 6.52% and 4.93% for COMP., CONT., EXP. and TEMP. respectively. This suggests that normalization is useful for generalization of shallow models.

From Table 2, we found that our models do not achieve consistent improvements in precision, but benefit greatly from the gains of recall. Besides, our model works quite well for small dataset (Both accuracy and F1 score are improved in TEMP.). All of these demonstrate that our model is suitable for implicit DRR.

4 Conclusion and Future Work

In this paper, we have presented a convolutional neural network based approach to learn better DRR classifiers. The method is simple but effective for relation recognition. Experiment results show that our approach achieves satisfactory performance against the baseline models.

In the future, we will verify our model on other languages, for example, Chinese and Arabic. Besides, since our model is general to classification problems, we would like to investigate its effectiveness on other similar tasks, such as sentiment classification and movie review classification, etc.

[7]Without special illustration, all improvements and declines are against **SVM**.

On the Role of Discourse Markers for Discriminating Claims and Premises in Argumentative Discourse

Abstract

This paper presents a study on the role of discourse markers in argumentative discourse. We annotated a German corpus with arguments according to the common claim-premise model of argumentation and performed various statistical analyses regarding the discriminative nature of discourse markers for claims and premises. Our experiments show that particular semantic groups of discourse markers are indicative of either claims or premises and constitute highly predictive features for discriminating between them.

1 Introduction

The growing field of argumentation mining in NLP develops methods to automatically analyze argumentative discourse for enhanced Information Extraction.

Terminology: We understand argumentation as a rhetorical arrangement of *arguments* with the intent to convince or persuade the reader of a particular state of affairs. Following previous work in argumentation mining (e.g., (Palau and Moens, 2009; Florou et al., 2013; Peldszus and Stede, 2013a; Stab and Gurevych, 2014)), we define an *argument* as the pairing of a single *claim* (an arguable text unit) and a (possibly empty) set of *premises*, which each either support or attack the claim (Besnard and Hunter, 2008). We subsume claims and premises under the term *argument unit* (AU).

Discourse markers in argumentative discourse: Since an argumentation line can only be captured in the context of a coherent text, argumentation mining is closely related to automated discourse analysis (Cabrio et al., 2013), which aims at identifying discourse functions of text segments, and discourse relations (DRs) between adjacent text segments (Webber et al., 2012). Often, so-called discourse markers (DMs) are used to signal DRs. The following example shows that DMs act as lexical markers in argumentative discourse as well: the DM *however* (marking the DR *contrast*) positions the claim in (1) in the overall argumentation line, while in (2), the DMs *as* (marking *reason*) and *also* (marking *elaboration*) connect the premises with each other and with the claim.

> (1) *However*, staying down is pointless from a pedagogic point of view.
>
> (2) *As* the students get frustrated, their performance generally does not improve. *Also*, the point of repeating all courses because of only one or two bad grades is arguable.

DMs belong to the word classes of conjunctions and adverbs (also called discourse particles) and are semantically characterized in traditional grammar books. The correspondence between DM semantics and DR semantics has received considerable attention in previous research in linguistics, most of which is based on corpora annotated with DRs (Carlson et al., 2003; Wolf and Gibson, 2005; Prasad et al., 2008). In contrast, the role of DMs as potential lexical signals in *argumentative* discourse is not well-understood, yet. While Stab and Gurevych (2014) used DMs as features for classifying AUs into different types, they did not analyze the semantics of DMs with respect to AU classification or considered different DM resources.

As far as we are aware, there is no prior work performing a detailed investigation on the role of DMs as lexical signals for discriminating between the two fundamental argumentative roles of AUs, i.e., between claims and premises.

Our contribution: In this paper, we address this gap by analyzing the role of DMs for the automatic discrimination of claims and premises in a

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2236–2242,
Lisbon, Portugal, 17-21 September 2015.

new dataset of argumentative texts annotated with arguments. More specifically, we (i) present the results of an annotation study that we performed to annotate a German dataset of news documents with arguments, and (ii) performed a detailed investigation of the role of DMs in our annotated dataset which highlights correspondences between DM semantics and semantic properties of claims and premises, and shows that DMs are highly predictive features for automatically discriminating premises and claims.

2 Related Work

Related to our work are prior investigations (i) on the relationship of DMs and DRs, and (ii) on the role of DMs in classification tasks.

2.1 Relation of DMs and DRs

Previous work on the relation between DMs and DRs is mostly based on corpora annotated with DRs (Wolf et al., 2004; Taboada, 2006; Prasad et al., 2008), most notably the Penn Discourse Treebank (PDTB) for English (Prasad et al., 2008). The PDTB is annotated with DRs, such as *contrast* or *result*, and the corresponding DMs, even if they were not realized in the text. For instance, the *contrast* relation can be expressed by the DMs *however* and *but*. DRs that are lexically signaled by DMs in the text are called *explicit* DRs. Some DMs are highly polysemous, e.g., *while* appears in 12 DRs in the PDTB.

Asr and Demberg (2013) analyzed the DMs and their corresponding DRs annotated in the PDTB and addressed the question, which information is conveyed by discourse connectives in the context of human sentence processing, i.e., how they contribute in the process of inferring a particular DR.

Taboada (2006) performed a corpus-based analysis of DRs annotated in the Rhetorical Structure Theory (RST) Discourse Treebank (Carlson et al., 2003). The most frequent relation in the RST Discourse Treebank is *concession*, and this relation also received particular attention in the corpus linguistics literature: Taboada and Gómez-González (2012) present a corpus-based comparative study of DMs that express *concession* across English and Spanish in different genres. A classification of DMs signaling *concession* across English and German is presented by Grote et al. (1997). They also point out the importance of *concession* in argumentative discourse: DMs expressing *concession* are often used to introduce counter-arguments in an argumentation line.

2.2 DMs in Classification

There is previous work in sentiment classification and argumentation mining using DMs as features, as well as work in predicting DMs for natural language generation tasks, such as abstractive summarization. Taboada et al. (2011) successfully employed discourse particles as features for the calculation of polarity scores in automated sentiment analysis. They focused on particles acting as intensifiers, which modify the semantic intensity of the lexical item they refer to.[1] Mukherjee and Bhattacharyya (2012) demonstrated that using discourse connectives as features in a system for sentiment classification of Twitter posts significantly improves classification accuracy over state-of-the art systems not considering DMs as features.

In argumentation mining, Stab and Gurevych (2014) experimented with different types of features, including DMs from the PDTB annotation guidelines, to classify text units into the classes non-argumentative, major claim, claim, and premise. While the PDTB DMs appeared to be not helpful for discriminating between argumentative and non-argumentative text units, they were useful to distinguish between the classes premise and claim.

Patterson and Kehler (2013) describe a classification model, trained and evaluated on PDTB data, for predicting whether or not a DR is signaled by an explicit DM. The most predictive features in their model are discourse level features that encode dependencies between neighboring DRs given by the overall discourse structure. Other highly predictive features turned out to be the DMs themselves, because DMs vary as to their rates of being realized explicitly.[2]

3 Annotation Study

For our study, we used a dataset of 88 documents in German – mainly news (ca. 83% of the documents) – from seven current topics related to the German educational system (e.g., mainstreaming, staying down at school). The documents were manually selected from a focused crawl and the top 100 search engine hits per topic (Vovk, 2013).

[1] Amplifiers such as *very* increase the semantic intensity, while downtoners such as *slightly* decrease it.

[2] In the PDTB, DMs are also given for implicit DRs.

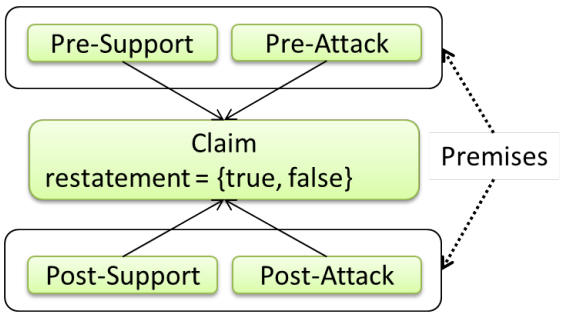

Figure 1: Claim-Premise scheme.

3.1 Annotation Scheme

Since argumentation theory offers a wide range of models, we performed a pre-study on a held-out development set to develop the annotation scheme. We found that most arguments consisted of adjacent claims and premises, related by a support or attack relation; premises and claims were rarely nested. Therefore, we decided to use a simplified claim-premises scheme (see Figure 1), using the terminology set up in Section 1.

Our scheme models an argument as a linked set of AUs and encodes the argumentative support and attack relations by assigning an argumentative role to *non-nested* (e.g., adjacent) AUs. The non-nested structure in combination with the *pre-* and *post-* prefixes of premises (indicating if a premise precedes or follows the claim) makes sure that all premises are correctly attached to their respective claims.

For claims, we also annotated whether the claim is a restatement. In total, we distinguish six argumentative roles as shown in Figure 1: *claim, restatement, pre-claim support, post-claim support, pre-claim attack and post-claim attack*. Annotators could freely select annotation boundaries, but we encouraged them to annotate clauses or sentences.

In the main study, three annotators annotated the remaining 80 documents (3 863 sentences) belonging to six topics. On average, each annotator marked 1 708 AUs (53 % premises, 47 % claims) and 783 arguments (2.2 AUs per argument). An average claim spans 1.1 sentences, whereas an average premise spans 2.2 sentences. On average, 74 % of the tokens are covered by an AU, indicating that the documents are highly argumentative.

	$A_{o,t}$	κ_t	$A_{o,s}$	κ_s	α_u
all	61.0	44.2	60.9	45.2	40.2
prem. / claims	62.7	45.1	62.6	46.3	41.7
AU / non-AU	79.0	50.0	77.0	50.0	56.6

Table 1: Inter-annotator agreement scores (percentages): A_o – observed agreement, κ_t– token-based kappa; κ_s– sentence-based kappa; α_u– unitized alpha.

3.2 Inter-annotator Agreement

Like in other discourse annotation tasks, there is no straightforward way to compute inter-annotator agreement (IAA) due to free annotation boundaries, see for instance (Miltsakaki et al., 2004; Wilson and Wiebe, 2003). We selected sentence-based *kappa* κ_s, token-based *kappa* κ_t and *Krippendorff's unitized alpha* α_u as IAA metrics.[3] The *token-based kappa* κ_t metric treats each token as annotation item and, thereon, calculates Fleiss' kappa (Fleiss, 1971). The tokens are labeled with the IOB scheme, i.e., every token is annotated as inside an AU (I), beginning of an AU (B) or outside an AU (O). In contrast, *Krippendorff's unitized alpha* α_u operates on whole annotation spans instead of isolated tokens. For comparison, we also calculated the observed agreement A_o (token-based and sentence-based).

Table 1 summarizes the IAA scores for three scenarios: (i) considering all six labels and non-AUs, (ii) only premise, claim and non-AUs, and (iii) AUs versus non-AUs. The IAA scores are in line with previous results: Peldszus and Stede (2013b) report κ=38.4 % and α=42.5 % for their sentence-level annotation study, which used artificially created documents.

4 Experiments

This section describes the experiments we performed to understand the role of DMs for the automatic discrimination of claims and premises. Since the IAA was not substantial, we performed all experiments on three separate datasets, one per annotator.

[3] We calculated the metrics using DKPro Statistics (Meyer et al., 2014).

4.1 Semantically Categorized DMs

Our first set of experiments aimed at understanding the correspondence of DM semantics and semantic aspects of claims and premises. For this, we used semantically characterized lists of DMs compiled from three different sources: (i) 28 semantically categorized particles from a German grammar (Helbig and Buscha, 1996, pp. 481–484), (ii) 51 discourse connectives based on a manual translation of the DMs in Appendix B of the PDTB annotation guidelines, and (iii) a large German lexicon of about 170 DMs called DiMLex[4] (Stede, 2002).

First, we applied a two-sample statistical test to find out if the two classes *claim* and *premise* are significantly different regarding the number of occurrences of individual DMs and semantic groups of DMs (based on the semantic information given in our lists). We chose Fisher's exact test (Fisher, 1932), a non-parametric randomization test that makes no assumptions about the underlying probability distribution of the DMs.[5] Lacking DR annotations, we counted surface word forms of single word and continuous multi-word DMs in the AUs annotated in our dataset.[6] For each semantically categorized DM, we computed a contingency table containing the number of observed occurrences in the two samples of claims and premises. For each semantic group of DMs given in DiMLex and PDTB, we calculated the per-group contingency table by adding up the contingency tables for each DM in that particular group.

The results of the significance tests revealed both single DMs and semantic groups of DMs that occur with significantly different frequency in claims or premises. The following individual DMs and semantic groups of DMs appeared to be indicative for claims and premises (note that the sentence-initial variants are counted separately):

Claims: four DMs expressing *result, comparison, contrast*:

- *also* (therefore), *Doch* (However), *jedoch* (though), *sondern* (but), as well as the amplifier *ganz* (quite);
- semantic groups of DMs from PDTB: *comparison* (expressing *concession* and *contrast*) and *result*.

Premises: three DMs expressing *cause, reason, elaboration, alternative*:

- *Denn* (As), *oder* (or), *und* (and), as well as the downtoner *etwa* (roughly);
- semantic groups of DMs from PDTB: *alternative* (e.g., *or*), *reason* (e.g., *because*), and from DiMLex, the group *sequence* (e.g., *then*).

In the group of high-frequent but non-indicative DMs are DMs expressing *elaboration* (*Auch* (Also), *Und* (And), *So* (Therefore)), *sequence* (*dann* (then)), and *contrast* (*aber/Aber* (but/But)), as well as some highly ambiguous particles (e.g., *immer* (always), *schon* (already)).

Second, we ranked the DMs according to their Information Gain (IG) using Weka (Hall et al., 2009). For this, we mapped each DM to a boolean feature indicating if it is present in an AU or not. We considered all the DMs from the three resources as features and ranked them by IG separately for each annotator. The resulting ranking revealed additional DMs indicative for premises, e.g. further DMs expressing *elaboration* and the downtoner *nur* (only).

Our findings are in accordance to the ability of a claim to act as conclusion or result of an argument, and to the role of premises as providing support for a claim by giving reasons and elaborating on them. Moreover, we found that particular intensifying discourse particles play an important role in discriminating claims and premises: Downtoners seem to be significant for premises, amplifiers for claims. Finally, semantic groups of DMs expressing *concession* appeared to be significant for claims, since claims often introduce a counter-argument in the overall argumentation structure (Grote et al., 1997).

4.2 Classification

The significance test and the IG ranking evaluated the DMs in isolation. In order to examine the predictiveness of all DMs *in combination* for claims vs. premises, we used a classification model. Given an AU, the model predicts its argumentative role, i.e., claim vs. premise. In this experiment, we used a list of single word DMs, extracted from the three DM resources described above, as boolean features (DMres).

[4] https://github.com/discourse-lab/dimlex

[5] We used the implementation given in http://stat.ethz.ch/R-manual/R-patched/library/stats/html/fisher.test.html and a p-value of 0.05.

[6] Sentence initial DMs were counted separately to capture DRs being signaled by a sentence initial position.

For comparison, we used two sets of data-driven DMs extracted from the Tiger corpus (Brants et al., 2004), a German newspaper corpus: one set containing the 350 most frequent conjunctions and adverbs (DMtiger), and another set containing the 300 most frequent non-open-class words (NOCtiger, excluding the word classes of nouns, main verbs and adjectives).[7] In addition, we considered the top 1 800 unigrams (with minimum frequency 5) as baseline features.

We trained three Machine Learning algorithms (Naive Bayes (NB), Random Forests (RF) and Support Vector Machine (SVM)) on the three datasets annotated by the annotators A1, A2 and A3, using 10-fold cross-validation and the DKPro TC framework (Daxenberger et al., 2014). For the classification experiments, we used all 88 documents in the annotated corpus (including the documents from the pre-study).

Table 2 summarizes the results. All classifiers show significant improvement compared to the majority class baseline (MC), indicating that DMs might be useful as predictive features for discriminating claims and premises. The DMs extracted from Tiger did not improve the performance consistently for all three datasets, showing that the coverage of the manually compiled DMs is good. Using the NOCtiger set, however, improved the performance by up to 4 pp., compared to DMres; the improvement of NOCtiger over DMres is statistically significant for NB across all datasets A1 - A3 (using Fisher's exact test and a p-value of 0.05). These results suggest that not only DMs, but also other function words, as well as auxiliaries and modals, play an important role in discriminating claims and premises.

While the unigram baseline also outperforms DMres, it is on par with NOCtiger (no significant improvement for any of NB, RF, SVM across the three datasets), but at the cost of a much larger feature space and a model less able to generalize to other datasets from the news domain.

	A1	**A2**	**A3**
MC	53.04	52.05	51.71
DMres-NB	64.74	65.21	64.53
DMres-RF	64.89	63.61	63.50
DMres-SVM	68.50	66.31	67.06
DMtiger-NB	67.81	65.65	66.65
DMtiger-RF	64.65	61.12	63.44
DMtiger-SVM	70.37	65.59	67.57
NOCtiger-NB	70.86	68.80	68.87
NOCtiger-RF	67.06	64.71	65.51
NOCtiger-SVM	71.80	68.25	68.41
unigram-NB	72.79	69.69	69.60
unigram-RF	70.32	68.75	68.15
unigram-SVM	71.21	69.97	71.14

Table 2: Accuracy (percent) using different feature sets.

5 Summary

Our goal was to understand some of the lexical-semantic characteristics of claims and premises with a focus on DMs acting as lexical signals for the argumentative role of AUs. Such insights into the way claims and premises are signaled by lexical markers can be exploited not only for the automatic analysis of argumentative discourse, but also for language generation tasks such as creating abstractive summaries of argumentative documents.

We investigated the role of a large set of DMs in argumentative discourse based on a German dataset annotated with arguments and identified semantic groups of DMs that are indicative of either claims or premises. These semantic groups also shed light on semantic aspects of claims and premises. Our classification model shows that DMs are important features for the discrimination of claims and premises. In order to foster further research on DMs in argumentative discourse, we publicly released the annotation guidelines, as well as the semantically categorized DM lists used in our experiments.[8]

Fatal or not? Finding errors that lead to dialogue breakdowns in chat-oriented dialogue systems

Abstract

This paper aims to find errors that lead to dialogue breakdowns in chat-oriented dialogue systems. We collected chat dialogue data, annotated them with dialogue breakdown labels, and collected comments describing the error that led to the breakdown. By mining the comments, we first identified error types. Then, we calculated the correlation between an error type and the degree of dialogue breakdown it incurred, quantifying its impact on dialogue breakdown. This is the first study to quantitatively analyze error types and their effect in chat-oriented dialogue systems.

1 Introduction

Chat-oriented or open-domain dialogue systems have recently been attracting attention from social and entertainment aspects (Bickmore and Cassell, 2001; Banchs and Li, 2012; Wilcock and Jokinen, 2013). However, since they need to deal with open-domain utterances, which current natural language processing techniques are not mature enough to handle appropriately, the system inevitably makes errors. This discourages users from talking to the system, leading to dialogue breakdowns in conversation (Martinovsky and Traum, 2003). Here, dialogue breakdowns denote points in dialogue where users are unable to continue the conversation.

This paper aims to find errors that lead to dialogue breakdowns in chat-oriented dialogue systems. Our approach is two-fold: (1) identify error types in chat-oriented dialogue systems, and (2) calculate their impact on dialogue breakdown. For (1), we first collect chat dialogues between an automated system and users, annotate the dialogues with dialogue breakdown labels, and collect comments that describe the error that led to the breakdowns. After that, we apply automatic clustering methods to the comments to obtain clusters of comments, each of which corresponds to a particular error type. For (2), we calculate the correlation between an error type and the degree of dialogue breakdown it incurs. This way, we can quantify the impact of an error type on dialogue breakdown. By our approach, we hope to distinguish fatal errors from non-fatal ones, providing useful guidelines for dialogue system developers to avoid breakdowns in chat-oriented dialogue systems.

2 Data Collection

For data collection, we asked dialogue researchers and their collaborators in Japan to use our chat-oriented dialogue system. The system is text-based and enables chatting in Japanese. It was built by wrapping a chat API provided by NTT DOCOMO (Onishi and Yoshimura, 2014). Since the API works on the basis of (Higashinaka et al., 2014), which uses a number of natural language processing techniques to understand and generate utterances, we expected to obtain a wide variety of dialogues, and hence, a variety of errors.

A total of 116 users chatted with the system, resulting in 1,146 dialogues. Here, each dialogue was controlled to be 21 utterances long: one system prompt with ten utterances each from the user and system. Then, we randomly sampled 100 dialogues (called the *init100* data set) for dialogue breakdown annotation. Twenty-four annotators subjectively labeled each system utterance in init100 with one of the following three dialogue breakdown labels:

(NB) Not a breakdown: The conversation is easy to continue after the system utterance in question.

(PB) Possible breakdown: The conversation is difficult to continue smoothly after the system utterance in question.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2243–2248,
Lisbon, Portugal, 17-21 September 2015.

	Utterance	NB	PB	B	C	Comments
S0	Hello! Talk to me anytime.	24	0	0	0	
U1	It's hot today, isn't it?					
S1	Please tell me your favorite movie genre.	20	2	2	2	User utterance is not considered. / The system ignored user's intended topic.
U2	I like action movies.					
S2	Action movies, I like them.	21	3	0	0	
U3	What kind of movies do you like?					
S3	I like Japanese ones.	23	1	0	0	
U4	That's great.					
S4	Thank you.	24	0	0	0	
U5	Do you know what movie will be aired on Friday night?					
S5	Yes, yes.	4	11	9	4	The system did not mention a movie name. / It answered only "yes" but without saying a movie name. / This is not an answer to the question. / The conversation is not valid.
U6	I haven't heard of that movie.					
S6	That's good.	3	10	11	4	This is not a response to a question. / Strange answer. / It is not clear what is good. / The conversation is not valid.
U7	Oh, is it good? I will watch it then.					
S7	That's good!	18	3	3	1	It is not clear what is good.
U8	Recently, I have had lots of free time.					
S8	That's great.	15	7	2	0	
U9	Are you busy?					
S9	Indeed so.	24	0	0	0	
U10	Take care. Have some rest.					
S10	I see.	10	9	5	2	The system should thank the user. / Strange answer.

Figure 1: Example dialogue with the number of breakdown labels for each system utterance. S and U stand for system and user utterances, respectively. C stands for the number of comments provided. The dialogue was originally in Japanese and was translated by the authors.

(B) Breakdown: The conversation is difficult to continue at all after the system utterance in question.

The annotators were instructed to provide voluntary comments to describe the errors that led to the breakdowns. Table 1 shows the statistics of the dialogue breakdown labels and comments. Figure 1 shows an example dialogue with the number of breakdown labels and comments for each system utterance. In this example, S5 and S6 were annotated with nine and eleven breakdown labels, respectively, both having four comments.

The inter-annotator agreement of dialogue breakdown annotation in Fleiss' kappa was 0.276, which seems relatively low. One reason for this is obviously the subjective nature of the task. Another possible reason is that we intentionally did not set rigid guidelines for dialogue breakdown annotation so as to explore possible error types in chat-oriented dialogue systems. When we merge PB and B and make it a two-class annotation, the agreement becomes 0.396 (moderate agreement), showing that the subjects share some common conception about dialogue breakdown.

Breakdown label	# of labels	# of comments
NB	14,212	57
PB	5,322	1,818
B	4,466	1,511

Table 1: Statistics related to breakdown labels and comments in init100 data set. Note that NB also had some opinions as comments.

3 Analysis

3.1 Automatic clustering of comments

We first need to identify the error types in chat-oriented dialogue systems. For this, we applied an automatic clustering method to the comments to obtain clusters of comments. Our idea is that, since each comment describes a particular error that led to a breakdown, a cluster of comments is likely to represent an error type. Since the number of clusters is difficult to know in advance, we turn to a non-parametric Bayesian method called the Chinese restaurant process (CRP) as a clustering method. CRP can infer the number of clusters automatically from data (Pitman, 1995).

We applied CRP to the 1,511 comments given

ID	Size	Interpretation	Representative words in the cluster
2	259	General quality	dialogue, well-formed, consideration, conversation
0	194	Not understandable	understand, meaning, what
6	148	Ignore user utterance	ignore, user, utterance
7	134	Ignore user question	answer, question, partner, respond
1	113	Unclear intention	unclear, intention, meaning, utterance
8	107	Contradiction	doubtful, change, negative (as opposed to positive), previous
16	100	Analysis failure	analysis, recognition, related, understand
4	95	Inappropriate answer	response, inappropriate, invalid, answer
5	77	Repetition	say, add, mind, strange, tired
3	54	Grammatical error	(words specific to particular grammar usage)
14	53	Expression error	(words specific to particular expressions)
11	39	Topic-change error	change, topic, sudden, mismatch, response
12	38	Violation of common sense	match, flow, common sense, against, connection
13	36	Word usage error	(words specific to particular word usage)
10	35	Diversion	story, different
15	25	Mismatch in conversation	match, story
9	4	Social error	(no words)

Table 2: Clusters by CRP of 1,511 comments given to breakdowns. The clusters are ordered by size.

to breakdown labels (B labels). For the clustering, we used the same procedure as (Higashinaka et al., 2011); each datum (comment) was represented by a word frequency vector, and the probability that it belonged to a particular cluster was calculated by using the likelihood that the words are generated from the word distribution of that cluster. The hyper-parameters α and β were both set to 0.1 and the number of iterations for Gibbs sampling was 10,000. See (Higashinaka et al., 2011) for the details of the procedure.

Table 2 shows the clustering results. We obtained 17 clusters. For each cluster, we mined representative words by a log-likelihood ratio test, which uses a two-by-two matrix to test the independence of a word to a particular cluster. By looking at the representative words and also the raw comments, we came up with the interpretations of the clusters as indicated in the table. Although we do not go into the details of the clusters one by one, each cluster seems to successfully represent a certain error type in chat-oriented dialogue systems. We also applied CRP to the 3,329 comments given to PB and B to obtain similar clusters except that we additionally had clusters whose interpretations are as follows: inability to handle invalid user input, missing topic, missing information, mismatch in response, no reaction, and no information. They account for about 13.3% of the comments and mostly concern missing elements (such as missing arguments) in dialogue. Since such missing elements can be complemented by follow-on utterances in dialogue, they only appear in the comments for PB; they do not lead to an immediate dialogue breakdown.

To further categorize the clusters, we applied a hierarchical clustering (an agglomerative clustering) to the clusters. Here, a cluster was represented by the word frequency vector of all comments contained in the cluster, and the similarity of the clusters was calculated by cosine similarity of word frequency vectors. For the linkage criterion, we used Ward's method. Figure 2 shows the clustering results. The figure indicates that there are the following eight main error categories (E1–E8):

(E1) Clusters 2 and 16 concern the general ability of a system.

(E2) Clusters 7, 5, and 8 relate to context awareness: the ability to recognize when it is asked a question and to recognize what has been said before.

(E3) Clusters 13, 3, and 14 concern the language generation (surface realization) ability.

(E4) Clusters 4 and 6 concern the response ability: the ability to answer questions and to create utterances relevant to the previous user utterance.

(E5) Cluster 1 relates to the exhibition of an intention or a plan: the ability to make clear the

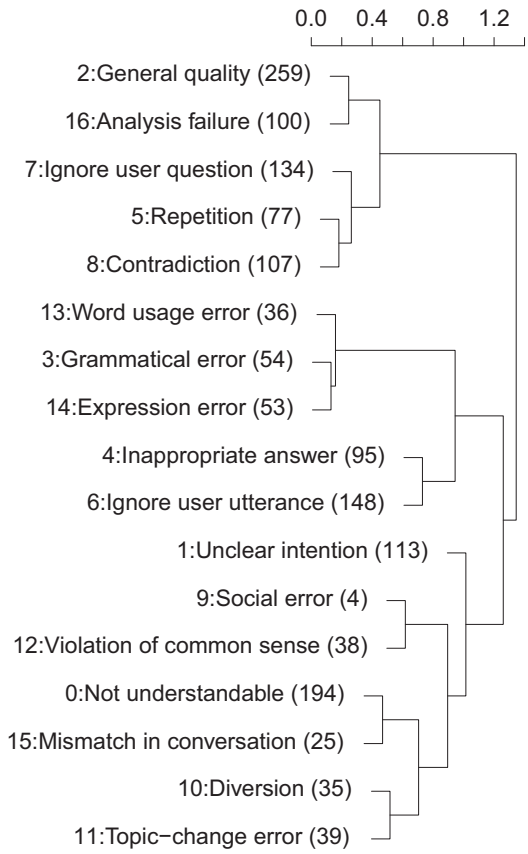

Figure 2: Hierarchical clustering applied to the obtained clusters. The numbers in parentheses denote cluster size.

purpose of an utterance.

(E6) Clusters 9 and 12 relate to the social ability: the ability not to offend users or say things that are not socially acceptable.

(E7) Clusters 0 and 15 concern the understandability of an utterance: the ability to generate utterances that have clear meanings in the context of the conversation.

(E8) Clusters 10 and 11 relate to the awareness of current topics.

3.2 Analyzing the impact of error types

Having identified the error types and error categories, we investigated their impact on dialogue breakdown. For this purpose, we examined the correlation between an error type and its degree of breakdown: the higher the correlation, the more it is related to dialogue breakdown. Specifically, we calculated the correlation ratio (η) between the existence of a comment belonging to a particular cluster (error type) and the number of breakdown labels (B labels). Note that the correlation ratio is equivalent to Pearson's correlation coefficient except that it can be applied to categorical data. The η ranges from 0 to 1. For calculation, we first extracted data that had one or more B labels and one or more corresponding comments (we had 556 such samples in our data). Then, we calculated the correlation ratios.

ID	Interpretation	Cat	η
0	Not understandable	E7	0.38
7	Ignore user question	E2	0.37
2	General quality	E1	0.36
1	Unclear intention	E5	0.36
6	Ignore user utterance	E4	0.24
13	Word usage error	E3	0.18
16	Analysis failure	E1	0.17
4	Inappropriate answer	E4	0.17
3	Grammatical error	E3	0.15
12	Violation of common sense	E6	0.15
8	Contradiction	E2	0.14
5	Repetition	E2	0.11
9	Social error	E6	0.10
10	Diversion	E8	0.09
11	Topic-change error	E8	0.06
15	Mismatch in conversation	E7	0.06
14	Expression error	E3	0.02

Table 3: Correlation ratio (η) between the existence of a comment of a cluster (error type) and the number of breakdown labels. "Cat" denotes the error category of an error type.

Table 3 shows the correlation ratios for the error types. Clearly, not all error types have the same level of correlation. At the top of the table, there are four salient error types with similar η values: "Not understandable", "Ignore user question", "General quality", and "Unclear intention". Putting aside "General quality", which seems to concern the overall dialogue ability, the error types that we need to consider as fatal would seem to be the other three. Other errors seem to be less important with lower η values. "Expression error", which concerns the use of unnatural expressions, was found the least important.

When we look at the error categories, we can see an interesting result that it is NOT the error category that determines the fatality of errors but the specificity of error types. For example, "Not understandable" and "Mismatch in conversation" are both under error category E7 but have totally different effects on perceived breakdown. The same can be said for error types in E2.

Note that, although the values of correlation ratio seem rather low, the correlation often becomes low when it comes to subjective judgments (Higashinaka et al., 2004). Considering that we deal with chat-oriented dialogues, which are less restricted than task-oriented ones, we consider the current values of correlation ratio to be acceptable. Here, the important finding is that several error types are comparatively more important than the others.

4 Related work

Few studies have analyzed breakdowns in conversation. One exception is the study by Martinovsky and Traum (2003), who discussed possible causes of breakdowns they observed. Our work is different in that we systematically identify error types and quantitatively evaluate their effect. Our work can be seen as listing up errors in dialogue systems. A number of studies have aimed to create a taxonomy of errors (Bernsen et al., 1996; Möller, 2002; Paek, 2003), but their taxonomies are created manually and focus on task-oriented dialogue systems.

5 Summary and future work

By processing dialogue data with dialogue breakdown annotations and comments, this paper identified 17 error types that can be further categorized into eight error categories. By calculating correlation ratios, we discovered three error types that can be fatal: "Not understandable", "Ignore user question", and "Unclear intention". To avoid dialogue breakdowns, it is suggested that we need to make clear the meanings of system utterances, not ignore user questions, and show some intention behind system utterances. The findings will be useful for dialogue system developers who want to realize smooth human-machine interaction in chat-oriented dialogue systems and possibly in dialogue design as a whole.

For future work, we plan to consider ways to improve systems on the basis of our findings and also verify the generality of the results on data using other systems. To accurately detect dialogue breakdowns, dialogue systems researchers will need to collaborate. To this end, we are planning to organize an evaluation workshop on dialogue breakdown detection. For use in the evaluation workshop as well as in dialogue research in general, we have released our data with all the annotations and comments to the public.[1]

Acknowledgments

The "Project Next NLP" project in Japan is addressing the problems related to analyzing errors in natural language processing systems. One subgroup, comprising more than 32 researchers from 15 institutions, is collaborating in the performance of a dialogue task. We thank the members of this sub-group for the data collection, annotation, and fruitful discussions. We also thank NTT DOCOMO for letting us use their chat API for data collection.

Abstract

If intelligent systems are to interact with humans in a natural manner, the ability to describe daily life activities is important. To achieve this, sensing human activities by capturing multimodal information is necessary. In this study, we consider a smart environment for sensing activities with respect to realistic scenarios. We next propose a sentence generation system from observed multimodal information in a bottom up manner using multilayered multimodal latent Dirichlet allocation and Bayesian hidden Markov models. We evaluate the grammar learning and sentence generation as a complete process within a realistic setting. The experimental result reveals the effectiveness of the proposed method.

1 Introduction

Describing daily life activities is an important ability of intelligent systems. In fact, we can use this ability to achieve a monitoring system that is able to report on an observed situation, or create an automatic diary of a user. Recently, several studies have been performed to generate sentences that describe images using Deep Learning (Vinyals et al., 2014; Fang et al., 2014; Donahue et al., 2014; Kiros et al., 2015). Although these results were good, we are interested in unsupervised frameworks. This is necessary to achieve a system that can adapt to the user, that is, one that can learn a user-unique language and generate it automatically. Moreover, the use of crowdsourcing should be avoided to respect the privacy of the user. Regarding this, studies on sentence generation from RGB videos have been discussed in (Yu and Siskind, 2013; Regneri et al., 2013). A promising result for language learning has been shown in (Yu and Siskind, 2013) and a quite challenging effort to describe cooking activities was made in (Regneri et al., 2013). However, these studies rely only on visual information, while we aim to build a system that is able to describe everyday activities using multimodal information. To realize such systems, we need to consider two problems. The first problem is the sensing of daily life activities. In this paper, we utilize a smart house (Motooka et al., 2010) for sensing human activities. Thanks to the smart house, multimodal information such as visual, motion, and audio data can be captured. The second problem to be tackled is verbalization of the observed scenes. To solve this problem, a multilayered multimodal latent Dirichlet allocation (mMLDA) was proposed in (Attamimi et al., 2014).

In this paper, we propose a sentence generation system from observed scenes in a bottom up manner using mMLDA and a Bayesian hidden Markov model (BHMM) (Goldwater and Griffiths, 2007). To generate sentences from scenes, we need to consider the words that represent the scenes and their order. Here, mMLDA is used to infer words for given scenes. To determine the order of words, inspired by (Kawai et al., 2014), a probabilistic grammar that considers syntactic information is learned using BHMM. In this study, the order of concepts is generated by sampling the learned grammar. The word selection for each generated concept is then performed using the observed data. Moreover, a language model that represents the relationship between words is also used to calculate

Lisbon, Portugal, 17-21 September 2015.

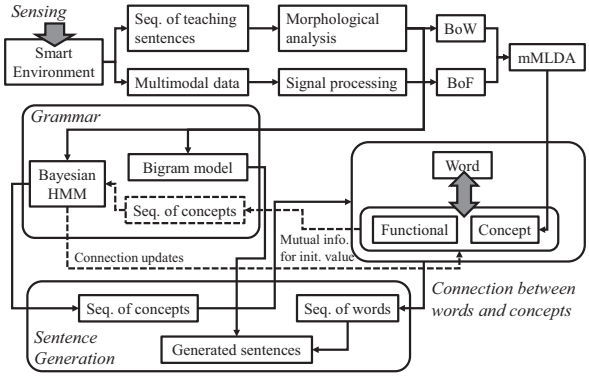

Figure 1: Language learning and sentence generation system.

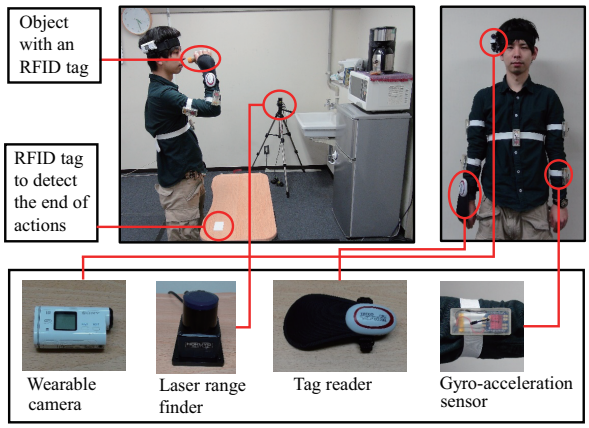

Figure 2: Multimodal information acquisition.

the transition probability between them. Considering the transition probability at word level, a lattice of word candidates corresponding to the concept sequence can be generated. Therefore, sentence generation can be thought of as a problem of finding the word sequence that has the highest probability from the lattice of word candidates, which can be solved by the Viterbi algorithm. Finally, sampling from grammar is performed multiple times to generate sentence candidates and select the most probable one.

2 Proposed method

2.1 Overview

Figure 1 illustrates the overall system of proposed language learning and sentence generation. In this study, we use a smart environment for sensing multimodal information. The system shown in Figure 2 is part of a smart house (Motooka et al., 2010) that is used to capture multimodal information. Here, an RFID tag is attached to an object

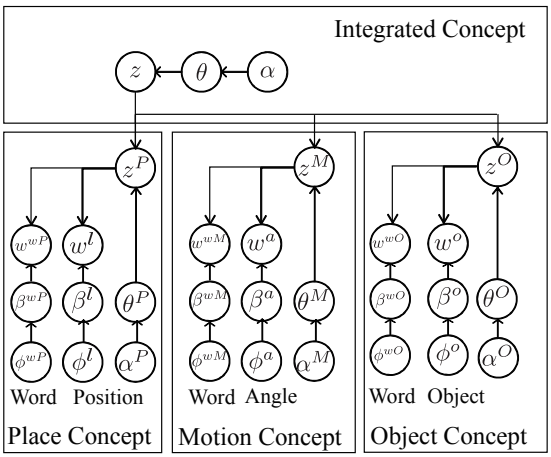

Figure 3: Graphical model of mMLDA.

to enable the object information to be read using a wearable tag reader. To capture motion, five sensors that consist of 3-axis acceleration with 3-axis gyroscope sensors are attached to the upper body, as shown in Figure 2. Moreover, a particle filter-based human tracker (Glas et al., 2007) applied to four laser range finders is used to estimate the location of a person while performing an action. This is a setup designed to demonstrate that language can be learned and generated from real human actions. Ultimately, our goal is sensing based on image recognition.

The acquired multimodal data is then processed, which results in a bag-of-words model (BoW) and bag-of-features model (BoF) (Csurka et al., 2004). Using mMLDA (see section 2.2), various concepts can be formed from the multimodal data. Given teaching sentences, the connection between words and concepts can be learned based on mMLDA and BHMM which is learned with mutual information (MI) as the initial value. On the other hand, the bigram model of words is calculated and used as the score when reordering words inferred from multimodal information using grammar. A morphological analyzer for parsing words in a sentence is also necessary in the proposed system. We use publicly available parser MeCab (Kudo et al., 2004). In the future, we plan to use the unsupervised morphological analysis technique proposed in (Mochihashi et al., 2009).

2.2 mMLDA

Figure 3 shows the graphical model of mMLDA used in this paper. Here, z represents the integrated category (concept), whereas z^O, z^M, and z^P represent the object, mo-

tion, and place concepts, respectively. In the bottom layer (lower panel of Figure 3), $w^m \in \{w^o, w^{wO}, w^a, w^{wM}, w^l, w^{wP}\}$ represents the multimodal information obtained from each object, motion, and place. Here, w^o, w^a, and w^l denote multimodal information obtained respectively from the object used in an action, motion of a person while using the object, and location of the action. Further, $w^{wC} \in \{w^{wO}, w^{wM}, w^{wP}\}$ denotes word information obtained from teaching sentences. Observation information is acquired by using the system shown in Figure 2. A brief explanation of each observation is as follows.

For object information, an N_o-dimensional vector $w^o = (o_1, o_2, \cdots, o_{N_o})$ is used, where N_o denotes the number of objects. In this vector, o_* takes a value of 0 or 1, where o_i is set to 1 if an object with index i is observed. Moreover, all of the teaching sentences are segmented into words and represented by a BoW as word information. Here, motion is segmented according to the object used. A sequence of 15-dimensional feature vectors for each motion is acquired. Using BoF, the acquired feature vectors are vector quantized, resulting in a 70-dimensional vector. The acquired two dimensional of human positions are processed using BoF to construct a 10-dimensional vector as place information.

In mMLDA, latent variables that represent upper and lower concepts z and $z^C \in \{z^O, z^M, z^P\}$ are learned simultaneously. Gibbs sampling is applied to the marginalized posterior probability of latent variables to learn the model from observed data w^m (Attamimi et al., 2014).

2.3 Language learning and generation

2.3.1 Word inference

In this study, word information is obtained from teaching sentences and employed for all concepts, as shown in Figure 3. Considering that appropriate words to express each concept exist, a criterion to measure the correlation between words and concepts is needed. At the start of grammar learning, MI, which can measure the mutual dependence of two stochastic variables, is used. Therefore, a word is considered to express a category when the MI between the word and category is large. On the other hand, a word with small MI is identified as a functional word. This determination is used as an initial value in the syntactic learning and needs not be strictly determined. Once the grammar is learned, we can utilize BHMM's parameters $P(w^w|c)$ to infer a word w^w from observed data $\boldsymbol{w}^m_{\text{obs}}$ as $\hat{P}(w^{wC}|\boldsymbol{w}^m_{\text{obs}}, c) \propto \max_k P(w^{wC}|c)P(w^{wC}|k)P(k|\boldsymbol{w}^m_{\text{obs}}, c)$, where $P(w^{wC}|k)$ and $P(k|\boldsymbol{w}^m_{\text{obs}}, c)$ can be estimated from mMLDA (Attamimi et al., 2014) and k is category of concept $c' \in \{object, motion, place\}$ and $c \in \{c', functional\}$. It should be note that $P(w^{wC}|k)$ and $P(k|\boldsymbol{w}^m_{\text{obs}}, c)$ are considered as uniform distribution for "functional" since they cannot be inferred from observed data using mMLDA. In this case, we can rely on syntactic information which is learned by BHMM.

2.3.2 Grammar learning using BHMM

Thanks to mMLDA and BHMM, appropriate words to represent the observed information can be inferred. Given an input consisting of a teaching sentence of a sequence of words, a BHMM can infer a sequence of concepts. In the learning phase, the MI results of concept selection for each word are used as the initial values of the BHMM. Here, grammar is defined as the concept transition probability $P(C_t|C_{t-1})$, which is estimated using Gibbs sampling, where $C_t \in c$ represents the corresponding concepts of the t-th word in the sentence. In addition, a language model that represent the bigram model of words in the teaching sentences is also used for generating sentences.

Motion	Object	Place	Motion	Object	Place	Motion	Object	Place

In each image, B, P, and G indicate the sentence structure in Japanese grammar generated by the baseline method, proposed method, and correct sentence, respectively; whereas the bottom line gives the meaning of the generated sentence. Words marked in red have been incorrectly generated.

2.3.3 Sentence generation of observed scenes

First, concepts are sampled from the begin of sentence "BOS" until the end of sentence "EOS" according to the learned grammar N times. Let the n-th ($n \in \{1, 2, \cdots, N\}$) sequence of concepts that excludes "BOS" and "EOS" be $\boldsymbol{C}^n = \{C_1^n, \cdots, C_t^n, \cdots, C_{T_n}^n\}$, where, T_n denotes the number of sampled concepts, which corresponds to the length of a sampled sentence.

Next, the word that corresponds to concept C_t^n is estimated. Here, for a given observed information $\boldsymbol{w}_{\text{obs}}^m$, the top-$K$ words that correspond to concept C_t^n and have high probabilities $\boldsymbol{w}_t^n = \{w_{t1}^n, w_{t2}^n, \cdots, w_{tK}^n\}$ are used. Hence, the set of all words for a sequence of concepts $\boldsymbol{C}^n$ can be written as $\boldsymbol{W}^n = \{\boldsymbol{w}_1^n, \boldsymbol{w}_2^n, \cdots, \boldsymbol{w}_{T_n}^n\}$. Therefore, K^{T_n} number of patterns for a candidate of the sentence can be considered for $\boldsymbol{C}^n$ and the corresponding words $\boldsymbol{W}^n$. Each candidate for sentence S^n is selected from these patterns and has the following probability:

$$P(S^n|\boldsymbol{C}^n, \boldsymbol{W}^n, \boldsymbol{w}_{obs}^m) \propto \prod_t P(C_t^n|C_{t-1}^n) P(w_t^n|\boldsymbol{w}_{obs}^m, C_t^n) P(w_t^n|w_{t-1}^n). \quad (1)$$

For observed information, the most probable sentence is selected from N sequences of concepts with sets of words. Here, the sentence $\hat{S}^n$ that maximizes Eq. (1) is determined for each sequence of concepts. Because many patterns of S^n exist, the Viterbi algorithm is applied to cut the computational cost and determine the most probable sentence. Thus, a set of sentences that consists of sentences with the highest probability for each sequence of concepts can be written as $\hat{\boldsymbol{S}} = \{\hat{S}^1, \cdots, \hat{S}^n, \cdots, \hat{S}^N\}$.

We can select the final sentence from $\hat{\boldsymbol{S}}$ by considering the most probable candidate. In fact, long sentences tend to have low probability and are less likely to be selected. To cope with this problem, adjustment coefficient $\ell(\hat{S}^n) = \frac{(L^{\max} - L_{\hat{S}^n})}{\sum_n^N L_{\hat{S}^n}} \sum_n^N \log P(\hat{S}^n|\boldsymbol{C}^n, \boldsymbol{W}^n, \boldsymbol{w}_{obs}^m)$ is introduced, where, $L_{\hat{S}^n}$ denotes the length of sentence $\hat{S}^n$ and $L^{\max}$ represents the maximum value of the sentence length in $\hat{\boldsymbol{S}}$. Using $\ell(\hat{S}^n)$, the logarithmic probability of the sentence can be calculated as $\log \bar{P}(\hat{S}^n|\boldsymbol{C}^n, \boldsymbol{W}^n, \boldsymbol{w}_{obs}^m) = \log P(\hat{S}^n|\boldsymbol{C}^n, \boldsymbol{W}^n, \boldsymbol{w}_{obs}^m) + \omega \ell(\hat{S}^n)$, where ω is a weight that controls the length of sentences. A large weight leads to longer sentences. The final sentence S is determined as $S = \text{argmax}_{\hat{S}^n \in \hat{\boldsymbol{S}}} \log \bar{P}(\hat{S}^n|\boldsymbol{C}^n, \boldsymbol{W}^n, \boldsymbol{w}_{obs}^m)$.

3 Experiments

The acquisition system shown in Figure 2 was used to capture multimodal information from human actions. Table 1 shows the actions that were performed by three subjects twice, resulting in a total of 195 multimodal data with 1170 sentences. We then divided the data into training data (99 multimodal data with 594 sentences) and test data (96 multimodal data with 576 sentences). Some examples of acquired multimodal data are shown in Figure 4(b). Using training data, various concepts were formed by mMLDA, and the categorization accuracies for object, motion, and place were respectively 100.00%, 52.53%, and 95.96%. Motion similarity was responsible for the false cat-

	♯ of words	Baseline	Proposed
w/o functional words	78	65.38%	**73.08%**
w functional words	98	–	**68.37%**

Table 2: Concepts selection results.

egorization of motion concepts. Since our goal is to generate sentences from observed scenes, these results are used as reference instead of comparing with the baseline.

To evaluate the concept selection of words, 98 words in teaching sentences were used. We compared the results of concept selection with hand-labeled ones. Table 2 shows the accuracy rate of concept selection. Here, we excluded the functional words (resulting in 78 words) for fair comparison with the baseline method (Attamimi et al., 2014). One can see that, better results can be achieved by the proposed method. It is clear that concept selection is improved by using the BHMM, indicating that a better grammar can be learned using this model.

Next, the learned grammar was used and sentences were generated. To reduce randomness of the results, sentence generation was conducted 10 times for each data. To verify sentence generation quantitatively, we evaluated the sentences automatically using BLEU score (Papineni et al., 2002). Figure 5 depicts the results of 2- to 4-gram of BLEU scores. Since functional words are not considered in (Attamimi et al., 2014), we used our grammar and performed sentence generation proposed in (Attamimi et al., 2014) as the baseline method. One can see from the figure that in all cases the BLEU scores of proposed method out performs the baseline method. It can be said that the sentences generated by the proposed method are of better quality than those generated by the baseline method.

Moreover, we also manually evaluated generated sentences by asking four subjects (i.e., college students who understand Japanese) whether the sentences were: correct both in grammar and meaning (E1), grammatically correct but incorrect in meaning (E2), grammatically incorrect but correct in meaning (E3), or incorrect both in grammar and meaning (E4). The average rates of E1, E2, E3, and E4 were shown in Table 3. We can see that the proposed method out performs the baseline method by providing high rates of E1 and E2; and low rates of E4. Because we want to generate sentences that explain actions, incorrect motion inference would lead to incorrect sentence generation. Examples of E2 are "Eating the plastic wrap in the dining room" and "Opening the dressing in the kitchen." One can see that these sentences are grammatically correct but do not express the scenes correctly because the words that represent the motion are incorrect. Hence, the misclassification that occurred in the motion concept formation was responsible for the incorrect meaning of the generated sentences. Figure 4(c) shows the sentences generated from the given scenes (Figure 4(a)). We can see that meaningful yet natural sentences that explain the observed scenes can be generated using the proposed method.

	Grammar	Meaning	Baseline	Proposed
E1	**correct**	**correct**	$(23.21 \pm 5.28)\%$	(45.39 ± 3.02)**%**
E2	**correct**	incorrect	$(35.07 \pm 9.32)\%$	(49.79 ± 3.77)**%**
E3	incorrect	**correct**	(11.34 ± 5.59)**%**	$(2.79 \pm 2.39)\%$
E4	incorrect	incorrect	(30.38 ± 10.54)**%**	$(2.03 \pm 2.10)\%$

Table 3: Evaluation results of generated sentences.

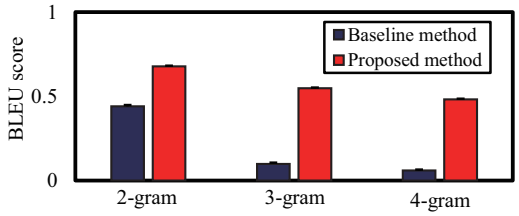

Figure 5: BLEU scores of generated sentences.

4 Conclusion

In this paper, we proposed an unsupervised method to generate natural sentences from observed scenes in a smart environment using mMLDA and BHMM. In the smart environment, multimodal information can be acquired for realistic scenarios. Thanks to mMLDA, various concepts can be formed and an initial determination of functional words can be made by assuming a weak connection of concepts and words calculated by MI. The possibility that grammar can be learned from BHMM by considering the syntactic information has also been shown. We conducted experiments to verify the proposed sentence generation, and promising preliminary results were obtained. In future work, we aim to implement a nonparametric Bayes model that will be able to estimate the number of concepts automatically.

Abstract

We present a method of using cohesion to improve discourse element identification for sentences in student essays. New features for each sentence are derived by considering its relations to global and local cohesion, which are created by means of cohesive resources and subtopic coverage. In our experiments, we obtain significant improvements on identifying all discourse elements, especially of +5% $F1$ score on *thesis* and *main idea*. The analysis shows that global cohesion can better capture *thesis statements*.

Element	Definition
Introduction (I)	introduces the background and/or grabs readers' attention
Prompt (P)	restates or summarize the prompt
Thesis (T)	states the author's main claim on the issue for which he/she is arguing
Main idea (M)	asserts foundational ideas or aspects that are related to the thesis
Supporting idea (S)	provides evidence to explain or support the thesis and main ideas
Conclusion (C)	concludes the whole essay or one of the main ideas
Other (O)	doesn't fit into the above elements or makes no meaningful contribution

Table 1: Definitions of discourse elements.

1 Introduction

Automatic discourse analysis of student essays can benefit many downstream applications such as essay rating, text organization assessment and writing instruction. In this paper we focus on identifying discourse elements for sentences in persuasive essays written by Chinese high school students. **Discourse elements** represent the contributions that sentences can make to text organization. Typical discourse elements and their functions in persuasive writing are summarized in Table 1.

Previous work mainly exploits the properties of a sentence itself or adjacent sentences for this task. In this work, we explore cohesion to express relations among sentences through the whole text. Cohesion can be defined as a set of resources linking within a text that organize the text together (Halliday and Hasan, 1976). It can be achieved through the use of reference, ellipsis, substitution, conjunction and lexical cohesion. Among them, lexical cohesion has been widely used for modeling local coherence and applied to related applications (Barzilay and Elhadad, 1999; Barzilay and Lapata, 2008; Galley et al., 2003; Hsueh et al., 2006; Filippova and Strube, 2006). Since cohesion is closely related to the structure of text (Morris and Hirst, 1991), it motivates us to explore similar techniques for discourse element identification. In addition, its ease of implementation is also attractive. Other options for representing text structure such as full-text discourse parsers (Marcu, 2000) may be not available or don't have satisfied performance, especially for non-English languages.

However, modeling local coherence alone is not adequate to distinguish discourse elements in persuasive essays. For example, a *main idea* may be followed by a *supporting idea* sentence. The two sentences can be coherent but their discourse elements are different. To deal with this, global cohesion should be exploited. Considering that in persuasive writing, *thesis*, *main ideas* and *conclusion*, which are termed *thesis statements* by Burstein et al. (2001), are expected to relate to each other (Higgins et al., 2004). It is likely that cohesive relations exist among them through the whole text.

We make a focused contribution by investigating global and local cohesive relations. We create sentence chains based on cohesive resources and examine whether the chains represent global cohesion or local cohesion. Our hypothesis is that global cohesion can better capture *thesis state-*

ments and help distinguishing them from overwhelming *supporting idea* sentences. Experiments were conducted on essays written by Chinese high school students in the mother tongue. The results confirm our hypothesis. Our method achieves significant improvements of +%5 $F1$ score on *thesis* and *main idea* sentences by adding cohesion features. The features related to global cohesion are most discriminative.

2 Data Annotation

We mainly use the discourse elements defined by Burstein et al. (2003b) except for adding a *prompt* element. The discourse element definitions are listed in Table 1. We asked two labelers from the college of liberal art of a university to conduct data annotation. Provided a detail manual with element definitions, explanations and examples, the labelers assigned a discourse element to each sentence.

We collected three corpora, two of which (C1 and C2) are prompt-directed and one (C3) is prompt-free. All essays were written by Chinese high school students in Chinese. The prompt-directed essays are samples of essays written by senior high school students when they were taking a mock examination. The students were required to write a pervasive essay related to a given prompt. The prompts of corpora C1 and C2 are different. The prompt-free essays in C3 were crawled from an online writing assistance website, where the essays were used as writing examples of persuasive essays written by high school students. The average essay lengths on three corpora are 795, 772 and 864 Chinese characters respectively. The other basic statistics of the annotated corpora are listed in Table 2.

During annotation, the labelers found cases of difficulties about ambiguous elements. For example, content about the prompt and the main thesis can be mentioned in the same sentence. In such cases, *thesis statements* have priority over other elements to be labeled, since identifying *thesis statements* is more important for some potential applications (Burstein et al., 2001).

From each corpus, 100 essays were labeled by both annotators for computing agreements, and the others were labeled independently. The label agreements measured with Kappa (Cohen et al., 1960) are high as shown in Table 2. The disagreements were resolved by discussion. The distributions of discourse elements are also shown in Table 2. We can see that they are imbalanced. The *supporting idea* sentences account for more than 53%, while the *thesis statements* account for only 34% in total. As a result, the distinction between minority *thesis statements* from overwhelming *supporting idea* sentences is a major challenge.

3 Discourse Element Identification

Identifying discourse elements in student essays can be seen as a functional segmentation of discourse (Webber et al., 2011). In this work, we focus on utilizing supervised feature-based machine learning models for this task.

3.1 Learning Models

Discourse element identification can be casted as a classification problem that sentences are classified independently using a classifier, e.g. naive Bayes (Burstein et al., 2001), decision tree (Burstein et al., 2003b) and Support Vector Machines (SVMs) (Stab and Gurevych, 2014). It can also be solved in a sequence labeling framework, which models the whole sentence sequence and captures the correlations among predictions. For example, Conditional Random Fields (CRFs) have be studied for similar task on argumentative zoning of scientific documents (Guo et al., 2011).

We will evaluate different types of features using two representative models respectively: the SVM model and the linear-chain CRF model.

3.2 Basic Features

Before feature extraction, sentence splitting, word segmentation,POS and NE tagging are done using a Chinese language processing toolkit (Che et al., 2010). Most basic features are adapted from previous work (Burstein et al., 2003a; Stab and Gurevych, 2014; Persing et al., 2010). For each sentence, the following feature sets are extracted.

Position features The relative position of its paragraph (first, last or body) in the essay and its relative position (first, last or body) in the paragraph are modeled as a set of binary features. The index of the sentence is also used as a feature.

Indicator features Cue words/phrases like "我认为(in my opinion)" and "总之(in conclusion)" are used as indicators. Partial indicators are adapted from the ones used by Persing et al. (2010). More Chinese specific indicators are then augmented manually. We use a binary feature denoting a reference to the first person ("我(I)","我们(We)") in the sentence. We also use a binary feature to indicate whether the sentence contains a modal verb like "应该(should)" and "希望(hope)".

Lexical features Binary features are modeled for all connectives and adverbs, which are identified based on POS tags.

Structural features The number of words, the number of clauses in the sentence and the number of sentences in the same paragraph are used as features. We also define binary features based on punctuation which indicate whether the sentence ends with a full stop, question mark, exclamation mark or no sentence-final punctuation.

Topic and prompt features For each sentence, the cosine similarities to the essay title and to the prompt are used as features.

4 Identification based on Cohesion

4.1 Cohesive Chains

We mainly exploit reference and lexical cohesion.

Creating identity chains Reference refers to resources for referring to a participant whose identity is recoverable (Schiffrin et al., 2008). We focus on person identities, because person names might be mentioned when describing facts. Firstly, we extract all nouns/entities with a POS/NE tag *person* as identities. Secondly, we conduct a simple third-person pronoun resolution by selecting the nearest proper antecedent identity within the same paragraph. Finally, an identity and all its anaphora together form an identity chain.

Creating lexical chains Lexical cohesion is referred to relations between text using lexical repetition, synonymy or near synonymy. We don't distinguish between systematic semantic relations and non-systematic semantic relations (Berzlánovich et al., 2008) nor use a thesaurus (Hirst and St-Onge, 1998). Instead, we compute the relatedness of two words based on their distributed representations, which are learned using the Word2Vec toolkit (Mikolov et al., 2013). The data for learning word representations consists of student essays and textbooks crawled from the Web. The vocabulary size is about $490k$.

We extract nouns, adjectives and verbs (excluding auxiliary verbs) instead of using nouns only (Hirst and St-Onge, 1998) for constructing lexical chains . We firstly cluster words into clusters in a graph based manner. Each word corresponds to a node in a graph. If the relatedness of two words is larger than a threshold T, they are considered as related and linked by an edge. After constructing all edges in this way, every connected subgraph forms a word cluster. Through the essay, all occurrences of the words from the same cluster form a lexical chain.

We discard identity and lexical chains that exist within single sentences, since they can't capture cohesive relations among sentences.

4.2 Global and Local Sentence Chains

We organize sentences based on cohesive chains. Sentences that contain members from the same identity chain or lexical chain form a sentence chain. The sentence chains represent cohesive relations among sentences.

In persuasive writing, discourse elements are commonly linked globally. For example, *main ideas* are usually related to each other because they are about different aspects of the main thesis, and *thesis* and *conclusion* should echo each other as well. Therefore, we attempt to explicitly categorize sentence chains into local chains and global chains based on subtopic coverage. A local chain represents sentences that share cohesive relations and gather locally within single subtopics. In contrast, a global chain represents sentences with cohesive relations distribute across multiple subtopics. Heuristically, we expect that *thesis statements* can be better captured by global chains, while sentences that state facts or provide evidences are associated to local chains.

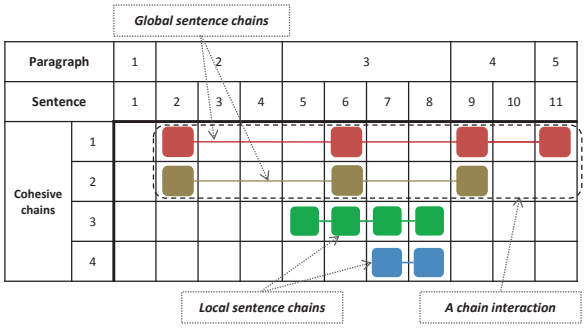

Figure 1: An illustration of global/local sentence chains. Each solid node in the grid indicates that a sentence contains a word from a cohesive chain.

Although subtopics can be identified by existing text segmentation algorithms (Hearst, 1997; Filippova and Strube, 2006), we observe that in student essays a subtopic boundary usually coincides with a paragraph boundary and almost all subtopic segments are within one paragraph and only a few of subtopics are within two or more paragraphs. Therefore, we simply assume that each paragraph corresponds to a subtopic. Based on the assumption, chain classification is approximated based on chain span over paragraphs. A sentence chain is classified as a global chain, if its members appear in at least N paragraphs, otherwise it is classified as a local chain. We set $N = 3$, which means a global chain would cover at least two subtopics considering most subtopics finish within two paragraphs. One sentence can be involved in multiple sentence chains. An illustration of global and local sentence chains is shown in Figure 1.

4.3 Cohesion Features from Sentence Chains

We develop cohesion features for a sentence from the sentence chains that involve it. Such features are beyond the intrinsic properties of the sentence itself but describe relations to other sentences.

Chain-type features We consider four combined types of sentence chains: *global-identity, local-identity, global-lexical* and *local-lexical* chains. The number of each type of chains that involve the sentence is used as a feature.

Global-title feature If the sentence is in a global sentence chain and the corresponding cohesive chain contains a word in the title, a binary feature *global-title* is set as *true*, otherwise set as *false*. Containing globally distributed title words is thought of as an indicator of *thesis statements*.

Interaction features Hasan (1984, 1985) defined that an interaction between two chains takes place when multiple members of a chain relate in the same way to more than one members of another chain, which can be used to distinguish central tokens from peripheral tokens. Hoey (1991) explored similar interactions to assess the centrality of sentences. This indicates that chain interactions might be signals of important content.

Similarly, we say two sentence chains interact with each other, if they have more than one sentence in common. An example is shown in Figure 1. Moreover, if two chains are both global chain, we term it a global interaction, otherwise a local interaction. The shared sentences by two chains are named as *global or local interaction sentences* accordingly. Two binary features are derived: the sentence is or not a *global-interaction* sentence and it is or not a *local-interaction* sentence.

Strength features We attempt to measure the overall strength of the sentence chains that involve the sentence. The features include the number of chains, the maximum and average number of covered sentences and paragraphs over chains, among which the ones related to paragraphs can be seen as measuring the global cohesion strength.

5 Evaluation

5.1 Settings

We evaluated the effectiveness of **Cohesion** features by comparing with the baseline that uses the **Basic** features introduced in Section 3.2.

We adopted $precision(P)$, $recall(R)$ and $F1$-measure($F1$) as evaluation metrics. The threshold T used to determine whether two words are related was set to 0.8 empirically. Because sentences with the discourse element *Other* are few, we didn't evaluate the performance on it.

We conducted experiments on three corpora respectively using 5-fold cross-validation. We compared various SVM classifiers with different kernels implemented in the LibSVM toolkit (Chang and Lin, 2011) and the linear-chain CRF model (Lafferty et al., 2001). When using CRF, the prediction of previous sentence is considered for current sentence. In our experiments, CRF achieves significant superior performance than SVM both when using basic features alone and after adding cohesion features. This indicates that incorporating correlations among sequential predictions are important for this task. Next, we only report the experimental results of using the CRF Model.

Element	Features	C1			C2			C3			
		P	R	$F1$	P	R	$F1$	P	R	$F1$	$avg. \triangle (F1)$
Introduction	Basic	84.5	89.6	86.8	82.2	80.7	81.5	80.6	90.1	85.0	+3.7
	+ Cohesion	87.2	90.8	88.8	85.6	84.8	85.2	87.3	94.4	90.6

Table 3: Experimental results on six discourse elements over three corpora using the CRF model.

5.2 Experimental Results

The experimental results on three corpora are shown in Table 3. We tested statistical significance for $F1$ scores and found that all improvements were significant with $p < 0.01$ based on the pairwise t-test. We can see that adding cohesion features obtain improvements on all discourse elements over three corpora. Especially, the cohesion features contribute to large improvements of +5.1% and +5.4% average $F1$ score on identifying *thesis* and *main idea* sentences. By analyzing the confusion matrix, we found that the improvements mainly come from more accurately distinguishing *thesis* and *main idea* sentences from *introduction* and *supporting idea* sentences.

We are interested in that which between the local and global cohesion contributes more to distinguish *thesis statements*. To this end, we used Area under the ROC Curve (AUC)(Swets, 1988) to measure the discriminative power of individual features. Larger AUC of a feature indicates better discriminative performance. The experiment was done on the dataset mixing all sentences from three corpora. We divided sentences into *thesis statements* and *non-thesis statements* according to their true element labels. As the results in Table 4 show, global cohesion related features are of higher rank with regard to the discriminative power. Local cohesion relates more to *non-thesis statements*, though it is not so discriminative as global cohesion. The results indicate that separating global cohesion from local cohesion help the distinction between *thesis statements* and others. Features related to identity chains alone don't show much discriminative ability. But they increase the macro $F1$ score by 0.9% in combination with other features.

Cohesion Feature	AUC
Global-lexical	0.712
Avg.#paras	0.670
Global-title	0.664
Max.#para	0.659
Global-interaction	0.654
Max.#sents	0.636
Avg.#sents	0.613
#Chains	0.601
Local-title	0.522
Global-identity	0.510
Local-identity	0.481
Local-interaction	0.476
Local-lexical	0.431

Table 4: Discriminative powers of individual features by Areas under ROC curve (AUC).

6 Conclusion

We have investigated the impact of cohesion for identifying discourse elements in student essays. Our method creates sentence chains by means of cohesive resources and separates global chains from local ones based on the subtopic coverage. New features for each sentence are derived from the properties of the sentence chains involving it. Experimental results show the effectiveness of cohesion features and the discriminative ability of global cohesion for identifying *thesis statements*.

Abstract

Domain adaptation is a challenge for supervised NLP systems because of expensive and time-consuming manual annotated resources. We present a novel method to adapt a supervised coreference resolution system trained on newswire to short narrative stories without retraining the system. The idea is to perform inference via an Integer Linear Programming (ILP) formulation with the features of narratives adopted as soft constraints. When testing on the UMIREC[1] and N2[2] corpora with the-state-of-the-art Berkeley coreference resolution system trained on OntoNotes[3], our inference substantially outperforms the original inference on the CoNLL 2011 metric.

1 Introduction

Coreference resolution is the task of partitioning the set of mentions of discourse referents in a text into classes (or 'chains') corresponding to those referents (Stede, 2011). To solve the problem, contextual and grammatical clues, as well as semantic information and world knowledge are necessary for either learning-based (Bengtson and Roth, 2008; Stoyanov et al., 2010; Haghighi and Klein, 2010) or rule-based (Haghighi and Klein, 2009; Lee et al., 2011) coreference systems. These systems draw on diverse information sources and complex heuristics to resolve pronouns, model discourse, determine anaphoricity, and identify semantically compatible mentions. However, this leads to systems with many hetorogenous parts that can be difficult to interpret or modify.

Durrett and Klein (2013) propose a learning-based, mention-synchronous coreference system to tackle the various aspects of coreference by using the simplest possible set of features. Its advantage is that the system can both implicitly model important linguistic effects and capture other patterns in the data that are not easily teased out by hand. With a simple set of features including head/first/last words, preceding/following words, length, exact string match, head match, sentence/mention distance, gender, number etc. and an efficient training using conditional log-likelihood augmented with a parameterized loss function optimization they report state-of-the-art results on CoNLL 2011 data.

But while CoNLL 2011 training data (OntoNotes) includes a few different source domains (newswire, weblogs, etc.), we witness significant drops in performance when systems trained on CoNLL 2011 are applied to new target domains such as narratives. Some linguistic effects and patterns that are very important for the target domain were never seen in the source domain on which the model was trained. In such cases, when adapting a coreference system to a new domain, it is necessary to incorporate these more complex linguistic features and patterns into the model.

We propose a novel method to adopt the target domain's features to a supervised coreference system without retraining the model. We present a case of transferring the system of (Durrett and Klein, 2013), which is trained on OntoNotes, to short narrative stories. The idea is to perform inference via a linear programming formulation with the features of narratives adopted as soft constraints. Since the new features are incorporated only into the linear program, there is no need to retrain the original model. Our formulation models three phenomena that are important for short narrative stories: local discourse coherence, which we model via centering theory constraints, speaker-listener relations, which we model via direct speech act constraints, and character-naming, which we model via definite noun phrase and exact match constraints.

Lisbon, Portugal, 17-21 September 2015.

We also suggest a method to compute back pointers (as defined in Durrett and Klein (2013)) globally.

2 Berkeley coreference system

Given N mentions $m_1, ..., m_N$ from a document x, each m_i has an associated random variable a_i taking values in the set of $\{1, ..., i-1, NEW\}$. This variable specifies m_i's selected antecedent or indicates that it begins a new coreference chain. We call a_i the *back pointer* of m_i. A setting of all the back pointers, denoted by $a = (a_1, ..., a_n)$, implies an unique set of coreference chains that serve as the system output.

A log-linear model of the conditional distribution $P(a|x) \propto \exp \sum_{i=1}^{n} \mathbf{f}(i, a_i, x)$ is used, where $\mathbf{f}(i, a_i, x)$ is a feature function that examines the coreference decision a_i for m_i with document context x. If $a_i = NEW$, the features indicate the suitability of the given mention to be anaphoric or not; when $a_i = j$ for some j, the features express aspects of the pairwise linkage, and examine relevant attributes of the anaphor i or the antecedent j. During training, the model is optimized with a parameterized loss function. The inference is simple and efficient: because $\log P(a|x)$ decomposes linearly over mentions, $a_i = \arg\max_{a_i} P(a_i|x)$ (Durrett and Klein, 2013).

3 Computing back pointers globally

A drawback of computing each a_i locally is that the system does not take into account constraints from mentions outside of the (mention, antecedent) pairs. For example, given three mentions m_1, m_2, m_3, if the system predicts that $a_2 = 1$ and $a_3 = 2$ (i.e., that m_2's antecedent is m_1 and m_3's antecedent is m_2), then m_3 will be automatically inferred as coreferent with m_1. But if there is a clear clue that m_1 and m_3 are not coreferent, leveraging this clue could help avoid the error of linking m_3 to m_2.

In this work, we perform inference via an ILP formulation which allows new linguistic features and patterns over mentions – not only (mention, antecedent) pairs – that were not part of training the original model to be adopted as constraints of the ILP problem.

Let $\mathbf{U}$ be the set of binary indicator variables corresponding to the values assigned to the back pointers. Specifically, $u_{ij} = 1$ iff $a_i = j$ and $u_{ii} = 1$ iff $a_i = NEW$.

$\mathbf{C}$ is the set of K binary constraint indicator variables indicating if linguistic constraints are violated. Specifically, $c_{k,i,j} = 1$ iff the linguistic constraint C_k is violated for the back pointer u_{ij}. Each C_k is associated with a penalty score ρ_k.

We aim to maximize the objective function:

$$\sum_{i=1}^{N} \sum_{j=1}^{i} u_{ij} P(a_i = j|x) - \sum_{k=1}^{K} \rho_k c_{k,i,j} \quad (1)$$

Subject to:

$$\forall i : \sum_{j=1}^{i} u_{ij} = 1$$

To incorporate coreference constraints, we introduce $\mathbf{V}$, a set of binary variables indicating if two mentions are in the same coreference chain. For each pair of $j < i$, a variable v_{ij} is added to the ILP model, where $v_{ij} = 1$ iff m_i and m_j are in the same chain. The definition of v_{ij} in terms of u_{ij} is encoded as the following ILP constraints:

$$\begin{aligned}
\forall j < i &: u_{ii} + v_{ij} \leq 1 \\
\forall j < i &: u_{ij} - v_{ij} \leq 0 \\
\forall k < j < i &: u_{ij} + v_{jk} - v_{ik} \leq 1 \\
\forall k < j < i &: u_{ij} - v_{jk} + v_{ik} \leq 1 \\
\forall j < k < i &: u_{ij} + v_{kj} - v_{ik} \leq 1 \\
\forall j < k < i &: u_{ij} - v_{kj} + v_{ik} \leq 1
\end{aligned}$$

For long texts, to reduce the complexity of the ILP problem, we set a threshold, $windows_v$, so that v_{ij} is only available if $i - windows_v \leq j$.

The framework of $\mathbf{V}$ variables allows coreference constraints to be adopted easily by any coreference resolution system that provides scores for each possible back pointer value. For example, consider the Stanford exact string match sieve, which "requires an exact string match between a mention and its antecedent" (Lee et al., 2011). If we want to encourage such matches, for each pair $j < i$ where the two nominal mentions m_i and m_j have an exact string match, we would introduce a constraint indicator variable $c_{exact,i,j}$ and add the constraint $v_{ij} + c_{exact,i,j} = 1$ to the ILP model. The result would be that when the exact match constraint is violated and some $v_{ij} = 0$, ILP would force the corresponding $c_{exact,i,j} = 1$ and the objective function would be reduced by ρ_{exact}.

ILP has been used previously to enforce global consistency in coreference resolution (Finkel and Manning, 2008; Denis and Baldridge, 2007; Barzilay and Lapata, 2006). These models were designed for an all-pairs classification approach to

coreference resolution, and are not directly applicable to the back pointer approach of (Durrett and Klein, 2013). But the back pointer approach allows features to be expressed more naturally using local context, rather than requiring, for example, judgments of whether two pronouns separated by many paragraphs are coreferent. Moreover, our ILP formulation is the only one to consider the problem of adapting to another domain and incorporating new features without retraining the original model.

4 Centering theory constraints

Pronouns, in particular, have a huge effect on information flow across sentences. Since they are almost void of meaning (only signal gender and number of the antecedent), the discourse referent to be picked up must be particularly salient, so that it can be readily identified by the reader (Stede, 2011). The discourse center hypothesis (Hudson-D'Zmura, 1988) states that at any point in discourse understanding, there is one single entity that is the most salient discourse referent at that point. This referent is called the center. Centering theory is a key element of the discourse center hypothesis used in anaphora resolution (Grosz et al., 1995). Beaver (2004) reformulates the centering theory in terms of Optimality Theory (Prince and Smolensky, 2004). Six ranked constraints – Agree, Disjoint, ProTop, FamDef, Cohere and Align – are used to make anaphora decisions. We adopt four of these constraints in our ILP model as follows:

Disjoint "Co-arguments of a predicate[4] are disjoint." For each $j < i$ such that m_i and m_j are subject and object arguments of a non-reflexive predicate, we introduce a constraint indicator variable $c_{disjoint,i,j}$, and add the ILP constraint $v_{ij} - c_{disjoint,i,j} = 0$.

ProTop "The *topic* of a sentence which is the entity referred to in both the current and the previous sentence, is pronominalized." If a sentence contains pronouns then at least one of its pronouns is coreferent with a mention in the previous sentence. For each sentence t containing pronouns, we introduce a constraint indicator variable $c_{protop,t,t-1}$, and add the ILP constraints:

$$\forall i \in \mathbf{P}_t, \forall j \in \mathbf{M}_{t-1} : v_{ij} + c_{protop,t,t-1} \leq 1$$

$$c_{protop,t,t-1} + \sum_{i \in \mathbf{P}_t} \sum_{j \in \mathbf{M}_{t-1}} v_{ij} \geq 1$$

[4] A word that evokes a semantic frame (event) in a sentence.

$\mathbf{P}_t$ is the set of all pronouns in sentence t. $\mathbf{M}_{t-1}$ is the set of all mentions in sentence $t-1$ [5].

FamDef "No new information about the referent is provided by the definite." We consider only pronouns here, though the original FamDef also includes definite descriptions and proper names (Beaver, 2004). For each pronoun m_i, we introduce a constraint indicator variable $c_{famdef,i,i}$ and add the ILP constraint $u_{ii} - c_{famdef,i,i} = 0$.

Align "The topic is in subject position." More specifically, the topic of a sentence is pronominalized and prefers the subject position over other positions. For each sentence containing only one pronoun m_i, if the previous sentence has only one verbal semantic frame and m_j is its subject, we introduce a constraint indicator variable $c_{align,i,j}$, and add the ILP constraint $v_{ij} + c_{align,i,j} = 1$.

Note: The ProTop, FamDef and Align constraints are not applied to sentences containing quotations.

5 Direct speech constraints

Direct speech acts (with quotation marks) are detected and attached to the closest verbal communication semantic frames. For each direct speech act q_t, we call the mentions m_{st}, m_{ot} the speaker and listener of q_t if they play the subject and object roles respectively in the semantic frame of q_t. We detect the set of subject pronouns[6] inside the quote marks of q_t and name it $\mathbf{S_t}$. The set of all mentions that refer to the speaker of q_t is $\text{SPEAKER}_t = \{m_{st}\} \cup \mathbf{S_t}$. For each $(m_i, m_j) \in \text{SPEAKER}_t \times \text{SPEAKER}_t$ with $i > j$, we introduce a constraint indicator variable $c_{subject,i,j}$, and add the ILP constraint $v_{ij} + c_{subject,i,j} = 1$.

Similarly, $\mathbf{O_t}$ is the set of object pronouns[7] inside the quote marks of q_t. The set of all mentions that refer to the listener of q_t is $\text{LISTENER}_t = \{m_{ot}\} \cup \mathbf{O_t}$. For each pair of mentions $(m_i, m_j) \in \text{LISTENER}_t \times \text{LISTENER}_t$ with $i > j$, we introduce a constraint indicator variable $c_{object,i,j}$, and add the constraint $v_{ij} + c_{object,i,j} = 1$.

If a conversation is detected (a sequence of "question" and "answer" semantic frames), the subject of the "question" is coreferent with the object

[5] We can relax the constraint by replacing $\mathbf{M}_{t-1}$ with $\mathbf{M}_{t-1} \cup \mathbf{M}_{t-2} \cup \mathbf{M}_{t-3}$

[6] ("I", "me", "my", "mine", "myself") if m_{st} is singular or ("we", "us", "our", "ourself") if m_{st} is plural

[7] ("you", "your", "yours", "yourself")

of the "answer" and vice versa. For each pair of direct speech acts (q_t, q_{t+1}) that is a ("question", "answer") pair, for each pair of mentions $(m_i, m_j) \in \{\text{LISTENER}_{t+1} \times \text{SPEAKER}_t\} \cup \{\text{SPEAKER}_{t+1} \times \text{LISTENER}_t\}$, we introduce a constraint indicator variable $c_{conversation,i,j}$ and add the ILP constraint $v_{ij} + c_{conversation,i,j} = 1$.

6 Definite noun phrase and exact match constraints

In short narrative stories, characters are frequently named via proper names, pronouns or definite noun phrases (Toolan, 2009). Character names are repeated regularly over the whole stories. A character is often first presented as an indefinite noun phrase (such as "a woman"), then later as a definite noun phrase (such as "the woman"). In this work we introduce the definite noun phrase constraint: For each pair $j < i$, if m_j is the indefinite form and m_i is the definite form of the same noun phrase, to enforce that m_i and m_j are coreferent, we introduce a constraint indicator variable $c_{name,i,j}$, and add the ILP constraint $v_{ij} + c_{name,i,j} = 1$. To boost the identification of characters in the stories, the definite noun phrase constraint is used together with the exact match constraint (See Section 3) applied to noun phrases and proper nouns.

7 Experiment

We test our model on 30 English folktales from the UCM/MIT Indications, Referring Expressions, and Coreference (UMIREC) Corpus v1.1 (Finlayson and Hervs, 2010), and 64 text stories from the Hadith section of the Narrative Networks (N2) Corpus (Finlayson et al., 2014). The texts are preprocessed using the Stanford sentence splitter (Manning et al., 2014)[8] and the Berkeley coreference system's preprocessor. The Berkeley coreference system is trained on OntoNotes (newswire, broadcast news/conversation, and web texts). We use Gurobi[9] to solve our ILP problem, and the Lund semantic role labeler (Björkelund et al., 2009) to detect semantic frames. Note that in our implementation, "subject" and "object" used in Section 4 and Section 5 refer to "subject role" and "object role" of the semantic frames respectively. We use a separate section of the N2 corpus, the Inspire story texts, as the held-out validation set used for parameter tuning, resulting in $window_v = 40$, $\rho_{subject} = \rho_{object} = \rho_{conversation} = \rho_{definite} = \rho_{exact} = \rho_{disjoint} = 1$, $\rho_{protop} = 0.2$, $\rho_{famdef} = 0.2$, $\rho_{align} = 0.1$.

We compare our ILP inference (ILPI) to the standard Berkeley coreference system (BER) with both gold and predicted mentions. Table 1 shows that our inference improves the MUC, BCUB and CEAFE scores on both datasets, especially when using gold mentions[10]. The average ILP running times are 42.37s per UMIREC document and 22.7s per N2 document on a Core I7 2.3 GHz quad-core computer. Table 2 shows the effects of each constraint type when used alone. Surprisingly, the simplest constraint type (definite & exact match constraints) gives us the best improvement especially in terms of CEAFE score. This may be because definite & exact match constraint links mentions in the whole document, while the centering theory and direct speech act constraints are more local. And since short narrative stories often have a small set of characters (usually represented by definite noun phrases or proper nouns), when these characters are linked correctly, the coreference resolution result is improved considerably.

8 Discussion

Our method provides a promising solution when retraining a system is impossible or difficult. However, it may raise a question of the computing cost

[8] If two direct speech acts enclosed in quotation marks are adjacent and one is placed at the end of a sentence, we separate them into two different sentences.

[9] http://www.gurobi.com/

[10] Using gold mentions, our method also improves the score on the CoNLL 2011 test set by +1.11% (AVG: 72.46).

Constraint	MUC	BCUB	CEAFE	AVG
Centering theory	81.15	61.80	43.01	61.99
Direct speech	81.26	62.74	42.93	62.31
Definite & Exact	83.09	62.85	49.60	65.18

Table 2: Effects of different constraints on ILP inference on UMIREC (Tales) with gold mentions.

for tuning penalty scores especially with the large number of constraints. In such these cases, dividing the constraints into different groups where all constraints in the same group have the same penalty score may help to limit the number of scores that need to be tuned. In our case study, the system is not very sensitive to the values of the penalty parameters. If we set all the penalty scores to 1, the final AVG results on UMIREC and N2 corpus are 66.05 and 66.68 respectively[11]. Those scores are a bit less than the scores obtained after tuning parameters but still higher than the results obtained without ILP. Regardless, it's true that the proposed ILP approach is not necessarily less costly in some settings, but it can be applied to any coreference system that provides back pointers, not just the Berkeley one.

Instead of adopting features of the target domain as soft constraints as in our method, one may consider to use them as linguistic features and retrain the model. A simple domain adaptation approach by augmenting the feature space (Daumé et al., 2010) based on a limited set of annotated data in the target domain might be an alternative solution. But note that our approach does not use any annotated data of the target domain. Also, an unsupervised system as (Lee et al., 2011) might encode the target domain features (exact match noun phrases, direct speech act) as sieves (**hard**), but with the **soft** constraints, our system is more flexible when making global decisions.

Our approach can be applied to another target domain, such as bio-medical domain where we have entities and a list of acronyms in texts. Constraining the entities with their acronyms might help to improve the coreference resolution for bio-medical texts.

9 Conclusion

We have proposed a novel approach to adapt a supervised coreference resolution system trained on newswire domain to short narrative stories without retraining the system by modeling the inference as an ILP problem with the features of narratives adopted as soft constraints. Three phenomena that are important for short narrative stories: local discourse coherence, speaker-listener relations, and character-naming are modeled via centering theory, direct speech act and definite noun phrase & exact match constraints. We obtain promising results when transferring the Berkeley coreference resolution trained on OntoNotes to UMIREC (Tales) and N2 (Hadith). We find that the simplest constraints, definite noun phrase & exact match constraints, are the most effective in our case study assuming the gold mentions. We also suggest an approach to compute back pointers in coreference resolution globally.

Abstract

We present LEMMING, a modular log-linear model that jointly models lemmatization and tagging and supports the integration of arbitrary global features. It is trainable on corpora annotated with gold standard tags and lemmata and does not rely on morphological dictionaries or analyzers. LEMMING sets the new state of the art in token-based statistical lemmatization on six languages; e.g., for Czech lemmatization, we reduce the error by 60%, from 4.05 to 1.58. We also give empirical evidence that jointly modeling morphological tags and lemmata is mutually beneficial.

1 Introduction

Lemmatization is important for many NLP tasks, including parsing (Björkelund et al., 2010; Seddah et al., 2010) and machine translation (Fraser et al., 2012). Lemmata are required whenever we want to map words to lexical resources and establish the relation between inflected forms, particularly critical for morphologically rich languages to address the sparsity of unlemmatized forms. This strongly motivates work on language-independent token-based lemmatization, but until now there has been little work (Chrupała et al., 2008).

Many regular transformations can be described by simple replacement rules, but lemmatization of unknown words requires more than this. For instance the Spanish paradigms for verbs ending in *ir* and *er* share the same 3rd person plural ending *en*; this makes it hard to decide which paradigm a form belongs to.[1] Solving these kinds of problems requires global features on the lemma. Global features of this kind were not supported by previous work (Dreyer et al., 2008; Chrupała, 2006; Toutanova and Cherry, 2009; Cotterell et al., 2014).

There is a strong mutual dependency between (i) lemmatization of a form in context and (ii) disambiguating its part-of-speech (POS) and morphological attributes. Attributes often disambiguate the lemma of a form, which explains why many NLP systems (Manning et al., 2014; Padró and Stanilovsky, 2012) apply a pipeline approach of tagging followed by lemmatization. Conversely, knowing the lemma of a form is often beneficial for tagging, for instance in the presence of syncretism; e.g., since German plural noun phrases do not mark gender, it is important to know the lemma (singular form) to correctly tag gender on the noun.

We make the following contributions. (i) We present the first joint log-linear model of morphological analysis and lemmatization that operates at the *token* level and is also able to lemmatize unknown forms; and release it as open-source (`http://cistern.cis.lmu.de/lemming`). It is trainable on corpora annotated with gold standard tags and lemmata. Unlike other work (e.g., (Smith et al., 2005)) it does not rely on morphological dictionaries or analyzers. (ii) We describe a log-linear model for lemmatization that can easily be incorporated into other models and supports arbitrary global features on the lemma. (iii) We set the new state of the art in token-based statistical lemmatization on six languages (English, German, Czech, Hungarian, Latin and Spanish). (iv) We experimentally show that jointly modeling morphological tags and lemmata is mutually beneficial and yields significant improvements in joint (tag+lemma) accuracy for four out of six languages; e.g., Czech lemma errors are reduced by $>37\%$ and tag+lemma errors by $>6\%$.

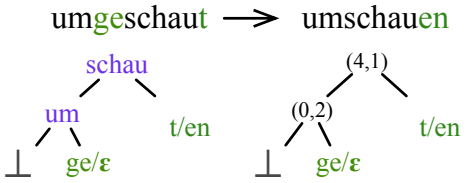

Figure 1: Edit tree for the inflected form *umgeschaut* "looked around" and its lemma *umschauen* "to look around". The right tree is the actual edit tree we use in our model, the left tree visualizes what each node corresponds to. The root node stores the length of the prefix *umge* (4) and the suffix *t* (1).

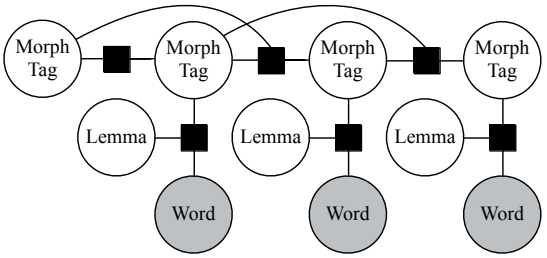

Figure 2: Our model is a 2nd-order linear-chain CRF augmented to predict lemmata. We heavily prune our model and can easily exploit higher-order (>2) tag dependencies.

2 Log-Linear Lemmatization

Chrupała (2006) formalizes lemmatization as a classification task through the deterministic pre-extraction of edit operations transforming forms into lemmata. Our lemmatization model is in this vein, but allows the addition of external lexical information, e.g., whether the candidate lemma is in a dictionary. Formally, lemmatization is a string-to-string transduction task. Given an alphabet Σ, it maps an inflected form $w \in \Sigma^*$ to its lemma $l \in \Sigma^*$ given its morphological attributes m. We model this process by a log-linear model:

$$p(l \mid w, m) \propto h_w(l) \cdot \exp\left(\boldsymbol{f}(l, w, m)^T \boldsymbol{\theta}\right),$$

where $\boldsymbol{f}$ represents hand-crafted feature functions, $\boldsymbol{\theta}$ is a weight vector, and $h_w : \Sigma^* \rightarrow \{0, 1\}$ determines the support of the distribution, i.e., the set of candidates with non-zero probability.

Candidate selection. A proper choice of the support function $h(\cdot)$ is crucial to the success of the model – too permissive a function and the computational cost will build up, too restrictive and the correct lemma may receive no probability mass. Following Chrupała (2008), we define $h(\cdot)$ through a deterministic pre-extraction of *edit trees*. To extract an edit tree e for a pair form-lemma $\langle w, l \rangle$, we first find the longest common substring (LCS) (Gusfield, 1997) between them and then recursively model the prefix and suffix pairs of the LCS. When no LCS can be found the string pair is represented as a substitution operation transforming the first string to the second. The resulting edit tree does not encode the LCSs but only the length of their prefixes and suffixes and the substitution nodes (cf. Figure 1); e.g., the same tree transforms *worked* into *work* and *touched* into *touch*.

As a preprocessing step, we extract all edit trees that can be used for more than one pair $\langle w, l \rangle$. To generate the candidates of a word-form, we apply all edit trees and also add all lemmata this form was seen with in the training set (note that only a small subset of the edit trees is applicable for any given form because most require incompatible substitution operations).[2]

Features. Our novel formalization lets us combine a wide variety of features that have been used in different previous models. All features are extracted given a form-lemma pair $\langle w, l \rangle$ created with an edit tree e.

We use the following three *edit tree features* of Chrupała (2008). (i) The edit tree e. (ii) The pair $\langle e, w \rangle$. This feature is crucial for the model to memorize irregular forms, e.g., the lemma of *was* is *be*. (iii) For each form affix (of maximum length 10): its conjunction with e. These features are useful in learning orthographic and phonological regularities, e.g., the lemma of *signalling* is *signal*, not *signall*.

We define the following *alignment features*. Similar to Toutanova and Cherry (2009) (TC), we define an alignment between w and l. Our alignments can be read from an edit tree by aligning the characters in LCS nodes character by character and characters in substitution nodes block-wise. Thus the alignment of *umgeschaut* - *umschauen* is: u-u, m-m, ge-ϵ, s-s, c-c, h-h, a-a, u-u, t-en. Each alignment pair constitutes a feature in our model. These features allow the model to learn that the substitution *t/en* is likely in German. We also concatenate each alignment pair with its form and lemma character context (of up to length 6) to learn, e.g., that *ge* is often deleted after *um*.

We define two simple *lemma features*. (i) We use the lemma itself as a feature, allowing us to learn which lemmata are common in the language. (ii) Prefixes and suffixes of the lemma (of maxi-

[2]Pseudo-code for edit tree creation and candidate lemma generation with examples can be found in the appendix (`http://cistern.cis.lmu.de/lemming/appendix.pdf`).

mum length 10). This feature allows us to learn that the typical endings of Spanish verbs are *ir*, *er*, *ar*.

We also use two *dictionary features* (on lemmata): Whether l occurs > 5 times in Wikipedia and whether it occurs in the dictionary ASPELL.[3] We use a similar feature for different capitalization variants of the lemma (lowercase, first letter uppercase, all uppercase, mixed). This differentiation is important for German, where nouns are capitalized and *en* is both a noun plural marker and a frequent verb ending. Ignoring capitalization would thus lead to confusion.

POS & morphological attributes. For each feature listed previously, we create a conjunction with the POS and each morphological attribute.[4]

3 Joint Tagging and Lemmatization

We model the sequence of morphological tags using MARMOT (Müller et al., 2013), a pruned higher-order CRF. This model avoids the exponential runtime of higher-order models by employing a pruning strategy. Its feature set consists of standard tagging features: the current word, its affixes and shape (capitalization, digits, hyphens) and the immediate lexical context. We combine lemmatization and higher-order CRF components in a tree-structured CRF. Given a sequence of forms $\boldsymbol{w}$ with lemmata $\boldsymbol{l}$ and morphological+POS tags $\boldsymbol{m}$, we define a globally normalized model:

$$p(\boldsymbol{l}, \boldsymbol{m} \mid \boldsymbol{w}) \propto \prod_i h_{w_i}(l_i) \exp(\boldsymbol{f}(l_i, w_i, m_i)^T \boldsymbol{\theta} + \boldsymbol{g}(m_i, m_{i-1}, m_{i-2}, \boldsymbol{w}, i)^T \boldsymbol{\lambda}),$$

where $\boldsymbol{f}$ and $\boldsymbol{g}$ are the features associated with lemma and tag cliques respectively and $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ are weight vectors. The graphical model is shown in Figure 2. We perform inference with belief propagation (Pearl, 1988) and estimate the parameters with SGD (Tsuruoka et al., 2009). We greatly improved the results of the joint model by initializing it with the parameters of a pretrained tagging model.

4 Related Work

In functionality, our system resembles MORFETTE (Chrupała et al., 2008), which generates lemma candidates by extracting edit operation sequences between lemmata and surface forms (Chrupała, 2006), and then trains two maximum entropy Markov models (Ratnaparkhi, 1996) for morphological tagging and lemmatization, which are queried using a beam search decoder.

In our experiments we use the latest version[5] of MORFETTE. This version is based on structured perceptron learning (Collins, 2002) and edit trees (Chrupała, 2008). Models similar to MORFETTE include those of Björkelund et al. (2010) and Gesmundo and Samardzic (2012) and have also been used for generation (Dušek and Jurčíček, 2013). Wicentowski (2002) similarly treats lemmatization as classification over a deterministically chosen candidate set, but uses distributional information extracted from large corpora as a key source of information.

Toutanova and Cherry (2009)'s joint morphological analyzer predicts the set of possible lemmata and *coarse-grained POS* for a word *type*. This is different from our problem of lemmatization and *fine-grained* morphological tagging of *tokens in context*. Despite the superficial similarity of the two problems, *direct comparison is not possible*. TC's model is best thought of as inducing a tagging dictionary for OOV types, mapping them to a set of tag and lemma pairs, whereas LEMMING is a token-level, context-based morphological tagger.

We do, however, use TC's model of lemmatization, a string-to-string transduction model based on Jiampojamarn et al. (2008) (JCK), as a standalone baseline. Our tagging-in-context model is faced with higher complexity of learning and inference since it addresses a more difficult task; thus, while we could in principle use JCK as a replacement for our candidate selection, the edit tree approach – which has high coverage at a low average number of lemma candidates (cf. Section 5) – allows us to train and apply LEMMING efficiently.

Smith et al. (2005) proposed a log-linear model for the context-based disambiguation of a morphological dictionary. This has the effect of joint tagging, morphological segmentation and lemmatization, but, critically, is limited to the entries in the morphological dictionary (without which the approach cannot be used), causing problems of recall. In contrast, LEMMING can analyze any word,

[3] `ftp://ftp.gnu.org/gnu/aspell/dict`

[4] Example: for the Spanish noun *medidas* "measures" with attributes NOUN, COMMON, PLURAL and FEMININE, we conjoin each feature above with NOUN, NOUN+COMMON, NOUN+PLURAL and NOUN+FEMININE.

Table 2: *Test* results for LEMMING-J, the joint model, and pipelines (lines 2–7) of MARMOT and (i) JCK and (ii) LEMMING-P. In each cell, overall token accuracy is left (all), accuracy on unknown forms is right (unk). Standalone MARMOT tagging accuracy (line 1) is not repeated for pipelines (lines 2–7). The best numbers are bold. LEMMING-J models significantly better than LEMMING-P ($+$), or LEMMING models not using morphology (+*dict*) ($\times$) or both ($*$) are marked. More baseline numbers in the appendix (Table A2).

including OOVs, and only requires the same training corpus as a generic tagger (containing tags and lemmata), a resource that is available for many languages.

5 Experiments

Datasets. We present experiments on the joint task of lemmatization and tagging in six diverse languages: English, German, Czech, Hungarian, Latin and Spanish. We use the same data sets as in Müller and Schütze (2015), but do not use the out-of-domain test sets. The English data is from the Penn Treebank (Marcus et al., 1993), Latin from PROIEL (Haug and Jøhndal, 2008), German and Hungarian from SPMRL 2013 (Seddah et al., 2013), and Spanish and Czech from CoNLL 2009 (Hajič et al., 2009). For German, Hungarian, Spanish and Czech we use the splits from the shared tasks; for English the split from SANCL (Petrov and McDonald, 2012); and for Latin a 8/1/1 split into *train/dev/test*. For all languages we limit our training data to the first 100,000 tokens. Dataset statistics can be found in Table A4 of the appendix. The lemma of Spanish *se* is set to be consistent.

Baselines. We compare our model to three baselines. (i) MORFETTE (see Section 4). (ii) SIMPLE, a system that for each form-POS pair, returns the most frequent lemma in the training data or the form if the pair is unknown. (iii) JCK, our reimplementation of Jiampojamarn et al. (2008). Recall that JCK is TC's lemmatization model and that the full TC model is a type-based model that cannot be applied to our task.

As JCK struggles to memorize irregulars, we only use it for unknown form-POS pairs and use SIMPLE otherwise. For aligning the training data we use the edit-tree-based alignment described in the feature section. We only use output alphabet symbols that are used for ≥ 5 form-lemma pairs and also add a special output symbol that indicates that the aligned input should simply be copied. We train the model using a structured averaged perceptron and stop after 10 training iterations. In preliminary experiments we found type-based training to outperform token-based training. This is understandable as we only apply our model to unseen form-POS pairs. The feature set is an exact reimplementation of (Jiampojamarn et al., 2008), it consists of input-output pairs and their character context in a window of 6.

Results. Our candidate selection strategy results in an average number of lemma candidates between 7 (Hungarian) and 91 (Czech) and a coverage of the correct lemma on *dev* of >99.4 (except 98.4 for Latin).[6] We first compare the baselines to LEMMING-P, a pipeline based on Section 2, that lemmatizes a word given a predicted tag and is trained using L-BFGS (Liu and Nocedal, 1989). We use the implementation of MALLET (McCallum, 2002). For these experiments we train all models on gold attributes and test on attributes predicted by MORFETTE. MORFETTE's lemmatizer can only be used with its own tags. We thus use MORFETTE tags to have a uniform setup,

[6]Note that our definition of lemmatization accuracy and unknown forms ignores capitalization.

which isolates the effects of the different taggers. Numbers for MARMOT tags are in the appendix (Table A1). For the initial experiments, we only use POS and ignore additional morphological attributes. We use different feature sets to illustrate the utility of our templates.

The first model uses the *edit tree features* (edittree). Table 1 shows that this version of LEMMING outperforms the baselines on half of the languages.[7] In a second experiment we add the *alignment* (+align) and *lemma features* (+lemma) and show that this consistently outperforms all baselines and edittree. We then add the *dictionary feature* (+dict). The resulting model outperforms all previous models and is significantly better than the best baselines for all languages.[8] These experiments show that LEMMING-P yields state-of-the-art results and that all our features are needed to obtain optimal performance. The improvements over the baselines are >1 for Czech and Latin and $\geq.5$ for German and Hungarian.

The last experiment also uses the additional morphological attributes predicted by MORFETTE (+mrph). This leads to a drop in lemmatization performance in all languages except Spanish (English has no additional attributes). However, preliminary experiments showed that correct morphological attributes would substantially improve lemmatization as they help in cases of ambiguity. As an example, number helps to lemmatize the singular German noun *Raps* "canola", which looks like the plural of *Rap* "rap". Numbers can be found in Table A3 of the appendix. This motivates the necessity of *joint tagging and lemmatization*.

For the final experiments, we run pipeline models on tags predicted by MARMOT (Müller et al., 2013) and compare them to LEMMING-J, the joint model described in Section 3. All LEMMING versions use exactly the same features. Table 2 shows that LEMMING-J outperforms LEMMING-P in three measures (see bold tag, lemma & joint (tag+lemma) accuracies) except for English, where we observe a tie in lemma accuracy and a small drop in tag and tag+lemma accuracy. Coupling morphological attributes and lemmatization (lines 8–10 vs 11–13) improves tag+lemma prediction for five languages. Improvements in lemma accuracy of the joint over the best pipeline systems range from .1 (Spanish), over $>.3$ (German, Hungarian) to $\geq.96$ (Czech, Latin).

Lemma accuracy improvements for our best models (lines 4–13) over the best baseline (lines 2–3) are >1 (German, Spanish, Hungarian), >2 (Czech, Latin) and even more pronounced on unknown forms: >1 (English), >5 (German, Spanish, Hungarian) and >12 (Czech, Latin).

6 Conclusion

LEMMING is a modular lemmatization model that supports arbitrary global lemma features and joint modeling of lemmata and morphological tags. It is trainable on corpora annotated with gold standard tags and lemmata, and does not rely on morphological dictionaries or analyzers. We have shown that modeling lemmatization and tagging jointly benefits both tasks, and we set the new state of the art in token-based lemmatization on six languages. LEMMING is available under an open-source licence (`http://cistern.cis.lmu.de/lemming`).

Abstract

We describe a simple and efficient algorithm to disambiguate non-functional weighted finite state transducers (WFSTs), i.e. to generate a new WFST that contains a unique, best-scoring path for each hypothesis in the input labels along with the best output labels. The algorithm uses topological features combined with a tropical sparse tuple vector semiring. We empirically show that our algorithm is more efficient than previous work in a PoS-tagging disambiguation task. We use our method to rescore very large translation lattices with a bilingual neural network language model, obtaining gains in line with the literature.

1 Introduction

Weighted finite-state transducers (WFSTs), or *lattices*, are used in speech and language processing to compactly represent and manipulate a large number of strings. Applying a finite-state operation (eg. PoS tagging) to a lattice via composition produces a WFST that maps input (eg. words) onto output strings (eg. PoS tags) and preserves the arc-level alignment between each input and output symbol (eg. each arc is labeled with a word-tag pair and has a weight). Typically, the result of such operation is a WFST that is *ambiguous* because it contains multiple paths with the same input string, and *non-functional* because it contains multiple output strings for a given input string (Mohri, 2009).

Disambiguating such WFSTs is the task of creating a WFST that encodes only the best-scoring path of each input string, while still maintaining the arc-level mapping between input and output symbols. This is a non-trivial task[1], and so far only one algorithm has been described (Shafran et al., 2011); the main steps are:

(a) Map the WFST into an equivalent weighted finite-state automata (WFSA) using weights that contain *both* the WFST weight *and* output symbols (using a special semiring)

(b) Apply WFSA determinization under this semiring to ensure that only one unique path per input string survives

(c) Expand the result back to an WFST that preserves arc-level alignments

We present a new disambiguation algorithm that can efficiently accomplish this. In Section 2 we describe how the *tropical sparse tuple vector* semiring can keep track of individual arcs in the original WFST as topological features during the mapping step (**a**). This allows us to describe in Section 3 an efficient expansion algorithm for step (**c**). We show in Section 4 empirical evidence that our algorithm is more efficient than Shafran et al. (2011) in their same PoS-tagging task. We also show how our method can be applied in rescoring translation lattices under a bilingual neural-network model (Devlin et al., 2014), obtaining BLEU score gains consistent with the literature. Section 5 reviews related work and concludes.

2 Semiring Definitions

A WFST $T = (\Sigma, \Delta, Q, I, F, E, \rho)$ over a semiring $(\mathbb{K}, \oplus, \otimes, \overline{0}, \overline{1})$ has input and output alphabets Σ and Δ, a set of states Q, the initial state $I \in Q$, a set of final states $F \subset Q$, a set of transitions (edges) $E \subset (Q \times \Sigma \times \Delta \times \mathbb{K} \times Q)$, and a final state function $\rho : F \to \mathbb{K}$. We focus on extensions to the tropical semiring $(\mathbb{R} \pm \infty, \min, +, \infty, 0)$.

[1]Unless one enumerates all the possible input strings in the lattice, searches for the best output string for each input string, and converts the resulting sequences back into a WFST, which is clearly inefficient.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2275–2280,
Lisbon, Portugal, 17-21 September 2015.

Let $e = (p[e], i[e], o[e], w[e], n[e])$ be an edge in E. A path $\pi = e_1 ... e_n$ is a sequence of edges such that $n[e_j] = p[e_{j+1}], 1 \leq j < n$. $w[\pi] = \bigotimes_{e_j \in \pi} w[e_j]$; $p[\pi] = p[e_1], n[\pi] = n[e_n]$. A path is accepting if $p[\pi] = I$ and $n[\pi] \in F$. The weight associated by T to a set of paths Π is $T(\Pi) = \bigoplus_{\pi \in \Pi} w[\pi] \otimes \rho(n[\pi])$.

2.1 Tropical Sparse Vector Semiring

Let $\bar{f}[e_i] = f_i \in \mathbb{R}^N$ be the unweighted feature vector associated with edge e_i, and let $\bar{\alpha} \in \mathbb{R}^N$ be a global feature weight vector. The tropical weight is then found as $w_i = w[e_i] = \bar{\alpha} \cdot \bar{f}_i = \sum_k \alpha_k f_{i,k}$.

Given a fixed $\bar{\alpha}$, we define the operators for the *tropical vector* semiring as: $\bar{f}_i \oplus_\alpha \bar{f}_j = \min(\bar{\alpha} \cdot \bar{f}_i, \bar{\alpha} \cdot \bar{f}_j)$ and $\bar{f}_i \otimes_\alpha \bar{f}_j = \sum_k \alpha_k (f_{i,k} + f_{j,k})$. The tropical weights are maintained correctly by the vector semiring as $\bar{f}_i \oplus_\alpha \bar{f}_j = w_i \oplus w_j$ and $\bar{f}_i \otimes_\alpha \bar{f}_j = w_i \otimes w_j$. Finally, we define the element-wise times operator as: $\bar{f}_i * \bar{f}_j = \bar{f}_m$, where $f_{m,k} = f_{i,k} + f_{j,k}, \forall k$. It follows that $w_i \otimes w_j = \alpha \cdot (\bar{f}_i * \bar{f}_j)$.

When dealing with high-dimensional feature vectors which have few non-zero elements, it is convenient in practice (for computational efficiency) to use a sparse representation for vectors: $\bar{f} = [(i, f_i), i : f_i \neq 0]$. That is, $\bar{f}$ is comprised of a sparse set of tuples (i, f_i), where i is a feature index and f_i is its value; e.g. $[(2, f_2)]$ is short for $[0, f_2, 0, 0]$ if $N = 4$.

The semiring that operates on sparse feature vectors, which we call *tropical sparse tuple vector* semiring[2], uses conceptually identical operators as the non-sparse version defined above, so it also maintains the tropical weights w correctly.

3 A Disambiguation Algorithm

We now describe how we use the semiring described in Section 2 for steps (**a**) and (**b**), and describe an expansion algorithm for step (**c**) that efficiently converts the output of determinization into an unambiguous WFST with arc-level alignments.

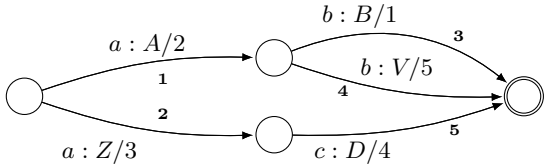
WFSA with Sparse Topological Features

Let T be a tropical-weight WFST with K edges. T is topologically sorted so that if an edge e_k preceeds an edge $e_{k'}$ on a path, then $k < k'$. We now use tropical sparse tuple vector weights to create a WFSA A that maintains (in its weights) pointers to specific edges in T. These 'pointers' are sparse topological features.

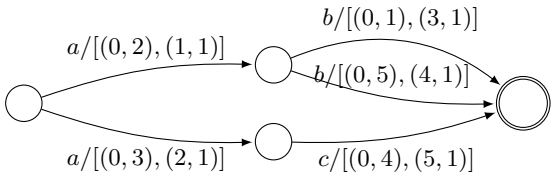
[2]We implement this semiring as an extension to the sparse tuple weights of the OpenFst library (Allauzen et al., 2007).

For each edge $e_k = (p_k, i_k, o_k, w_k, n_k)$ of T, we create an edge $e'_k = (p_k, i_k, i_k, \bar{f}_k, n_k)$ in A, where $\bar{f}_k = [w_k, 0, \ldots, 0, 1, 0, \ldots, 0]$; the 1 is in the k^{th} position. In other words, $f_{k,0}$ is the tropical weight of the k^{th} edge in T and $f_{k,k} = 1$ indicates that this tropical weight belongs to edge k in T. In sparse notation, $\bar{f}_k = [(0, w_k), (k, 1)]$.

For example, this non-deterministic transducer T:



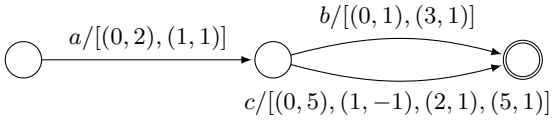
is mapped to acceptor A with topological features:



Given $\alpha = [1, 0, \ldots, 0]$, operations on A yield the same path weights as in the usual tropical semiring.

WFSA determinization

We now apply the standard determinization algorithm to A, which yields A^D:



This now accepts only one best-scoring path for each input string, and the weights 'point' to the sequence of arcs traversed by the relevant path in T. In turn, this reveals the best output string for the given input string. For example, the path-level features associated with '$a\,b$' are $[(0, 3), (1, 1), (3, 1)]$, indicating a path $\pi = e_1 e_3$ with tropical weight 3 through T (and hence output string 'AB').

The topology of A^D is compact because multiple input strings may share arcs while still encoding different output strings in their weights. This is achieved by 'cancelling' topological features in subsequent arcs and 'replacing' them by new ones as one traverses the path. For example, the string '$a\,c$' initially has feature $(1, 1)$, but this gets cancelled later in the path by $(1, -1)$, and replaced by $[(2, 1), (5, 1)]$, indicating a path $\pi = e_2 e_5$ through T with output string 'ZD'.

Figure 1: Expansion and topological feature repositioning algorithm for step (**c**).

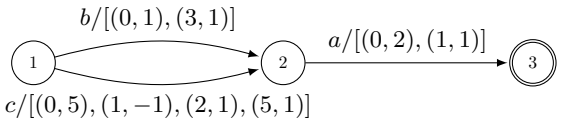
Expansion Algorithm

We now describe an expansion algorithm to convert A^D into an unambiguous WFST T' that maintains the arc-level input-output alignments of the original transducer T. In our example, T' should be identical to T except for edge **4**, which is removed.

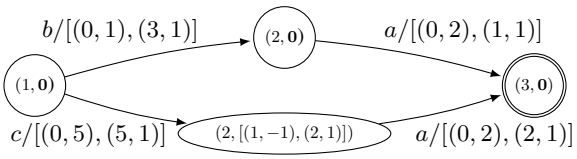
Due to the WFSA determinization algorithm, we observe empirically that the cancelling features in A^D *tend* to appear in a path *after* the feature itself. This allows us to define an algorithm that traverses A^D in reverse (from its final states to its initial state) and creates an equivalent acceptor with the topology of T'.

The algorithm is described in Figure 1. It performs a forward pass through A^r (the reverse of A^D). The intuition is that, for each arc, we create a new arc where we 'pop' the highest topological feature (as it will not be cancelled later) and its tropical weight. The new states encode the original state q and the residual features that have not been 'popped' yet. For each edge $E(q)$, the auxiliary POPTFEA($\bar{f}, e$) returns a $(w', t', \bar{f}')$ tuple, where w' is the tropical weight obtained as $\bar{f} \otimes_\alpha \bar{f}[e]$ (which is equivalent to $f_0 + f[e]_0$ given our $\bar{\alpha}$); t' is the index of the highest topological feature of $\bar{f} * \bar{f}[e]$; and $\bar{f}'$ is the vector of residual topological features after excluding f_0 and $f_{t'}$, that is, $\bar{f} * \bar{f}[e] * [(0, -w'), (t', -1)]$. For example, POPTFEA($[(0,5),(1,-1),(2,1),(6,1)]$) returns $(5, 6, [(1,-1),(2,1)])$; if w has only one topological feature, the residual is $\mathbf{0}$. The residual in all final states of B^r will be $\mathbf{0}$ (no topological features still to be popped).

Graphically, in our running example A^r is:



and the output is B^r:



Reversing B^r yields an acceptor B (still in the sparse tuple vector semiring) which has the same topology as our goal T' and can be trivially mapped to T' in linear time: each arc takes the tropical weight via $\bar{\alpha}$ and has only one topological feature which points to the arc in T containing the required output symbol.

Two-pass Expansion

As mentioned earlier, our algorithm relies on 'cancelling' topological features appearing after the feature they cancel in a given path. In general, consider T a weighted transducer and A it's equivalent automaton with sparse topological features, as described here. A^p is the result of applying standard WFST operations, such as determinization, minimization or shortest path. Assume as a final step that the weights have been pushed towards the final states. It is worth noting the property that: two topological features in a path accepted by A will never get reordered in A^p, although they can appear together on the same edge, as shown in our running example. Indeed, if A^p contains only one single path, all the topological features would appear on the final state.

Let us define a function $d_A(e)$ as the minimum number of edges on any path in A from the start state to $n[e]$ through edge e.

Consider all edges e_i in A and e^p in A^p, with $f[e_i]_i = 1$ and $f[e^p]_i \neq 0$, i.e. we are interested in the topological feature contribution on e^p due to the edge e_i in A. If $d_A(e_i) \leq d_{A^p}(e^p)$ is always satisfied, then EXPANDTFEA will yield the correct answer because the residual at each state, together with the the weight of the current edge, contains all the necessary information to pop the next correct topological feature.

However, many deterministic WFSAs will not exhibit this behaviour (eg. minimised WFSAs), even after pushing the weights towards the final states. For example see this acceptor A:

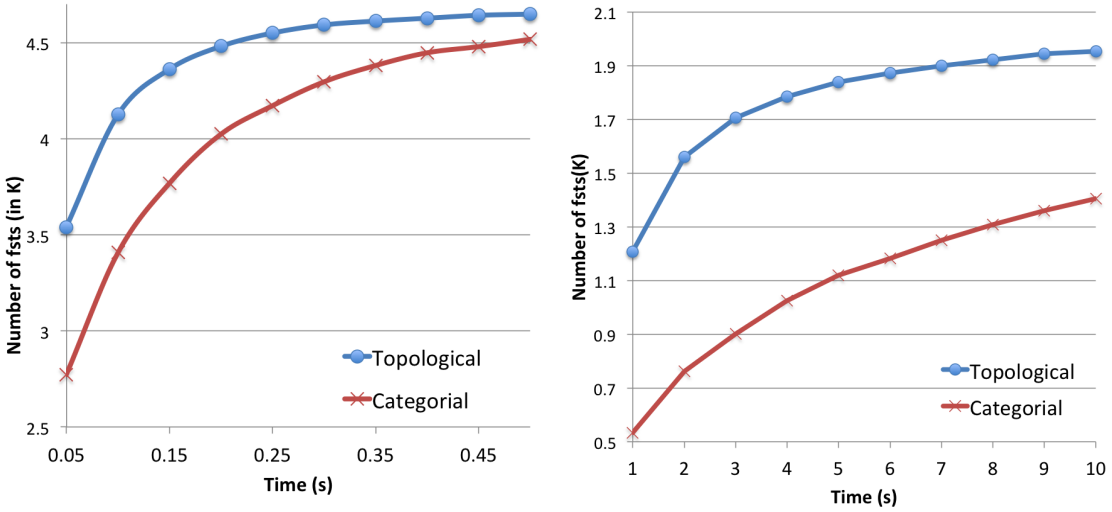


Figure 2: Number of succesfully disambiguated transducers over time for PoS tagged lattices (left) and HiFST lattices (right).

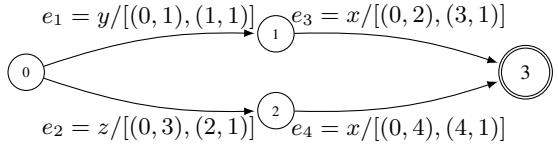
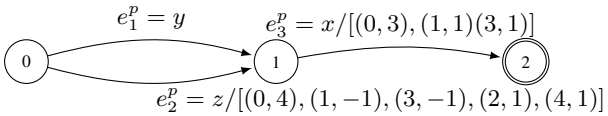


And A^p is a minimised version of A:



As $d_A(e_3) = d_A(e_4) = 2$ and $d_{A^p}(e_2^p) = 1$, the distance test fails for both topological features $(3,-1)(4,1)$. Running B^r=EXPANDTFEA($(A^p)^r$) will not cancel feature $(3,1)$ along the path 'z x' and will pop $(4,1)$ instead, storing the remaining none-$\mathbf{0}$ residual in a final state of B^r.

As mentioned before, two topological features along the same path in A will not reorder in A^p. In this example, as $(4,1)$ appears in edge e_2^p, feature $(2,1)$ must also appear in this edge (or on an earlier edge, in a more complicated machine). In general, any remaining topological features along the path back to the start state of A^p will all be popped *after* their correct edges in B^r. All edges in B^r pass the distance test compared to A^r, the reversed form of A: for all edges e_i with $f[e_i]_i = 1$ in A^r and e^q in B^r such that $f[e^q]_i \neq 0$, $d_{A^r}(e_i) \leq d_{B^r}(e^q)$. Edges in these machines are now reverse sorted, i.e. if an edge e_k precedes an edge $e_{k'}$ on a path, then $k' < k$.

We can perform a second pass with the same algorithm over B, with the only minor modification that t' is now the index of the *lowest* topological feature of $\bar{f} * \bar{f}[e]$. This expands the acceptor correctly. Because correct expansions yield $\mathbf{0}$ residuals on the final states, the algorithm can be trivially modified to trigger the second pass automatically if the residual on any final state is not $\mathbf{0}$.

4 Experiments

We evaluate our algorithm, henceforth called *topological*, in two ways: we empirically contrast disambiguation times against previous work, and then apply it to rescore translation lattices with bilingual neural network models.

4.1 PoS Transducer Disambiguation

We apply our algorithm to the 4,664 NIST English CTS RT Dev04 set PoS tagged lattices used by Sproat el al. (2014); these were generated with a speech recognizer similar to (Soltau et al., 2005) and tagged with a WFST-based HMM tagger. The average number of states is 493. We contrast with the *lexicographic tropical categorial semiring* implementation of Shafran et al. (2011), henceforth referred to as the *categorial* method.

Figure 2 (left) shows the number of disambiguated WFSTs as processing time increases. The topological algorithm proves much faster (and we observe no memory footprint differences). In 50ms it disambiguates 3540 transducers, as opposed to the 2771 completed by the categorial procedure; the slowest WFST to disambiguate takes 230 seconds in the categorial procedure and 60 seconds in our method. Using sparse topological features with our semiring disambiguates all WF-

STs faster in 99.8% of cases.

4.2 Neural Network Bilingual Rescoring

We use the disambiguation algorithm to apply the bilingual neural network language model (BiLM) of Devlin et al. (2014) to the output lattices of the CUED OpenMT12 Arabic-English hierarchical phrase-based translation system[3] using HiFST (de Gispert et al., 2010). We use a development set *mt0205tune* (2075 sentences) and a validation set *mt0205test* (2040 sentences) from the NIST MT02 through MT05 evaluation sets.

The edges in these WFSTs are of the form $t{:}i/w$, where t is the target word, i is the source sentence position t aligns to, and w contains the translation and language model score. HiFST outputs these WFSTs by using a standard hiero grammar (Chiang, 2007) augmented with target side heuristic alignments or *affiliations* to the source (Devlin et al., 2014).

In a rule over source and target words

$$X \rightarrow < s_1\, X\, s_2\, s_3,\, t_1\, X\, t_2 > / 2, 1$$

the feature '$2, 1$' indicates that the target word t_1 is aligned to source word s_2 and that t_2 aligns to s_1. As rules are applied in translation, this information can be used to link target words to absolute positions within the source sentence.

Allowing for admissible pruning, all possible affiliation sequences under the grammar for every translation are available in the WFSTs; disambiguation keeps the best affiliation sequence for each translation hypothesis, which allows the rescoring of very large lattices with the BiLM model.

This disambiguation task involves much bigger lattices than the POS-tagging task: the average number of states of the HiFST lattices is 38,200. Figure 2 (right) shows the number of *mt0205tune* disambiguated WFSTs over time compared to the categorial method. As with the PoS disambiguation task, the topological method is always much faster than the categorial one. After 10 seconds, our method has disambiguated 1953 lattices out of 2075, whereas the categorial method has only finished 1405. The slowest WFST to disambiguate takes 6700 seconds with the categorial procedure, which compares to 1000 seconds in our case.

The BiLM model is trained with NPLM (Vaswani et al., 2013) with a context of 3 source and 4 target words. Lattice rescoring with this model requires a special variation of the standard WFST composition which looks at both input and output labels on a transducer arc; we use KenLM (Heafield, 2011) to retrieve neural network scores for on-the-fly composition. We retune the parameters with Lattice MERT (Macherey et al., 2008) . Results are shown in Table 1. Acknowledging the task differences with respect to (Devlin et al., 2014), we find BLEU gains consistent with rescoring results reported in their Table 5.

5 Conclusions and Related Work

We have described a tagging disambiguation algorithm that supports non-functional WFSTs, which cannot be handled directly by neither WFST determinization (Mohri, 1997) nor WFST disambiguation (Mohri, 2012). We show it is faster than the implementation with a lexicographic-tropical-categorial semiring described by Shafran et al. (2011) and describe a use case in a practical rescoring task of an MT system with bilingual neural networks that yield 1.0 BLEU gain.

Povey et al. (2012) also use a special semiring that allows to map non-functional WFSTs into WFSAs by inserting the tag into a string weight. However, in contrast to our implementation and that of Shafran et al (2011), no expansion into an WFST with aligned input/output is described.

Lexicographic semirings, used for PoS tagging disambiguation (Shafran et al., 2011), have been also shown to be useful in other tasks (Sproat et al., 2014), such as optimized epsilon encoding for backoff language models (Roark et al., 2011), and hierarchical phrase-based decoding with Pushdown Automata (Allauzen et al., 2014).

The tools for disambiguation and WFST composition with bilingual models, along with a tutorial to replicate Section 4.2, are all available at `http://ucam-smt.github.io`.

Acknowledgments

We thank the authors of (Sproat et al., 2014) for generously sharing their PoS-tagging experiments.

Arabic Diacritization with Recurrent Neural Networks

Yonatan Belinkov and **James Glass**
Massachusetts Institute of Technology
Computer Science and Artificial Intelligence Laboratory
{belinkov, glass}@mit.edu

Abstract

Arabic, Hebrew, and similar languages are typically written without diacritics, leading to ambiguity and posing a major challenge for core language processing tasks like speech recognition. Previous approaches to automatic diacritization employed a variety of machine learning techniques. However, they typically rely on existing tools like morphological analyzers and therefore cannot be easily extended to new genres and languages. We develop a recurrent neural network with long short-term memory layers for predicting diacritics in Arabic text. Our language-independent approach is trained solely from diacritized text without relying on external tools. We show experimentally that our model can rival state-of-the-art methods that have access to additional resources.

1 Introduction

Hebrew, Arabic, and other languages based on the Arabic script usually represent only consonants in writing and do not mark vowels. In such writing systems, diacritics are used for marking short vowels, gemination, and other phonetic units. In practice, diacritics are usually restricted to specific settings such as language teaching or to religious texts. Faced with a non-diacritized word, readers infer missing diacritics based on their prior knowledge and the context of the word in order to resolve ambiguities. For example, Maamouri et al. (2006) mention several types of ambiguity for the Arabic string عـلـم *Elm*, both within and across part-of-speech tags, and at a grammatical level. In practice, a morphological analyzer like MADA (Habash et al., 2009) produces at least 13 different diacritized forms for this word, a subset of which is shown in Table 1.[1]

Word	Gloss
Ealima	he knew
Eulima	it was known
Eal~ama	he taught
Eilomu	knowledge (def.nom)
...	...
EilomK	knowledge (indef.gen)
Ealamu	flag (def.nom)
...	...
EalamK	flag (indef.gen)

Table 1: Possible diacritized forms for عَلَم *Elm*.

The ambiguity in Arabic orthography presents a problem for many language processing tasks, including acoustic modeling for speech recognition, language modeling, text-to-speech, and morphological analysis. Automatic methods for diacritization aim to restore diacritics in a non-diacritized text. While earlier work used rule-based methods, more recent studies attempted to learn a diacritization model from diacritized text. A variety of methods have been used, including hidden Markov models, finite-state transducers, and maximum entropy – see the review in (Zitouni and Sarikaya, 2009) – and more recently, deep neural networks (Al Sallab et al., 2014). In addition to learning from diacritized text, these methods typically rely on external resources such as part-of-speech taggers and morphological analyzers like the MADA tool (Habash and Rambow, 2007). However, building such resources is a labor-intensive task and cannot be easily extended to new languages, dialects, and domains.

دْ	*o*	No vowel

Table 2: Arabic diacritics.

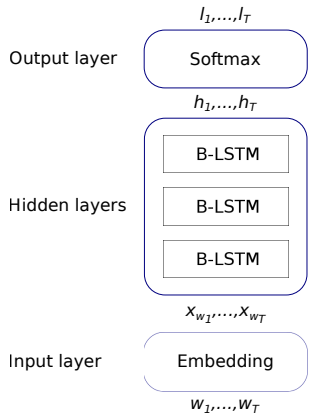

Figure 1: An illustration of our network topology.

In this work, we propose a diacritization method based solely on diacritized text. We treat the problem as a sequence classification task, where each character has a corresponding diacritic label. The sequence is modeled with a recurrent neural network whose input is a sequence of characters and whose output is a probability distribution over the diacritics. Any RNN architecture can be used in this framework; here we focus on long short-term memory (LSTM) networks, which have shown recent success in a number of NLP tasks. We experiment with several architectures and show that we can achieve state-of-the-art results, without relying on external resources. Error analysis demonstrates the benefit of using LSTM over simpler neural networks.

2 Linguistic Background

Languages based on the Arabic script typically employ an *abjad* writing system, where each symbol represents a consonant while vowels and other phonetic units, commonly known as diacritics, are usually omitted in writing. In modern standard and classical Arabic, these include the short vowels *a*, *u*, and *i*, the case endings *F*, *N*, and *K*, the gemination marker ~, and the silence marker *o*.[2] Table 2, modified from (Habash et al., 2007), lists the diacritics. Importantly, the gemination marker ~ can combine with short vowels and case endings (e.g. Table 1, row 3).

3 Approach

We define the following sequence classification task, similarly to (Zitouni and Sarikaya, 2009).

[2]We also include the low-frequency superscript Alif ‘ that is usually ignored due to its limitation to fixed lexical items.

Let $\mathbf{w} = (w_1, ..., w_T)$ denote a sequence of characters, where each character w_t is associated with a label l_t. A label may represent 0, 1, or more diacritics, depending on the language. Assume further that each character w in the alphabet is represented as a real-valued vector x_w. This character embedding may be learned during training or fixed.

Our neural network has the following structure, illustrated in Figure 1:

- Input layer: mapping the letter sequence $\mathbf{w}$ to a vector sequence $\mathbf{x}$.
- Hidden layer(s): mapping the vector sequence $\mathbf{x}$ to a hidden sequence $\mathbf{h}$.
- Output layer: mapping each hidden vector h_t to a probability distribution over labels l.

During training, each sequence is fed into this network to create a prediction for each character. As errors are back-propagated down the network, the weights at each layer are updated. During testing, the learned weights are used in a forward step to compute a prediction over the labels. We always take the best predicted label for evaluation.

Hidden layer Our main system relies on long short-term memory networks (LSTM) (Hochreiter and Schmidhuber, 1997; Graves et al., 2013). Here we describe a single LSTM layer and refer to Graves et al. (2013) for the extension to bidirectional LSTM (B-LSTM) and to multiple layers. The LSTM computes the hidden representation for

input x_t with the following iterative process:

$$
\begin{aligned}
i_t &= \sigma(W_{xi}x_t + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i) \\
f_t &= \sigma(W_{xf}x_t + W_{hf}h_{t-1} + W_{cf}c_{t-1} + b_f) \\
c_t &= f_t \odot c_{t-1} + \\
&\quad i_t \odot \tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \\
o_t &= \sigma(W_{xo}x_t + W_{ho}h_{t-1} + W_{co}c_t + b_o) \\
h_t &= o_t \odot \tanh(c_t)
\end{aligned}
$$

where σ is the sigmoid function, $\odot$ is element-wise multiplication, and i, f, o, and c are input, forget, output, and memory cell activation vectors. The crucial element is the memory cell c that is able to store and reuse long term dependencies over the sequence. The W matrices and b bias vectors are learned during training.

Implementation details The input layer maps the character sequence to a sequence of letter vectors, initialized randomly. We also tried initializing with letter vectors trained from raw text with `word2vec` (Mikolov et al., 2013a; Mikolov et al., 2013b), but did not notice any improvement, probably due to the small letter vocabulary size. The input layer also stacks previous and future letter vectors, enabling the model to learn contextual information. We use a letter embedding size of 10 and a window size of 5 characters, so the input size is 110.

We experiment with several types of hidden layers, ranging from one feed-forward layer to multiple B-LSTM layers. We also add a linear projection after the input layer. This has the effect of learning a new representation for the letter embeddings. The output layer is a Softmax over labels:

$$P(l|w_t) = \frac{\exp(y_t[l])}{\sum_{l'} \exp(y_t[l'])}$$

where $y_t = W_{hy}h_t + b_y$ and $y_t[l]$ is the l^{th} element of y_t.

Training is done with stochastic gradient descent with momentum, optimizing the cross-entropy objective function. Layer sizes and other hyper-parameters are tuned on the Dev set. Our implementation is based on Currennt (Weninger et al., 2015).

4 Experiments

Data We extract diacritizied and non-diacritized texts from the Arabic treebank, following the Train/Dev/Test split in (Zitouni and Sarikaya, 2009). Table 3 provides statistics for the corpus.

Every character in our corpus has a label corresponding to 0, 1, or 2 diacritics, in the case of the gemination marker combining with another diacritic. Thus the label set almost doubles. We opted for this formulation due to its simplicity and generalizability to other languages, even though previous work reported improved results by first predicting gemination and then all other diacritics (Zitouni and Sarikaya, 2009).

Results Table 4 shows the results of our models on the Dev set in terms of the diacritic error rate (DER). Clearly, LSTM models perform much better than simple feed-forward networks. To make the comparison fair, we increased the number of parameters in the feed-forward model to match that of the LSTM. In this setting, the LSTM is still much better, indicating that it is far more successful at exploiting the larger parameter set. Interestingly, the bidirectional LSTM works better than a unidirectional one, despite having less parameters. Finally, deeper models achieve the best results.

On the Test set (Table 5), our 3-layer B-LSTM model beats the lexical variant of Zitouni and Sarikaya (2009) by 3.25% DER, a 40% error reduction. Moreover, we outperform their best model, which also used a segmenter and part-of-

speech tagger. This shows that our model can effectively learn to diacritize without relying on any resources other than diacritized text.

Finally, some studies report work on a Train/Test data split, without a dedicated Dev set (Zitouni et al., 2006; Habash and Rambow, 2007; Rashwan et al., 2011; Al Sallab et al., 2014). We were reluctant to follow this setting so we performed all development on the Dev set of (Zitouni and Sarikaya, 2009). Still, we ran our best model on the Train/Test split and achieved a DER of 5.39% on all diacritics and 8.74% on case endings. The first result is behind the state-of-the-art (Al Sallab et al., 2014) by 2% but the second one is better by 3%. Given that we did not tune the system for this data set, this result is encouraging.

Error Analysis A quantitative analysis of the errors produced by one of our models on the Dev set is shown in Figure 2. The heat map denotes the number of errors produced. The major source of errors comes from confusing the short vowels *a*, *i*, and *u*, among themselves and with no diacritic. This is expected due to the high rate of short vowels in Arabic compared to other diacritics. It also explains why methods that take the confusion matrix into account in their classification algorithm do quite well (Al Sallab et al., 2014).

We also analyzed some errors qualitatively. Figure 3 shows the errors produced by several of our diacritization models on a sample sentence. Interestingly, the simple feed-forward model fails to predict the correct case ending on the word *AlqaDA}iy~ap* ("judicial"), while both LSTM models succeed. This may indicate that LSTM indeed captures the kind of long-distance dependencies that are responsible for case marking. Other errors are more difficult to explain, but note that all models struggle with the proper name *tuwayoniy~* ("Tueini"), which is difficult to solve without external resources.

5 Conclusion

In this work, we develop a recurrent neural network that predicts diacritics in non-diacritized texts. Our model is language agnostic: it is trained solely from diacritized text without relying on additional resources. Using LSTM units, we demonstrate that our model can effectively learn to diacritize Arabic texts and rivals state-of-the-art methods that rely on language-specific tools.

In future work, we intend to incorporate our diacritization system in a speech recognizer. Recent work has shown improvements in Arabic speech recognition by diacritizing with MADA (Al Hanai and Glass, 2014). Since creating such tools is a labor-intensive task, we expect our diacritization approach to promote the development of speech recognizers for other languages and dialects.

Abstract

In this paper, we describe a method based on statistical machine translation (SMT) that is able to restore accents in Hungarian texts with high accuracy. Due to the agglutination in Hungarian, there are always plenty of word forms unknown to a system trained on a fixed vocabulary. In order to be able to handle such words, we integrated a morphological analyzer into the system that can suggest accented word candidates for unknown words. We evaluated the system in different setups, achieving an accuracy above 99% at the highest.

1 Introduction

Due to clumsy mobile device interfaces and reluctance of users to spend too much time entering their message, a great amount of text is generated in a format that lacks the diacritic marks normally used in the orthography of the language the text is written in. Whatever the causes for the missing accents are, NLP applications should be able to restore or generate the accented version of such texts prior to any further syntactic or semantic processing to avoid upstream errors.

In this paper, we aim at solving the problem of restoring accents in Hungarian texts with the combined application of a statistical machine translation system and a morphological analyzer. Our method can be applied to any other languages that have an accurate morphological analyzer.

2 Related work

For Hungarian, there have been some attempts at creating accent restoration systems. Zainkó et al. (2000) and Mihalcea and Nastase (2002) are examples for ML approaches, where the correct places of diacritics are predicted from the immediate grapheme-level context of the unaccented letter with an accuracy of 95%. Thus, unseen words can also be accented, but incorrect forms may also be introduced into the text. Dictionary-based approaches rely on large text corpora and the distribution of the different accented forms. Zainkó et al. (2000) report to have achieved a performance of 98% of accuracy with their dictionary-based method. Nevertheless, their system cannot recognize unseen wordforms quite common in Hungarian. Németh et al. (2000) have implemented a complex text processing system for TTS applications, applying morphological and syntactic analysis. The authors report that the performance of accent restoration depends very much on the performance of the analyzers (achieving 95% accuracy at best). Neither the implementations nor the resources used in these systems have been made publicly available.

A language-independent tool, Charlifter (Scannell, 2011), is based on statistical methods relying on a lexicon, a bigram contextual model and character distributions built from a training corpus. Its performance on Hungarian with its pre-built models is compared to our results in Section 5.

For other languages, similar methods are used. Yarowsky (1994) presents a comprehensive report on corpus-based techniques used for French and Spanish texts. The role of the context is emphasized in this report, however, both word form and accent variations are relatively moderate in the investigated languages compared to Hungarian. The study of Zweigenbaum and Grabar (2002) is also aiming at French, but in the medical domain, which contains a higher ratio of unknown words than general language. In their work, a tagging method is applied in combination with transducers, resulting in a tag sequence corresponding to each letter. The method is successfully (92% precision) applied to single headwords of a medical thesaurus (without exploiting any context). The most similar method to ours is that of Pham et al. (2013), who also applied SMT in order to au-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2286–2291,
Lisbon, Portugal, 17-21 September 2015.

tomatically restore accents in Vietnamese texts. In their case, the best results produced an accuracy of 93%. However, their system is augmented with a dictionary, and the distribution of accents and grammatical behaviour are also quite different from Hungarian.

3 Hungarian

Hungarian is an agglutinating language with an orthography that represents compounds as single word forms. These may result in rather complex word forms and words are often composed of long sequences of morphemes. Thus, agglutination and compounding yield a huge number of different word forms.

In Hungarian, umlauts and acute accents are used as diacritics for vowels. Acute accents mark long vowels, while umlauts are used to indicate the frontness of rounded vowels *o*→*ö* [o→ø] and *u*→*ü* [u→y], like in German. A combination of acutes and umlauts is the double acute diacritic to mark long front rounded vowels *ő* [øː] and *ű* [yː]. Long vowels generally have essentially the same quality as their short counterpart (*i-í, ü-ű, u-ú, ö-ő, o-ó*). The long pairs of the low vowels *a* [ɔ] and *e* [ɛ], on the other hand, also differ in quality: *á* [aː] and *é* [eː]. There are a few lexicalized cases where there is a free variation of vowel length without distinguishing meaning, e.g. *hova*∼*hová* 'where to'. In most cases, however, the meaning of differently accented variants of a word is quite different. Table 1 shows all the possible unaccented-accented pairs of vowels in Hungarian together with their distribution in a corpus of 1 804 252 tokens.

a	a: 70.33%; á: 29.66%
e	e: 73.40% é: 26.59%
i	i: 86.04% í: 13.95%

u	u: 46.96% ú: 12.72% ü: 29.98% ű: 10.32%

Table 1: Possible accent variations in Hungarian

4 Method

In this research, we considered the problem of accent restoration as a translation task, where the source language is the unaccented version, and the target language is accented Hungarian. Since it is easy to come up with a parallel training corpus for this task, methods of SMT can be applied.

In our experiments, we used Moses (Koehn et al., 2007), a widely used SMT toolkit for building the translation models and performing decoding, and SRILM (Stolcke et al., 2011) to build the necessary language models. Moses was used with its default configuration settings and monotone decoding (i.e. reordering was not allowed), and without the alignment step, which was not needed in our case.

4.1 The baseline setup

In the baseline setup, only the translation and language models built from the training corpus were used. The input for the decoder was Hungarian raw texts with all the accents removed. The translation model contained only unigram phrases (larger n-grams were also tried, but did not change the results) and the language model contained phrases up to 5 grams. Thus, the translation model was responsible for predicting the distribution of accented forms and the language model exploited contextual information.

Another baseline was also created in order to monitor the effect of the SMT system. In this second baseline, each unaccented word form was replaced by its most frequent accented form in the training set.

4.2 Incorporating a morphological analyzer

In order to be able to restore accents in unseen words as well, a Hungarian morphological analyzer (Prószéky and Kis, 1999; Novák, 2003) was integrated. A special version of the analyzer was created that directly maps unaccented word forms to their possible accented variants while also marking morpheme boundaries and adding morphosyntactic category tags. The segmentation marks (e.g. compound and derivational suffix boundaries) and the tags are used when we assign a score to the accented candidates. We also reanalyze accented forms to retrieve lemmas not directly returned by the accenting analyzer. In our test set of 1 804 252 tokens, about 1% of the words were not found in the translation model even in the case of the largest, 440 million words, training set. Table 2 shows the ratio of unknown words (OOV) as a function of the size of the training set used for building the phrase table.

For these unknown words, all possible correct accented candidates were generated by the morphological analyzer. These candidates were then fed to the Moses decoder using its `-xml-input`

train	sentences	M words	OOV in test
100K	100 000	1.738	9.63%
1000K	1 000 000	18.078	3.44%
5000K	5 000 000	89.907	1.23%
10M	10 000 000	180.644	1.68%
ALL	24 048 302	437.559	0.81%

Table 2: Ratio of OOV after building a translation model from a training set of a certain size

parameter. In order to be able to use this feature of the decoder, a probability for each candidate form had to be estimated. First, we assumed uniform distribution among the candidates. However, this approach assigned the same probability to the most common and the most nonsensical (although grammatical) candidates as well. Thus, in some cases these forms showed up in the results. In order to avoid the system to make such errors, a more sophisticated distribution was estimated for the candidate set. For this, we applied a linear regression model based on corpus frequency data determined for the lemma and other features of the candidate word (since the actual wordform was not present in the corpus). Thus, for each candidate, its lemma frequency (LEM), the number of productively applied compounding (CMP), the number of productively applied derivational affixes (DER), and the frequency of the inflectional suffix sequence returned by the analysis were determined. Compounding and derivation were penalized (i.e. they were given a negative sign), because the morphological analyzer could suggest some nonsensical, though grammatical compound or derived forms. Sometimes such forms could be the correct ones, but the more productive compounding and derivation there is in a word, the lower score it should get. On the other hand, the frequencies of the lemma and the inflectional pattern should increase the score of a candidate, thus these components were given positive weights. Based on these components, a score was assigned to each candidate based on Formula (1).

$$score = -\lambda_c \#CMP - \lambda_d \#DER + log_{10}LEM + \lambda_i log_{10}INF + MS \quad (1)$$

, where

$$MS = \begin{cases} |minscore| + 1 & if \quad minscore \leq 0 \\ 0 & otherwise \end{cases} \quad (2)$$

The MS component was used to scale up the scores by adding $|minscore| + 1$, i.e. the lowest score received for any candidate in the actual candidate set in order to evade negative scores. The λ weights were set by the `mert` tuning of the Moses system. We used a separate development set for this, on which we observed the distribution of compounds, derivational and inflectional suffixes in OOV words analyzed by the morphology and from which we sampled 1000 words approximating the observed distributions. The target of the optimization in the `mert` tuning was the accuracy of the system on these words, resulting in the optimal values for each λ. Even though, in linear regression, it is standard to use an additional bias weight, we did not find it necessary, because we did not need to bring our estimates in sync with estimates from other sources. And assuming one factor to have a fixed unit value was just another simplification that would not affect the overall ranking, just its scaling.

Even though, following an appropriate scaling of the scores, the ranked candidates could be used the same way as the entries in the translation table, the system would never select any accented form other than the most probable one, since the language model does not include any of these forms. Thus, only the candidate with the highest relative score was made available to the system.

5 Experiments and results

In our experiments, the Hungarian webcorpus (Halácsy et al., 2004) was used for training and testing purposes. A set of 100 000 sentences were separated from the corpus as the test set, and another 100 000 sentences were used as a development set. The rest were used for training in different settings. The size of each training set is shown in Table 2.

We evaluated the performance on all the 1 804 252 tokens of the test set (56.84% correct without accent) and on a subset of 1 472 200 words that included any vowels (47.09% correct without accent). The experiments were then performed for the baseline system using the most frequent form (BL-FREQ), for the baseline SMT system (BL-SMT) and for the one augmented by the morphology with the first-ranked candidate (RANK). Table 3 shows the detailed results for the smallest and largest training sets for all words (ALL) and for words that include vowels (VOWEL). It can be seen that the precision of the system is only

	100K			ALL		
system	prec	rec	acc	prec	rec	acc
BL-FREQ-ALL	98.25	82.82	92.34	98.37	96.26	98.13
BL-FREQ-VOW	98.25	82.82	90.62	98.37	96.26	97.71
BL-SMT-ALL	99.03	83.88	92.91	99.09	97.36	98.72
BL-SMT-VOW	99.03	83.88	**91.31**	99.09	97.36	**98.44**
RANK-ALL	98.81	98.08	98.99	99.01	98.56	99.23
RANK-VOW	98.82	98.08	**98.77**	99.02	98.56	**99.06**

Table 3: Performance results for each experimental settings and training size

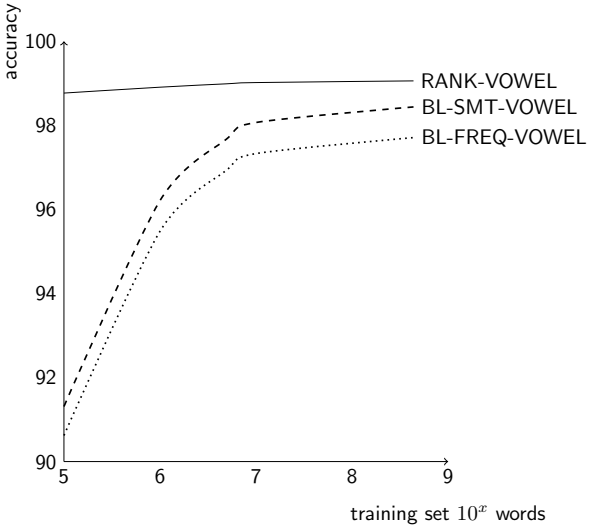

Figure 1: Accuracy as a function of the size of the training set for each system, measured on words containing vowels.

slightly improved when increasing the size of the training corpus, but the values of recall and accuracy do dramatically improve in the case of the baseline system. However, the integration of the suggestions of the morphology can make up for the lack of information due to the small training set improving recall a great deal while only slightly affecting precision. Even for the biggest 437.6M-word training corpus, incorporating the morphological analyzer with ranking yielded a relative error rate reduction of 39.74%, reducing the word error rate from 1.56% to 0.94%. For the smallest 1.74M-word training corpus tested, the relative error rate reduction was 85.85%. The system including the morphological analyzer performs better even with the smallest training corpus in terms of word accuracy than the baseline Moses system with the biggest corpus. Figure 1 shows the learning curves for each system with accuracy as a function of training set size.

Comparing our results to those we obtained using Charlifter (89.75% with most frequent accented form baseline, 90.00% with the lexicon-lookup+bigram contextual model and 93.31% with lookup+bigram context+character-n-gram-based model), the results reveal that both the contextual model in the SMT system improves accuracy better than the bigram context model of Charlifter, and the performance boost we get by incorporating morphology vastly exceeds the accuracy improvement yielded by the incorporation of the character-n-gram-based model used in Charlifter.

6 Error analysis

We performed a detailed error analysis on a 5000-sentence (87786-token) fragment of the test set. The results of the error analysis are presented in Table 4.

The detailed analysis showed that 14.7% of mismatches between the original and the system output is in fact not due to the latter being erroneous. 3.55% are equivalent forms , while the rest is correct in the output and erroneous in the reference, i.e. the system corrected errors in the original.

Another part of the reference (17.91%) is likewise erroneous, however, since the error in these cases was not in the accents, the system was not able to correct it. Missing or substituted letters are the most common mistakes (10.81%), and further 6.42% of the errors is due to punctuation errors in the original.

About $2/3$ of the mismatches are real errors. 5.57% of these could be attributed to the stem of the word missing from the database of the morphological analyzer. In 3.55% of the cases, the system transforms a name to a more frequent word: sometimes to another name, but more often to some common frequent word. A similar case is when some common noun is transformed to a more frequent name (another 1.35%). The number of these errors could be reduced to some extent by making the system rely on case information (in the case of some proper name-common noun ambiguities), however this could make the system perform worse elsewhere due to increased data sparseness. 2.20% of the errors is due to errors in the training corpus. Since rare word forms are quite frequent in Hungarian, the chances are high that a specific form is more often mistyped

Mismatch type	Ratio	Examples
Output correct	**14.70%**	
Equivalent forms	3.55%	lévő→levő fele→felé áhá→aha periférikus→periferikus
Corrected erroneous name	1.01%	USÁ-ban→USA-ban Szóladon→Szóládon
Other corrected erroneous	10.14%	un.→ún. kollegánk→kollégánk lejto→lejtő lathato→látható
Real errors	**67.40%**	
Missing from MA	5.57%	hemokromatózis-gén→hemokromatozis-gen
Correct name to erroneous output	3.55%	MIG→míg Bösz→Bősz Ladd→Ládd Márton→Marton
Other correct original to some erroneous form	2.20%	megőrzést→megorzést routeréhez→routerehez
Other correct original to contextually inadequate name	1.35%	logó→logo eperjeskein→eperjeskéin
Other correct original to some contextually inadequate form	51.01%	még→meg termek→termék gépét→gépet címét→címet vágyók→vagyok érméket→érmeket képé→képe
Original is a filename or a url containing accents	3.72%	latok→látok viz→víz szantok→szántók telepok→telepók felhasználó@profinter.hu→felhasznalo@profinter.hu www.valamicég.hu→www.valamiceg.hu
Uncorrected error in original	**17.91%**	
Punctuation error in original	6.42%	közalk.tan→kozalk.tan 1922.évi→1922.evi
Hyphenation error in original	0.68%	bemuta-tásra→bemuta-tasra
Other error in original	10.81%	véri→veri ra→rá gonolkozásában→gonolkozasaban imátkoztok→imatkoztok hirújsághoz→hirujsasghoz változaban→változabán környezetkíméli→kornyezetkimeli

Table 4: Analysis of mismatches between the system output and the input on a 5000-sentence test sample

than not (this is especially true for word forms that occur only once in the training data). 3.72% of the errors in the analyzed test data was due to either transforming arbitrary unaccented letter sequences used as file names in the text being transformed to some meaningful words or to accented words being used in an url in the original text.

The most common error (51.01% of all mismatches) is the case where the system is simply unable to correctly disambiguate the word in context, and this is not due to some other error or information loss. Interestingly, more than half (51%) of these errors belong to a single type where the system is unable to distinguish a possessive and a non-possessive form of the same nominal lemma: *gyereket∼gyerekét* 'the child (accusative)' vs.'his/her child (accusative)', *gyereken∼gyerekén* 'on/about the child' vs. 'on/about his/her child', and *gyereke∼gyereké* 'his/her child' vs.'(belongs to a) child' (anaphoric possessive).

Another 26% of the mismatches is due to a similar problem concerning verbs. In Hungarian, transitive verbs agree with their object in definiteness. Certain past, present and conditional verb forms differing in definiteness are only distinguished by an accent: *hajtottak∼hajtották* 'they drove' vs. 'they drove it'; *hajtanak∼hajtanák* 'they drive' vs. 'they would drive it'; *hajtana∼hajtaná* 'he/she would drive' vs. 'he/she would drive it'.

A factored model could in theory improve the recognition of these structures. It is questionable however, whether the improvement would justify the costs.

7 Conclusion

We have described a method to restore accents in Hungarian texts. The baseline method using only a fixed training corpus to build translation and language models for a statistical machine translation system, which is limited to handling word forms present in the training corpus achieved an accuracy of 98.44% at best. In order to process unknown words, a morphological analyzer was integrated to produce accented candidates for these unknown words as well, resulting in an improved accuracy of 99.06%. This performance could only be achieved by a system that is able to produce correct word forms and takes context into account. Our method can be applied to any other languages for which a training corpus and a morphological analyzer are available.

Morphological Analysis for Unsegmented Languages using Recurrent Neural Network Language Model

Abstract

We present a new morphological analysis model that considers semantic plausibility of word sequences by using a recurrent neural network language model (RNNLM). In unsegmented languages, since language models are learned from automatically segmented texts and inevitably contain errors, it is not apparent that conventional language models contribute to morphological analysis. To solve this problem, we do not use language models based on raw word sequences but use a semantically generalized language model, RNNLM, in morphological analysis. In our experiments on two Japanese corpora, our proposed model significantly outperformed baseline models. This result indicates the effectiveness of RNNLM in morphological analysis.

1 Introduction

In contrast to space-delimited languages like English, word segmentation is the first and most crucial step for natural language processing (NLP) in unsegmented languages like Japanese, Chinese, and Thai (Kudo et al., 2004; Kaji and Kitsuregawa, 2014; Shen et al., 2014; Kruengkrai et al., 2006). Word segmentation is usually performed jointly with related analysis: POS tagging for Chinese, and POS tagging and lemmatization (analysis of inflected words) for Japanese. Morphological analysis including word segmentation has been widely and actively studied, and for example, Japanese word segmentation accuracy is in the high 90s. However, we often observe that strange outputs of downstream NLP applications such as machine translation and question answering come from incorrect word segmentations.

For example, the state-of-the-art and popular Japanese morphological analyzers, JUMAN (Kurohashi and Kawahara, 2009) and MeCab (Kudo et al., 2004) both analyze "外国人参政権 (foreigner's right to vote)" not into the correct segmentation of (1a), but into the incorrect and awkward segmentation of (1b).

(1) a. 外国 / 人 / 参政 / 権
foreigner right to vote
b. 外国 / 人参 / 政権
foreign carrot regime

JUMAN is a rule-based morphological analyzer, defining word-to-word (including inflection) connectivities and their scores. MeCab is a supervised morphological analyzer, learning the probabilities of word/POS/inflection sequence from an annotated corpus of tens of thousands of sentences. Both systems, however, cannot realize semantically appropriate analysis, and often produce totally strange outputs like the above.

This paper proposes a semantically appropriate morphological analysis method for unsegmented languages using a language model. For unsegmented languages, morphological analysis and language modeling form a chicken-and-egg problem. That is, if high-quality morphological analysis is available, we can learn a high-quality language model from a morphologically analyzed large corpus. On the other hand, if a high-quality language model is available, we can achieve high-quality morphological analysis by looking for a segmented word sequence with a large language model score. However, even if we learn a language model from a corpus analyzed by a certain level of morphological analyzer, the language model is affected by the analysis errors of the morphological analyzer and it is no practical use for the improvement of the morphological analyzer. A language model trained by incorrectly segmented "外国 (foreign)/人参 (carrot)/政権 (regime)" just supports that incorrect segmentation.

The point of the paper is that we have tackled the chicken-and-egg problem, not by using a lan-

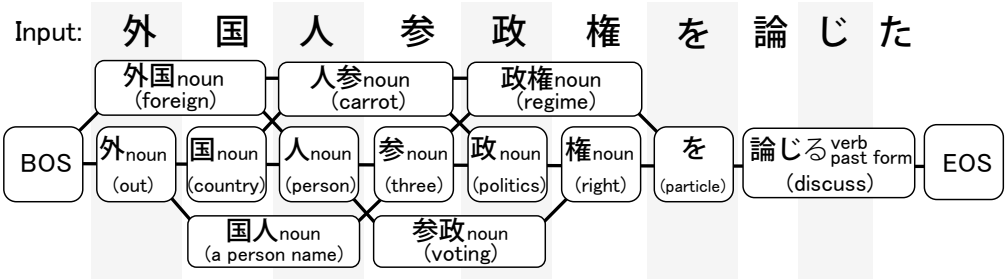

Figure 1: An example of a word lattice.

guage model of raw word sequences, but by using a semantically generalized language model based on word embeddings, RNNLM (Recurrent Neural Network Language Model) (Mikolov et al., 2010; Mikolov et al., 2011). The RNNLM is trained on an automatically analyzed corpus of ten million sentences, which possibly includes incorrect segmentations such as "外国 (foreign)/人参 (carrot)/政権 (regime)." However, on semantically generalized level, it is an unnatural semantic sequence like *nation vegetable politics*. Since the state-of-the-art morphological analyzer achieves the high accuracy, it does not often produce incorrect analyses which support such a semantically strange sequence. This would prefer analysis toward semantically appropriate word sequences. When a morphological analyzer utilizes such a generalized and reasonable language model, it can penalize strange segmentations like "外国 (foreign)/人参 (carrot)/政権 (regime)," leading to better accuracy.

We furthermore retrain RNNLM using an annotated corpus of manually segmented 45k sentences, which further improves morphological analysis.

2 Related Work

There have been several studies that have integrated language models into morphological analysis. Wang et al. (2011) improved Chinese word segmentation and POS tagging by using N-gram features learned from an automatically segmented corpus. However, since the auto-segmented corpus inevitably contains segmentation errors, frequent N-grams are not always correct and thus this problem might affect the performance of morphological analysis. They also divided N-gram frequencies into three binned features: high-frequency, middle-frequency and low-frequency. Such coarse features cannot express slight differences in the likelihood of language models.

Kaji and Kitsuregawa (2014) used a bigram language model feature for Japanese word segmentation and POS tagging. Their objective of using a language model is to normalize informally spelled words in microblogs. Therefore, their objective is different from ours.

Some studies have used character-based language models for Chinese word segmentation and POS tagging (Zheng et al., 2013; Liu et al., 2014). Although their approaches have no drawbacks of learning incorrect segmentations, they only capture more local information than word-based language models.

Word embeddings have been also used for morphological analysis. Neural network based models have been proposed for Chinese word segmentation and POS tagging (Pei et al., 2014) or word segmentation (Mansur et al., 2013). These methods acquire word embeddings from a corpus, and then use them as the input of the neural networks. Our proposed model learns word embeddings via RNNLM, and these embeddings are used for scoring word transitions in morphological analysis. Our usage of word embeddings is different from the previous studies.

3 Proposed Method

We propose a new morphological analysis model that considers semantic plausibility of word sequences by using RNNLM. We integrate RNNLM into morphological analysis (Figure 2). We train the RNNLM using both an automatically analyzed corpus and a manually labeled corpus.

3.1 Recurrent Neural Network Language Model

RNNLM is a recurrent neural network language model (Mikolov et al., 2010), which outputs a probability distribution of the next word, given the embedding of the last word and its context. We

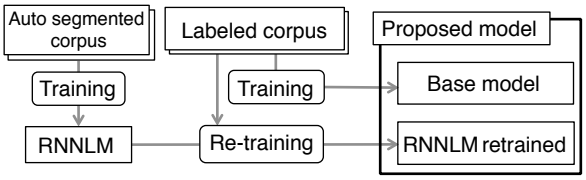

Figure 2: Workflow for training RNNLM and base model.

employ the RNNME language model[1] proposed by (Mikolov et al., 2011; Mikolov, 2012) as the implementation of RNNLM. The RNNME language model has direct connections from the input layer of the recurrent neural network to the output layer, which act as a maximum entropy model and avoid to waste a lot of parameters to describe simple patterns. Hereafter, we refer to the RNNME language model simply as RNNLM.

To train RNNLM, we use a raw corpus of 10 million sentences from the web corpus (Kawahara and Kurohashi, 2006). These sentences are automatically segmented by JUMAN (Kurohashi and Kawahara, 2009). The training of RNNLM is based on lemmatized word sequences without POS tags.

The trained model contains errors caused by an automatically analyzed corpus. We retrain RNNLM using a manually labeled corpus after training RNNLM using the automatically analyzed corpus as shown in Figure 2. The retraining aims to cope with errors related to function word sequences.

3.2 Base Model

For our base model, we adopt a model for supervised morphological analysis, which performs segmentation, lemmatization and POS tagging jointly. We train this model using a tagged corpus of tens of thousands of sentences that contain gold segmentations, lemmas, inflection forms and POS tags. To predict the most probable sequence of words with lemmas and POS tags given an input sentence, we execute the following procedure:

1. Look up the string of the input sentence using a dictionary.
2. Make a word lattice.
3. Search for the path with the highest score from the lattice.

[1]RNNME is the abbreviation of Recurrent Neural Network trained jointly with Maximum Entropy model.

Figure 1 illustrates the constructed lattice during the procedure. At the dictionary lookup step, we use the basic dictionary of JUMAN and an additional dictionary comprising 0.8 million words, both of which have lemma, POS and inflection information. The additional dictionary mainly consists of itemizations in articles and article titles in Japanese Wikipedia.

We define the scoring function as follows:

$$\text{score}_B(\mathbf{y}) = \Phi(\mathbf{y}) \cdot \vec{w}, \quad (1)$$

where $\mathbf{y}$ is a tagged word sequence, $\Phi(\mathbf{y})$ is a feature vector for $\mathbf{y}$, and $\vec{w}$ is a weight vector. Each element in $\vec{w}$ gives a weight to its corresponding feature in $\Phi(\mathbf{y})$. We use the unigram and the bigram features composed from word base form, POS and inflection described in Kudo et al. (2004). We also use additional lexical features such as character type, and trigram features used in Zhang and Clark (2008). To learn the weight vector, we adopt exact soft confidence-weighted learning (Wang et al., 2012).

To consider out-of-vocabulary (OOV) words that are not found in the dictionary, we automatically generate words at the lookup step by segmenting the input string by character types[2]. For training, we regard words that are not found in the dictionary but found in the training corpus as OOV words to learn their weights.

3.3 RNNLM Integrated Model

Based on retrained RNNLM, we calculate an RNNLM score ($\text{score}_R(\mathbf{y})$) to be integrated into the base model. The RNNLM score is defined as the log probability of the next word given its context (path). Here, the score for an OOV word is given by the following formula:

$$-C_p - L_p \cdot \text{length}(n), \quad (2)$$

where C_p is a constant penalty for OOV words, L_p is a factor for the character length penalty, and $\text{length}(n)$ returns the character length of the next word n. This formula is defined to penalize longer words, which are likely to produce segmentation errors.

We then integrate the RNNLM score into the base model using the following equation:

$$\text{score}_I(\mathbf{y}) = (1-\alpha)\text{score}_B(\mathbf{y}) + \alpha\ \text{score}_R(\mathbf{y}), \quad (3)$$

[2]Japanese has three types of characters: Kanji, Hiragana and Katakana.

where α is an interpolation parameter that is tuned on development data.

For decoding, we employ beam search as used in Zhang and Clark (2008). Since the possible context (paths in the word lattice) considered in RNNLM falls into combinatorial explosion in morphological analysis, we keep only probable context candidates inside the beam. That is, each node keeps candidates inside the beam width. Each candidate has a vector representing context, and two words of history. The recurrent model makes decoding harder than non-recurrent neural network language models. However, we use RNNLM because the model outperforms other NNLMs (Mikolov, 2012) and the result suggests that the model is more likely to capture semantic plausibility. Since a sentence rarely contains ambiguous and semantically appropriate word sequences, we think that beam search with enough beam size is able to keep the ambiguous candidates of word sequences. In the case of non-recurrent NNLMs and the base model, which uses trigram features, we can conduct exact decoding using the second-order Viterbi algorithm (Thede and Harper, 1999).

4 Experiments

4.1 Experimental Settings

In our experiments, we used the Kyoto University Text Corpus (Kawahara et al., 2002) and Kyoto University Web Document Leads Corpus (Hangyo et al., 2012) as manually tagged corpora. We randomly chose 2,000 sentences from each corpus for test data, and 500 sentences for development data. We used the remaining part of the corpora as training data to train our base model and retrain RNNLM. In total, we used 45,000 sentences for training.

For comparative purposes, we used the following four baselines: the Japanese morphological analyzer JUMAN, the supervised morphological analyzer MeCab, the base model, and a model using a conventional language model. For this language model, we built a trigram language model with Kneser-Ney smoothing using SRILM (Stolcke, 2002) from the same automatically segmented corpus. The language model is modified to have an interpolation parameter α and length penalty for OOV, L_p.

We set the beam width to 5 by preliminary experiments. We also set a constant penalty for OOV words (C_p) as 5, which is the default value in the implementation of Mikolov et al. (2011). We tuned the parameters of our proposed model and the baseline model (α and L_p) and the parameters of language models using grid search on the development data. We set α = 0.3, L_p =1.5 for the proposed model (" Base + $\text{RNNLM}_{\text{retrain}}$").[3]

We measured the performance of the baseline models and the proposed model by F-value of word segmentation and F-value of joint evaluation of word segmentation and POS tagging. We calculated F-value for the two corpora (news and web) and the merged corpus (all).

We used the bootstrapping method (Zhang et al., 2004) to test statistical significance between proposed models and other models. Suppose we have a test set T that includes N sentences. The method repeatedly creates M new test sets by resampling N sentences with replacement from T. We calculate the F-value of each model on $M + 1$ test sets including T, and then we have $M + 1$ score differences. From the scores, we calculate the 95% confidence interval. If the interval does not overlap with zero, the two models are considered as statistically significantly different. In our evaluation, M is set to 2,000.

4.2 Results and Discussions

Table 1 lists the results of our proposed model and the baseline models. Our proposed model ("Base + $\text{RNNLM}_{\text{retrain}}$") significantly outperforms all the baseline models and "Base + RNNLM," which does not use retraining. In particular, we achieved a large improvement for segmentation. This can be attributed to the use of RNNLM that was learned based on lemmatized word sequence without POS tags.

"Base + SRILM" segmented the example described in Section 1 ("外国人参政権") into the incorrect segmentation "外国/人参/政権" in the same way as JUMAN. This segmentation error was caused by errors in the automatically segmented corpus that was used to train the language model. Our proposed model can correctly segment this example if a proper context is available by semantically capturing word transitions using RNNLM.

The base model, JUMAN and "Base + SRILM" incorrectly segmented "健康 (healthy)/など (etc.)/

[3] We set α = 0.1, L_p = 2.0 for "Base + RNNLM", and α = 0.3, L_p = 0.5 for "Base + SRILM."

	Segmentation (news)	Seg + POS (news)	Segmentation (web)	Seg + POS (web)	Segmentation (all)	Seg + POS (all)
JUMAN	98.92	98.47	98.20	97.64	98.64	98.14

Base model	98.94	98.46	97.71	96.90	98.46	97.85
Base + SRILM	98.94	98.40	98.13	97.33	98.62	97.98
Base + RNNLM	99.06	98.59	98.17	97.45	98.71	98.14
Base + $\text{RNNLM}_{\text{retrain}}$	$\mathbf{99.15}^*$	$\mathbf{98.70}^*$	$\mathbf{98.37}^*$	$\mathbf{97.68}^*$	$\mathbf{98.84}^*$	$\mathbf{98.30}^*$

Table 1: Results for test datasets. $*$ means the score of "Base + $\text{RNNLM}_{\text{retrain}}$" is significantly improved from that of all other models.

の (of)/点 (point)/で (in)/……" (in terms of health and so on) into "健康 な(healthy)/どの(any)/点 (point)/で (in)/……." Although this segmentation can be grammatically accepted, it is difficult to semantically interpret this word sequence. Our proposed model can correctly segment this example because RNNLM learns semantically plausible word sequences.

5 Conclusion

In this paper, we proposed a new model for morphological analysis that is integrated with RNNLM. We trained RNNLM on an automatically segmented corpus and tuned on a manually tagged corpus. The proposed model was able to significantly reduce errors in the base model by capturing semantic plausibility of word sequences using RNNLM. In the future, we will design features derived from RNNLM models, and integrate them into a unified learning framework. We also intend to apply our method to unsegmented languages other than Japanese, such as Chinese and Thai.

Abstract

We propose a novel framework for improving a word segmenter using information acquired from symbol grounding. We generate a term dictionary in three steps: generating a pseudo-stochastically segmented corpus, building a symbol grounding model to enumerate word candidates, and filtering them according to the grounding scores. We applied our method to game records of Japanese chess with commentaries. The experimental results show that the accuracy of a word segmenter can be improved by incorporating the generated dictionary.

1 Introduction

Today we can easily obtain a large amount of text associated with multi-modal information, and there is a growing interest in the use of non-textual information in the natural language processing (NLP) community. Many of these studies aim to output natural language sentences from a nonlinguistic modality, such as image (Farhadi et al., 2010; Yang et al., 2011; Rohrbach et al., 2013). Kiros et al. (2014) showed that multi-modal information improves the performance of a language model.

Inspired by these studies, we explore a method for improving the performance of a low-level NLP task using multi-modal information. In this work, we focus on the task of word segmentation (WS) in Japanese. WS is often performed as the first processing step for languages without clear word boundaries, and it is as important as part-of-speech (POS) tagging in English. We assume that a large set of pairs of non-textual data and sentences describing them is available as the information source. In our experiments, the pairs consist of game states in *Shogi* (Japanese chess) and textual comments on them, which were made by Shogi experts. We enumerate substrings (character sequences) in the sentences and match them with *Shogi* states by a neural network model. The rationale here is that substrings which match with non-language data well tend to be real words.

Our method consists of three steps (see Figure 1). First, we segment commentary sentences for a game state in various ways to produce word candidates. Then, we match them with game states of a Shogi playing program. Finally, we compile the symbol grounding results at all states and incorporate them to an automatic WS. To the best of our knowledge, this is the first result reporting a performance improvement in an NLP task by symbol grounding.

2 Stochastically Segmented Corpus

Before symbol grounding, we need to segment the text into words that include probable candidate words. For this purpose, we use a stochastically segmented corpus (SSC) (Mori and Takuma, 2004). Then we propose to simulate it by a normal (deterministically) segmented corpus to avoid the problem of computational cost.

2.1 Stochastically Segmented Corpora

An SSC is defined as a combination of a raw corpus C_r (hereafter referred to as the character sequence $\boldsymbol{x}_1^{n_r}$) and word boundary probabilities of the form P_i, which is the probability that a word boundary exists between two characters x_i and x_{i+1}. These probabilities are estimated by a model based on logistic regression (LR) (Fan et al., 2008) trained on a manually segmented corpus by referring to the surrounding characters[1]. Since there are word boundaries before the first character and after the last character of the corpus, $P_0 = P_{n_r} = 1$. The expected frequency of a word

[1]In the experiment we used the same features as those used in Neubig et al., (2011). .

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2298–2303,
Lisbon, Portugal, 17-21 September 2015.

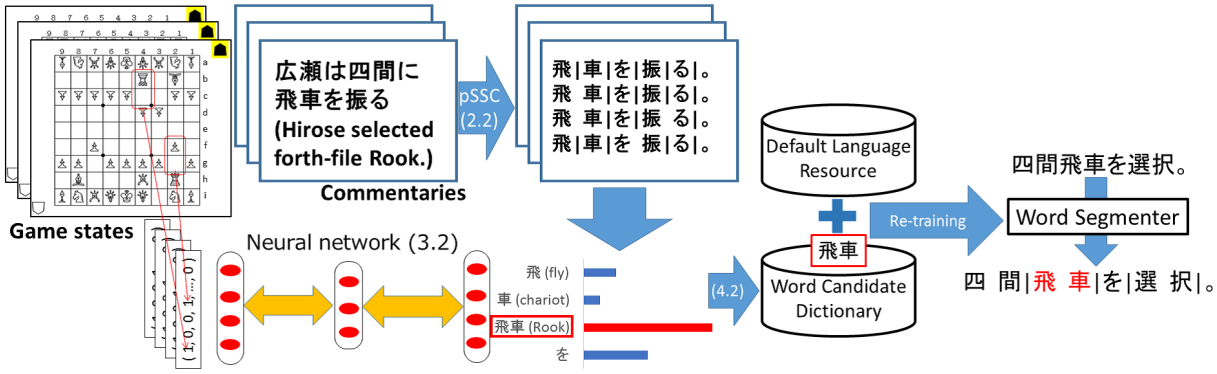

Figure 1: Overview of our method.

$\boldsymbol{w}$ in an SSC is calculated as follows: $f_r(\boldsymbol{w}) = \sum_{i \in O} P_i \left\{ \prod_{j=1}^{k-1} (1 - P_{i+j}) \right\} P_{i+k}$, where $O = \{i \mid x_{i+1}^{i+k} = \boldsymbol{w}\}$ is the set of all the occurrences of the string matching with $\boldsymbol{w}$[2].

2.2 Pseudo-Stochastically Segmented Corpora

The computational cost (in terms of both time and space) for calculating the expected frequencies in an SSC is very high[3], so it is not a practical approach for symbol grounding. In this work, we approximate an SSC using a deterministically segmented corpus, which we call a pseudo-stochastically segmented corpus (pSSC). The following is the process we use to produce a pSSC from an SSC.

- For i = 1 to $n_r - 1$
  1. output a character x_i,
  2. generate a random number $0 \leq p < 1$,
  3. output a word boundary if $p < P_i$ or output nothing otherwise.

Now we have a corpus in the same format as a standard segmented corpus with variable (non-constant) segmentation, where x_i and x_{i+1} are segmented with the probability of P_i. We execute the above procedure m times and divide the counts by m. The law of large numbers guarantees that the approximation errors decrease to 0 when $m \to \infty$.

3 Symbol Grounding

As the target of symbol grounding, we use states (piece positions) of a Shogi game and commentaries associated with them. We should note, however, that our framework is general and applicable to different types of combinations such as image/description pairs (Regneri et al., 2013).

3.1 Game Commentary

The Japanese language is one of the languages without clear word boundaries and we need an automatic WS as the first step of NLP. In Shogi, there are many professional players and many commentaries about game states are available.

3.2 Grounding Words

We build a symbol grounding model using a Shogi commentary dataset. We use a set of pairs of a Shogi state S_i and a commentary sentence C_i as the training set. A Shogi state S_i is converted into a feature vector f(S_i). We generate m (in our experiment, $m = 4$) pSSC C'_i from C_i. C'_i contains m corpora of the same text body but with different word segmentation, C'_{ij} ($j = 1, \ldots, m$). We treat these as m pairs of a feature vector of Shogi state f(S_i) and a sequence of words C'_{ij}. We train a model which predicts words in C'_{ij} using f(S_i) as input.

We use a multi-layer perceptron as the prediction model. The input is a vector of the features of a state. The hidden layer is a 100-dimensional vector and is activated by a bipolar sigmoid function. Its output is a d-dimensional real-valued vector, each of whose elements indicates whether a word in the vocabulary of d words appears in the commentary or not. The output layer is activated by a binary sigmoid function.

We use features of Shogi states which a computer Shogi program called Gekisashi (Tsuruoka et al., 2002) uses to evaluate the states in game tree search as input. The features of Shogi states used in this experiment are below:

a) Positions of pieces (e.g. my rook is at 2h).

[2]For a detailed explanation and a mathematical proof of this method, please refer to Mori and Takuma (2004) .

[3]This is because an SSC has many words and word fragments. Additionally, word 1-gram frequencies must be calculated using floating point numbers instead of integers.

b) Pieces captured (e.g. the opponent has a bishop).
c) Combinations of a) and b) (e.g. my king is at 7h and the opponent's rook is at 7b).
d) Other heuristic features.

Among them, a), b) and c) occupy the majority.

Unlike normal symbol grounding, the vocabulary contains many word candidates appearing in the pSSC generated from the commentaries. Some are real words and some are wrong fragments. These wrong fragments will appear more or less randomly in the commentaries than real words. The perceptron therefore cannot acquire strong relation between states and fragments and the output values of the perceptron will be smaller than those of real words.

4 Word Segmentation Using Symbol Grounding Result

This section describes a baseline automatic word segmenter and a method for incorporating the symbol grounding result to it.

4.1 Baseline Word Segmenter

Among many Japanese WS and morphological analyzers (word segmentation and POS tagging), we adopt pointwise WS (Neubig et al., 2011), because it is the only word segmenter which is capable of adding new words without POS information.

The input of the pointwise WS is an unsegmented character sequence $\boldsymbol{x} = x_1 x_2 \cdots x_k$. The word segmenter decides if there is a word boundary $t_i = 1$ or not $t_i = 0$ by using support vector machines (SVMs) (Fan et al., 2008). The features are character n-grams and character type n-grams ($n = 1, 2, 3$) around the decision points in a window with a width of 6 characters. Additional features are triggered if character n-grams in the window match with character sequences in the dictionary.

4.2 Training a Word Segmenter with Grounded Words

As a first trial for incorporating symbol grounding results to an NLP task, we propose to generate a dictionary based on the symbol grounding result. We can expect that the word candidates that are given high scores by the perceptron in the symbol grounding result have strong relationship to the positions. In other words, we can make a good dictionary by selecting word candidates in descending order of the scores. As a method for taking all the occurrences into account, we test the following three functions:

sum: the summation of the scores of all the output vectors,
ave: the average of them,
max: the maximum in them.

First, we acquire a V-dimensional real-valued vector for each Shogi state S_i as the result of symbol grounding. Then, for each candidate in C'_{ij}, we get the element of the vector which corresponds to the candidate as the score of the candidate. After that, we get the summation of, the average of, or the maximum in the scores of the same candidate over the whole dataset.

Finally we select the top R percent of word candidates in descending order of the value of **sum**, **ave**, or **max** and add them to the WS dictionary and retrain the model.

5 Evaluation

We conducted word segmentation experiments in the following settings.

5.1 Corpora

The annotated corpus we used to build the baseline word segmenter is the manually annotated part (core data) of the Balanced Corpus of Contemporary Written Japanese (BCCWJ) (Maekawa, 2008), plus newspaper articles and daily conversation sentences. We also used a 234,652-word dictionary (UniDic) provided with the BCCWJ. A small portion of the BCCWJ core data is reserved for testing. In addition, we manually segmented sentences randomly obtained from Shogi commentaries. We divided these sentences into two parts: a development set and a test set. Table 1 shows the details of these corpora.

To make a pSSC, we prepared 33,151 pairs of a Shogi position and a commentary sentence. The

Table 2: WS accuracy on BCCWJ.

	Recall	Prec.	F-meas.
Baseline	98.99	99.06	99.03

Table 3: WS accuracy on Shogi commentaries.

	Recall	Prec.	F-meas.
Baseline	90.12	91.43	90.77
+ Sym.Gro.	90.60	91.66	91.13

sentences are converted into pSSC $m = 4$ times by an LR word segmentation model trained from the training data in Table 1 and sent to the symbol grounding module.

5.2 Word Segmentation Systems

We built the following two word segmentation models (Neubig et al., 2011) to evaluate our framework.

Baseline: The model is trained from training data shown in Table 1 and UniDic.

+Sym.Gro.: The model is trained from the language resources for the **Baseline** and the symbol grounding result.

To decide the function and the value of R for **+Sym.Gro.** (see Section 4.2), we measured the accuracies on the development set of all the combinations. The best combination was **sum** and $R = 0.011$[4]. In this case, 127 words were added to the dictionary.

5.3 Results and Discussion

Following the standard in word segmentation experiments, the evaluation criteria are recall, precision, and F-measure (their harmonic mean).

Table 2 and 3 show WS accuracies on BCCWJ-test and Shogi-test, respectively. The difference in accuracy of the baseline method on BCCWJ-test and Shogi-test shows that WS of Shogi commentaries is very difficult. Like many other domains, Shogi commentaries contain many special words and expressions, which decrease the accuracy.

When we compare the F-measures on Shogi-test (Table 3), **+Sym.Gro.** outperforms **Baseline**. The improvement is statistically significant (at 5% level). The error reduction ratio is comparable to a natural annotation case (Liu et al., 2014), despite the fact that our method is unsupervised except for a hyperparameter. Thus we can say that WS improvement by symbol grounding is as valuable as the annotation additions.

From a close look at the comparison of the recall and the precision, we see that the improvement in the recall is higher than that of the precision. This result shows that the symbol grounding successfully acquired new words with a few erroneous words. As the final remark, the result on the general domain (Table 2) shows that our framework does not cause a severe performance degradation in the general domain.

6 Related Work

The NLP task we focus on in this paper is word segmentation. One of the first empirical methods was based on a hidden Markov model (Nagata, 1994). In parallel, there were attempts at solving Chinese word segmentation in a similar way (Sproat and Chang, 1996). These methods take words as the modeling unit.

Recently, Neubig et al. (2011) have presented a method for directly deciding whether there is a word boundary or not at each point between characters. For Chinese word segmentation, there are some attempts at tagging characters with BIES tags (Xue, 2003) by a sequence labeller such as CRFs (Lafferty et al., 2001), where B, I, E, and S means the beginning of a word, intermediate of a word, the end of a word, and a single character word, respectively. The pointwise WS can be seen as character tagging with the BI tag system, in which there is no constraint between neighboring tags. For Japanese WS, our preliminary experiments showed that the combination of the BI tag system with SVMs is slightly better than the BIES tag system with CRFs. This is another reason why we used the former in this paper. Our extension of word segmentation is, however, applicable to the BIES/CRFs combination as well.

The method we describe in this paper is unsupervised and requires a small amount of annotated data to tune the hyperparameter. From this viewpoint, the approach based on natural annotation (Yang and Vozila, 2014; Jiang et al., 2013; Liu et al., 2014) may come to readers' mind. In these studies, tags in hyper-texts were regarded as partial annotations and used to improve WS performance using CRFs trainable from such data (Tsuboi et al., 2008). Mori and Nagao (1996) proposed a method for extracting new words from a large amount of raw text. Murawaki and Kuro-

[4] In addition we measured the accuracies on the test set of all the combinations and found that the same function and the value of the parameter are the best. This indicates the stability of the function and the parameter.

hashi (2008) proposed an online method in a similar setting. In contrast to these studies, this paper proposes to use other modalities, game states as the first trial, than languages.

7 Conclusion

We have described an unsupervised method for improving word segmentation based on symbol grounding results. To extract word candidates from raw sentences, we first segment sentences stochastically, and then match the word candidate sequences with game states that are described by the sentences. Finally, we selected word candidates referring to the grounding scores. The experimental results showed that we can improve word segmentation by using symbol grounding results. Our framework is general and it is worth testing on other NLP tasks. As future work, we will apply other deep neural network models to our approach. It is interesting to apply the symbol grounding results to an embedding model-based word segmentation approach (Ma and Hinrichs, 2015). It is also interesting to extend our method to deal with other types of non-textual information such as images and economic indices.

Abstract

Recursive neural models, which use syntactic parse trees to recursively generate representations bottom-up, are a popular architecture. However there have not been rigorous evaluations showing for exactly which tasks this syntax-based method is appropriate. In this paper, we benchmark *recursive* neural models against sequential *recurrent* neural models, enforcing apples-to-apples comparison as much as possible. We investigate 4 tasks: (1) sentiment classification at the sentence level and phrase level; (2) matching questions to answer-phrases; (3) discourse parsing; (4) semantic relation extraction.

Our goal is to understand better when, and why, recursive models can outperform simpler models. We find that recursive models help mainly on tasks (like semantic relation extraction) that require long-distance connection modeling, particularly on very long sequences. We then introduce a method for allowing recurrent models to achieve similar performance: breaking long sentences into clause-like units at punctuation and processing them separately before combining. Our results thus help understand the limitations of both classes of models, and suggest directions for improving recurrent models.

1 Introduction

Deep learning based methods learn low-dimensional, real-valued vectors for word tokens, mostly from large-scale data corpus (e.g., (Mikolov et al., 2013; Le and Mikolov, 2014; Collobert et al., 2011)), successfully capturing syntactic and semantic aspects of text.

For tasks where the inputs are larger text units (e.g., phrases, sentences or documents), a compositional model is first needed to aggregate tokens into a vector with fixed dimensionality that can be used as a feature for other NLP tasks. Models for achieving this usually fall into two categories: *recurrent* models and *recursive* models:

Recurrent models (also referred to as *sequence* models) deal successfully with time-series data (Pearlmutter, 1989; Dorffner, 1996) like speech (Robinson et al., 1996; Lippmann, 1989; Graves et al., 2013) or handwriting recognition (Graves and Schmidhuber, 2009; Graves, 2012). They were applied early on to NLP (Elman, 1990), by modeling a sentence as tokens processed sequentially and at each step combining the current token with previously built embeddings. Recurrent models can be extended to bidirectional ones from both left-to-right and right-to-left. These models generally consider no linguistic structure aside from word order.

Recursive neural models (also referred to as *tree* models), by contrast, are structured by syntactic parse trees. Instead of considering tokens sequentially, recursive models combine neighbors based on the recursive structure of parse trees, starting from the leaves and proceeding recursively in a bottom-up fashion until the root of the parse tree is reached. For example, for the phrase *the food is delicious*, following the operation sequence *((the food) (is delicious))* rather than the sequential order *(((the food) is) delicious)*. Many recursive models have been proposed (e.g., (Paulus et al., 2014; Irsoy and Cardie, 2014)), and applied to various NLP tasks, among them entailment (Bowman, 2013; Bowman et al., 2014), sentiment analysis (Socher et al., 2013; Irsoy and Cardie, 2013; Dong et al., 2014), question-answering (Iyyer et al., 2014), relation classification (Socher et al., 2012; Hashimoto et al., 2013), and discourse (Li and Hovy, 2014).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2304–2314,
Lisbon, Portugal, 17-21 September 2015.

One possible advantage of recursive models is their potential for capturing long-distance dependencies: two tokens may be structurally close to each other, even though they are far away in word sequence. For example, a verb and its corresponding direct object can be far away in terms of tokens if many adjectives lies in between, but they are adjacent in the parse tree (Irsoy and Cardie, 2013). However we do not know if this advantage is truly important, and if so for which tasks, or whether other issues are at play. Indeed, the reliance of recursive models on parsing is also a potential disadvantage, given that parsing is relatively slow, domain-dependent, and can be errorful.

On the other hand, recent progress in multiple subfields of neural NLP has suggested that recurrent nets may be sufficient to deal with many of the tasks for which recursive models have been proposed. Recurrent models without parse structures have shown good results in sequence-to-sequence generation (Sutskever et al., 2014) for machine translation (e.g., (Kalchbrenner and Blunsom, 2013; 3; Luong et al., 2014)), parsing (Vinyals et al., 2014), and sentiment, where for example recurrent-based paragraph vectors (Le and Mikolov, 2014) outperform recursive models (Socher et al., 2013) on the Stanford sentimentbank dataset.

Our goal in this paper is thus to investigate a number of tasks with the goal of understanding for which kinds of problems recurrent models may be sufficient, and for which kinds recursive models offer specific advantages. We investigate four tasks with different properties.

- Binary **sentiment classification** at the sentence level (Pang et al., 2002) and phrase level (Socher et al., 2013) that focus on understanding the role of recursive models in dealing with semantic compositionally in various scenarios such as different lengths of inputs and whether or not supervision is comprehensive.

- **Phrase Matching** on the UMD-QA dataset (Iyyer et al., 2014) can help see the difference between outputs from intermediate components from different models, i.e., representations for intermediate parse tree nodes and outputs from recurrent models at different time steps. It also helps see whether parsing is useful for finding similarities between question sentences and target phrases.

- **Semantic Relation Classification** on the SemEval-2010 (Hendrickx et al., 2009) data can help understand whether parsing is helpful in dealing with long-term dependencies, such as relations between two words that are far apart in the sequence.

- **Discourse parsing** (RST dataset) is useful for measuring the extent to which parsing improves discourse tasks that need to combine meanings of larger text units. Discourse parsing treats elementary discourse units (EDUs) as basic units to operate on, which are usually short clauses. The task also sheds light on the extent to which syntactic structures help acquire shot text representations.

The principal motivation for this paper is to understand better when, and why, recursive models are needed to outperform simpler models by enforcing apples-to-apples comparison as much as possible. This paper applies existing models to existing tasks, barely offering novel algorithms or tasks. Our goal is rather an analytic one, to investigate different versions of recursive and recurrent models. This work helps understand the limitations of both classes of models, and suggest directions for improving recurrent models.

The rest of this paper organized as follows: We detail versions of recursive/recurrent models in Section 2, present the tasks and results in Section 3, and conclude with discussions in Section 4.

2 Recursive and Recurrent Models

2.1 Notations

We assume that the text unit S, which could be a phrase, a sentence or a document, is comprised of a sequence of tokens/words: $S = \{w_1, w_2, ..., w_{N_S}\}$, where N_s denotes the number of tokens in S. Each word w is associated with a K-dimensional vector embedding $e_w = \{e_w^1, e_w^2, ..., e_w^K\}$. The goal of recursive and recurrent models is to map the sequence to a K-dimensional e_S, based on its tokens and their correspondent embeddings.

Standard Recurrent/Sequence Models successively take word w_t at step t, combines its vector representation e_t with the previously built hidden vector h_{t-1} from time $t-1$, calculates the re-

sulting current embedding h_t, and passes it to the next step. The embedding h_t for the current time t is thus:

$$h_t = f(W \cdot h_{t-1} + V \cdot e_t) \tag{1}$$

where W and V denote compositional matrices. If N_s denotes the length of the sequence, h_{N_s} represents the whole sequence S.

Standard recursive/Tree models work in a similar way, but processing neighboring words by parse tree order rather than sequence order. It computes a representation for each parent node based on its immediate children recursively in a bottom-up fashion until reaching the root of the tree. For a given node η in the tree and its left child η_{left} (with representation e_{left}) and right child η_{right} (with representation e_{right}), the standard recursive network calculates e_η as follows:

$$e_\eta = f(W \cdot e_{\eta_{\text{left}}} + V \cdot e_{\eta_{\text{right}}}) \tag{2}$$

Bidirectional Models (Schuster and Paliwal, 1997) add bidirectionality to the recurrent framework where embeddings for each time are calculated both forwardly and backwardly:

$$\begin{aligned} h_t^{\rightarrow} &= f(W^{\rightarrow} \cdot h_{t-1}^{\rightarrow} + V^{\rightarrow} \cdot e_t) \\ h_t^{\leftarrow} &= f(W^{\leftarrow} \cdot h_{t+1}^{\leftarrow} + V^{\leftarrow} \cdot e_t) \end{aligned} \tag{3}$$

Normally, final representations for sentences can be achieved either by concatenating vectors calculated from both directions $[e_1^{\leftarrow}, e_{N_S}^{\rightarrow}]$ or using further compositional operation to preserve vector dimensionality

$$h_t = f(W_L \cdot [h_t^{\leftarrow}, h_t^{\rightarrow}]) \tag{4}$$

where W_L denotes a $K \times 2K$ dimensional matrix.

Long Short Term Memory (LSTM) LSTM models (Hochreiter and Schmidhuber, 1997) are defined as follows: given a sequence of inputs $X = \{x_1, x_2, ..., x_{n_X}\}$, an LSTM associates each timestep with an input, memory and output gate, respectively denoted as i_t, f_t and o_t. We notationally disambiguate e and h: e_t denotes the vector for individual text units (e.g., word or sentence) at time step t, while h_t denotes the vector computed by the LSTM model at time t by combining e_t and h_{t-1}. σ denotes the sigmoid function. The vector representation h_t for each time-step t is given by:

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ l_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} W \cdot \begin{bmatrix} h_{t-1} \\ e_t \end{bmatrix} \tag{5}$$

$$c_t = f_t \cdot c_{t-1} + i_t \cdot l_t \tag{6}$$

$$h_t^s = o_t \cdot c_t \tag{7}$$

where $W \in \mathbb{R}^{4K \times 2K}$. Labels at the phrase/sentence level are predicted representations outputted from the last time step.

Tree LSTMs Recent research has extended the LSTM idea to tree-based structures (Zhu et al., 2015; Tai et al., 2015) that associate memory and forget gates to nodes of the parse trees.

Bi-directional LSTMs These combine bi-directional models and LSTMs.

3 Experiments

In this section, we detail our experimental settings and results. We consider the following tasks, each representative of a different class of NLP tasks.

- **Binary sentiment classification** on the Pang et al. (2002) dataset. This addresses the issues where supervision only appears globally after a long sequence of operations.
- **Sentiment Classification on the Stanford Sentiment Treebank** (Socher et al., 2013): comprehensive labels are found for words and phrases where local compositionally (such as from negation, mood, or others cued by phrase-structure) is to be learned.
- **Sentence-Target Matching** on the UMD-QA dataset (Iyyer et al., 2014): Learns matches between target and components in the source sentences, which are parse tree nodes for recursive models and different time-steps for recurrent models.
- **Semantic Relation Classification** on the SemEval-2010 task (Hendrickx et al., 2009). Learns long-distance relationships between two words that may be far apart sequentially.
- **Discourse Parsing** (Li et al., 2014; Hernault et al., 2010): Learns sentence-to-sentence relations based on calculated representations.

In each case we followed the protocols described in the original papers. We first group the algorithm variants into two groups as follows:

- Standard tree models vs standard sequence models vs standard bi-directional sequence models
- LSTM tree models, LSTM sequence models vs LSTM bi-directional sequence models.

We employed standard training frameworks for neural models: for each task, we used stochastic gradient decent using AdaGrad (Duchi et al., 2011) with minibatches (Cotter et al., 2011). Parameters are tuned using the development dataset if available in the original datasets or from cross-validation if not. Derivatives are calculated from standard back-propagation (Goller and Kuchler, 1996). Parameters to tune include size of mini batches, learning rate, and parameters for L2 penalizations. The number of running iterations is treated as a parameter to tune and the model achieving best performance on the development set is used as the final model to be evaluated.

For settings where no repeated experiments are performed, the bootstrap test is adopted for statistical significance testing (Efron and Tibshirani, 1994). Test scores that achieve significance level of 0.05 are marked by an asterisk (*).

3.1 Stanford Sentiment TreeBank

Task Description We start with the Stanford Sentiment TreeBank (Socher et al., 2013). This dataset contains gold-standard labels for every parse tree constituent, from the sentence to phrases to individual words.

Of course, any conclusions drawn from implementing sequence models on a dataset that was based on parse trees may have to be weakened, since sequence models may still benefit from the way that the dataset was collected. Nevertheless we add an evaluation on this dataset because it has been a widely used benchmark dataset for neural model evaluations.

For recursive models, we followed the protocols in Socher et al. (2013) where node embeddings in the parse trees are obtained from recursive models and then fed to a softmax classifier. We transformed the dataset for recurrent model use as illustrated in Figure 1. Each phrase is reconstructed from parse tree nodes and treated as a separate data point. As the treebank contains 11,855 sentences with 215,154 phrases, the reconstructed dataset for recurrent models comprises 215,154 examples. Models are evaluated at both the phrase level (82,600 instances) and the sentence root level (2,210 instances).

	Fine-Grained	Binary
Tree	0.433	0.815
Sequence	0.420 (-0.013)	0.807 (-0.007)
P-value	0.042*	0.098
Bi-Sequence	0.435 (+0.08)	0.816 (+0.002)
P-value	0.078	0.210

Table 1: Test set accuracies on the Stanford Sentiment Treebank at root level.

	Fine-Grained	Binary
Tree	0.820	0.860
Sequence	0.818 (-0.002)	0.864 (+0.004)
P-value	0.486	0.305
Bi-Sequence	0.826 (+0.06)	0.862 (+0.002)
P-value	0.148	0.450

Table 2: Test set accuracies on the Stanford Sentiment Treebank at phrase level.

Results are shown in Table 1 and 2[1]. When comparing the standard version of tree models to sequence models, we find it helps a bit at root level identification (for sequences but not bi-sequences), but yields no significant improvement at the phrase level.

LSTM Tai et al. (2015) discovered that LSTM tree models generate better performances in terms of sentence **root** level evaluation than sequence models. We explore this task a bit more by training deeper and more sophisticated models. We examine the following three models:

1. Tree-structured LSTM models (Tai et al., 2015)[2].
2. Deep Bi-LSTM sequence models (denoted as **Sequence**) that treat the whole sentence as just one sequence.
3. Deep Bi-LSTM hierarchical sequence models (denoted as **Hierarchical Sequence**) that first slice the sentence into a sequence of subsentences by using a look-up table of punctuations (i.e., comma, period, question mark

[1]The performance of our implementations of recursive models is not exactly identical to that reported in Socher et al. (2013), but the relative difference is around 1% to 2%.

[2]Tai et al.. achieved 0.510 accuracy in terms of fine-grained evaluation at the root level as reported in (Tai et al., 2015), similar to results from our implementations (0.504).

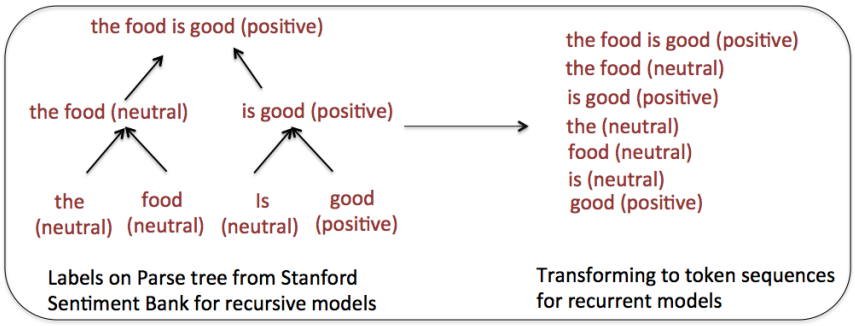

Figure 1: Transforming Stanford Sentiment Treebank to Sequences for Sequence Models.

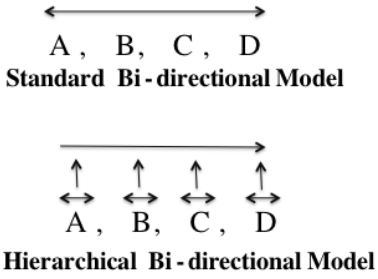

Figure 2: Illustration of two sequence models. A, B, C, D denote clauses or sub sentences separated by punctuation.

and exclamation mark). The representation for each sub-sentence is first computed separately, and another level of sequence LSTM (one-directional) is then used to join the sub-sentences. Illustrations are shown in Figure2.

We consider the third model because the dataset used in Tai et al. (2015) contains long sentences and the evaluation is performed only at the sentence root level. Since a parsing algorithm will naturally break long sentences into sub-sentences, we would like to know whether any performance boost is introduced by the intra-clause parse tree structure or just by this broader segmentation of a sentence into clause-like units; this latter advantage could be approximated by using punctuation-based approximations to clause boundaries.

We run 15 iterations for each algorithm. Parameters are harvested at the end of each iteration; those performing best on the development set are used on the test set. The whole process takes roughly 15-20 minutes on a single GPU machine[3]. For a more convincing comparison, we did not use the bootstrap test where parallel examples are generated from one same dataset. Instead, we repeated the aforementioned procedure for each algorithm 20 times and report accuracies with standard deviation in Table 3.

[3]Tesla K40m, 2880 Cuda cores.

Model	all-fine	root-fine	root-coarse
Tree LSTM	**83.4** (0.3)	50.4 (0.9)	86.7 (0.5)
Bi-Sequence	83.3 (0.4)	49.8 (0.9)	86.7 (0.5)
Hier-Sequence	82.9 (0.3)	**50.7** (0.8)	**86.9** (0.6)

Table 3: Test set accuracies on the Stanford Sentiment Treebank with deviations. For our experiments, we report accuracies over 20 runs with standard deviation.

Tree LSTMs are equivalent or marginally better than standard bi-directional sequence model (two-tailed p-value equals 0.041*, and only at the root level, with p-value for the phrase level at 0.376). The hierarchical sequence model achieves the same performance with a p-value of 0.198.

Discussion The results above suggest that clausal segmentation of long sentences offers a slight performance boost, a result also supported by the fact that very little difference exists between the three models for phrase-level sentiment evaluation. Clausal segmentation of long sentences thus provides a simple approximation to parse-tree based models.

We suggest a few reasons for this slightly better performances introduced by clausal segmentation:

1. Treating clauses as basic units (to the extent that punctuation approximates clauses) preserves the semantic structure of text.

2. Semantic compositions such as negations or conjunctions usually appear at the clause level. Working on clauses individually and then combining them model inter-clause compositions.

3. Errors are back-propagated to individual tokens using fewer steps in hierarchical models than in standard models. Consider a movie

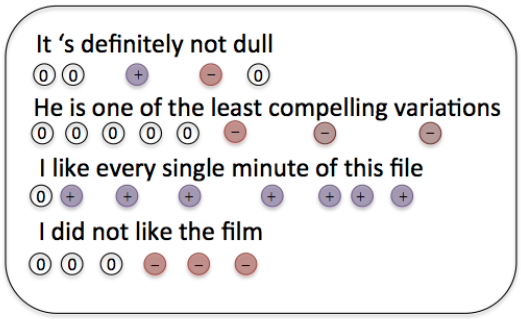

Figure 3: Sentiment prediction using a one-directional (left to right) LSTM. Decisions at each time step are made by feeding embeddings calculated from the LSTM into a softmax classifier.

review "simple as the plot was , i still like it a lot". With standard recurrent models it takes 12 steps before the prediction error gets back to the first token "simple":

error→lot→a→it→like→still→i→,→was →plot→ the→as→simple

In a hierarchical model, the second clause is compacted into one component, and the error propagation is thus given by:

error→ second-clause → first-clause → was→plot→the→as→simple.

Propagation with clause segmentation consists of only 8 operations. Such a procedure thus tends to attenuate the gradient vanishing problem, potentially yielding better performance.

3.2 Binary Sentiment Classification (Pang)

Task Description: The sentiment dataset of Pang et al. (2002) consists of sentences with a sentiment label for each sentence. We divide the original dataset into training(8101)/dev(500)/testing(2000). No pre-training procedure as described in Socher et al. (2011b) is employed. Word embeddings are initialized using skip-grams and kept fixed in the learning procedure. We trained skip-gram embeddings on the Wikipedia+Gigaword dataset using the word2vec package[4]. Sentence level embeddings are fed into a sigmoid classifier. Performances for 50 dimensional vectors are given in the table below:

Discussion Why don't parse trees help on this task? One possible explanation is the distance

[4]https://code.google.com/p/word2vec/

	Standard	LSTM
Tree	0.745	0.774
Sequence	0.733 (-0.012)	0.783 (+0.008)
P-value	0.060	0.136
Bi-Sequence	0.754 (+0.09)	0.790 (+0.016)
P-value	0.058	0.024*

Table 4: Test set accuracies on the Pang's sentiment dataset using Standard model settings.

of the supervision signal from the local compositional structure. The Pang et al. dataset has an average sentence length of 22.5 words, which means it takes multiple steps before sentiment related evidence comes up to the surface. It is therefore unclear whether local compositional operators (such as negation) can be learned; there is only a small amount of training data (around 8,000 examples) and the sentiment supervision only at the level of the sentence may not be easy to propagate down to deeply buried local phrases.

3.3 Question-Answer Matching

Task Description: In the question-answering dataset QANTA[5], each answer is a token or short phrase. The task is different from standard generation focused QA task but formalized as a multi-class classification task that matches a source question with a candidates phrase from a predefined pool of candidate phrases We give an illustrative example here:

Question: *He left unfinished a novel whose title character forges his father's signature to get out of school and avoids the draft by feigning desire to join. Name this German author of The Magic Mountain and Death in Venice.*

Answer: *Thomas Mann* from the pool of phrases. Other candidates might include George Washington, Charlie Chaplin, etc.

The model of Iyyer et al. (2014) minimizes the distances between answer embeddings and node embeddings along the parse tree of the question. Concretely, let c denote the correct answer to question S, with embedding $\vec{c}$, and z denoting any random wrong answer. The objective function sums over the dot product between representation for every node η along the question parse trees and the answer representations:

$$L = \sum_{\eta \in [\text{parse tree}]} \sum_{z} max(0, 1 - \vec{c} \cdot e_\eta + \vec{z} \cdot e_\eta) \quad (8)$$

[5]http://cs.umd.edu/~miyyer/qblearn/. Because the publicly released dataset is smaller than the version used in (Iyyer et al., 2014) due to privacy issues, our numbers are not comparable to those in (Iyyer et al., 2014).

where e_η denotes the embedding for parse tree node calculated from the recursive neural model. Here the parse trees are dependency parses following (Iyyer et al., 2014).

By adjusting the framework to recurrent models, we minimize the distance between the answer embedding and the embeddings calculated from each timestep t of the sequence:

$$L = \sum_{t \in [1, N_s]} \sum_{z} max(0, 1 - \vec{c} \cdot e_t + \vec{z} \cdot e_t) \quad (9)$$

At test time, the model chooses the answer (from the set of candidates) that gives the lowest loss score. As can be seen from results presented in Table 5, the difference is only significant for the LSTM setting between the tree model and the sequence model; no significant difference is observed for other settings.

	Standard	LSTM
Tree	0.523	0.558
Sequence	0.525 (+0.002)	0.546 (-0.012)
P-value	0.490	0.046*
Bi-Sequence	0.530 (+0.007)	0.564 (+0.006)
P-value	0.075	0.120

Table 5: Test set accuracies for UMD-QA dataset.

Discussion The UMD-QA task represents a group of situations where because we have insufficient supervision about matching (it's hard to know which node in the parse tree or which timestep provides the most direct evidence for the answer), decisions have to be made by looking at and iterating over all subunits (all nodes in parse trees or timesteps). Similar ideas can be found in pooling structures (e.g. Socher et al. (2011a)).

The results above illustrate that for tasks where we try to align the target with different source components (i.e., parse tree nodes for tree models and different time steps for sequence models), components from sequence models are able to embed important information, despite the fact that sequence model components are just sentence fragments and hence usually not linguistically meaningful components in the way that parse tree constituents are.

3.4 Semantic Relationship Classification

Task Description: SemEval-2010 Task 8 (Hendrickx et al., 2009) is to find semantic relationships between pairs of nominals, e.g., in "My [apartment]$_{e1}$ has a pretty large [kitchen]$_{e2}$" classifying the relation between [apartment] and [kitchen] as *component-whole*. The dataset contains 9 ordered relationships, so the task is formalized as a 19-class classification problem, with directed relations treated as separate labels; see Hendrickx et al. (2009; Socher et al. (2012) for details.

For the recursive implementations, we follow the neural framework defined in Socher et al. (2012). The path in the parse tree between the two nominals is retrieved, and the embedding is calculated based on recursive models and fed to a softmax classifier[6]. Retrieved paths are transformed for the recurrent models as shown in Figure 5.

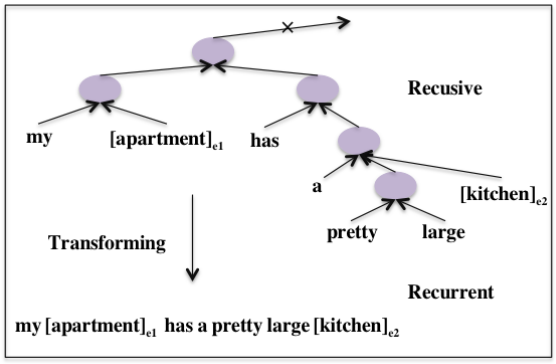

Figure 4: Illustration of Models for Semantic Relationship Classification.

Discussion Unlike for earlier tasks, here recursive models yield much better performance than the corresponding recurrent versions for all versions (e.g., standard tree vs. standard sequence, $p = 0.004$). These results suggest that it is the need to integrate structures far apart in the sentence that characterizes the tasks where recursive models surpass recurrent models. In parse-based models, the two target words are drawn together much earlier in the decision process than in recurrent models, which must remember one target until the other one appears.

3.5 Discourse Parsing

Task Description: Our final task, discourse parsing based on the RST-DT corpus (Carlson et

[6](Socher et al., 2012) achieve state-of-art performance by combining a sophisticated model, MV-RNN, in which each word is presented with both a matrix and a vector with human-feature engineering. Again, because MV-RNN is difficult to adapt to a recurrent version, we do not employ this state-of-the-art model, adhering only to the general versions of recursive models described in Section 2, since our main goal is to compare equivalent recursive and recurrent models rather than implement the state of the art.

	Standard	LSTM
Tree	0.748	0.767
Sequence	0.712 (-0.036)	0.740 (-0.027)
P-value	0.004*	0.020*
Bi-Sequence	0.730 (-0.018)	0.752 (-0.014)
P-value	0.017*	0.041*

Table 6: Test set accuracies on the SemEval-2010 Semantic Relationship Classification task.

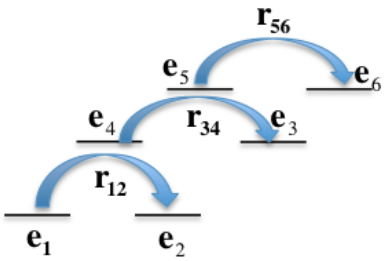

Figure 5: An illustration of discourse parsing. $[e_1, e_2, ...]$ denote EDUs (elementary discourse units), each consisting of a sequence of tokens. $[r_{12}, r_{34}, r_{56}]$ denote relationships to be classified. A binary classification model is first used to decide whether two EDUs should be merged and a multi-class classifier is then used to decide the relation type.

al., 2003), is to build a discourse tree for a document, based on assigning Rhetorical Structure Theory (RST) relations between elementary discourse units (EDUs). Because discourse relations express the coherence structure of discourse, they presumably express different aspects of compositional meaning than sentiment or nominal relations. See Hernault et al. (2010) for more details on discourse parsing and the RST-DT corpus.

Representations for adjacent EDUs are fed into binary classification (whether two EDUs are related) and multi-class relation classification models, as defined in Li et al. (2014). Related EDUs are then merged into a new EDU, the representation of which is obtained through an operation of neural composition based on the previous two related EDUs. This step is repeated until all units are merged.

Discourse parsing takes EDUs as the basic units to operate on; EDUs are short clauses, not full sentences, with an average length of 7.2 words. Recursive and recurrent models are applied on EDUs to create embeddings to be used as inputs for discourse parsing. We use this task for two reasons: (1) to illustrate whether syntactic parse trees are useful for acquiring representations for short clauses. (2) to measure the extent to which parsing improves discourse tasks that need to combine the meanings of larger text units.

Models are traditionally evaluated in terms of three metrics, i.e., spans[7], nuclearity[8], and identifying the rhetorical relation between two clauses. Due to space limits, we only focus the last one, rhetorical relation identification, because (1) relation labels are treated as correct only if spans and nuclearity are correctly labeled (2) relation identification between clauses offer more insights about model's abilities to represent sentence semantics. In order to perform a plain comparison, no additional human-developed features are added.

	Standard	LSTM
Tree	0.568	0.564
Sequence	0.572 (+0.004)	0.563 (-0.002)
P-value	0.160	0.422
Bi-Sequence	0.578 (+0.01)	0.575 (+0.012)
P-value	0.054	0.040*

Table 7: Test set accuracies for relation identification on RST discourse parsing data set.

Discussion We see no large differences between equivalent recurrent and recursive models. We suggest two possible explanations. (1) EDUs tend to be short; thus for some clauses, parsing might not change the order of operations on words. Even for those whose orders are changed by parse trees, the influence of short phrases on the final representation may not be great enough. (2) Unlike earlier tasks, where text representations are immediately used as inputs into classifiers, the algorithm presented here adopts additional levels of neural composition during the process of EDU merging. We suspect that neural layers may act as information filters, separating the informational chaff from the wheat, which in turn makes the model a bit more immune to the initial inputs.

4 Discussions and Conclusions

We compared recursive and recurrent neural models for representation learning on 5 distinct NLP tasks in 4 areas for which recursive neural models are known to achieve good performance (Socher et al., 2012; Socher et al., 2013; Li et al., 2014; Iyyer et al., 2014).

As with any comparison between models, our results come with some caveats: First, we explore the most general or basic forms of recur-

[7] on blank tree structures.

[8] on tree structures with nuclearity indication.

sive/recurrent models rather than various sophisticated algorithm variants. This is because fair comparison becomes more and more difficult as models get complex (e.g., the number of layers, number of hidden units within each layer, etc.). Thus most neural models employed in this work are comprised of only one layer of neural compositions—despite the fact that deep neural models with multiple layers give better results. Our conclusions might thus be limited to the algorithms employed in this paper, and it is unclear whether they can be extended to other variants or to the latest state-of-the-art. Second, in order to compare models "fairly", we force every model to be trained exactly in the same way: AdaGrad with minibatches, same set of initializations, etc. However, this may not necessarily be the optimal way to train every model; different training strategies tailored for specific models may improve their performances. In that sense, our attempts to be "fair" in this paper may nevertheless be unfair.

Pace these caveats, our conclusions can be summarized as follows:

- In tasks like semantic relation extraction, in which single headwords need to be associated across a long distance, recursive models shine. This suggests that for the many other kinds of tasks in which long-distance semantic dependencies play a role (e.g., translation between languages with significant reordering like Chinese-English translation), syntactic structures from recursive models may offer useful power.

- Tree models tend to help more on long sequences than shorter ones with sufficient supervision: tree models slightly help root level identification on the Stanford Sentiment Treebank, but do not help much at the phrase level. Adopting bi-directional versions of recurrent models seem to largely bridge this gap, producing equivalent or sometimes better results.

- On long sequences where supervision is not sufficient, e.g., in Pang at al.,'s dataset (supervision only exists on top of long sequences), no significant difference is observed between tree based and sequence based models.

- In cases where tree-based models do well, a simple approximation to tree-based models seems to improve recurrent models to equivalent or almost equivalent performance: (1) break long sentences (on punctuation) into a series of clause-like units, (2) work on these clauses separately, and (3) join them together. This model sometimes works as well as tree models for the sentiment task, suggesting that one of the reasons tree models help is by breaking down long sentences into more manageable units.

- Despite that the fact that components (outputs from different time steps) in recurrent models are not linguistically meaningful, they may do as well as linguistically meaningful phrases (represented by parse tree nodes) in embedding informative evidence, as demonstrated in UMD-QA task. Indeed, recent work in parallel with ours (Bowman et al., 2015) has shown that recurrent models like LSTMs can discover implicit recursive compositional structure.

5 Acknowledgments

We would especially like to thank Richard Socher and Kai-Sheng Tai for insightful comments, advice, and suggestions. We would also like to thank Sam Bowman, Ignacio Cases, Jon Gauthier, Kevin Gu, Gabor Angeli, Sida Wang, Percy Liang and other members of the Stanford NLP group, as well as the anonymous reviewers for their helpful advice on various aspects of this work. Abstract

This paper proposes a tree-based convolutional neural network (TBCNN) for discriminative sentence modeling. Our model leverages either constituency trees or dependency trees of sentences. The tree-based convolution process extracts sentences structural features, which are then aggregated by max pooling. Such architecture allows short propagation paths between the output layer and underlying feature detectors, enabling effective structural feature learning and extraction. We evaluate our models on two tasks: sentiment analysis and question classification. In both experiments, TBCNN outperforms previous state-of-the-art results, including existing neural networks and dedicated feature/rule engineering. We also make efforts to visualize the tree-based convolution process, shedding light on how our models work.

1 Introduction

Discriminative sentence modeling aims to capture sentence meanings, and classify sentences according to certain criteria (e.g., sentiment). It is related to various tasks of interest, and has attracted much attention in the NLP community (Allan et al., 2003; Su and Markert, 2008; Zhao et al., 2015). Feature engineering—for example, n-gram features (Cui et al., 2006), dependency subtree features (Nakagawa et al., 2010), or more dedicated ones (Silva et al., 2011)—can play an important role in modeling sentences. Kernel machines, e.g., SVM, are exploited in Moschitti (2006) and Reichartz et al. (2010) by specifying a certain measure of similarity between sentences, without explicit feature representation.

Recent advances of neural networks bring new techniques in understanding natural languages, and have exhibited considerable potential. Bengio et al. (2003) and Mikolov et al. (2013) propose unsupervised approaches to learn word embeddings, mapping discrete words to real-valued vectors in a meaning space. Le and Mikolov (2014) extend such approaches to learn sentences' and paragraphs' representations. Compared with human engineering, neural networks serve as a way of automatic feature learning (Bengio et al., 2013).

Two widely used neural sentence models are convolutional neural networks (CNNs) and recursive neural networks (RNNs). CNNs can extract words' neighboring features effectively with short propagation paths, but they do not capture inherent sentence structures (e.g., parse trees). RNNs encode, to some extent, structural information by recursive semantic composition along a parse tree. However, they may have difficulties in learning deep dependencies because of long propagation paths (Erhan et al., 2009). (CNNs/RNNs and a variant, recurrent networks, will be reviewed in Section 2.)

A curious question is whether we can combine the advantages of CNNs and RNNs, i.e., whether we can exploit sentence structures (like RNNs) effectively with short propagation paths (like CNNs).

In this paper, we propose a novel neural architecture for discriminative sentence modeling, called the *Tree-Based Convolutional Neural Network* (TBCNN).[1] Our models can leverage different sentence parse trees, e.g., constituency trees and dependency trees. The model variants are denoted as c-TBCNN and d-TBCNN, respectively. The idea of tree-based convolution is to apply a set of subtree feature detectors, sliding over the entire

Lisbon, Portugal, 17-21 September 2015.

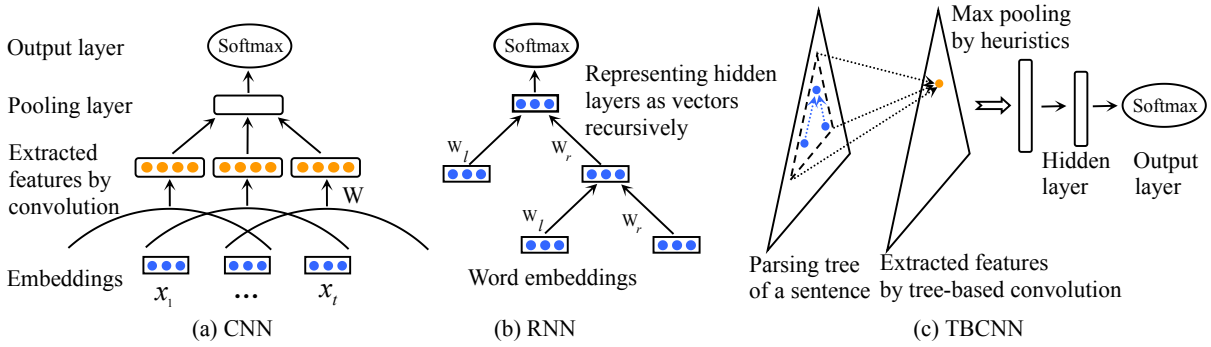

Figure 1: A comparison of information flow in the convolutional neural network (CNN), the recursive neural network (RNN), and the tree-based convolutional neural network (TBCNN).

parse tree of a sentence; then pooling aggregates these extracted feature vectors by taking the maximum value in each dimension. One merit of such architecture is that all features, along the tree, have short propagation paths to the output layer, and hence structural information can be learned effectively.

TBCNNs are evaluated on two tasks, sentiment analysis and question classification; our models have outperformed previous state-of-the-art results in both experiments. To understand how TBCNNs work, we also visualize the network by plotting the convolution process. We make our code and results available on our project website.[2]

2 Background and Related Work

In this section, we present the background and related work regarding two prevailing neural architectures for discriminative sentence modeling.

2.1 Convolutional Neural Networks

Convolutional neural networks (CNNs), early used for image processing (LeCun, 1995), turn out to be effective with natural languages as well. Figure 1a depicts a classic convolution process on a sentence (Collobert and Weston, 2008). A set of fixed-width-window feature detectors slide over the sentence, and output the extracted features. Let t be the window size, and $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_t \in \mathbb{R}^{n_e}$ be n_e-dimensional word embeddings. The output of convolution, evaluated at the current position, is

$$\boldsymbol{y} = f\left(W \cdot [\boldsymbol{x}_1; \cdots; \boldsymbol{x}_t] + \boldsymbol{b}\right)$$

where $\boldsymbol{y} \in \mathbb{R}^{n_c}$ (n_c is the number of feature detectors). $W \in \mathbb{R}^{n_c \times (t \cdot n_e)}$ and $\boldsymbol{b} \in \mathbb{R}^{n_c}$ are parameters; f is the activation function. Semicolons represent column vector concatenation. After convolution, the extracted features are pooled to a fixed-size vector for classification.

Convolution can extract neighboring information effectively. However, the features are "local"—words that are not in a same convolution window do not interact with each other, even though they may be semantically related. Blunsom et al. (2014) build deep convolutional networks so that local features can mix at high-level layers. Similar CNNs include Kim (2014) and Hu et al. (2014). All these models are "flat," by which we mean no structural information is used explicitly.

2.2 Recursive Neural Networks

Recursive neural networks (RNNs), proposed in Socher et al. (2011b), utilize sentence parse trees. In the original version, RNN is built upon a binarized constituency tree. Leaf nodes correspond to words in a sentence, represented by n_e-dimensional embeddings. Non-leaf nodes are sentence constituents, coded by child nodes recursively. Let node p be the parent of c_1 and c_2, vector representations denoted as $\boldsymbol{p}$, $\boldsymbol{c}_1$, and $\boldsymbol{c}_2$. The parent's representation is composited by

$$\boldsymbol{p} = f(W \cdot [\boldsymbol{c}_1; \boldsymbol{c}_2] + \boldsymbol{b}) \quad (1)$$

where W and $\boldsymbol{b}$ are parameters. This process is done recursively along the tree; the root vector is then used for supervised classification (Figure 1b).

Dependency parse and the combinatory categorical grammar can also be exploited as RNNs' skeletons (Hermann and Blunsom, 2013; Iyyer et al., 2014). Irsoy and Cardie (2014) build deep RNNs to enhance information interaction. Im-

[2] https://sites.google.com/site/tbcnnsentence/

provements for semantic compositionality include matrix-vector interaction (Socher et al., 2012), tensor interaction (Socher et al., 2013). They are more suitable for capturing logical information in sentences, such as negation and exclamation.

One potential problem of RNNs is that the long propagation paths—through which leaf nodes are connected to the output layer—may lead to information loss. Thus, RNNs bury illuminating information under a complicated neural architecture. Further, during back-propagation over a long path, gradients tend to vanish (or blow up), which makes training difficult (Erhan et al., 2009). Long short term memory (LSTM), first proposed for modeling time-series data (Hochreiter and Schmidhuber, 1997), is integrated to RNNs to alleviate this problem (Tai et al., 2015; Le and Zuidema, 2015; Zhu et al., 2015).

Recurrent networks. A variant class of RNNs is the recurrent neural network (Bengio et al., 1994; Shang et al., 2015), whose architecture is a rightmost tree. In such models, meaningful tree structures are also lost, similar to CNNs.

3 Tree-based Convolution

This section introduces the proposed tree-based convolutional neural networks (TBCNNs). Figure 1c depicts the convolution process on a tree.

First, a sentence is converted to a parse tree, either a constituency or dependency tree. The corresponding model variants are denoted as c-TBCNN and d-TBCNN. Each node in the tree is represented as a distributed, real-valued vector.

Then, we design a set of fixed-depth subtree feature detectors, called the *tree-based convolution window*. The window slides over the entire tree to extract structural information of the sentence, illustrated by a dashed triangle in Figure 1c. Formally, let us assume we have t nodes in the convolution window, $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_t$, each represented as an n_e-dimensional vector. Let n_c be the number of feature detectors. The output of the tree-based convolution window, evaluated at the current subtree, is given by the following generic equation.

$$\boldsymbol{y} = f\left(\sum_{i=1}^{t} W_i \cdot \boldsymbol{x}_i + \boldsymbol{b}\right) \tag{2}$$

where $W_i \in \mathbb{R}^{n_c \times n_e}$ is the weight parameter associated with node x_i; $\boldsymbol{b} \in \mathbb{R}^{n_c}$ is the bias term.

Extracted features are thereafter packed into one or more fixed-size vectors by max pooling, that is, the maximum value in each dimension is taken. Finally, we add a fully connected hidden layer, and a $\mathrm{softmax}$ output layer.

From the designed architecture (Figure 1c), we see that our TBCNN models allow short propagation paths between the output layer and any position in the tree. Therefore structural feature learning becomes effective.

Several main technical points in tree-based convolution include: (1) How can we represent hidden nodes as vectors in constituency trees? (2) How can we determine weights, W_i, for dependency trees, where nodes may have different numbers of children? (3) How can we pool varying sized and shaped features to fixed-size vectors?

In the rest of this section, we explain model variants in detail. Particularly, Subsections 3.1 and 3.2 address the first and second problems; Subsection 3.3 deals with the third problem by introducing several pooling heuristics. Subsection 3.4 presents our training objective.

3.1 c-TBCNN

Figure 2a illustrates an example of the constituency tree, where leaf nodes are words in the sentence, and non-leaf nodes represent a grammatical constituent, e.g., a noun phrase. Sentences are parsed by the Stanford parser;[3] further, constituency trees are binarized for simplicity.

One problem of constituency trees is that non-leaf nodes do not have such vector representations as word embeddings. Our strategy is to pretrain the constituency tree with an RNN by Equation 1 (Socher et al., 2011b). After pretraining, vector representations of nodes are fixed.

We now consider the tree-based convolution process in c-TBCNN with a two-layer-subtree convolution window, which operates on a parent node p and its direct children c_l and c_r, their vector representations denoted as $\boldsymbol{p}$, $\boldsymbol{c}_l$, and $\boldsymbol{c}_r$. The convolution equation, specific for c-TBCNN, is

$$\boldsymbol{y} = f\left(W_p^{(c)} \cdot \boldsymbol{p} + W_l^{(c)} \cdot \boldsymbol{c}_l + W_r^{(c)} \cdot \boldsymbol{c}_r + \boldsymbol{b}^{(c)}\right)$$

where $W_p^{(c)}$, $W_l^{(c)}$, and $W_r^{(c)}$ are weights associated with the parent and its child nodes. Superscript (c) indicates that the weights are for c-TBCNN. For leaf nodes, which do not have children, we set $\boldsymbol{c}_l$ and $\boldsymbol{c}_r$ to be $\mathbf{0}$.

[3] http://nlp.stanford.edu/software/lex-parser.shtml

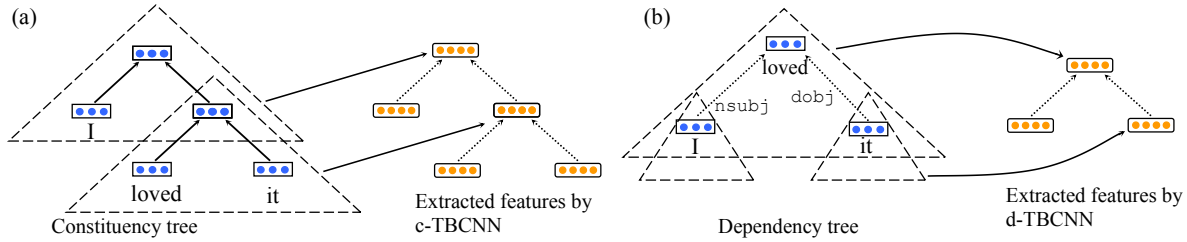

Figure 2: Tree-based convolution in (a) c-TBCNN, and (b) d-TBCNN. The parse trees correspond to the sentence "I loved it." The dashed triangles illustrate a shared-weight convolution window sliding over the tree. For clarity, only two positions are drawn in c-TBCNN. Notice that dotted arrows are not part of neural connections; they merely indicate the topologies of tree structures. Specially, an edge $a \xrightarrow{r} b$ in the dependency tree refers to a being governed by b with dependency type r.

Tree-based convolution windows can be extended to arbitrary depths straightforwardly. The complexity is exponential to the depth of the window, but linear to the number of nodes. Hence, tree-based convolution, compared with "flat" CNNs, does not add to computational cost, provided the same amount of information to process at a time. In our experiments, we use convolution windows of depth 2.

3.2 d-TBCNN

Dependency trees are another representation of sentence structures. The nature of dependency representation leads to d-TBCNN's major difference from traditional convolution: there exist nodes with different numbers of child nodes. This causes trouble if we associate weight parameters according to positions in the window, which is standard for traditional convolution, e.g., Collobert and Weston (2008) or c-TBCNN.

To overcome the problem, we extend the notion of convolution by assigning weights according to dependency types (e.g, `nsubj`) rather than positions. We believe this strategy makes much sense because dependency types (de Marneffe et al., 2006) reflect the relationship between a governing word and its child words. To be concrete, the generic convolution formula (Equation 2) for d-TBCNN becomes

$$\boldsymbol{y} = f\left(W_p^{(d)} \cdot \boldsymbol{p} + \sum_{i=1}^{n} W_{r[c_i]}^{(d)} \cdot \boldsymbol{c}_i + \boldsymbol{b}^{(d)}\right)$$

where $W_p^{(d)}$ is the weight parameter for the parent p (governing word); $W_{r[c_i]}^{(d)}$ is the weight for child c_i, who has grammatical relationship $r[c_i]$ to its parent, p. Superscript (d) indicates the parameters are for d-TBCNN. Note that we keep 15 most frequently occurred dependency types; others appearing rarely in the corpus are mapped to one shared weight matrix.

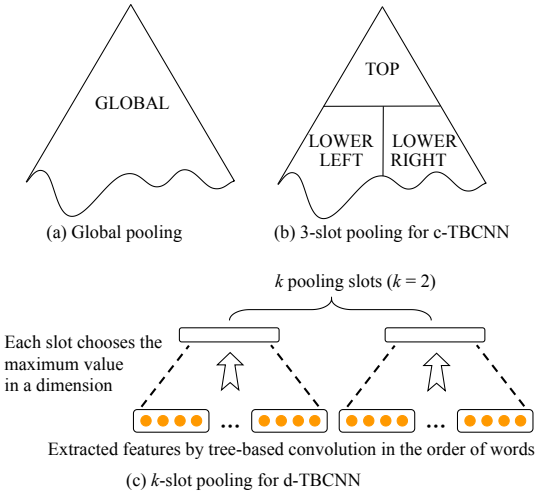

Figure 3: Pooling heuristics. (a) Global pooling. (b) 3-slot pooling for c-TBCNN. (c) k-slot pooling for d-TBCNN.

Both c-TBCNN and d-TBCNN have their own advantages: d-TBCNN exploits structural features more efficiently because of the compact expressiveness of dependency trees; c-TBCNN may be more effective in integrating global features due to the underneath pretrained RNN.

3.3 Pooling Heuristics

As different sentences may have different lengths and tree structures, the extracted features by tree-based convolution also have topologies varying in size and shape. Dynamic pooling (Socher et al., 2011a) is a common technique for dealing with

Task	Data samples	Label
Sentiment Analysis	Offers that rare combination of entertainment and education.	++
	An idealistic love story that brings out the latent 15-year-old romantic in everyone.	+
	Its mysteries are transparently obvious, and it's too slowly paced to be a thriller.	−
Question Classification	What is the temperature at the center of the earth?	`number`
	What state did the Battle of Bighorn take place in?	`location`

Table 1: Data samples in sentiment analysis and question classification. In the first task, "++" refers to strongly positive; "+" and "−" refer to positive and negative, respectively.

this problem. We propose several heuristics for pooling along a tree structure. Our generic design criteria for pooling include: (1) Nodes that are pooled to one slot should be "neighboring" from some viewpoint. (2) Each slot should have similar numbers of nodes, in expectation, that are pooled to it. Thus, (approximately) equal amount of information is aggregated along different parts of the tree. Following the above intuition, we propose pooling heuristics as follows.

- Global pooling. All features are pooled to one vector, shown in Figure 3a. We take the maximum value in each dimension. This simple heuristic is applicable to any structure, including c-TBCNN and d-TBCNN.
- 3-slot pooling for c-TBCNN. To preserve more information over different parts of constituency trees, we propose 3-slot pooling (Figure 3b). If a tree has maximum depth d, we pool nodes of less than $\alpha \cdot d$ layers to a TOP slot (α is set to 0.6); lower nodes are pooled to slots LOWER_LEFT or LOWER_RIGHT according to their relative position with respect to the root node.
  For a constituency tree, it is not completely obvious how to pool features to more than 3 slots and comply with the aforementioned criteria at the same time. Therefore, we regard 3-slot pooling for c-TBCNN is a "hard mechanism" temporarily. Further improvement can be addressed in future work.
- k-slot pooling for d-TBCNN. Different from constituency trees, nodes in dependency trees are one-one corresponding to words in a sentence. Thus, a total order on features (after convolution) can be defined according to their corresponding word orders. For k-slot pooling, we can adopt an "equal allocation" strategy, shown in Figure 3c. Let i be the position of a word in a sentence ($i = 1, 2, \cdots, n$). Its extracted feature vector is pooled to the j-th slot, if

$$(j-1)\frac{n}{k} \leq i \leq j\frac{n}{k}$$

We assess the efficacy of pooling quantitatively in Section 4.3.1. As we shall see by the experimental results, complicated pooling methods do preserve more information along tree structures to some extent, but the effect is not large. TBCNNs are not very sensitive to pooling methods.

3.4 Training Objective

After pooling, information is packed into one or more fixed-size vectors (slots). We add a hidden layer, and then a $\mathrm{softmax}$ layer to predict the probability of each target label in a classification task. The error function of a sample is the standard cross entropy loss, i.e., $J = -\sum_{i=1}^{c} t_i \log y_i$, where $\boldsymbol{t}$ is the ground truth (one-hot represented), $\boldsymbol{y}$ the output by $\mathrm{softmax}$, and c the number of classes. To regularize our model, we apply both ℓ_2 penalty and dropout (Srivastava et al., 2014). Training details are further presented in Section 4.1 and 4.2.

4 Experimental Results

In this section, we evaluate our models with two tasks, sentiment analysis and question classification. We also conduct quantitative and qualitative model analysis in Subsection 4.3.

4.1 Sentiment Analysis

4.1.1 The Task and Dataset

Sentiment analysis is a widely studied task for discriminative sentence modeling. The Stanford sentiment treebank[4] consists of more than 10,000 movie reviews. Two settings are considered for sentiment prediction: (1) fine-grained classification with 5 labels (`strongly positive`, `positive`, `neutral`, `negative`, and `strongly negative`), and (2) coarse-gained polarity classification with 2 labels (`positive` versus `negative`). Some examples are shown in

[4] http://nlp.stanford.edu/sentiment/

Table 1. We use the standard split for training, validating, and testing, containing 8544/1101/2210 sentences for 5-class prediction. Binary classification does not contain the `neutral` class.

In the dataset, phrases (sub-sentences) are also tagged with sentiment labels. RNNs deal with them naturally during the recursive process. We regard sub-sentences as individual samples during training, like Blunsom et al. (2014) and Le and Mikolov (2014). The training set therefore has more than 150,000 entries in total. For validating and testing, only whole sentences (root labels) are considered in our experiments.

Both c-TBCNN and d-TBCNN use the Stanford parser for data preprocessing.

4.1.2 Training Details

This subsection describes training details for d-TBCNN, where hyperparameters are chosen by validation. c-TBCNN is mostly tuned synchronously (e.g., optimization algorithm, activation function) with some changes in hyperparameters. c-TBCNN's settings can be found on our website.

In our d-TBCNN model, the number of units is 300 for convolution and 200 for the last hidden layer. Word embeddings are 300 dimensional, pretrained ourselves using `word2vec` (Mikolov et al., 2013) on the English Wikipedia corpus. 2-slot pooling is applied for d-TBCNN. (c-TBCNN uses 3-slot pooling.)

To train our model, we compute gradient by back-propagation and apply stochastic gradient descent with mini-batch 200. We use ReLU (Nair and Hinton, 2010) as the activation function .

For regularization, we add ℓ_2 penalty for weights with a coefficient of 10^{-5}. Dropout (Srivastava et al., 2014) is further applied to both weights and embeddings. All hidden layers are dropped out by 50%, and embeddings 40%.

4.1.3 Performance

Table 2 compares our models to state-of-the-art results in the task of sentiment analysis. For 5-class prediction, d-TBCNN yields 51.4% accuracy, outperforming the previous state-of-the-art result, achieved by the RNN based on long-short term memory (Tai et al., 2015). c-TBCNN is slightly worse. It achieves 50.4% accuracy, ranking third in the state-of-the-art list (including our d-TBCNN model).

Regarding 2-class prediction, we adopted a simple strategy in Irsoy and Cardie (2014),[5] where the 5-class network is "transferred" directly for binary classification, with estimated target probabilities (by 5-way $\mathrm{softmax}$) reinterpreted for 2 classes. (The `neutral` class is discarded as in other studies.) This strategy enables us to take a glance at the stability of our TBCNN models, but places itself in a difficult position. Nonetheless, our d-TBCNN model achieves 87.9% accuracy, ranking forth in the list.

In a more controlled comparison—with shallow architectures and the basic interaction (linearly transformed and non-linearly squashed)—TBCNNs, of both variants, consistently outperform RNNs (Socher et al., 2011b) to a large extent (50.4–51.4% versus 43.2%); they also consistently outperform "flat" CNNs by more than 10%. Such results show that structures are important when modeling sentences; tree-based convolution can capture these structural information more effectively than RNNs.

We also observe d-TBCNN achieves higher performance than c-TBCNN. This suggests that compact tree expressiveness is more important than integrating global information in this task.

4.2 Question Classification

We further evaluate TBCNN models on a question classification task.[6] The dataset contains 5452 annotated sentences plus 500 test samples in TREC 10. We also use the standard split, like Silva et al. (2011). Target labels contain 6 classes, namely `abbreviation`, `entity`, `description`, `human`, `location`, and `numeric`. Some examples are also shown in Table 1.

We chose this task to evaluate our models because the number of training samples is rather small, so that we can know TBCNNs' performance when applied to datasets of different sizes. To alleviate the problem of data sparseness, we set the dimensions of convolutional layer and the last hidden layer to 30 and 25, respectively. We do not back-propagate gradient to embeddings in this

[5] Richard Socher, who first applies neural networks to this task, thinks direct transfer is fine for binary classification. We followed this strategy for simplicity as it is non-trivial to deal with the neutral sub-sentences in the training set if we train a separate model. Our website reviews some related work and provides more discussions.

task. Dropout rate for embeddings is 30%; hidden layers are dropped out by 5%.

Table 3 compares our models to various other methods. The first entry presents the previous state-of-the-art result, achieved by traditional feature/rule engineering (Silva et al., 2011). Their method utilizes more than 10k features and 60 hand-coded rules. On the contrary, our TBCNN models do not use a single human-engineered feature or rule. Despite this, c-TBCNN achieves similar accuracy compared with feature engineering; d-TBCNN pushes the state-of-the-art result to 96%. To the best of our knowledge, this is the first time that neural networks beat dedicated human engineering in this question classification task.

The result also shows that both c-TBCNN and d-TBCNN reduce the error rate to a large extent, compared with other neural architectures in this task.

4.3 Model Analysis

In this part, we analyze our models quantitatively and qualitatively in several aspects, shedding some light on the mechanism of TBCNNs.

4.3.1 The Effect of Pooling

The extracted features by tree-based convolution have topologies varying in size and shape. We propose in Section 3.3 several heuristics for pooling. This subsection aims to provide a fair comparison among these pooling methods.

One reasonable protocol for comparison is to tune all hyperparameters for each setting and compare the highest accuracy. This methodology, however, is too time-consuming, and depends largely on the quality of hyperparameter tuning. An alternative is to predefine a set of sensible hyperparameters and report the accuracy under the same setting. In this experiment, we chose the latter protocol, where hidden layers are all 300-dimensional; no ℓ_2 penalty is added. Each configuration was run five times with different random initializations. We summarize the mean and standard deviation in Table 4.

As the results imply, complicated pooling is better than global pooling to some degree for both model variants. But the effect is not strong; our models are not that sensitive to pooling methods, which mainly serve as a necessity for dealing with varying-structure data. In our experiments, we apply 3-slot pooling for c-TBCNN and 2-slot pooling for d-TBCNN.

Model	Pooling method	5-class accuracy (%)
c-TBCNN	Global	48.48 ± 0.54
	3-slot	48.69 ± 0.40
d-TBCNN	Global	49.39 ± 0.24
	2-slot	49.94 ± 0.63

Table 4: Accuracies of different pooling methods, averaged over 5 random initializations. We chose sensible hyperparameters manually in advance to make a fair comparison. This leads to performance degradation (1–2%) vis-a-vis Table 2.

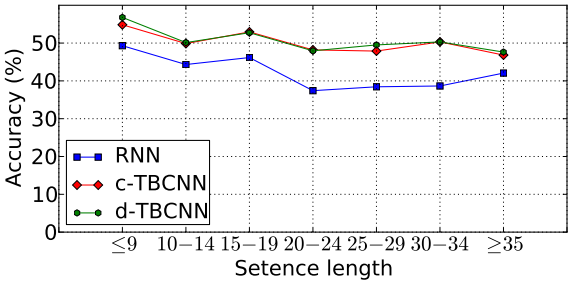

Figure 4: Accuracies versus sentence lengths.

Comparing with other studies in the literature, we also notice that pooling is very effective and efficient in information gathering. Irsoy and Cardie (2014) report 200 epochs for training a deep RNN, which achieves 49.8% accuracy in the 5-class sentiment classification. Our TBCNNs are typically trained within 25 epochs.

4.3.2 The Effect of Sentence Lengths

We analyze how sentence lengths affect our models. Sentences are split into 7 groups by length, with granularity 5. A few too long or too short sentences are grouped together for smoothing; the numbers of sentences in each group vary from 126 to 457. Figure 4 presents accuracies versus lengths in TBCNNs. For comparison, we also reimplemented RNN, achieving 42.7% overall accuracy, slightly worse than 43.2% reported in Socher et al. (2011b). Thus, we think our reimplementation is fair and that the comparison is sensible.

We observe that c-TBCNN and d-TBCNN yield very similar behaviors. They consistently outperform the RNN in all scenarios. We also notice the gap, between TBCNNs and RNN, increases when sentences contain more than 20 words. This result confirms our theoretical analysis in Section 2—for long sentences, the propagation paths in RNNs are deep, causing RNNs' difficulty in information processing. By contrast, our models explore structural information more effectively with tree-based convolution. As information from any part of the tree can propagate to the output layer with short paths, TBCNNs are more capable for sentence modeling, especially for long sentences.

4.3.3 Visualization

Visualization is important to understanding the mechanism of neural networks. For TBCNNs, we would like to see how the extracted features (after convolution) are further processed by the max pooling layer, and ultimately related to the supervised task.

To show this, we trace back where the max pooling layer's features come from. For each dimension, the pooling layer chooses the maximum value from the nodes that are pooled to it. Thus, we can count the fraction in which a node's features are gathered by pooling. Intuitively, if a node's features are more related to the task, the fraction tends to be larger, and vice versa.

Figure 5 illustrates an example processed by d-TBCNN in the task of sentiment analysis.[7] Here, we applied global pooling because information tracing is more sensible with one pooling slot. As shown in the figure, tree-based convolution can effectively extract information relevant to the task of interest. The 2-layer windows corresponding to "*visual will impress viewers*," "*the stunning dreamlike visual*," say, are discriminative to the sentence's sentiment. Hence, large fractions (0.24 and 0.19) of their features, after convolution, are gathered by pooling. On the other hand, words like *the*, *will*, *even* are known as stop words (Fox, 1989). They are mostly noninformative for sentiment; hence, no (or minimal) features are gathered. Such results are consistent with human intuition.

We further observe that tree-based convolution does integrate information of different words in the window. For example, the word *stunning* appears in two windows: (a) the window "*stunning*" itself, and (b) the window of "*the stunning dreamlike visual*," with root node *visual*, *stunning* acting as a child. We see that Window b is more relevant to the ultimate sentiment than Window a, with fractions 0.19 versus 0.07, even though the root *visual* itself is neutral in sentiment. In fact,

[7] We only have space to present one example in the paper. This example was not chosen deliberately. Similar traits can be found through out the entire gallery, available on our website. Also, we only present d-TBCNN, noticing that dependency trees are intrinsically more suitable for visualization since we know the "meaning" of every node.

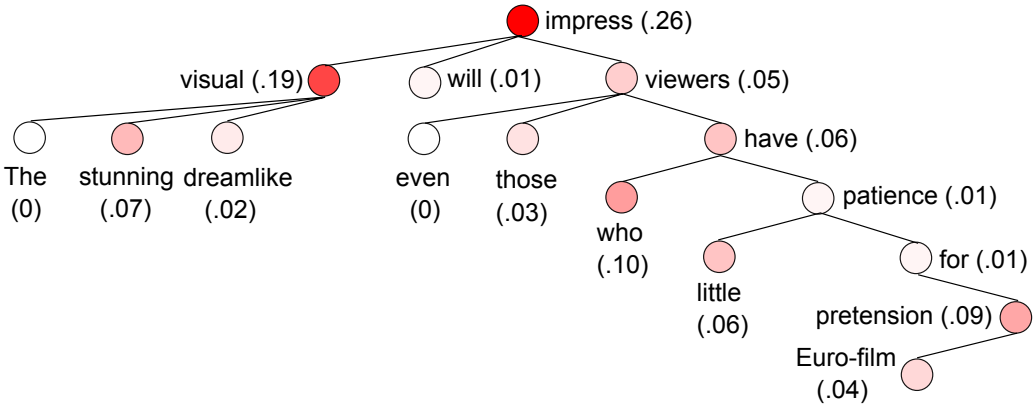

Figure 5: Visualizing how features (after convolution) are related to the sentiment of a sentence. The sample corresponds a sentence in the dataset, "The stunning dreamlike visual will impress even those viewers who have little patience for Euro-film pretension." The numbers in brackets denote the fraction of a node's features that are gathered by the max pooling layer (also indicated by colors).

Window a has a larger fraction than the sum of its children's (the windows of "*the*," "*stunning*," and "*dreamlike*").

5 Conclusion

In this paper, we proposed a novel neural discriminative sentence model based on sentence parsing structures. Our model can be built upon either constituency trees (denoted as c-TBCNN) or dependency trees (d-TBCNN).

Both variants have achieved high performance in sentiment analysis and question classification. d-TBCNN is slightly better than c-TBCNN in our experiments, and has outperformed previous state-of-the-art results in both tasks. The results show that tree-based convolution can capture sentences' structural information effectively, which is useful for sentence modeling.

Abstract

Neural network based methods have obtained great progress on a variety of natural language processing tasks. However, it is still a challenge task to model long texts, such as sentences and documents. In this paper, we propose a multi-timescale long short-term memory (MT-LSTM) neural network to model long texts. MT-LSTM partitions the hidden states of the standard LSTM into several groups. Each group is activated at different time periods. Thus, MT-LSTM can model very long documents as well as short sentences. Experiments on four benchmark datasets show that our model outperforms the other neural models in text classification task.

1 Introduction

Distributed representations of words have been widely used in many natural language processing (NLP) tasks (Collobert et al., 2011; Turian et al., 2010; Mikolov et al., 2013b; Bengio et al., 2003). Following this success, it is rising a substantial interest to learn the distributed representations of the continuous words, such as phrases, sentences, paragraphs and documents (Mitchell and Lapata, 2010; Socher et al., 2013; Mikolov et al., 2013b; Le and Mikolov, 2014; Kalchbrenner et al., 2014). The primary role of these models is to represent the variable-length sentence or document as a fixed-length vector. A good representation of the variable-length text should fully capture the semantics of natural language.

Recently, the long short-term memory neural network (LSTM) (Hochreiter and Schmidhuber, 1997) has been applied successfully in many NLP tasks, such as spoken language understanding (Yao et al., 2014), sequence labeling (Chen et al., 2015) and machine translation (Sutskever et al., 2014). LSTM is an extension of the recurrent neural network (RNN) (Elman, 1990), which can capture the long-term and short-term dependencies and is very suitable to model the variable-length texts. Besides, LSTM is also sensitive to word order and does not rely on the external syntactic structure as recursive neural network (Socher et al., 2013). However, when modeling long texts, such as documents, LSTM need to keep the useful features for a quite long period of time. The long-term dependencies need to be transmitted one-by-one along the sequence. Some important features could be lost in transmission process. Besides, the error signal is also back-propagated one-by-one through multiple time steps in the training phase with back-propagation through time (BPTT) (Werbos, 1990) algorithm. The learning efficiency could also be decreased for the long texts. For example, if a valuable feature occurs at the begin of a long document, we need to back-propagate the error through the whole document.

In this paper, we propose a multi-timescale long short-term memory (MT-LSTM) to capture the valuable information with different timescales. Inspired by the works of (El Hihi and Bengio, 1995) and (Koutnik et al., 2014), we partition the hidden states of the standard LSTM into several groups. Each group is activated and updated at different time periods. The fast-speed groups keep the short-term memories, while the slow-speed groups keep the long-term memories. We evaluate our model on four benchmark datasets of text classification. Experimental results show that our model can not only handle short texts, but can model long texts.

Our contributions can be summarized as follows.

- With the multiple different timescale memories, MT-LSTM easily carries the crucial information over a long distance. MT-LSTM

Lisbon, Portugal, 17-21 September 2015.

can well model both short and long texts.

- MT-LSTM has faster convergence speed than the standard LSTM since the error signal can be back-propagated through multiple timescales in the training phase.

2 Neural Models for Sentences and Documents

The primary role of the neural models is to represent the variable-length sentence or document as a fixed-length vector. These models generally consist of a projection layer that maps words, subword units or n-grams to vector representations (often trained beforehand with unsupervised methods), and then combine them with the different architectures of neural networks. Most of these models for distributed representations of sentences or documents can be classified into four categories.

Bag-of-words models A simple and intuitive method is the Neural Bag-of-Words (NBOW) model, in which the representation of sentences or documents can be generated by averaging constituent word representations. However, the main drawback of NBOW is that the word order is lost. Although NBOW is effective for general document classification, it is not suitable for short sentences.

Sequence models Sequence models construct the representation of sentences or documents based on the recurrent neural network (RNN) (Mikolov et al., 2010) or the gated versions of RNN (Sutskever et al., 2014; Chung et al., 2014). Sequence models are sensitive to word order, but they have a bias towards the latest input words. This gives the RNN excellent performance at language modelling, but it is suboptimal for modeling the whole sentence, especially for the long texts. Le and Mikolov (2014) proposed a Paragraph Vector (PV) to learn continuous distributed vector representations for pieces of texts, which can be regarded as a long-term memory of sentences as opposed to the short-memory in RNN.

Topological models Topological models compose the sentence representation following a given topological structure over the words (Socher et al., 2011a; Socher et al., 2012; Socher et al., 2013). Recursive neural network (RecNN) adopts a more general structure to encode sentence (Pollack, 1990; Socher et al., 2013). At every node in the tree the contexts at the left and right children of the node are combined by a classical layer. The weights of the layer are shared across all nodes in the tree. The layer computed at the top node gives a representation for the sentence. However, RecNN depends on external constituency parse trees provided by an external topological structure, such as parse tree.

Convolutional models Convolutional neural network (CNN) is also used to model sentences (Collobert et al., 2011; Kalchbrenner et al., 2014; Hu et al., 2014). It takes as input the embeddings of words in the sentence aligned sequentially, and summarizes the meaning of a sentence through layers of convolution and pooling, until reaching a fixed length vectorial representation in the final layer. CNN can maintain the word order information and learn more abstract characteristics.

3 Long Short-Term Memory Networks

A recurrent neural network (RNN) (Elman, 1990) is able to process a sequence of arbitrary length by recursively applying a transition function to its *internal hidden state vector* h_t of the input sequence. The activation of the hidden state h_t at time-step t is computed as a function f of the current input symbol $\mathbf{x}_t$ and the previous hidden state $\mathbf{h}_{t-1}$

$$\mathbf{h}_t = \begin{cases} 0 & t = 0 \\ f(\mathbf{h}_{t-1}, \mathbf{x}_t) & \text{otherwise} \end{cases} \quad (1)$$

It is common to use the state-to-state transition function f as the composition of an element-wise nonlinearity with an affine transformation of both $\mathbf{x}_t$ and $\mathbf{h}_{t-1}$.

Traditionally, a simple strategy for modeling sequence is to map the input sequence to a fixed-sized vector using one RNN, and then to feed the vector to a softmax layer for classification or other tasks (Sutskever et al., 2014; Cho et al., 2014).

Unfortunately, a problem with RNNs with transition functions of this form is that during training, components of the gradient vector can grow or decay exponentially over long sequences (Bengio et al., 1994; Hochreiter et al., 2001; Hochreiter and Schmidhuber, 1997). This problem with *exploding* or *vanishing gradients* makes it difficult for the RNN model to learn long-distance correlations in a sequence.

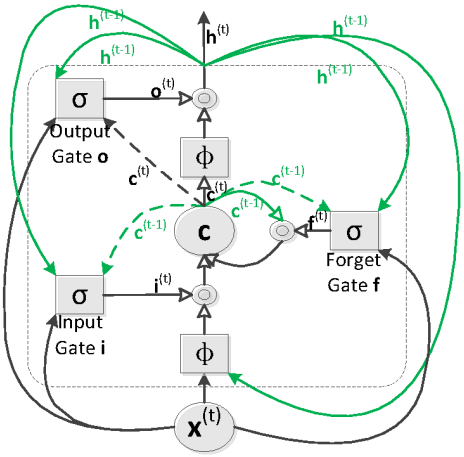

Figure 1: A LSTM unit. The dashed line is the recurrent connection, and the solid link is the connection at the current time.

Long short-term memory network (LSTM) was proposed by (Hochreiter and Schmidhuber, 1997) to specifically address this issue of learning long-term dependencies. The LSTM maintains a separate memory cell inside it that updates and exposes its content only when deemed necessary. A number of minor modifications to the standard LSTM unit have been made. While there are numerous LSTM variants, here we describe the implementation used by Graves (2013).

We define the LSTM *units* at each time step t to be a collection of vectors in $\mathbb{R}^d$: an *input gate* $\mathbf{i}_t$, a *forget gate* $\mathbf{f}_t$, an *output gate* $\mathbf{o}_t$, a *memory cell* $\mathbf{c}_t$ and a hidden state $\mathbf{h}_t$. d is the number of the LSTM units. The entries of the gating vectors $\mathbf{i}_t$, $\mathbf{f}_t$ and $\mathbf{o}_t$ are in $[0, 1]$. The LSTM transition equations are the following:

$$\mathbf{i}_t = \sigma(\mathbf{W}_i\mathbf{x}_t + \mathbf{U}_i\mathbf{h}_{t-1} + \mathbf{V}_i\mathbf{c}_{t-1}) \quad (2)$$

$$\mathbf{f}_t = \sigma(\mathbf{W}_f\mathbf{x}_t + \mathbf{U}_f\mathbf{h}_{t-1} + \mathbf{V}_f\mathbf{c}_{t-1}), \quad (3)$$

$$\mathbf{o}_t = \sigma(\mathbf{W}_o\mathbf{x}_t + \mathbf{U}_o\mathbf{h}_{t-1} + \mathbf{V}_o\mathbf{c}_t), \quad (4)$$

$$\tilde{\mathbf{c}}_t = \tanh(\mathbf{W}_c\mathbf{x}_t + \mathbf{U}_c\mathbf{h}_{t-1}), \quad (5)$$

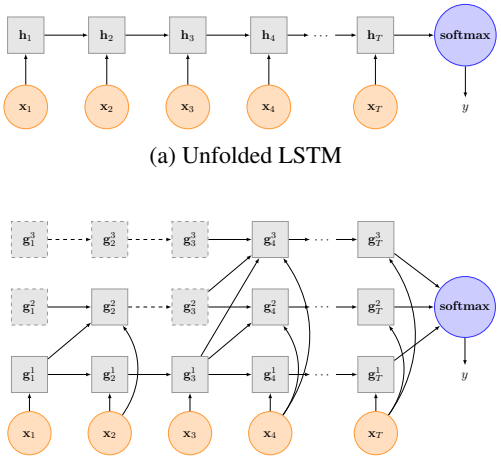
$$\mathbf{c}_t = \mathbf{f}_t^i \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tilde{\mathbf{c}}_t, \quad (6)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t), \quad (7)$$

where x_t is the input at the current time step, σ denotes the logistic sigmoid function and $\odot$ denotes elementwise multiplication. Intuitively, the forget gate controls the amount of which each unit of the memory cell is erased, the input gate controls how much each unit is updated, and the output gate controls the exposure of the internal memory state.

Figure 1 shows the structure of a LSTM unit. In particular, these gates and the memory cell allow a LSTM unit to adaptively forget, memorize and expose the memory content. If the detected feature, i.e., the memory content, is deemed important, the forget gate will be closed and carry the memory content across many time-steps, which is equivalent to capturing a long-term dependency. On the other hand, the unit may decide to reset the memory content by opening the forget gate.

4 Multi-Timescale Long Short-Term Memory Neural Network



(a) Unfolded LSTM

(b) Unfolded MT-LSTM with Fast-to-Slow Feedback Strategy

Figure 2: Illustration of the unfolded LSTM and unfolded MT-LSTM. The dotted node indicates the unit which is inactivated at current time, while the solid node indicates the unit which is activated. The dotted lines indicate the units which kept unchanged, while the solid lines indicate the units which will be updated at the next time step.

LSTM can capture the long-term and short-term dependencies in a sequence. But the long-term dependencies need to be transmitted one-by-one along the sequence. Some important information could be lost in transmission process for long texts, such as documents. Besides, the error signal is back-propagated through multiple time steps when we use the back-propagation through time (BPTT) (Werbos, 1990) algorithm. The training efficiency could also be low for the long texts. For example, if a valuable feature occurs at the begin of a long document, we need to back-propagate the error through the whole document.

Inspired by the works of (El Hihi and Bengio, 1995) and (Koutnik et al., 2014), which use de-

layed connections and units operating at different timescales to improve the simple RNN, we separate the LSTM units into several groups. Different groups capture different timescales dependencies.

More formally, the LSTM units are partitioned into g groups $\{G_1, \cdots, G_g\}$. Each group $G_k, (1 \leq k \leq g)$ is activated at different time periods T_k. Accordingly, the gates and weight matrices are also partitioned to maintain the corresponding LSTM groups. The MT-LSTM with just one group is the same to the standard LSTM.

At each time step t, only the groups G_k that satisfy $(t \,\mathrm{MOD}\, T_k) = 0$ are executed. The choice of the set of periods $T_k \in \{T_1, \cdots, T_g\}$ is arbitrary. Here, we use the exponential series of periods: group G_k has the period of $T_k = 2^{k-1}$. The group G_1 is the fastest one and can be executed at every time step, which works like the standard LSTM. The group G_k is the slowest one.

At time step t, the memory cell vector and hidden state vector of group G_k are calculate in two cases:

(1) When group G_k is activated at time step t, the LSMT units of this group are calculated by the following equations:

$$\mathbf{i}_t^k = \sigma(\mathbf{W}_i^k \mathbf{x}_t + \sum_{j=1}^{g} \mathbf{U}_i^{j\to k} \mathbf{h}_{t-1}^j + \sum_{j=1}^{g} \mathbf{V}_i^{j\to k} \mathbf{c}_{t-1}^j), \quad (8)$$

$$\mathbf{f}_t^k = \sigma(\mathbf{W}_f^k \mathbf{x}_t + \sum_{j=1}^{g} \mathbf{U}_f^{j\to k} \mathbf{h}_{t-1}^j + \sum_{j=1}^{g} \mathbf{V}_f^{j\to k} \mathbf{c}_{t-1}^j), \quad (9)$$

$$\mathbf{o}_t^k = \sigma(\mathbf{W}_o^k \mathbf{x}_t + \sum_{j=1}^{g} \mathbf{U}_o^{j\to k} \mathbf{h}_{t-1}^j + \sum_{j=1}^{g} \mathbf{V}_o^{j\to k} \mathbf{c}_{t}^j), \quad (10)$$

$$\tilde{\mathbf{c}}_t^k = \tanh(\mathbf{W}_c^k \mathbf{x}_t + \sum_{j=1}^{g} \mathbf{U}_c^{j\to k} \mathbf{h}_{t-1}^j), \quad (11)$$

$$\mathbf{c}_t^k = \mathbf{f}_t^k \odot \mathbf{c}_{t-1}^k + \mathbf{i}_t^k \odot \tilde{\mathbf{c}}_t^k, \quad (12)$$

$$\mathbf{h}_t^k = \mathbf{o}_t^k \odot \tanh(\mathbf{c}_t^k), \quad (13)$$

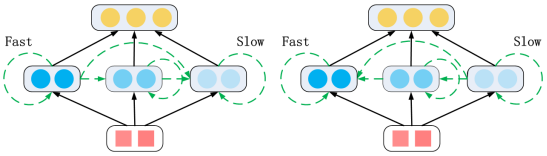
where $\mathbf{i}_t^k$, $\mathbf{f}_t^k$ and $\mathbf{o}_t^k$ are the vectors of input gates, forget gates, and output gates of group G_k at time step t respectively; $\mathbf{c}_t^k$ and $\mathbf{h}_t^k$ are the memory cell vector and hidden state vector of group G_k at time step t respectively.

(2) When group G_k is non-activated at time step t, its LSMT units keep unchanged.

$$\mathbf{c}_t^k = \mathbf{c}_{t-1}^k, \quad (14)$$

$$\mathbf{h}_t^k = \mathbf{h}_{t-1}^k. \quad (15)$$

Figure 3 shows the different between the standard LSTM and MT-LSTM.



(a) Fast-to-Slow Strategy (b) Slow-to-Fast Strategy

Figure 3: Two feedback strategies of our model. The dashed line shows the feedback connection, and the solid link shows the connection at current time.

4.1 Two Feedback Strategies

The feedback mechanism of LSTM is implemented by the recurrent connections from time step $t-1$ to t. Since the MT-LSTM groups are updated with the different frequencies, we can regard the different group as the human memory. The fast-speed groups are short-term memories, while the slow-speed groups are long-term memories. Therefore, an important consideration is what feedback mechanism is between the short-term and long-term memories.

For the proposed MT-LSTM, we consider two feedback strategies to define the connectivity patterns among the different groups.

Fast-to-Slow (F2S) Strategy Intuitively, when we accumulate the short-term memory to a certain degree, we store some valuable information from the short-term memory into the long-term memory. Therefore, we firstly define a fast to slow strategy, which updates the slower group using the faster group. The connections from group j to group k exist if and only if $T_j \leq T_k$. The weight matrices $\mathbf{U}_i^{j\to k}$, $\mathbf{U}_f^{j\to k}$, $\mathbf{U}_o^{j\to k}$, $\mathbf{U}_c^{j\to k}$, $\mathbf{V}_i^{j\to k}$, $\mathbf{V}_f^{j\to k}$, $\mathbf{V}_o^{j\to k}$ are set to zero when $T_j > T_k$.

The F2S updating strategy is shown in Figure 3a.

Slow-to-Fast (S2F) Strategy Following the work of (Koutnik et al., 2014), we also investigate another update scheme from slow-speed group to fast-speed group. The motivation is that a long term memory can be "distilled" into a short-term memory. The connections from group j to group i exist only if $T_j \geq T_i$. The weight matrices $\mathbf{U}_i^{j\to k}$, $\mathbf{U}_f^{j\to k}$, $\mathbf{U}_o^{j\to k}$, $\mathbf{U}_c^{j\to k}$, $\mathbf{V}_i^{j\to k}$, $\mathbf{V}_f^{j\to k}$, $\mathbf{V}_o^{j\to k}$ are set to zero when $T_j < T_k$.

The S2F update strategy is shown in Figure 3b.

Dataset	Type	Train Size	Dev. Size	Test Size	Class	Averaged Length	Vocabulary Size
SST-1	Sentence	8544	1101	2210	5	19	18K
SST-2	Sentence	6920	872	1821	2	18	15K
QC	Sentence	5452	-	500	6	10	9.4K
IMDB	Document	25,000	-	25,000	2	294	392K

Table 1: Statistics of the four datasets used in this paper.

4.2 Dynamic Selection of the Number of the MT-LSTM Unit Groups

Another consideration is how many groups need to be used. An intuitive way is that we need more groups for long texts than short texts. The number of the group depends the length of the texts.

Here, we use a simple dynamic strategy to choose the maximum number of groups, and then the best g is chosen as a hyperparameter according to different tasks. The upper bound of the number of groups is calculated by

$$g = \log_2 L - 1, \tag{16}$$

where L is the average length of the corpus. Thus, the slowest group is activated at least twice.

5 Training

In each of the experiments, the hidden layer at the last moment has a fully connected layer followed by a softmax non-linear layer that predicts the probability distribution over classes given the input sentence. The network is trained to minimise the cross-entropy of the predicted and true distributions; the objective includes an L_2 regularization term over the parameters. The network is trained with backpropagation and the gradient-based optimization is performed using the Adagrad update rule (Duchi et al., 2011).

The back propagation of the error propagation is similar to LSTM as well. The only difference is that the error propagates only from groups that were executed at time step t. The error of non-activated groups gets copied back in time (similarly to copying the activations of nodes not activated at the time step t during the corresponding forward pass), where it is added to the back-propagated error.

6 Experiments

In this section, we investigate the empirical performances of our proposed MT-LSTM model on four benchmark datasets for sentence and document classification and then compare it to other competitor models.

6.1 Datasets

We evaluate our model on four different datasets. The first three datasets are sentence-level, and the last dataset is document-level. The detailed statistics about the four datasets are listed in Table 1. Each dataset is briefly described as follows.

- **SST-1** The movie reviews with five classes (negative, somewhat negative, neutral, somewhat positive, positive) in the Stanford Sentiment Treebank[1] (Socher et al., 2013).
- **SST-2** The movie reviews with binary classes. It is also from the Stanford Sentiment Treebank.
- **QC** The TREC questions dataset[2] involves six different question types, e.g. whether the question is about a location, about a person or about some numeric information (Li and Roth, 2002).
- **IMDB** The IMDB dataset[3] consists of 100,000 movie reviews with binary classes (Maas et al., 2011). One key aspect of this dataset is that each movie review has several sentences.

6.2 Competitor Models

We compare our model with the following models:

- **NB-SVM** and **MNB**. Naive Bayes SVM and Multinomial Naive Bayes with uni and bigram features (Wang and Manning, 2012).
- **NBOW** The NBOW sums the word vectors and applies a non-linearity followed by a softmax classification layer.
- **RAE** Recursive Autoencoders with pre-trained word vectors from Wikipedia (Socher et al., 2011b).
- **MV-RNN** Matrix-Vector Recursive Neural Network with parse trees (Socher et al., 2012).

Number of Groups	3	3	3	5

Table 2: Hyper-parameter settings for the LSTM and MT-LSTM.

- **RNTN** Recursive Neural Tensor Network with tensor-based feature function and parse trees (Socher et al., 2013).
- **AdaSent** Self-adaptive hierarchical sentence model with gated mechanism (Zhao et al., 2015).
- **DCNN** Dynamic Convolutional Neural Network with dynamic k-max pooling (Kalchbrenner et al., 2014).
- **CNN-non-static** and **CNN-multichannel** Convolutional Neural Network (Kim, 2014).
- **PV** Logistic regression on top of paragraph vectors (Le and Mikolov, 2014). Here, we use the popular open source implementation of PV in Gensim[4].
- **LSTM** The standard LSTM for text classification. We use the implementation of Graves (2013). The unfolded illustration is shown in Figure 2a.

6.3 Hyperparameters and Training

In all of our experiments, the word embeddings are trained using word2vec (Mikolov et al., 2013a) on the Wikipedia corpus (1B words). The vocabulary size is about 500,000. The the word embeddings are fine-tuned during training to improve the performance (Collobert et al., 2011). The other parameters are initialized by randomly sampling from uniform distribution in [-0.1, 0.1]. The hyperparameters which achieve the best performance on the development set will be chosen for the final evaluation. For datasets without development set, we use 10-fold cross-validation (CV) instead. The final hyper-parameters for the LSTM and MT-LSTM are set as Figure 2.

6.4 Results

Table 3 shows the classification accuracies of the standard LSTM, MT-LSTM compared with the competitor models.

Firstly, we compare two feedback strategies of MT-LSTM. The fast-to-slow feedback strategy (MT-LSTM (F2S)) is better than the slow-to-fast strategy (MT-LSTM (S2F)), which indicates that MT-LSTM benefits from periodically storing some valuable information "purified" from the short-term memory into the long-term memory. In the following discussion, we use fast-to-slow feedback strategy as the default setting of MT-LSTM.

[4] https://github.com/piskvorky/gensim/

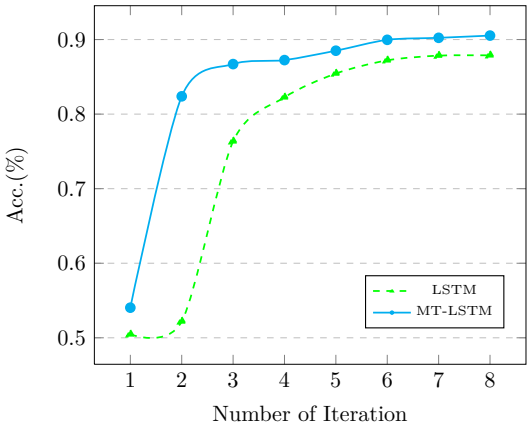

Figure 4: Convergence Speeds on IMDB dataset.

Compared with the standard LSTM, MT-LSTM results in significantly improvements with the same size of hidden layers.

MT-LSTM outperforms the competitor models on the SST-1, QC and IMDB datasets, and is close to the two best CNN based models on the SST-2 dataset. But MT-LSTM uses much fewer parameters than the CNN based models. The number of parameters of LSTM range from 10K to 40K while the number of parameters is about 400K in CNN.

Moreover, MT-LSTM can not only handle short texts, but can model long texts in classification task.

Documents Modeling Most of the competitor models cannot deal with the texts of with several sentences (paragraphs, documents). For instance, MV-RNN and RNTN (Socher et al., 2013) are based on the parsing over each sentence and it is unclear how to combine the representations over many sentences. The convolutional models, such as CNN (Kim, 2014) and AdaSent (Zhao et al., 2015), need more hidden layers or nodes for long texts and result in a very complicated model. These models therefore are restricted to working on sentences instead of paragraphs or documents. Denil et al. (2014) used two-level version of DCNN (Kalchbrenner et al., 2014) to model documents. The first level uses a DCNN to trans-

Model	SST-1	SST-2	QC	IMDB

Table 3: Results of our MT-LSTM model against state-of-the-art neural models. All the results without marks are reported in the corresponding paper.

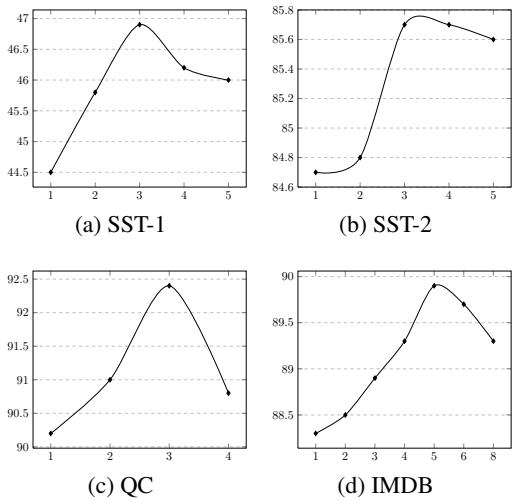

Figure 5: Performances of our model with the different numbers of memory groups g on four development datasets: SST-1,SST-2, QC, and IMDB. Y-axis represents the accuracy(%), and X-axis represents different numbers of memory groups. All memory groups share a fixed-size memory layer h, and here we set h=120.

form embeddings for the words in each sentence into an embedding for the entire sentence. The second level uses another DCNN to transform sentence embeddings from the first level into a single embedding vector that represents the entire document. However, their result is unsatisfactory and they reported that the IMDB dataset is too small to train a CNN model.

The standard LSTM has an advantage to model documents due to its simplification. However, it is also difficult to train LSTM since the error signals need to be back-propagated over a long distance with the BPTT algorithm.

Our MT-LSTM can alleviate this problem with multiple timescale memories. The experiment on IMDB dataset demonstrates this advantage. MT-LSTM achieves the accuracy of 92.1% , which are better than the other models.

Moreover, MT-LSTM converges at a faster rate than the standard LSTM. Figure 4 plots the convergence on the IMDB dataset. In practice, MT-LSTM is approximately three times faster than the standard LSTM since the hidden states of low-speed group often keep unchanged and need not to be re-calculated at each time step.

Impact of the Different Number of Memory Groups In our model, the number of memory groups is a hyperparameter. Here we plotted the accuracy curves of our model with the different numbers of memory groups in Figure 5 to show its impacts on the four datasets.

When the length of text (SST-1, SST-2 and QC) is small, not all memory groups can be activated if we set too many groups, which may harm the performance. When dealing with the long texts (IMBD), more groups lead to a better performance. The performance can be improved with the increase of the number of memory groups.

According to our dynamic strategy, the maximum numbers of groups is 3, 3, 2, 7 for the four datasets. The best numbers of groups from experiments are 3, 3, 3, 5 respectively. Therefor, our dynamic strategy is reasonable. All the datasets except QC, the best number of groups is equal to or smaller than our calculated upper bound. MT-LSMT suffers underfitting when the number of groups is larger than the upper bound.

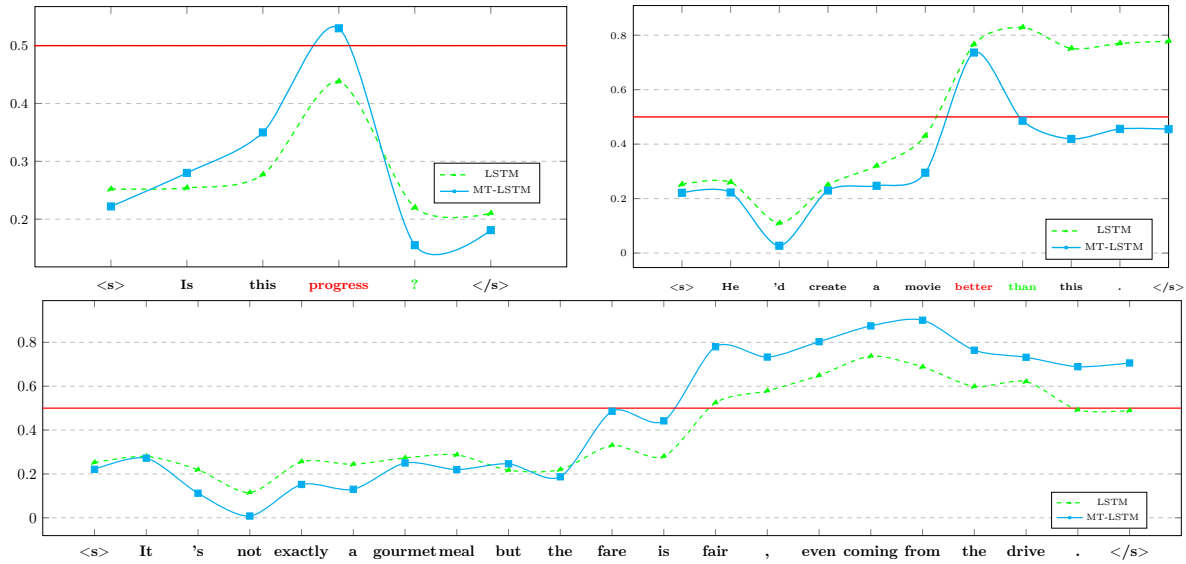

Figure 6: The dynamical changes of the predicted sentiment score over time. Y-axis represents the sentiment score, while X-axis represents the input words in chronological order. The red horizontal line gives a border between the positive and negative sentiments.

6.5 Case Study

To get an intuitive understanding of what is happening when we use LSTM or MT-LSTM to predict the class of text, we design an experiment to analyze the output of LSTM and MT-LSTM at each time step.

We sample three sentences from the SST-2 test dataset, and the dynamical changes of the predicted sentiment score over time are shown in Figure 6. It is intriguing to notice that our model can handle the rhetorical question well.

The first sentence "`Is this progress ?`" has a negative sentiment. Although the word "`progress`" is positive, our model can adjust the sentiment correctly after seeing the question mark "`?`", and finally gets a correct prediction.

The second sentence "`He 'd create a movie better than this .`" also has a negative sentiment. The word "`better`" is positive. Our model finally gets a correct negative prediction after seeing "than this", while LSTM gets a wrong prediction.

The third sentence "`It 's not exactly a gourmet meal but fare is fair , even coming from the drive .`" is positive and has more complicated semantic composition. Our model can still capture the useful long-term features and gets the correct prediction, while LSTM does not work well.

7 Related Work

There are many previous works to model the variable-length text as a fixed-length vector. Specific to text classification task, most of the models cannot deal with the texts of several sentences (paragraphs, documents), such as MV-RNN (Socher et al., 2012), RNTN (Socher et al., 2013), CNN (Kim, 2014), AdaSent (Zhao et al., 2015), and so on. The simple neural bag-of-words model can deal with long texts, but it loses the word order information. PV (Le and Mikolov, 2014) works in unsupervised way, and the learned vector cannot be fine-tuned on the specific task.

Our proposed MT-LSTM can handle short texts as well as long texts in classification task.

8 Conclusion

In this paper, we introduce the MT-LSTM, a generalization of LSTMs to capture the information with different timescales. MT-LSTM can well model both short and long texts. With the multiple different timescale memories. Intuitively, MT-LSTM easily carries the crucial information over a long distance. Another advantage of MT-LSTM is that the training speed is faster than the standard LSTM (approximately three times faster in practice).

In future work, we would like to investigate the other feedback mechanism between the short-term and long-term memories.

Verbal and Nonverbal Clues for Real-life Deception Detection

Verónica Pérez-Rosas, Mohamed Abouelenien, Rada Mihalcea,

Abstract

Deception detection has been receiving an increasing amount of attention from the computational linguistics, speech, and multimodal processing communities. One of the major challenges encountered in this task is the availability of data, and most of the research work to date has been conducted on acted or artificially collected data. The generated deception models are thus lacking real-world evidence. In this paper, we explore the use of multimodal real-life data for the task of deception detection. We develop a new deception dataset consisting of videos from real-life scenarios, and build deception tools relying on verbal and nonverbal features. We achieve classification accuracies in the range of 77-82% when using a model that extracts and fuses features from the linguistic and visual modalities. We show that these results outperform the human capability of identifying deceit.

1 Introduction

As deceptive behavior occurs on a daily basis in different areas of life (Meyer, 2010; Smith et al., 2014), the need arises for automated methodologies to detect deception in an efficient, yet reliable manner. There are many applications that can benefit from automatic deception identification, such as airport security screening, crime investigation and interrogation, interviews, advertisement, and others. In many of these settings, the polygraph test has been used as the main method to identify deceptive behavior. However, this method requires the use of skin-contact devices and human expertise, making it infeasible for large-scale applications. Moreover, polygraph tests were shown to be misleading in multiple cases (Vrij, 2001; Gannon et al., 2009), as human judgment is often biased.

Given the difficulties associated with the use of polygraph-like methods, learning-based approaches have been proposed to address the deception detection task using a number of modalities, including text (Feng et al., 2012) and speech (Hirschberg et al., 2005; Newman et al., 2003). Unlike the polygraph methods, learning-based methods for deception detection rely mainly on data collected from deceivers and truth-tellers. The data is usually elicited from human contributors, in a lab setting or via crowdsourcing. An important problem identified in this data-driven research is the lack of real data. Because of the artificial setting, the subjects may not be emotionally aroused, as they may not take the experiments seriously given the lack of motivation and/or penalty.

In this paper, we describe what we believe is a first attempt at building a multimodal system that detects deception in real-life settings. We collect a dataset consisting of 118 deceptive and truthful video clips, from real trials and live street interviews aired in television shows. We use the transcription of these videos to extract several linguistic features, and we manually annotate the videos for the presence of several gestures that are used to extract nonverbal features. We then build a system that jointly uses the verbal and nonverbal modalities to automatically detect the presence of deception. Our experiments show that the multimodal system can identify deception with an accuracy in the range of 77-82%, significantly improving over the baseline. In addition, we present a study on the human ability to detect deception in single or multimodal data streams, and show that our system outperforms humans on this task.

2 Dataset

Our goal is to build a multimodal collection of occurrences of real deception, which will allow us to analyze both verbal and nonverbal behaviors in relation to deception.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2336–2346,
Lisbon, Portugal, 17-21 September 2015.

Figure 1: Sample screenshots showing facial displays and hand gestures from real-life deception and truthful clips. Starting at the top left-hand corner: deceptive interview with up gaze (*Up*), deceptive interview with side gaze (*Side*), deceptive trial with both hands (*Both-H*), truthful trial with forward head (*Forward*), truthful interview with side turn (*Side-Turn*), and truthful interview with single hand (*Single-H*).

Truthful	Deceptive
I was sentenced to forty to sixty years in prison for this crime that I didn't commit. At the trial the judge had exceeded the sentence guidelines because he said I failed to show remorse. And I told him, you know, I felt terrible for what happen to this woman, shouldn't happen to anyone, but I can't show remorse for something I didn't do.	We had some drinks at the bar, maybe one ... two. um I got onto the dance floor myself as I explained, um I have been a trained dancer for some time, going to be able to dance freely is like a ... release. I'm very much in my own space when I do that and so I got up, and I was dancing alone on the dance floor.
It's difficult to pick just one but um I think Tender Mercies uh is ... really captured my imagination um when I was in junior high. Had a lot to do with Robert Duval's performance certainly and that got me excited about the possibility of um .... pulling off an acting career for myself.	Yeah, yeah he was convincing as a wolf. Ahhh actually you know ahhh this is like crazy I'm terrified from wolves, it's my worst fear even though they don't exist but thats my worst fear, sharks and stuff like that. Yeah its my worst fear, I am being honest with you.

Table 1: Sample transcripts for deceptive and truthful clips. The first row presents transcripts from the *Trials* domain while the second shows transcripts corresponding to the *Interviews* domain.

2.1 Data Collection

To collect real deception data, we start by identifying online multimedia sources where deceptive behavior can be observed and verified. We specifically target videos of people, on which we enforce some of the constraints imposed by current data processing technologies: the person in the video should be in front of the camera; her face should be clearly visible; visual quality should be clear enough to identify the facial expressions; and finally, audio quality should be clear enough to hear the voices and understand what the person is saying. We collect video clips from public real trials and interviews aired during television shows, where the truth or falsehood of the participant's statements ends up being known. Video clips from trials consist of statements from witnesses and defendants in the same trial. In order to have a clear distinction between deceptive and truthful trial videos portraying defendants, the process of labeling the trial relies on the verdict. Thus, clips with a guilty verdict are considered deceptive whereas clips with a non-guilty verdict or exoneration are labeled as truthful. Clips containing witness testimonies are labeled as truthful if their statements are verified by police investigations. Examples of trials included in our dataset are Jodi Arias, Andrea Sneiderman, and Amanda Hayes. Exoneree's statements were taken from "The Innocence Project" (`http://www.innocenceproject.org`).

Deceptive and truthful responses are also collected from TV shows and interviews. Examples of such shows are "Lie Witness," "Golden Balls," and the "American Film Institute" and "RevYOU" You-Tube channels. Deceptive videos portray scenarios where interviewees' responses were known to be a lie. For example, the interviewer asks a random individual on his opinion on a non-existing film where the interviewee fabricates a story. On the other hand, truthful videos are collected from individuals asked on their opinions on real movies.

Given our goals and constraints, data collection ended up being a lengthy and laborious process consisting of several iterations of Web mining, data processing and analysis, and content validation.

The final dataset includes 118 videos, including 59 that are labeled as deceptive and 59 labeled as truthful. Among them, 62 belong to the TV street interviews and shows category (*Interviews*) with 28 deceptive and 34 truthful video clips, and 56 belong to the trials category (*Trials*) with 31 deceptive and 25 truthful clips. The average length of the videos in the dataset is 27.28 seconds, with an average length of 33.02 seconds for the truthful clips and 21.54 seconds for the deceptive clips. Collected trial samples cover famous murder cases, while street interviews cover several topics such as movies, music, politics, and religion. The dataset contains 23 unique female and 39 unique male speakers, with their ages ranging approximately between 16 and 60 years.

2.2 Transcriptions and Nonverbal Behavior Annotations

Our goal is to analyze both verbal and nonverbal behavior to understand their relation to deception.

First, all the video clips were manually transcribed. The transcription was performed by two transcribers using the Elan software (Wittenburg et al., 2006). We asked transcribers to include word repetitions and fillers such as um, ah, and uh, as well as long pauses that were marked using three consecutive dots. The final set of transcriptions contain 7835 words, with an average of 66 words per transcript. Table 1 shows transcriptions of sample deceptive and truthful statements from both trials and reality shows.

Second, we annotate the gestures[1] observed during the interactions in the video clips. We specifically focus on the annotation of facial displays and hand movements, as they have been previously found to correlate with deceptive behavior (Depaulo et al., 2003). The gesture annotation is performed using the MUMIN coding scheme (Allwood et al., 2007).

Gesture Category	Agreement	Kappa
Facial Expressions	72.88%	0.576
Eyebrows	80.51%	0.656
Eyes	68.64%	0.517
Gaze	61.40%	0.432
Mouth Openness	77.97%	0.361
Mouth Lips	82.20%	0.684
Head Movements	55.08%	0.420
Hand Movements	91.53%	0.858
Hand Trajectory	84.75%	0.753
Average	75.00%	0.584

Table 2: Gesture annotation agreement

In the MUMIN scheme, facial displays consist of several different facial expressions associated with eyebrows, eyes, gaze, and mouth. Smile, laughter, and scowl are also included, as well as general head and hand movements.

The multimodal annotation was performed by two annotators using the Elan software (Wittenburg et al., 2006). We decided to perform the gesture annotations at video level, rather than at utterance level, because the overall judgment of truthfulness and deceitfulness is based on the whole video content. During the annotation process, annotators were allowed to watch each video clip as many times as they needed. They were asked to identify the facial displays and hand gestures that were most frequently observed or dominating during the entire clip duration. For each video clip, the annotators had to choose one label for each of the nine gestures listed in Table 3.

Table 3 shows the frequency counts associated with the nine gestures considered during the annotation. Note that the counts under each gesture add up to 118, reflecting the fact that for every gesture, the annotators had to choose one label for every video clip. When none of the labels applied, the "Other" category was selected. In the case of gestures associated with hand movements, the "Other" label also accounted for those cases where the speaker's hands were not moving or were not visible.

After all the video clips were annotated for gestures, the inter-annotator agreement was mea-

[1]As done in the Human-Computer Interaction community, we use the term "gesture" to broadly refer to body movements, including facial expressions and hand gestures.

Label	Count

Table 3: Frequency counts for nine facial displays and hand gestures

sured. Table 2 shows the observed annotation agreement between the two annotators, along with the Kappa statistic. The agreement measure represents the percentage of times the two annotators agreed on the same label for each gesture category. For instance, 72.88% of the time the annotators agreed on the label assigned to the *General Face* category. On average, the observed agreement was measured at 75%, with a Kappa of 0.58 (macro-averaged over the nine categories), which reflects substantial agreement. Observed agreement for Head Movements and Gaze is noticeably lower than other categories, which can be attributed to a higher number of available gesture choices, as seen in Table 3.

3 Features of Verbal and Nonverbal Behaviors

Given the multimodal nature of our dataset, we decided to focus on the linguistic and gesture components. In this section, we describe the sets of features extracted for each modality, which will then be used to build classifiers of deception.

3.1 Verbal Features

We implement three types of features, consisting of unigrams, psycholinguistic features, and syntactic complexity features.

Unigrams. We extract unigrams derived from the bag-of-words representation of the video transcripts. The unigram features are encoded as word frequencies and include all the words present in the transcripts.

Psycholinguistic Features. The Linguistic Word Count (LIWC) is a psycholinguistics lexicon that has been frequently used to incorporate semantic and psychological information into linguistic analysis (Pennebaker and Francis, 1999). It has been successfully used in previous work on deception detection (Newman et al., 2003; Mihalcea and Strapparava, 2009; Ott et al., 2011). We obtain features for each of the 80 psycholinguistic classes present in the lexicon by calculating the percentage of words in the transcription belonging to each class.

Syntactic Complexity. We also extract features to measure the syntactic complexity of the speech produced by the speakers in truthful and deceptive clips. This set of features is motivated by previous research that has suggested that deceivers' speech has lower complexity (Depaulo et al., 2003). We use the tool described in (Lu, 2010), which generates indexes of syntactic complexity, including general complexity metrics, length of production, and amount of coordination. The set of features consists of fourteen indexes including statistics related to T-units, which are linguistic units that include a main clause in addition to attached subordinate clauses. T-unit analysis is extensively used to analyze syntactic complexity in speech and written content. The set of features includes the mean length of sentence, mean length of T-

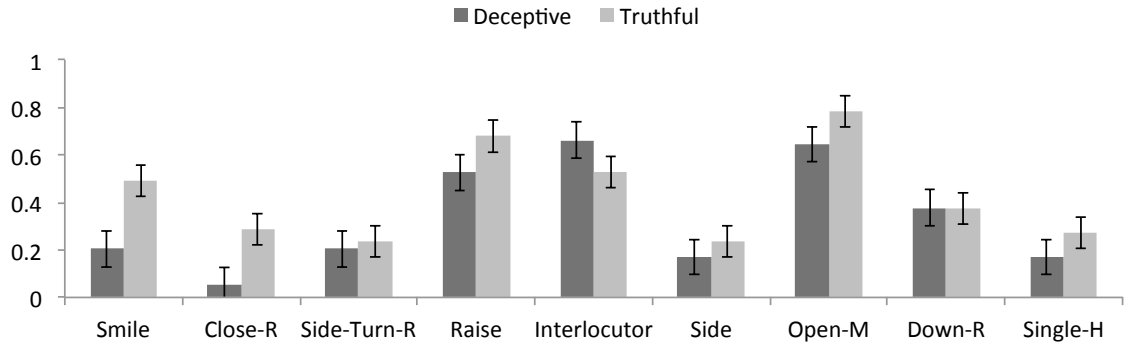

Figure 2: Distribution of nonverbal features for deceptive and truthful groups

unit, mean length of clause, clauses per sentence, verb phrases per T-unit, clauses per T-unit, dependent clauses per clause, dependent clauses per T-unit, T-units per sentence, complex T-unit ratio, coordinate phrases per T-unit, coordinate phrases per clause, complex nominals per T-unit, and complex nominals per clause.

3.2 Nonverbal Features

The nonverbal features are derived from the annotations performed using the MUMIN coding scheme as described in section 2.2. We create a binary feature for each of the 40 available gesture labels. Each feature indicates the presence of a gesture only if it is observed during the majority of the interaction duration. The generated features represent nine different gesture categories covering facial displays and hand movements.

Facial Displays. These are facial expressions or head movements displayed by the speaker during the deceptive or truthful interaction. They include all the behaviors listed in Table 3 under the General Facial Expressions, Eyebrows, Eyes, Mouth Openness, Mouth Lips, and Head Movements.

Hand Gestures. The second broad category covers gestures made with the hands, and it includes the Hand Movements and Hand Trajectories listed in Table 3.

4 Experiments

We start our experiments with an analysis of the nonverbal behaviors occurring in deceptive and truthful videos. We compare the percentage of each behavior as observed in each class. For instance, there is a total of 41 videos in the dataset that include the Smile feature (as shown in Table 3), out of which 12 are part of the deceptive set of 59 videos, and 29 are part of the truthful set (again, of 59 videos). Hence, the percentages for this feature are 20.33% in the deceptive class, and 49.13% in the truthful class. Figure 2 shows the percentages of all the nonverbal features for which we observe noticeable differences for the deceptive and truthful groups. As the figure suggests, facial displays seem to help differentiate between the deceptive and truthful conditions. For instance, we can observe that truth-tellers smile (Smile) and blink more (Close-R). Interestingly deceivers seem to make more eye contact (Interlocutor gaze) and nod (Side-Turn-R) more frequently than truth-tellers. This agrees with the findings in (Depaulo et al., 2003) that liars who are more motivated to get away with their lies (i.e., trials) are likely to increase their eye-contact behavior.

Feature Set	SVM	DT	RF
Unigrams	69.49%	76.27%	67.79%
Psycholinguistic	53.38%	50.00%	66.10%
Syntactic Complexity	52.54%	62.71%	53.38%
Facial Displays	78.81%	74.57%	67.79%
Hand Gestures	59.32%	57.62%	57.62%
Unigr.+Facial Disp.	71.18%	70.33%	68.64%
All Verbal	65.25%	63.55 %	57.62 %
All Nonverbal	75.42%	68.64%	72.03%
All Features	77.11%	69.49%	73.72%

Table 4: Deception classifiers using individual and combined sets of verbal and nonverbal features.

Motivated by these results, we proceed to conduct further experiments to evaluate the performance of the extracted features using a machine learning approach.

Feature Set	SVM
All	**77.11%**
– Hand gestures	74.57%
– Facial displays	64.40%
– Syntactic	76.27%
– Semantic	72.03%
– Unigrams	73.72%

Table 5: Feature ablation study.

We run our learning experiments on the real-deception dataset introduced earlier. Given the even distribution between deceptive and truthful clips, the baseline on this dataset is 50%. For each video clip, we create feature vectors formed by combinations of the verbal and nonverbal features described in the previous section. We build deception classifiers using three classification algorithms: Support Vector Machines (SVM), Decision Trees (DT), and Random Forest (RF).[2] We run several comparative experiments using leave-one-out cross-validation. Table 4 shows the accuracy figures obtained by the three classifiers on the major feature groups described in Section 3. As shown in this table, the facial displays classifier achieves the highest accuracy among the individual classifiers, followed by the unigrams classifier.

We also evaluate classifiers that rely on combined sets of features. The nonverbal features clearly outperform the verbal features, and the classifier that includes all the features improves over the classifiers that rely on all the verbal features or all the nonverbal features. Importantly, several of the classifiers improve significantly over the baseline.

4.1 Analysis of Feature Contribution

To better understand the contribution of the different feature sets to the overall classifier performance, we conduct an ablation study where we remove one group of features at a time. Given that SVM had the best performance in our initial set of experiments, we run all our analysis experiments only using this classifier. Table 5 shows the accuracies obtained when one feature group is removed and the deception classifier is built using the remaining features. From this table, we can again observe that Facial Displays contribute the most to the classifier performance, while Syntactic Features show the lowest contribution.

[2]We use the implementation available in the Weka toolkit with the default parameters.

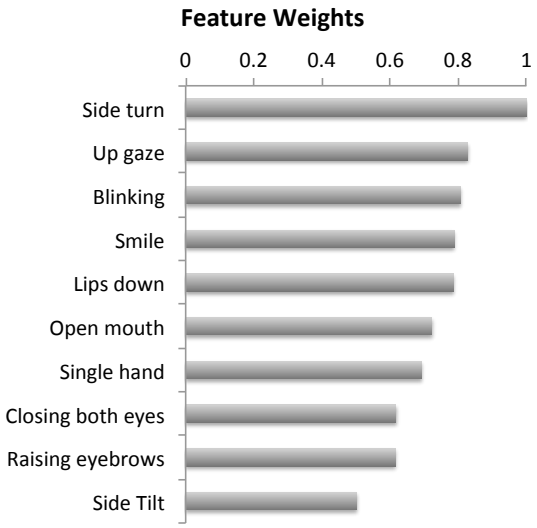

Figure 3: Weights of top nonverbal features

For a closer look at the contribution of individual features included in the group of *Facial Displays*, we analyzed the absolute values of the weights assigned by the learning algorithm to the features in this group. Figure 3 shows the features normalized with respect to the largest feature weight. The five most predictive features are the presence of side turns, up gazes, blinking, and smiling, which we previously identified as possible indicators of deception. This further confirms our initial hypothesis that gestures associated with human interaction are an important component of human deception.

We also analyze the contribution of the linguistic features. Using the linguistic ethnography method (Mihalcea and Pulman, 2009), we obtain the most dominant LIWC word classes associated with deceptive and truthful transcripts extracted from trials and interviews clips. Results are shown in Table 6. Interestingly, the most dominant classes in truthful clips, regardless of being from interviews or trials, correspond to words related to Family, Home, and Humans. This suggests that truth-tellers show similar word usage when interviewed on a real scenario. On the other hand, dominant classes associated to deceivers are less consistent as they discuss aspects related to the topic being discussed. For instance, while being interviewed about a non-existing movie, deceivers talk about their Past, Assent, and use Motion words in order to support their lies. In contrast, while being on trial stating their (false) innocence, they use Anxiety, Anger, and negative emo-

Truthful			
Interviews		Trials	
Class	Score	Class	Score

Motion	1.68	Physical	1.77
Negemo	1.44	Negemo	1.52

Table 6: LIWC word classes most strongly associated with deception and truth.

tion words (class Negemo). In line with earlier observations (Mihalcea and Strapparava, 2009), deceptive texts include more words that reflect certainty (class Certain, with words such as *completely, truly, always*) and more references to others (class Other, with words such as *she, day, him*).

4.2 Domain Experiments

We perform three sets of experiments to determine the role played by the domain. The first set of experiments uses only the *Interviews* video clips (62 in total), and the results are shown in the left column of Table 7. The second set uses only the *Trials* instances (56 in total), with results shown in the right column of Table 7. Finally, we also perform cross-domain experiments, with the training data drawn from one domain and the test data from the other. The results of these experiments are shown in Table 8. Given the uneven distribution of the truthful and deceptive video clips in two domains, the baselines are 54.83% for the *Interviews* domain (34 truthful, 28 deceptive), and 55.35% for the *Trials* domain (25 truthful, 31 deceptive).

What we learn from these experiments is that the domain does matter. Despite the smaller dataset, the experiments run on one domain at a time lead to results that are higher than the ones obtained with more data but with a mix of domains. The cross-domain experiments also support this argument, as the performance drops significantly when there is no overlap in domain between the training and the test instances. Overall, in all our machine learning experiments, the combined classifier that makes use of all the verbal and nonverbal features achieves the best trade-off between performance and robustness, as it always leads to the best or second best performance across all the experiments using individual or combined feature sets. While a classifier based on an individual feature set can sometime lead to a better performance (e.g., the Facial Displays classifier has better performance when all the video clips are used), that same classifier may not perform well in another setting (e.g., the Facial Displays classifier is significantly below the All Features classifier in the domain experiments).

Feature Set	Interviews	Trials
Baseline	54.83%	55.35%
Unigrams	75.80 %	82.14%
Psycholinguistics	59.67%	50.00%
Syntactic Complexity	54.83%	60.71%
Facial Displays	70.96%	80.35%
Hand Gestures	56.45%	48.21%
Unigr.+Facial Disp.	70.96%	76.78%
All Verbal	70.96%	64.28%
All Nonverbal	67.14%	83.92%
All features	79.03%	82.14%

5 Human Performance

An important remaining question is concerned with the human performance on the task of deception detection. An answer to this question can shed light on the difficulty of the task, and can also place our results in perspective.

We conduct a study where we evaluate the human ability to identify deceit when exposed to four different modalities: *Text*, consisting of the language transcript; *Audio*, consisting of the audio track of the clip; *Silent video*, consisting of only the video with muted audio; and *Full video*, where

Modality	Agreement	Kappa
Text	58.80%	0.047
Audio	66.70%	0.288
Silent video	52.00%	0.065
Full Video	61.60%	0.191

Table 9: Agreement among three human annotators on text, audio, silent video, and full video modalities.

	Text	Audio	Silent video	Full video
A1	54.24%	58.47%	50.85%	63.00%
A2	55.93%	67.80%	45.76%	68.00%
A3	65.25%	70.34%	55.93%	71.00%
Sys.	65.75%	NA	75.42%	77.11%

Table 10: Performance of three annotators and the developed automatic system (Sys) on the real-deception dataset over four modalities.

audio and video are played simultaneously. We create an annotation interface that shows an annotator instances for each modality in random order, and ask him or her to select a label of either "Deception" or "Truth" according to his or her perception of truthfulness or falsehood.

To avoid annotation bias, we show the modalities in the following order: first we show either *Text* or *Silent video*, then we show *Audio*, followed by *Full video*. Note that apart from this constraint which is enforced over the four modalities belonging to each video clip, the order in which instances are presented to an annotator is random. Furthermore, the annotators did not have access to any information that would reveal the true label of an instance. The only exception to this could have been the annotators' previous knowledge of some of the public trials in our dataset. A discussion with the annotators after the annotation took place indicated however that this was not the case.

Three annotators labeled all the 118 video clips in the dataset. Since four modalities were extracted from each video, each annotator annotated a total of 412 instances. Annotators were not offered a monetary reward and we considered their judgments to be honest as they participated voluntarily in this experiment. Table 9 shows the observed agreement and Kappa statistics among the three annotators for each modality.[3] The agreement for most modalities is rather low and the Kappa scores range between slight to fair agreement. As noted before (Ott et al., 2011), this low agreement can be interpreted as an indication that people are poor judges of deception.

We also determine each annotator's performance for each modality. The results, shown in Table 10, additionally support the argument that human judges have difficulty performing the deception detection task. An interesting, yet perhaps unsurprising observation is that the human performance increases with the availability of modalities. The poorest accuracy is obtained in *Silent video*, followed by *Text*, *Audio*, and *Full Video* where the judges have the highest performance.

Overall, our study indicates that detecting deception is indeed a difficult task for humans and further verifies previous findings where human ability to spot liars was found to be slightly better than chance (Aamodt and Custer, 2006). Moreover, the performance of the human annotators appears to be significantly below that of our system.

6 Related Work

Verbal Deception Detection. To date, several research publications on verbal-based deception detection have explored the identification of deceptive content in a variety of domains, including online dating websites (Toma and Hancock, 2010; Guadagno et al., 2012), forums (Warkentin et al., 2010; Joinson and Dietz-Uhler, 2002), social networks (Ho and Hollister, 2013), and consumer report websites (Ott et al., 2011; Li et al., 2014). Research findings have shown the effectiveness of features derived from text analysis, which frequently includes basic linguistic representations such as n-grams and sentence count statistics (Mihalcea and Strapparava, 2009), and also more complex linguistic features derived from syntactic CFG trees and part of speech tags (Feng et al., 2012; Xu and Zhao, 2012). Research work has also relied on the LIWC lexicon to build deception models using machine learning approaches (Mihalcea and Strapparava, 2009; Ángela Almela et al., 2012) and showed that the use of psycholinguistic information is helpful for the automatic identification of deceit. Following the hypothesis that deceivers might create less complex sentences in an effort to conceal the truth and being able to recall their lies more easily, several researchers have also studied the relation between text syntactic complexity and deception (Yancheva and Rudzicz, 2013).

Nonverbal Deception Detection. Earlier approaches to nonverbal deception detection relied

[3] Inter-rater agreement with multiple raters and variables. https://mlnl.net/jg/software/ira/

on polygraph tests to detect deceptive behavior. These tests are mainly based on such physiological features such as heart rate, respiration rate, skin temperature. Several studies (Vrij, 2001; Gannon et al., 2009; Derksen, 2012) indicated that relying solely on physiological measurements can be biased and misleading. Chittaranjan et al. (Chittaranjan and Hung, 2010) created an audio visual recording of the "Are you a Werewolf?" game in order to detect deceptive behaviour using non-verbal audio cues and to predict the subjects' decisions in the game. For hand gestures, blob analysis was used to detect deceit by tracking the hand movements of the subjects (Lu et al., 2005; Tsechpenakis et al., 2005), or using geometric features related to the hand and head motion (Meservy et al., 2005). Caso et al. (Caso et al., 2006) identified particular hand gestures that can be related to the act of deception using data from simulated interviews. Cohen et al. (2010) found that fewer iconic hand gestures were a sign of a deceptive narration, and Hillman et al. (2012) determined that increased speech prompting gestures were associated with deception while increased rhythmic pulsing gestures were associated with truthful behavior. Also related is the taxonomy of hand gestures developed by (Maricchiolo et al.,) for deception and social behavior. Facial expressions also played a critical role in the identification of deception. (Ekman, 2001) defined micro-expressions as relatively short involuntary expressions, which can be indicative of deceptive behavior. Moreover, these expressions were analyzed using smoothness and asymmetry measurements to further relate them to an act of deceit (Ekman, 2003). Tian et al. (Tian et al., 2005) considered features such as face orientation and facial expression intensity. Owayjan et al. (Owayjan et al., 2012) extracted geometric-based features from facial expressions, and Pfister and Pietikainen (Pfister and Pietikäinen, 2012) developed a micro-expression dataset to identify expressions that are clues for deception. Recently, features from different modalities were integrated in order to find a combination of multimodal features with superior performance (Burgoon et al., 2009; Jensen et al., 2010). A multimodal deception dataset consisting of linguistic, thermal, and physiological features was introduced in (Pérez-Rosas et al., 2014), which was then used to develop a multimodal deception detection system (Abouelenien et al., 2014). An extensive review of approaches for evaluating human credibility using physiological, visual, acoustic, and linguistic features is available in (Nunamaker et al., 2012).

7 Conclusions

In this paper we presented a study of multimodal deception detection using real-life occurrences of deceit. We introduced a novel dataset covering recordings from public real trials and street interviews, and used this dataset to perform both qualitative and quantitative experiments. Our analysis of nonverbal behaviors occurring in deceptive and truthful videos brought insight into the gestures that play a role in deception. We also built classifiers relying on individual or combined sets of verbal and nonverbal features, and showed that we can achieve accuracies in the range of 77-82%.

Additional analyses showed the role played by the various feature sets used in the experiments, and the importance of the domain. To place our results in perspective and better understand the difficulty of the task, we performed a study of human ability to detect deception, which revealed high disagreement among the annotators. Our automatic system outperforms the human detection of deceit by 6-15%.

To our knowledge this is the first work to automatically detect instances of deceit using both verbal and nonverbal features extracted from real deception data. In order to develop a fully automated deception deception system, our future work will address the use of automatic gesture and facial expression identification and automated speech transcription. Our goal is to move forward towards a real-time deception detection system.

The dataset introduced in this paper is publicly available from http://lit.eecs.umich.edu.

Social Media Text Classification under Negative Covariate Shift

Geli Fei and Bing Liu
University of Illinois at Chicago
Chicago, IL 60607, USA
gfei2@uic.edu, liub@cs.uic.edu

Abstract

In a typical social media content analysis task, the user is interested in analyzing posts of a particular topic. Identifying such posts is often formulated as a classification problem. However, this problem is challenging. One key issue is *covariate shift*. That is, the training data is not fully representative of the test data. We observed that the covariate shift mainly occurs in the negative data because topics discussed in social media are highly diverse and numerous, but the user-labeled negative training data may cover only a small number of topics. This paper proposes a novel technique to solve the problem. The key novelty of the technique is the transformation of document representation from the traditional *n-gram feature* space to a *center-based similarity* (CBS) space. In the CBS space, the covariate shift problem is significantly mitigated, which enables us to build much better classifiers. Experiment results show that the proposed approach markedly improves classification.

1 Introduction

Applications using social media data, such as reviews, discussion posts, and (micro) blogs are becoming increasingly popular. We observed from our collaborations with social science and health science researchers that in a typical application, the researcher first need to obtain a set of posts of a particular topic that he/she wants to study, e.g., a political issue. Keyword search is often used as the first step. However, that is not sufficient due to low precision and low recall. A post containing the keyword "politics" may not be a political post while a post that does not contain the keyword may be a political post. Thus, text classification is needed to make more sophisticated decisions to improve accuracy.

For classification, the user first manually labels a set of relevant posts (positive data) about the political issue and irrelevant posts (negative data) not about the political issue and then builds a classifier by running a learning algorithm, e.g. SVM or naïve Bayes. However, the resulting classifier may not be satisfactory. There may be many reasons. One key reason we observed is that the labeled negative training data is not fully representative of the negative test data.

Let the user-interested topic be P (positive), and the set of all other irrelevant topics discussed in a social media source be $T = \{T_1, T_2, \ldots, T_n\}$, which forms the negative data. n is usually large. However, due to the labor-intensive effort of manual labeling, the user can label only a certain number of training posts. Then the labeled negative training posts may cover only a small number of irrelevant topics S of T ($S \subseteq T$) as negative. Further, due to the highly dynamic nature of social media, it is probably impossible to label all possible negative topics. In testing, when posts of other negative topics in $T–S$ show up, their classification can be unpredictable. For example, in an application, the training data has no negative examples about *sports*. However, in testing, some sports posts show up. These unexpected sports posts may be classified arbitrarily, which results in low classification accuracy. In this paper, we aim to solve this problem.

In machine learning, this problem is called *covariate shift*, a type of *sample selection bias*. In classic machine learning, it is assumed that the training and testing data are drawn from the same distribution. However, this assumption may not hold in practice such as in our case above, i.e., the training and the test distributions are different (Heckman 1979; Shimodaira 2000; Zadrozny 2004; Huang et al. 2007; Sugiyama et al. 2008; Bickel et al. 2009). In general, the sample selection bias problem is not solvable because the two

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2347–2356,
Lisbon, Portugal, 17-21 September 2015.

distributions can be arbitrarily far apart from each other. Various assumptions were made to solve special cases of the problem. One main assumption was that the conditional distribution of the class given a data instance is the same in the training and test data sets (Shimodaira 2000; Huang et al. 2007; Bickel et al. 2009). This gives the *covariate shift* problem.

In this paper, we focus on a special case of the covariate shift problem. We assume that the covariate shift problem occurs mainly in the negative training and test data, and no or minimum covariate shift exists in the positive training and test data. This assumption is reasonable because the user knows the type of posts/documents that s/he is looking for and can label many of them.

Following the notations in (Bickel et al. 2009), our special case of the covariate shift problem can be stated formally as follows: let the set of training examples be $\{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \ldots, (\mathbf{x}_k, y_k)\}$, where $\mathbf{x}_i$ is the data/feature vector and y_i is the class label of $\mathbf{x}_i$. Let the set of test cases be $\{\mathbf{x}_{k+1}, \mathbf{x}_{k+2}, \ldots, \mathbf{x}_n\}$, which have no class labels. Since we are interested in binary classification, y_i is either 1 (positive class) or -1 (negative class). The labeled training data and the unseen test data have the same target conditional distribution $p(y|\mathbf{x})$ and the marginal distributions of the positive data in both the training and testing are also the same. But the marginal distributions of the negative data in the training and testing are different, i.e., $p_L(\mathbf{x}^-) \neq p_T(\mathbf{x}^-)$, where L, T, and $-$ represent the labeled training data, test data, and the negative class respectively.

Existing methods for addressing the covariate shift problem basically work as follows (see the Related Work section). First, they estimate the bias of the training data based on the given test data using some statistical techniques. Then, a classifier is trained on a weighted version of the original training set based on the estimated bias. Requiring the test data to be available in training is, however, a major weakness. In the social media post classification setting, the system needs to constantly classify the incoming data. It is infeasible to perform training constantly.

In this paper, we propose a novel learning technique that does not need the test data to be available during training due to the specific nature of our problem, i.e., the positive training data does not have the covariate shift issue.

One obvious solution to this problem is one-class classification (Schölkopf et al. 1999; Tax and Duin, 1999a), i.e., one-class SVM. We simply discard the negative training posts/documents completely because they have the covariate shift problem. Although this is a valid solution, as we will see in the evaluation section, the models built based on one-class SVM perform poorly. Although it is conceivable to use an unsupervised method such clustering, SVD (Alter et al., 2000) or LDA (Blei et al., 2003), supervised learning usually give much higher accuracy.

In our proposed method, instead of performing supervised learning in the original document space based on n-grams, we perform learning in a similarity space. Thus, the key novelty of the method is the transformation from the original *document space* (DS) to a *center-based similarity space* (CBS). In the new space, the covariate shift problem is significantly mitigated, which enables us to build more accurate classifiers. The reason for this is that in CBS based learning the vectors in the similarity space enable SVM (which is the learning algorithm that we use) to find a good boundary of the positive class data based on similarity and to separate it from all possible negative class data, including those negative data that is not represented in training. We will explain this in greater detail in Section 3.5 after we present the proposed algorithm, which we call CBS-L (for CBS Learning).

This paper makes three contributions: First, it formulates a special case of the covariate shift problem. This case occurs frequently in social media data classification as we discussed above. Second, it proposes a novel CBS space based learning method, CBS-L, which avoids the covariate shift problem to a large extent because it is able to find a good similarity boundary of the positive data. Third, it experimentally demonstrates the effectiveness of the proposed method.

2 Related Work

Traditional supervised learning assumes that the training and test examples are drawn from the same distribution. However, this assumption can be violated in many applications. This is especially the case for social media data because of the high topic diversity and constant changes of topics. This problem is known as *covariate shift*, which is a form of sample selection bias.

Sample selection bias was first introduced in econometrics by Heckman (1979). It came into the field of machine learning through the work of Zadrozny (2004). The main approach in machine learning is to first estimate the distribution bias of the training data based on the test data, and then learn using weighted training examples to

compensate for the bias (Bickel et al. 2009).

For example, Shimodaira (2000) and Sugiyama and Muller (2005) proposed to estimate the training and test data distributions using kernel density estimation. The estimated density ratio is then used to generate weighted training examples. Dudik et al. (2005) and Bickel and Scheffer (2007) used maximum entropy density estimation, while Huang et al. (2007) proposed kernel mean matching. Sugiyama et al. (2008) and Tsuboi et al. (2008) estimated the weights for the training instances by minimizing the Kullback-Leibler divergence between the test and the weighted training distributions. Bickel et al. (2009) proposed an integrated model. As we discussed in the introduction, the need for the test data at the training time is a major weakness for social media data classification. The proposed technique CBS-L doesn't have this restriction.

As mentioned in the introduction, one-class classification is a suitable approach to solve the problem. Tax and Duin (1999a and 1999b) proposed a model for one-class classification called Support Vector Data Description (SVDD) to seek a hyper-sphere around the positive data that encompasses points in the data with the minimum radius. In order to balance between model over-fitting and under-fitting, Tax and Duin (2001) proposed a method that tries to use artificially generated outliers to optimize the model parameters. However, their experiments suggest that the procedure to generate artificial outliers in a hyper-sphere is only feasible for up to 30 dimensions. Also, as pointed out by (Khan and Madden, 2010; 2014), one drawback of their methods is that they often require a large dataset and the methods become very inefficient in high dimensional feature spaces. Since text documents are usually represented in a much higher dimensional space, these methods are less suitable for text applications. Manevitz and Yousef (2001) performed one-class text classification using one-class SVM as proposed by Schölkopf et al. (1999). The method is based on identifying outlier data that are representative of the second class. Instead of assuming the origin is the only member of the outlier class, it assumes those data points with few non-zero entries are also outliers. However, as reported in the paper, their methods produce quite weak results (Schölkopf et al., 1999; 2000). Li et al. (2003) presented an improved version of one-class SVM for detecting anomalies. Their idea is to consider all data points that are close to the origin as outliers. Both (Yang and Madden, 2007) and (Tian and Gu, 2010) tried to refine Schölkopf's models by searching optimal parameters. Luo et al., (2007) proposed a cost-sensitive one-class SVM algorithm for intrusion detection. We will see in the experiment section that one-class classification is far inferior to our proposed CBS-L method.

In this work, we propose to represent documents in the similarity space and thus it is related to works on document representation. Alternative document representations have been proposed in the past and have been shown to perform well in many applications (Radev et al., 2000; He et al., 2004; Lebanon 2006; Ranzato and Szummer, 2008, Wang and Domeniconi, 2008). In (Radev et al., 2000), although the centroid sentence/document vector was computed, it was not transformed to a similarity space vector representation. Wang and Domeniconi (2008) proposed to use external knowledge to build semantic kernels for documents in order to improve text classification. In our problem, the main difficulty is that testing negative documents cannot be well covered in training. It is not clear how the enriched document representations could help solve our problem.

Our work is also related to learning from positive and unlabeled examples, also known as PU learning (Denis, 1998; Yu et al. 2002; Liu et al. 2003; Lee and Liu, 2003; Elkan and Noto, 2008; Li et al. 2010). In this learning model, there is a set of labeled positive training data and a set of unlabeled data, but there is no labeled negative training data. Clearly, their setting is different from ours too. There is also no guarantee that the unlabeled data has the same distribution as the future test data.

Our problem is also very different from domain adaption as we work in the same domain. Due to the use of document similarity, our method has some resemblance to learning to rank (Li, 2011; Liu, 2011). However, CBS-L is very different because we perform supervised classification. Our similarity is also center-based rather than pair-wise document similarity, which is also used in (Qian and Liu 2013) for spam detection.

3 The Proposed CBS Learning

We now formulate the proposed supervised learning in the CBS space, called CSB-L. The key difference between CBS learning and the classic document space (DS) learning is in the document representation, which applies to both training and testing documents or posts. In the next subsection, we first give the intuitive idea

and a simple example. The detailed algorithm follows. In Section 3.5, we explain why CBS-L is better than DS-based learning when unexpected negative data appear in the test set.

3.1 Basic Idea

In the proposed CBS-L formulation, each document d is still represented as a feature vector, but the vector no longer represents the document d itself based on n-grams. Instead, it represents a set of similarity values between document d and the center of the positive documents. Specifically, the learning consists of the following steps:

1. Each document d (in the positive or negative class) is first represented with a set of document representations, i.e., *document space vectors* (*ds-vectors*) based on the document itself as in traditional text classification. Each vector denotes one representation of the document. For example, one representation may be based on only unigrams, and another representation may be based on only bigrams. For simplicity, we use only one representation/vector **x** (e.g., unigrams) here to represent d. Note that we use bold lower case letters to represent vectors. Each feature in a *ds*-vector is called a *ds-feature*.
2. A center vector **c** is then computed for each document representation for the positive class documents using the *ds-vectors* of all positive and negative documents of that representation. **c** is thus also a *ds-vector*.
3. Each document d in the positive and negative class is then transformed to a *center-based similarity space vector* $\mathbf{s}_d$ (called a *cbs-vector*). $\mathbf{s}_d$ consists of a set of similarity values between document d's set of ds-vectors, i.e., {**x**} in our case here (since we use only one representation), and the set of corresponding positive class center vectors, i.e., {**c**} in our case:

   $$\mathbf{s}_d = Sim(\{\mathbf{x}\}, \{\mathbf{c}\}),$$

   where *Sim* is a similarity function consisting of a set of similarity measures. Each feature in $\mathbf{s}_d$ is called an *cbs-feature*. $\mathbf{s}_d$ still has the same original class label as d. Let us see an actual example. We assume that our single center vector for the positive class has been computed (see Section 3.2) based on the unigram representation of documents:

   c: 1:1 2:1 6:2

   where *y*:*z* represents a *ds*-feature *y* (e.g., a word) and its feature value (e.g., term frequency, *tf*). We want to transform the following positive document d_1 and negative document d_2 (*ds-vectors*) to their *cbs*-vectors (the first number is the class):

   d_1: 1 1:2 2:1 3:1 d_2: -1 2:2 3:1 5:2

   If we use *cosine* as the first similarity measure in *Sim*, we can generate a *cbs*-feature 1:0.50 for d_1 (as cosine(c, d_1) = 0.50) and a *cbs*-feature 1:0.27 for d_2 (as cosine(c, d_2) = 0.27). If we have more similarity measures, more *cbs*-features will be produced. The resulting *cbs*-vectors for d_1 and d_2 with their class labels, 1 and -1, are:

   d_1: 1 1:0.50 … d_2: -1 1:0.27 …
4. We now have a binary classification problem in the CBS space. This step simply runs a classification algorithm, e.g., SVM, to build a classifier. We use SVM in our work.

3.2 CBS Based Learning

We are given a binary text classification problem. Let $D = \{(d_1, y_1), (d_2, y_2), \ldots, (d_n, y_n)\}$ be the set of training examples, where d_i is a document and $y_i \in \{1, -1\}$ is its class label. Traditional classification directly uses D to build a binary classifier. However, in the CBS space, we learn a classifier that returns 1 for documents that are "close enough" to the center of the training positive documents and -1 for documents elsewhere.

We now detail the proposed technique. As we mentioned above, instead of using one single *ds*-vector to represent a document $d_i \in D$, we use a set R_d of p *ds*-vectors $R_d = \{\mathbf{x}_1^d, \mathbf{x}_2^d, \ldots, \mathbf{x}_p^d\}$. Each vector $\mathbf{x}_i^d$ denotes one document space representation of the document, e.g., unigram representation. We then compute the center of positive training documents, which is represented as a set of p centroids $C = \{\mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_p\}$, each of which corresponds to one document space representation in R_d. The way to compute each center $\mathbf{c}_i$ is similar to that in the Rocchio relevance feedback method in information retrieval (Rocchio, 1971; Manning et al. 2008), which uses the corresponding *ds*-vectors of all training positive and negative documents. The detail will be given below. Based on R_d for document d and the center C, we can transform a document d from its document space representations R_d to one center-based similarity vector **cbs-v** by applying a similarity function *Sim* on each element $\mathbf{x}_i^d$ of R_d and its corresponding center $\mathbf{c}_i$. We now detail document transformation.

Training document transformation: The train-

ing data transformation from *ds*-vectors to *cbs*-vectors performs the following two steps:

Step 1: Compute the set C of centroids for the positive class. Each centroid vector $\mathbf{c}_i \in C$ is for one document representation $\mathbf{x}_i^d$. And it is computed by applying the Rocchio method to the corresponding *ds*-vectors of all documents in both positive and negative training data.

$$\mathbf{c}_i = \frac{\alpha}{|D_+|} \sum_{\mathbf{ds}_i^d \in D_+} \frac{\mathbf{x}_i^d}{\|\mathbf{x}_i^d\|} - \frac{\beta}{|D - D_+|} \sum_{\mathbf{x}_j^d \in D - D_+} \frac{\mathbf{x}_j^d}{\|\mathbf{x}_j^d\|}$$

where D_+ is the set of documents in the positive class and |.| is the size function. α and β are parameters, which are usually set empirically. It is reported that using *tf-idf* representation, $\alpha = 16$ and $\beta = 4$ usually work quite well (Buckley et al. 1994). The subtraction is used to reduce the influence of those terms that are not discriminative (i.e., terms appearing in both positive and negative documents).

Step 2: Compute the similarity vector **cbs-v**$_d$ (center-based similarity space vector) for each document $d \in D$ based on its set of document space vectors R_d and the corresponding centroids C of the positive documents.

$$\textbf{cbs-v}_d = Sim(R_d, C)$$

Sim has a set of similarity measures, and each measure m_j is applied to p document representations $\mathbf{x}_i^d$ in R_d and their corresponding centers $\mathbf{c}_i$ in C to generate p similarity features (*cbs*-features) in **cbs-v**$_d$. We discuss the *ds*-features and similarity measures for computing *cbs*-features in the next two subsections.

Complexity: The data transformation step is clearly linear in the number of examples, i.e., n.

Test document transformation: For each test document d, we can use step 2 above to produce a *cbs*-vector for d.

3.3 DS-Features

In order to compute *cbs*-features (center-based similarity space features) for each document, we need to have the *ds*-features of a document and the center of the positive class. We discuss *ds*-features first, which are extracted from each document itself.

Since our task is document classification, we use the popular unigram, bigram and trigram with *tf-idf* weighting as the *ds*-features for a document. These three types of *ds*-features also give us three different document representations.

3.4 CBS-Features

Ds-vectors are transformed into *cbs*-vectors by applying a set of similarity measures on each document space vector and the corresponding center vector. In this work, we employed five similarity measures from (Cha, 2007) to gauge the similarity of two vectors. Based on these measures, we produce 15 CBS features using the unigram, bigram, and trigrams representations of each document. The similarity measures we used are listed in Table 1, where P and Q are two vectors and d represents the dimension of P and Q.

$s_{Cos} = \frac{\sum_{i=1}^{d} P_i Q_i}{\sqrt{\sum_{i=1}^{d} {P_i}^2} \sqrt{\sum_{i=1}^{d} {Q_i}^2}}$
$s_{gow} = 1 - \frac{1}{d} \sum_{i=1}^{d} \left\| \frac{P_i}{\sqrt{\sum_{i=1}^{d} {P_i}^2}} - \frac{Q_i}{\sqrt{\sum_{i=1}^{d} {Q_i}^2}} \right\|$
$s_{Lor} = 1 - \sum_{i=1}^{d} ln(1 + \|P_i - Q_i\|)$
$s_{Dice} = \frac{2 \sum_{i=1}^{d} P_i Q_i}{\sum_{i=1}^{d} {P_i}^2 + \sum_{i=1}^{d} {Q_i}^2}$
$s_{jac} = \frac{\sum_{i=1}^{d} P_i Q_i}{\sum_{i=1}^{d} {P_i}^2 + \sum_{i=1}^{d} {Q_i}^2 - \sum_{i=1}^{d} P_i Q_i}$

Table 1: similarity measures for CBS-Features

3.5 Why Does CBS Space Learning Work?

We now try to explain why CBS learning (CBS-L) can deal with the covariate shift problem, and thus can perform better than document space learning. The reason is that due to the use of similarity features, CBS-L is essentially trying to generate a boundary for the positive training data because similarity is not directional and thus covers all directions in a spherical shape in the space. In classification, the negative data from anywhere or direction outside the spherical shape can be detected. The covariate shift problem will not affect the classification much. Many types of documents that are not represented in the negative training data will still be detected due to their low similarity. For example, in Figure 1, we want to build a SVM classifier to separate positive data represented as black squares and negative data represented as empty circles. The constructed CBS-L classifier would look like a circle (in dashed line) in the original document space

covering the positive data. The size of this (boundary) circle depends on the separation margin between the two classes. Although data points represented by empty triangles are not represented in the negative training data (which has only empty circles) in building the classifier, our classifier is able to identify them as *not positive* at the test time because they are outside the boundary circle.

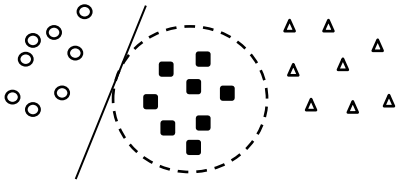

Figure 1: CBS learning vs. DS learning.

If we had used the document space (DS) features to build a SVM classifier, the classifier would be a line (see Figure 1) between the positive data (black squares) and the negative data (empty circles). This line unfortunately will not be able to identify data points represented as empty triangles as not positive because the triangles actually lie on the positive side and would be classified as positive, which is clearly wrong.

4 Experiments

In this section, we evaluate the proposed learning in the center-based similarity space (CBS-L) and compare it with baselines.

4.1 Experimental Dataset

As stated at the beginning of the paper, this work was motivated by the real-life problem of identifying the right social media posts or documents for specific applications. For an effective evaluation, we need a large number of classes in the data to reflect the topic richness and diversity of the social media. The whole data also has to be labeled for evaluation. Using online reviews of a large number of products is a natural choice because there are many types of products and services and there is no need to do manual labeling, which is very labor intensive, time consuming, and error prone. We obtained the Amazon review database from the authors of (Jindal and Liu 2008), and constructed a dataset with reviews of 50 types of products, which we also call 50 topics. Each topic (a type of products) have 1000 reviews. For each topic, we randomly sampled 700 reviews/documents for training and the remaining 300 reviews for testing. Note that although we use this product review collection, we do not perform sentiment classification. Instead, we still perform the traditional topic based classification. That is, given a review, the system decides what type of product the review is about. In our experiments, we use every topic as the positive class. This gives us 50 classification results.

4.2 Baselines

We use three baselines in our evaluation.

Document space one-class SVM (ds-osvm): As we discussed earlier, due to the covariate shift problem in the negative training data, one solution is to drop the negative training data completely to build a one-class classifier. One-class SVM is the state-of-the-art one-class classification algorithm. We apply one-class SVM to the documents in the document space as one of the baselines. One-class SVM was first introduced by Schölkopf et al. (1999; 2000), which is based on the assumption that the origin is the only member of the second class. The data is first mapped into a transformed feature space via a kernel and then standard two-class SVM is employed to construct a hyper-plane that separates the data and the original with maximum margin. As mentioned earlier, there is also the support vector data description (SVDD) formulation for one-class classification proposed by Tax and Duin (1999a; 1999b). SVDD seeks to distinguish the positive class from all other possible data in space. It basically finds a hyper-sphere around the positive class data that contains almost all points in the data set with the minimum radius. It has been shown that the use of Gaussian kernel makes SVDD and One-class SVM equivalent, and the results reported in (Khan and Madden, 2014) demonstrate that SVDD and One-class SVM are comparable when the Gaussian kernel is applied. Thus in this paper, we just use one-class SVM, which is one of the SVM-based classification tools in the LIBSVM[1] library (version 3.20) (Chang and Lin, 2011).

Center-based similarity space one-class SVM (cbs-osvm): Instead of applying one-class SVM to documents in the original document space, this baseline applies it to the CBS space after the documents are transformed to CBS vectors.

SVM: This baseline is the SVM applied in the original document space. Although in this case, there is covariate shift problem, we want to see how serious the problem might be, and how the proposed CBS-L technique can deal with the

problem. We use the SVM tool in LIBSVM.

4.3 Kernels and Parameters

As Khan and Madden (2014) pointed out that one-class SVM performs the best when Gaussian kernel is used, we use Gaussian kernel as well. Manevitz and Yousef (2001) applied one-class SVM to text classification, and the authors reported that one-class SVM works the best with binary feature weighting scheme compared to *tf* or *tf-idf* weighting schemes. Also, they reported that a small number of features (10) with highest document frequency performed the best with Gaussian kernel. We also use binary representation, but found that 10 features are already too many in our case. In fact, 5 features give the best results. Using a small number of features is intuitive because to find the boundary of a very high dimensional space is very difficult. We also tried more features but they were poorer.

For SVM classification in the document space, we use the linear kernel as it has been shown by many researchers that the linear kernel performs the best (e.g., Joachims, 1998; Colas and Brazdil, 2006). We experimented with RBF kernels extensively, but they did not perform well with the traditional document representation. The term weighting scheme is *tf-idf* (Colas and Brazdil, 2006) with no feature selection.

For our proposed method CBS-L, we use *tf-idf* values of unigram, bigram and trigram to represent a document in three ways in the document space. As mentioned earlier, five document similarity functions are used to transform document space vectors to CBS space vectors. And in order to filter out less useful features for the center vector of the positive class, we performed feature selection in the document space using the classic information gain method (Yang and Pedersen, 1997) to empirically choose the most effective 100 features for the positive class.

For all the kernels, we use the default parameter settings in the LIBSVM systems. We tried to tune the parameters, but did not get better results.

4.4 Results

We now present the experiment results. As mentioned above, we treat each topic as the positive class. This gives 50 tests. To test the effect of covariate shift, we also vary the number of topics in the negative class. We used 10, 20, 30, and 40 topics in the training negative class. The test set always has 49 topics of negative data.

For each setting, we give three sets of results for the positive class, which is the target topic data that we are interested in obtaining through classification. Each set of results includes the standard measures of precision, recall, and F1-score for the positive class. The three sets are:

1. *In-training*: In this case, the test negative data

contains only data from those topics used in training. This is the classical supervised learning setting where the training and test data are randomly drawn from the same distribution.

2. *Not-in-training*: In this case, the test negative set contains only data from the other topics not used in training. The classical setting of supervised learning does not deal with this problem. This represents covariate shift.
3. Combined: In this case, the test data contains both in-training and not-in-training negative topics. Due to the use of not-in-training test data, this is also not the classical setting.

Due to a large number of experiment results, we cannot report all the details. Table 2 summarizes the results. Notice that for ds-osvm, it does not make sense to have in-training and not-in-training results because it does not use any training negative data. Thus, there is only one set of results for "Combined," which is duplicated in the table for easy comparison. However, note that cbs-osvm uses negative data for training in order to compute the center for the positive class.

From the table, we can make the following observations (since there are many numbers, we only focus on F1-scores).

1. The proposed CBS-L method performs markedly better than all baselines. For the results of in-training, not-in-training, and combined, CBS-L is consistently better in all cases than all baselines. Even for in-training, CBS-L perform better than SVM. This clearly shows the superiority of the proposed CBS-L method.
2. ds-osvm performs poorly. cbs-osvm is much better because it uses the negative data in feature selection and center computation.
3. SVM in the document space performed poorly (Combined) when only a small number of negative topics are used in training. It gets better than both one-class SVM baselines when more negative topics are used in training (see the reason in the next point).
4. Finally, we can also see that with the number of training negative topics increases, the results of the combined case of both SVM and CBS-L improve. This is expected because with the increased number of negative topics for training, the number of not-in-training negative topics for testing decreases and the covariate shift problem gets smaller. We can also see that cbs-osvm, SVM and CBS-L's F1-scores for not-in-training improve with the increased training negative topics due to the same reason. However, their F1-scores drop for in-training because with more negative

Table 3: F1-score for each positive topic or class in the combined case

topics, the data becomes more skewed, which hurts in-training classification.

To give a flavor of the detailed results for each topic (product), we give the full results for one setting with 30 randomly selected topics as the training negative data (Table 3). The results in the table are F1-scores of the combined case.

5 Conclusion

The ability to get relevant posts accurately about a topic from social media is a challenging problem. This paper attempted to solve this problem by identifying and dealing with the technical issue of covariate shift. The key idea of our technique is to transform document representation from the traditional n-gram feature space to a similarity based space. Our experimental results show that the proposed method CBS-L outperformed strong baselines by large margins.

Co-Training for Topic Classification of Scholarly Data

Abstract

With the exponential growth of scholarly data during the past few years, effective methods for topic classification are greatly needed. Current approaches usually require large amounts of expensive labeled data in order to make accurate predictions. In this paper, we posit that, in addition to a research article's textual content, its citation network also contains valuable information. We describe a co-training approach that uses the text and citation information of a research article as two different views to predict the topic of an article. We show that this method improves significantly over the individual classifiers, while also bringing a substantial reduction in the amount of labeled data required for training accurate classifiers.

1 Introduction

As science advances, scientists around the world continue to produce a large number of research articles, which provide the technological basis for worldwide dissemination of scientific discoveries. Online digital libraries such as Google Scholar, CiteSeer^{x}, and PubMed store and index millions of such research articles and their metadata, and make it easier for researchers to search for scientific information. These libraries require *effective* and *efficient* methods for topic classification of research articles in order to facilitate the retrieval of content that is tailored to the interests of specific individuals or groups. Supervised approaches for topic classification of research articles have been developed, which generally use either the content of the articles (Caragea et al., 2011), or take into account the citation relation between research articles (Lu and Getoor, 2003).

To be successful, these supervised approaches assume the availability of large amounts of labeled data, which require intensive human labeling effort. In this paper, we explore a semi-supervised approach that can exploit large amounts of unlabeled data together with small amounts of labeled data for accurate topic classification of research articles, while minimizing the human effort required for data labeling. In the scholarly domain, research articles (or papers) are highly interconnected in giant citation networks, in which papers cite or are cited by other papers. We posit that, in addition to a document's textual content and its local neighborhood in the citation network, other information exists that has the potential to improve topic classification. For example, in a citation network, information flows from one paper to another via the citation relation (Shi et al., 2010). This information flow and the topical influence of one paper on another are specifically captured by means of citation contexts, i.e., short text segments surrounding a citation's mention.

These contexts are not arbitrary, but they often serve as brief summaries of a cited paper. We therefore hypothesize that these *micro-summaries* can be successfully used as an independent view of a research article in a co-training framework to reduce the amount of labeled data needed for the task of topic classification.

The idea of using terms from citation contexts stems from the analysis of hyperlinks and the graph structure of the Web, which are instrumental in Web search (Manning et al., 2008). Many search engines follow the intuition that the anchor text pointing to a page is a good descriptor of its content, and thus anchor text terms are used as additional index terms for a target webpage. The use of links and anchor text was thoroughly researched for information retrieval (Koolen and Kamps, 2010), broadening a user's search (Chakrabarti et al., 1998), query refinement (Kraft and Zien, 2004), and enriching document representations (Metzler et al., 2009). Blum and

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2357–2366,
Lisbon, Portugal, 17-21 September 2015.

Mitchell (1998) introduced the co-training algorithm using hyperlinks and anchor text as a second, independent view of the data for classifying webpages, in addition to a webpage content.

Contributions and Organization. We present a co-training approach to topic classification of research papers that effectively incorporates information from a citation network, in addition to the information contained in each paper. The result of this classification task will aid indexing of documents in digital libraries, and hence, will lead to improved organization, search, retrieval, and recommendation of scientific documents. Our contributions are as follows:

- We propose the use of citation contexts as an additional view in a co-training approach, which results in high accuracy classifiers. To our knowledge, this has not been addressed in the literature.
- We show experimentally that our co-training classifiers significantly outperform: (1) supervised classifiers trained using either content or citation contexts independently, for the same fraction of labeled data; and (2) several other semi-supervised classifiers, trained on the same fractions of labeled and unlabeled data as co-training.
- We also show that using the citation context information available in citation networks, the human effort involved in data labeling for training accurate classifiers can be largely reduced. Our co-training classifiers trained on a very small sample of labeled data and a large sample of unlabeled data yield accurate topic classification of research articles.

The rest of the paper is organized as follows. In Section 2, we discuss related work. Section 3 describes our data and its characteristics, followed by the presentation of our proposed co-training approach in Section 4. We present experiments and results in Section 5, and conclude the paper and present future directions of our work in Section 6.

2 Related Work

We discuss here the most relevant works to our study. A large variety of methods have been proposed in the literature with regard to automatic text classification and topic prediction. Different classifiers have been applied on the Vector Space Model (VSM), in which a document is represented as a vector of words or phrases associated with their TF-IDF score, i.e. *term frequency - inverse document frequency* (Zhang et al., 2011; Kansheng et al., 2011). VSM is the most used method due to its simple, efficient and easy to understand implementation. Another widely used model is the Latent Semantic Indexing (LSI) where co-occurrences are analyzed to find semantic relationships between words or phrases (Zhang et al., 2011; Ganiz et al., 2011). Moreover, a great range of classifiers were used for this task, including: Naïve Bayes (Lewis and Ringuette, 1994), K-nearest neighbors (Yang, 1999) and Support Vector Machines (Joachims, 1998). These techniques, however, all require a large number of labeled documents in order to build accurate classifiers. In contrast, we propose a co-training algorithm that only requires a small amount of labeled data in order to make accurate topic classification.

Semi-supervised methods essentially involve different means of transferring labels from *labeled* to *unlabeled* samples in the process of learning a classifier that can generalize well on new unseen data. Co-training was originally introduced in (Blum and Mitchell, 1998) where it was used to classify web pages into *academic course home page* or not. This approach has two views of the data as follows: the content of a web page, and the words found in the anchor text of the hyperlinks that point to the web page. Wan (2009) used co-training for cross-lingual sentiment classification of product reviews, where English and Chinese features were considered as two independent views of the data. Furthermore, Gollapalli et al. (2013) used co-training to identify authors' homepages from the current-day university websites. The paper presents novel features, extracted from the URL of a page, that were used in conjunction with content features, forming two complementary views of the data.

Citation networks have been used before in other problems. Caragea et al. (2014) used citation contexts to extract informative features for keyphrase extraction. Lu and Getoor (2003) proposed an approach for document classification that used only citation links, without any textual data from the citation contexts. Ritchie et al. (2006) used a combination of terms from citation contexts and existing index terms of a paper to improve indexing of cited papers. Citation contexts were also used to improve the performance of citation recommendation systems (Kataria et al., 2010) and to study author influence in document networks

(Kataria et al., 2011). Moreover, citation contexts were used for scientific paper summarization (Abu-Jbara and Radev, 2011; Qazvinian et al., 2010; Qazvinian and Radev, 2008; Mei and Zhai, 2008; Lehnert et al., 1990) For example, in Qazvinian et al. (2010), a set of important keyphrases is extracted first from the citation contexts in which the paper to be summarized is cited by other papers and then the "best" subset of sentences that contain such keyphrases is returned as the summary. Mei and Zhai (2008) used information from citation contexts to determine what sentences of a paper are of high impact (as measured by the influence of a target paper on further studies of similar or related topics). These sentences constitute the impact-based summary of the paper.

Despite the use of citation contexts and anchor text in many information retrieval and natural language processing tasks, to our knowledge, we are the first to propose the incorporation of citation context information available in citation networks in a co-training framework for topic classification of research papers.

3 Data

The dataset used in our experiments is a subset sampled from the CiteSeer^x digital library[1] and labeled by Dr. Lise Getoor's research group at the University of Maryland. This subset was previously used in several studies including (Lu and Getoor, 2003) and (Kataria et al., 2010). The dataset consists of 3186 labeled papers, with each paper being categorized into one of six classes: Agents, Artificial Intelligence (AI), Information Retrieval (IR), Machine Learning (ML), Human-Computer Interaction (HCI) and Databases (DB). For each paper, we acquire the citation contexts directly from CiteSeer^x. A citation context is defined as a window of n words surrounding a citation mention. We differentiate between cited and citing contexts for a paper as follows: let d be a target paper and $\mathcal{C}$ be a citation network such that $d \in \mathcal{C}$. A *cited context* for d is a context in which d is cited by some paper d_i in $\mathcal{C}$. A *citing context* for d is a context in which d is citing some paper d_j in $\mathcal{C}$. If a paper is cited in multiple contexts within another paper, the contexts are aggregated into a single context. For each paper in the dataset, we have at least one cited or one citing context. A summary of the dataset is provided in Table 1.

[1] http://citeseerx.ist.psu.edu/

Number of papers in each class						
Agents	AI	IR	ML	HCI	DB	Total
562	239	641	569	490	685	3186

Avg. Cited Contexts	Avg. Citing Contexts
45.59	20.77

Table 1: Dataset summary.

As expected, we have a higher number of cited contexts than citing contexts. This is due to the page restrictions often imposed to research articles that can limit the number of papers each article can cite. On the other hand, a good research paper can accumulate hundreds of citations, and hence, cited contexts over the years.

Context lengths. In CiteSeer^x, citation contexts have about 50 words on each side of a citation mention. A previous study by Ritchie et al. (2008) shows that a fixed window length of about 100 words around a citation mention is generally effective for information retrieval tasks. For this reason, we use the contexts provided by CiteSeer^x directly. In future, it would be interesting to study more sophisticated approaches to identifying the text that is relevant to a target citation (Abu-Jbara and Radev, 2012; Teufel, 1999) and study the influence of context lengths on our task.

For all experiments, our labeled dataset is split in train, validation and test sets. The validation and test sets have about 200 papers each. We sampled another set of papers from the labeled dataset in order to simulate the existence of unlabeled data, with a fixed size of around 2000 papers. The remaining 786 papers are used as labeled training data. Each experiment was repeated 10 times with 10 different random seeds and the results were averaged.

4 Co-Training for Topic Classification

Blum and Mitchell (1998) proposed the co-training algorithm in the context of webpage classification. In co-training, the idea is that two classifiers trained on two different views of the data teach one another by re-training each classifier on the data enriched with predicted examples that the other classifier is most confident about. In Blum and Mitchell (1998), webpages are represented using two different views: (1) using terms from webpages' content and (2) using terms from the anchor text of hyperlinks pointing to these pages.

Algorithm 1 Co-Training

    $U \leftarrow U \cup [S \backslash (S_1 \cup S_2)]$
  end while
Ouput: The combined classifier C of C_1 and C_2

In this paper, we study the applicability and extension of the co-training algorithm to the task of topic classification of research papers, which are embedded in large citation networks. Here, in addition to the information contained in a paper itself, *citing* and *cited* papers capture different aspects (e.g., topicality, domain of study, algorithms used) about the target paper (Teufel et al., 2006), with *citation contexts* playing an instrumental role. We conjecture that citation contexts, which act as brief summaries about a cited paper, provide important clues in predicting the topicality of a target paper. These clues give rise to the design of our co-training based model for topic classification of research papers. In our model, we use the content of a paper as one view and the citation contexts as another view of our data. In particular, for the content of a paper, we use its title and abstract as it is commonly used in the literature (Lu and Getoor, 2003); for the citation contexts, we use both the cited and citing contexts, as described in the previous section.

Our co-training procedure is described in Algorithm 1. L and U represent the labeled and unlabeled datasets and contain instances from both views. The fractions of the training set are obtained from the 786 papers by selecting $k\%$ random examples from each class. For a round of co-training, we train classifiers C_1 and C_2 on the two views. Next, s examples are sampled from the unlabeled data into S, and C_1, C_2 are used to obtain predictions for these s examples. The *GetMostConfidentExamples* method is a generic placeholder that stands for a function that determines what examples from S are chosen to be added into training. Finally, at the end of an iteration, the examples left into S are moved back to U, and the algorithm iterates until there are no more unlabeled examples in U. The final classifier C is obtained by combining C_1 and C_2 using the product of their class probability distributions. The class with the highest posterior probability (of the product of the two distributions) is chosen as the predicted class.

Unlike the original co-training algorithm described by Blum and Mitchell (1998), which tackled a binary classification task (*course* vs. *non-course* page classification), we address a multi-class classification problem, where each example (i.e., research paper) is classified into one of six different classes. Moreover, in Blum and Mitchell (1998), the co-training algorithm moves p highest confidence positive examples and n highest confidence negative examples from S to L, where $p : n$ represents the class distribution in the original labeled training set (i.e., if there are 10 positive examples and 90 negative examples in the labeled set L, then $p = 1$ positive and $n = 9$ negative examples are moved to the labeled set at each iteration of co-training). Unlike, this approach that preserves the class distribution of the original labeled training set, we move into L all examples that are classified with a confidence above a certain threshold.

5 Results and Discussion

First, the proposed method is evaluated on the validation set. We first compare it against various supervised and semi-supervised baselines. Next, we report the performance of our co-training algorithm under different scenarios, where either cited or citing contexts are used. We also show the most informative words for each classifier. Finally, with the best parameters obtained on the validation set, we report the precision, recall and F1-score, obtained by each method, on the test set.

In experiments, the sample size 's' from Algorithm 1 is set to 300, i.e. the number of documents sampled from the unlabeled pool at each iteration; the confidence threshold is set to 0.95, i.e. if both classifiers agree on the class label and have a confidence ≥ 0.95, the instance is labeled and moved into the labeled training set. These parameters are estimated on the validation set, but the results are not shown due to space limitation.

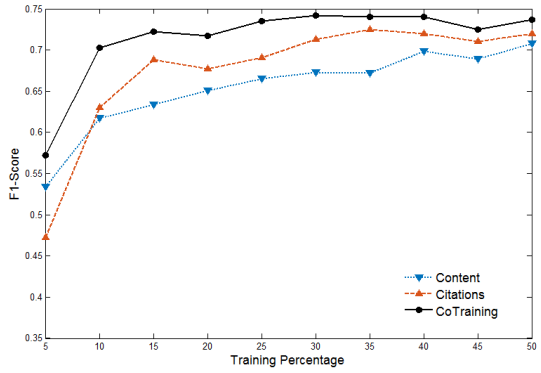

Figure 1: Co-Training vs. Supervised Learning.

Evaluation Measures. We report results averaged over ten different runs with random splits. For each random split, we return the weighted average precision, recall and F1-score. In all the experiments, we use the Naïve Bayes Multinomial classifier and its Weka implementation[2], with term-frequencies as feature values. We experimented with both TF and TF-IDF scores, using different classifiers (Support Vector Machine, Naïve Bayes Multinomial, and simple Naïve Bayes classifiers), but Naive Bayes Multinomial with TF performed best.

5.1 Baseline Comparisons

How does co-training compare with supervised learning techniques? In this experiment, we compare our co-training method with two supervised baselines: (1) when only document content is used and (2) when only citation contexts are used.

Figure 1 shows the F1-scores achieved using different initial training sizes. We can see that overall, the citation contexts are better at predicting the topic of a document compared with the content, outperforming them in 9 out of 10 experimental settings. The only exception to this trend is when a small number (5%) of training instances is available, in which case the supervised content view performs better, reaching an F1-score of 0.534. Regardless, the co-training method shows significant improvement over both baselines, in all experiments. Starting with an F1-score of 0.572, it continues to improve its performance as the training percentage is increasing. The maximum F1-score, i.e. 0.742, is reached when 30% of the labeled training set is used. Note that the difference in performance between co-training and the two supervised baselines is statistically significant for a p value of 0.05.

A fully supervised baseline that uses 100% of the training set achieves an F1-score of 0.720 (using content) and 0.738 (using citation contexts). In contrast, co-training requires only 15% of the labeled training set to outperform the fully supervised content baseline and 30% of the training set to outperform the fully supervised citation contexts baseline. Consequently, using a co-training approach that includes citation contexts as well as the document content can not only increase the performance, but will also significantly reduce the need of expensive labeled instances.

Figure 2 illustrates the confusion matrices of three experiments: (a) supervised content view, i.e. the title and abstract, (b) supervised citation contexts view, and (c) co-training that uses both views. These experiments use 10% of the training set. Each of the matrices are represented by a heat map, i.e. the redder the color, the higher the value assigned to that position. An accuracy of 1 will be represented by a matrix with red blocks on the main diagonal and white blocks everywhere else. This experiment was performed 10 times with 10 different seeds and the results have been averaged.

As can be seen, the matrix that uses only titles and abstracts, i.e. left side, is showing the highest percentage of misclassified documents, classifying correctly about 58.8% instances, on average. Using only citation contexts in a supervised framework, i.e. center matrix, we reach a higher accuracy of 60.7%. The co-training method, which uses the content of the paper and citations as two independent views, significantly increases the average accuracy to 67.3%. This experiment shows that citation contexts are better than titles and abstracts at predicting the topic of a document. Furthermore, our proposed approach, which uses the content of the paper as well as citation contexts, achieves higher results than each view used separately. The difference in accuracy is statistically significant across all three experiments for a p value of 0.05.

Overall, the *Agents* class seem to be the easiest to classify, reaching an accuracy value of 91.6% when using co-training. On the other hand, the *AI* class is the hardest to classify. One reason for this is that the *AI* class contains the lowest number of instances in the dataset. Another can be that the *AI* class is the most general among all classes and therefore, classifying documents with this la-

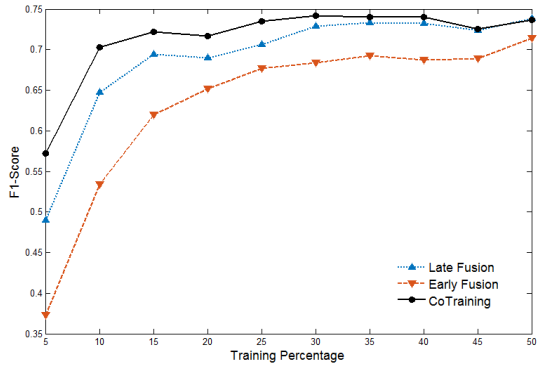

Figure 3: Co-Training vs. Early and Late Fusion.

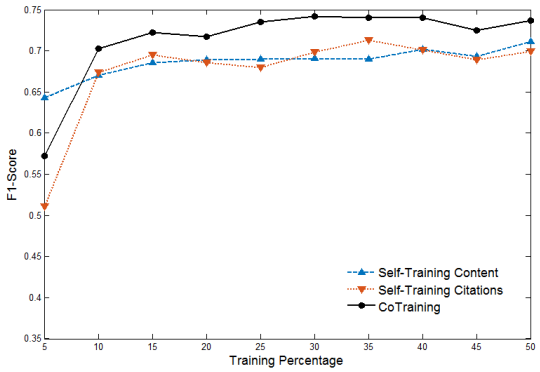

Figure 4: Co-Training vs. Self-Training.

bel can be a difficult task even for a human. Other common misclassifications occur between classes like *HCI* and *Agents*, *ML* and *IR* or *AI* and *ML*, due to their similarity.

How does our co-training method compare with other supervised approaches? In this experiment, we compare the performance of co-training against two other methods: early and late fusion. In early fusion, the feature vectors of the two views are concatenated, creating a single representation of the data. In contrast, late fusion trains two separate classifiers and then combines them by taking the label with the highest confidence.

Figure 3 shows this comparison over different training sizes. The results show that the co-training method is more accurate than all others, performing best in all 10 experimental settings. Late fusion has an overall lower performance compared with co-training, but is in a tight correlation with it. On the other hand, early fusion achieves the lowest F1-score across the experiments. The reported results are statistically significant at p value of 0.05, when the training percentage is between 5 and 35. Therefore, we can say that training two separate classifiers, one of each view, yields higher performance compared with training a single classifier that incorporates both views. Moreover, using a co-training approach that incorporates information from unlabeled data into the model, will help the two classifiers increase their confidences and minimize the error rate.

How does co-training compare with semi-supervised methods? Here, we present results comparing co-training with two other well-known semi-supervised techniques: self-training and Naïve Bayes with Expectation Maximization.

Self-Training. First, we show results of the comparison of co-training with two variations of self-training: (1) self-training using only document content, and (2) self-training using only citation contexts. Figure 4 shows the results of this experiment. Self-training is similar to co-training, except that it uses only one view of the data (Zhu, 2005). Self-training parameters, e.g., sample size 's' or number of iterations, are estimated as in co-training.

Although the document content version of self-training outperforms co-training when using 5%

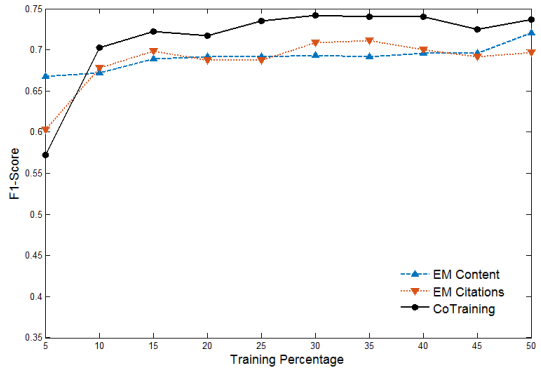

Figure 5: Co-Training vs. EM.

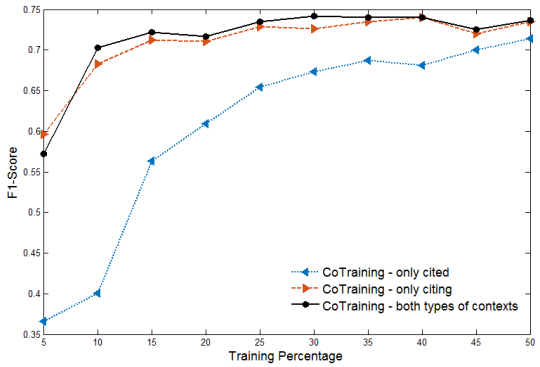

Figure 6: Performance when using only cited / only citing / or both citation contexts.

of the training instances, we can see that overall, there is a significant difference in terms of F1-score values in the favor of co-training. In 9 out of 10 experiments, our co-training approach is superior to both self-training methods. The results are statistically significant across all experimental setups for a p value of 0.05.

Expectation Maximization. Figure 5 shows the F1-score values obtained after running NBM with EM with the same training, unlabeled and test sets. The EM algorithm uses the same classifier, i.e. NBM, and the weight for each unlabeled instance is set to 1, as this setting achieved the highest results. Two different experiments were performed using EM: (1) using only document content, and (2) using only citation contexts. As can be seen in the figure, overall, the co-training approach significantly outperforms both variations of EM. However, the co-training method falls short when using 5% of the training instances, where *EM Content* and *EM Citations* methods are achieving higher F1-score values. Nonetheless, both EM variations tend to achieve an F1-score value below or equal to 0.710, whereas co-training reaches performance values of 0.74 or higher. Again, the comparison results between co-training and both variations of EM are statistically significant for training sizes between 10% and 50%, for a p value of 0.05.

5.2 Using Different Citation Context Types

Which of the two types of citation contexts (cited or citing) help the task of topic classification more and how does co-training perform in the absence of either one? The answer to this question is important as there are cases in which citation contexts are not readily available. One frequently encountered example includes newly published research papers that have no cited contexts. In this case, it is important to know how our method performs when we only have one type of citation contexts. Figure 6 shows the difference in performance when using: (1) only cited contexts, (2) only citing contexts, and (3) both context types. Note that the content view remains the same across all three experiments.

The plot is showing that citing contexts are bringing in a significantly higher margin of knowledge compared with cited contexts. This is consistent over different training set sizes, as shown in the figure, with a more prominent impact when a small training size is used, i.e. 5-30%. The fact that the citing contexts achieve higher F1-score than cited contexts is consistent with the intuition that when citing a paper y, an author generally summarizes the main ideas from y using important words from a target paper x, making the citing contexts to have higher overlap with words from x. In turn, a paper z that cites x may use paraphrasing to summarize ideas from x with words more similar to those from the content of z.

When the two types of contexts are used, co-training achieves higher results compared with cases when only one context type is used. This experiment shows that our method can be applied for both old and new research articles. Citing contexts will be available in the text of the target paper and are independent of the existence of the cited contexts.

5.3 Informative Features

What are the most informative words from each view: document content and citation contexts? Figure 7 shows the words from each view that are most useful for our topic classification task. The larger the word, the more informative is for our

Figure 7: Most informative words from document content (left) and citation contexts (right).

Method	Labeled docs. (%)	Precision	Recall	F1-Score
Co-Training	**30**	**0.749**	**0.743**	**0.742**
Co-Training - only citing	40	0.747	0.740	0.740
Co-Training - only cited	50	0.724	0.717	0.714
Self-Training - Content	50	0.723	0.711	0.711
Self-Training - Citations	35	0.730	0.710	0.713
EM - Content	50	0.738	0.714	0.721
EM - Citations	35	0.729	0.707	0.711
Early Fusion	50	0.718	0.710	0.714
Late Fusion	50	0.748	0.734	0.738
Content - Fully Supervised	100	0.730	0.728	0.720
Citations - Fully Supervised	100	0.745	0.740	0.738

Table 2: A comparison of all methods on the test set.

task. To determine the informativeness of a word, we used its Information Gain score. For these experiments, we used training sets consisting of 30% of the instances, setting in which we achieved the best results on the validation and test sets using our proposed co-training approach.

As can be seen, the two word clouds have a high word overlap. Words such as *agent*, *database* or *query* are almost equally important in the two views, dominating both clouds. However, differences can be observed. For example, words like *learning*, *multi-agent* or *interface* are more important in the content view. On the other hand, words such as *document* or *text* achieve a higher information gain score for the citation contexts view.

5.4 Co-Training vs. All Other Approaches

Table 2 summarizes the results obtained by all the baselines used so far, in comparison with our proposed co-training method. For this experiment, we show the training percentage used, the precision, recall and F1-score for each method, in the setting in which it returned the best results. All measures were averaged after 10 runs with 10 different seeds.

The results in Table 2 show that the proposed co-training method outperforms all compared models, reaching the highest F1-score of 0.742, while using the smallest amount of labeled documents, i.e. 30%. Using only the citing contexts, the performance is similar to that of co-training when both context types are used. However, using only the cited contexts, the performance decreases compared to that of the full model that uses both context types. We see that the citing contexts perform better, reaching an F1-score value of 0.740 compared against 0.714 when only cited contexts are used. Moreover, the method that uses only the citing contexts is using 10% less labeled data.

Self-training and EM show decreased performance compared with co-training. Late Fusion outperforms Early Fusion, i.e., 0.738 vs. 0.714, both obtaining lower results than co-training, while using significantly more labeled data.

The last two lines of the table show the results when all documents (except those in the validation and test), are used for training, in a supervised framework. As can be seen, a supervised method that uses only citations will achieve a higher performance, compared against a method that uses titles and abstracts. Nonetheless, co-training obtains higher results than both fully supervised approaches, while using only 30% of the labeled data.

6 Conclusion and Future Work

In this paper, we studied the problem of using citation contexts in order to predict more accurately the topic of a research article. We showed that a co-training technique, which uses the paper content and its citation contexts as two *conditionally independent* and *sufficient* views of the data, can effectively incorporate cheap, unlabeled data to improve the classification performance and to reduce the need of labeled examples to only a fraction. The results of the experiments showed that the proposed approach performs better than other semi-supervised and supervised methods.

This study also shows that citation contexts are rich sources of information that can be successfully used in various IR and NLP tasks. We showed that document content and citation contexts unified under the same algorithm can dramatically decrease the annotation costs as well. In the future, we plan to extend co-training to include active learning for more robust classification. Moreover, it would be interesting to extend the co-training approach to multi-views that could potentially handle more than two feature spaces, e.g., it could include topics by Latent Dirichlet Allocation (Blei et al., 2003) as an additional view.

Acknowledgments

We are thankful to Dr. Lise Getoor for making the Citeseer^x labeled subset publicly available. We are also grateful to Dr. C. Lee Giles for the CiteSeer^x data, which helped extract the citation contexts of the research papers in the collection. We very much thank our anonymous reviewers for their constructive feedback. Abstract

Humor is an essential component in personal communication. How to create computational models to discover the structures behind humor, recognize humor and even extract humor anchors remains a challenge. In this work, we first identify several semantic structures behind humor and design sets of features for each structure, and next employ a computational approach to recognize humor. Furthermore, we develop a simple and effective method to extract anchors that enable humor in a sentence. Experiments conducted on two datasets demonstrate that our humor recognizer is effective in automatically distinguishing between humorous and non-humorous texts and our extracted humor anchors correlate quite well with human annotations.

1 Introduction

Humor is one of the most interesting and puzzling research areas in the field of natural language understanding. Recently, computers have changed their roles from automatons that can only perform assigned tasks to intelligent agents that dynamically interact with people and learn to understand their users. When a computer converses with a human being, if it can figure out the humor in human's language, it can better understand the true meaning of human language, and thereby make better decisions that improve the user experience. Developing techniques that enable computers to understand humor in human conversations and adapt behavior accordingly deserves particular attention.

The task of *Humor Recognition* refers to determining whether a sentence in a given context expresses a certain degree of humor. Humor recognition is a challenging natural language problem (Attardo, 1994). First, a universal definition of humor is hard to achieve, because different people hold different understandings of even the same sentence. Second, humor is always situated in a broader context that sometimes requires a lot of external knowledge to fully understand it. For example, consider the sentence, "*The one who invented the door knocker got a No Bell prize*" and "*Veni, Vidi, Visa: I came, I saw, I did a little shopping*". One needs a larger cultural context to figure out the subtle humorous meaning expressed in these two sentences. Last but not least, there are different types of humor (Raz, 2012), such as wordplay, irony and sarcasm, but there exist few formal taxonomies of humor characteristics. Thus it is almost impossible to design a general algorithm that can classify all the different types of humor, since even human cannot perfectly classify all of them.

Although it is impossible to understand universal humor characteristics, one can still capture the possible latent structures behind humor (Bucaria, 2004; Binsted and Ritchie, 1997). In this work, we uncover several latent semantic structures behind humor, in terms of meaning incongruity, ambiguity, phonetic style and personal affect. In addition to humor recognition, identifying anchors, or which words prompt humor in a sentence, is essential in understanding the phenomenon of humor in language. Here, *Anchor Extraction* refers to extracting the semantic units (keywords or phrases) that enable the humor in a given sentence. The presence of such anchors plays an important role in generating humor within a sentence or phrase.

In this work, we formulate humor recognition as a classification task in which we distinguish between humorous and non-humorous instances. Then we explore the semantic structure behind humor from four perspectives: incongruity, am-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2367–2376,
Lisbon, Portugal, 17-21 September 2015.

biguity, interpersonal effect and phonetic style. For each latent structure, we design a set of features to capture the potential indicators of humor. With high classification accuracy, we then extract humor anchors in sentences via a simple and effective method. Both quantitative and qualitative experimental results are provided to validate the classification and anchor extraction performance.

2 Related Work

Most existing studies on humor recognition are formulated as a binary classification problem and try to recognize jokes via a set of linguistic features (Purandare and Litman, 2006; Kiddon and Brun, 2011). For example, Mihalcea and Strapparava (2005) defined three types of humor-specific stylistic features: Alliteration, Antonym and Adult Slang, and trained a classifier based on these feature representations. Similarly, Zhang and Liu (2014) designed several categories of humor-related features, derived from influential humor theories, linguistic norms, and affective dimensions, and input around fifty features into the Gradient Boosting Regression Tree model for humor recognition. Taylor and Mazlack (2004) recognized wordplay jokes based on statistical language recognition techniques, where they learned statistical patterns of text in N-grams and provided a heuristic focus for a location of where wordplay may or may not occur. Similar work can also be found in (Taylor, 2009), which described humor detection process through Ontological Semantics by automatically transposing the text into the formatted text-meaning representation to detect humor. In addition to language features, some other studies also utilize spoken or multimodal signals. For example, Purandare and Litman (2006) analyzed acoustic-prosodic and linguistic features to automatically recognize humor during spoken conversations. However, the humor related features in most of those works are not systematically derived or explained.

One essential component in humor recognition is the construction of negative data instances. Classifiers based on negative samples that lie in a different domain than humor positive instances will have high classification performance, but are not necessarily good classifiers. There are few existing benchmark datasets for humor recognition and most studies select negative instances specifically. For example, Mihalcea and Strapparava (2005) constructed the set of negative examples by using news title from Reuters news, proverbs and British National Corpus. (Zhang, el. al 2014) randomly sampled 1500 tweets and then asked annotators to filter out humorous tweets.

Compared to humor recognition, humor generation has received quite a lot attention in the past decades(Stock and Strapparava, 2005; Ritchie, 2005; Hong and Ong, 2009). Most generation work draws on humor theories to account for humor factors, such as the Script-based Semantic Theory of Humor (Raskin, 1985; Labutov and Lipson, 2012) and employs templates to generate jokes. For example, Ozbal and Strapparava (2012) created humorous neologism using WordNet and ConceptNet. In detail, their system combined several linguistic resources to generate creative names, more specifically neologisms based on homophonic puns and metaphors. Stock and Strapparava (2005) introduced HAHACRONYM, a system (an acronym ironic re-analyzer and generator) devoted to produce humorous acronyms mainly by exploiting incongruity theories (Stock and Strapparava, 2003).

In contrast to research on humor recognition and generation, there are few studies that identify the humor anchors that trigger humorous effects in general sentences. A certain type of jokes might have specific structures or characteristics that provide pointers to humor anchors. For example, in the problem of "That's what she said" (Kiddon and Brun, 2011), characteristics that involves the using of nouns that are euphemisms for sexually explicit nouns or structures common in the erotic domain might probably give clues to potential humor anchors. Similarly, in the Knock Knock jokes (Taylor and Mazlack, 2004), wordplay is what leads to the humor. However, the wordplay by itself is not enough to trigger the comic effect, thus not equivalent to the humor anchors for a joke. To address these issues, we introduce a formal definition of humor anchors and design an effective method to extract such anchors in this work. To the best of our knowledge, this is the first study on extracting humor anchors that trigger humor in general sentences.

3 Data Preparation

To perform automatic recognition of humor and humor anchor extraction, a data set consisting of both humorous (positive) and non-humorous (negative) examples is needed. The dataset we

use to conduct our humor recognition experiments includes two parts: Pun of the Day [1] and the 16000 One-Liner dataset (Mihalcea and Strapparava, 2005). The two data sets only contain humorous text. In order to acquire negative samples for the humor classification task, we sample negative samples from four resources, including AP News[2], New York Times, Yahoo! Answer[3] and Proverb[4]. Such datasets not only enable us to automatically learn computational models for humor recognition, but also provide us with the chances to evaluate the performance of our model.

However, directly applying sentences extracted from those four resources and simply treating them as negative instances of humor recognition could result in deceptively high performance of classification, due to the domain differences between positive and negative datasets. For example, the humor sentences in our positive datasets often relate to daily lives, such as "*My wife tells me I'm a skeptic, but I don't believe a word she says.*". Meanwhile, sentences in news websites sometimes describe scenes related to wars or politics, such as "*Judge Thomas P. Griesa of Federal District Court in Manhattan stopped short of issuing sanctions*". Such domain differences between descriptive words might make a naive bag of words model perform quite well, without taking into account the deeper semantic structures behind humor. To deal with this issue, we extract our negative instances in a way that tries to minimize such domain differences by (1) selecting negative instances whose words are all contained in our positive instance word dictionary and (2) forcing the text length of non-humorous instances to follow the similar length restriction as humorous examples, i.e. one sentence with an average length of 10-30 words. Here, we assume sentences come from the aforementioned four resources are all non-humorous in nature. Table 1 provides a detailed statistical description to our datasets.

Dataset	#Positive	#Negative
Pun of the Day	2423	2403
16000 One Liners	16000	16002

Table 1: Statistics on Two Datasets

4 Latent Structures behind Humor

In this section, we explore the latent semantic structures behind humor in four aspects: (a) Incongruity; (b) Ambiguity; (c) Interpersonal Effect and (d) Phonetic Style. For each latent structure, a set of features is designed to capture the corresponding indicators of humor.

4.1 Incongruity Structure

"Laughter arises from the view of two or more inconsistent, unsuitable, or incongruous parts or circumstances, considered as united in complex object or assemblage, or as acquiring a sort of mutual relation from the peculiar manner in which the mind takes notice of them" (Lefcourt, 2001). The essence of the laughable is the incongruous, the disconnecting of one idea from another (Paulos, 2008). Humor sometimes relies on a certain type of incongruity, such as opposition or contradiction. For example, the following 'clean desk' and 'cluttered desk drawer' example (Mihalcea and Strapparava, 2005) presents an incongruous/contrast structure, resulting in a comic effect.

A clean desk is a sign of a cluttered desk drawer.

Direct identification of incongruity is hard to achieve, however, it is relatively easier to measure the semantic disconnection in a sentence. Taking advantage of Word2Vec[5], we extract two types of features to evaluate the meaning distance[6] between content word pairs in a sentence (Mikolov et al., 2013):

- Disconnection: the maximum meaning distance of word pairs in a sentence.
- Repetition: the minimum meaning distance of word pairs in a sentence.

4.2 Ambiguity Theory

Ambiguity (Bucaria, 2004), the disambiguation of words with multiple meanings (Bekinschtein et al., 2011), is a crucial component of many humor jokes (Miller and Gurevych, 2015). Humor and ambiguity often come together when a listener expects one meaning, but is forced to use another

[5]https://code.google.com/p/word2vec/

[6]We take the generic Word2Vec vectors without training new vectors for our specific domain. In addition, vectors associated with senses (Kumar Jauhar et al., 2015) might be alternative advantageous in this task.

meaning. Ambiguity occurs when the words of the surface sentence structure can be grouped in more than one way, thus yielding more than one associated deep structures, as shown in the example below.

Did you hear about the guy whose whole left side was cut off? He's all right now.

The multiple possible meanings of words provide readers with different understandings. To capture the ambiguity contained in a sentence, we utilize the lexical resource WordNet (Fellbaum, 1998) and capture the ambiguity as follows:

- Sense Combination: the sense combination in a sentence computed as follows: we first use a POS tagger (Toutanova et al., 2003) to identify Noun, Verb, Adj, Adv. Then we consider the possible meanings of such words $\{w_1, w_2 \cdots w_k\}$ via WordNet and calculate the sense combinations as $log(\prod_{i=1}^{k} n_{w_i})$. n_{w_i} is the total number of senses of word w_i.
- Sense Farmost: the largest Path Similarity[7] of any word senses in a sentence.
- Sense Closest: the smallest Path Similarity of any word senses in a sentence.

4.3 Interpersonal Effect

Besides humor theories and linguistic style modeling, one important theory behind humor is its social/hostility focus, especially regarding its interpersonal effect on receivers. That is, humor is essentially associated with sentiment (Zhang and Liu, 2014) and subjectivity (Wiebe and Mihalcea, 2006). For example, a sentence is likely to be humorous if it contains some words carrying strong sentiment, such as 'idiot' as follows.

Your village called. They want their Idiot back.

Each word is associated with positive or negative sentiments and such measurements reflect the emotion expressed by the writer. To identify the word-associated sentiment, we use the word association resource in the work by (Wilson et al., 2005), which provides annotations and clues to measure the subjectivity and sentiment associated with words. This enables us to design the following features.

- Negative (Positive) Polarity: the number of occurrences of all Negative (Positive) words.
- Weak (Strong) Subjectivity: the number of occurrences of all Weak (Strong) Subjectivity oriented words in a sentence. It is the linguistic expression of people's opinions, evaluations, beliefs or speculations.

4.4 Phonetic Style

Many humorous texts play with sounds, creating incongruous sounds or words. Some studies (Mihalcea and Strapparava, 2005) have shown that the phonetic properties of humorous sentences are at least as important as their content. Many one-liner jokes contain linguistic phenomena such as alliteration, word repetition and rhyme that produce a comic effect even if the jokes are not necessarily meant to be humorous in content.

What is the difference between a nicely dressed man on a tricycle and a poorly dressed man on a bicycle? A tire.

An alliteration chain refers to two or more words beginning with the same phones. A rhyme chain is defined as the relationship that words end with the same syllable. To extract this phonetic feature, we take advantage of the CMU Pronouncing Dictionary [8] and design four features as follows:

- Alliteration: the number of alliteration chains in a sentence, and the maximum length of alliteration chains.
- Rhyme: the number of rhyme chains and the maximum length of rhyme chains.

5 Humor Anchor Extraction

In addition to humor recognition, identifying anchors, or which words prompt humor in a sentence, is also essential in understanding humor language phenomena. In this section, we first define what humor anchors are and then describe how to extract such semantic units that enable humor in a given sentence.

5.1 Humor Anchor Definition

The semantic units or humor anchors enable humor in a given sentence, and are reflected in the form of sentence words. However, not every single word can be a humor anchor. For example, *I am glad that I know sign language; it is pretty handy*. In this one-liner, words such as 'am' and 'is' are not able to enable humor

[7] Path Similarity: `http://www.nltk.org/howto/wordnet.html`

[8] http://www.speech.cs.cmu.edu/cgi-bin/cmudict

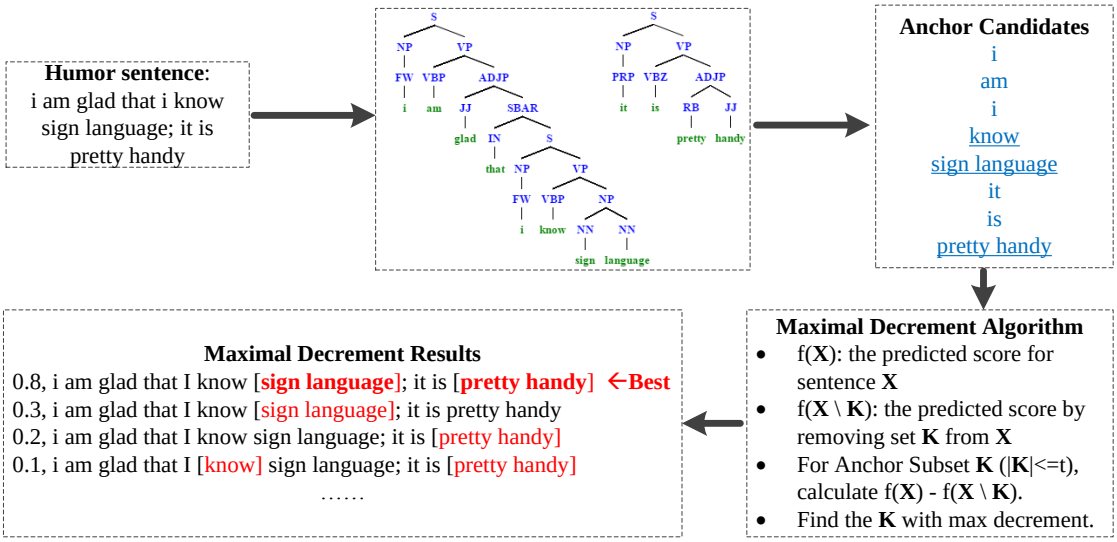

Figure 1: Humor Anchor Extraction Overview. Based on the parsing output of each sentence, we generate its humor anchor candidates. We then apply the Maximal Decrement algorithm to these candidates. The humor anchor subset that gives the maximal decrement is the extracted humor anchors for that sentence.

via themselves. Similarly, 'sign' or 'language' itself are not capable to prompt comic effect. The possible anchors in this example should contain both 'sign language' and 'handy'; it is the combination of these two spans that triggers humor. Therefore, formally defined, a humor anchor is a meaningful, complete, minimal set of word spans in a sentence that potentially enable one of the latent structures of Section 4 to occur. (1) *Meaningful* means humor anchors are meaningful word spans, not meaningless stop words in a sentence; (2) *Completeness* shows that all possible humor anchors should be covered by this anchor set and no individual span in this anchor set is capable enough to enable humor; (3) *Minimal* emphasizes that it is the combination of these anchors together that prompts comic effect; discarding any anchors from this candidate set destroys the humorous effect.

5.2 Anchor Extraction Method

Based on the humor anchor requirements listed above, we scoped humor anchor candidates to words or phrases that belong to the syntactic categories of Noun, Verb, Noun Phrase, Verb Phrase, ADVP or ADJP. Those properties are acquired via a sentence parse tree. To generate anchor candidates, we parsed each sentence and selected words or phrases that satisfy one or more of the latent structure criteria by first extracting the minimal parse subtrees of NP, VP, ADVP and ADJP and then adding remaining Nouns and Verbs into candidate sets.

The above anchor generation process provides us with all possible anchors that might enable humor. It satisfies the *Meaningful* and *Completeness* requirements. To extract a *Minimal* set of anchors, we proposed a simple and effective method of Maximal Decrement. Its basic idea is summarized as follows: Each complete sentence has a predicted humor score, which is computed via a humor recognition classifier trained on all data points. This humor recognizer is not limited to any specific classifiers or features as long as it provides good classification accuracy, which guarantees the generalization ability of our anchor extraction method. We next enumerate a subset of anchors from all potential anchors for this sentence. Then, we recompute the predicted humor score by providing the classifier with features associated with the current sentence, after removing that subset of anchors. Note that our designed humor structural features are all word order free, thereby not distinguishing between complete and incomplete sentences. The subset of humor anchor candidates that provides the maximum decrement of humor predicted scores is then returned as the extracted humor anchor set.

Mathematically, X_i is the word set of sentence i. Let f denote the trained classifier on all data instances. $f(X_i)$ is the predicted humor score

for sentence i before performing any operations. Denote $K_i (K_i \subset X_i)$ as the subset of words that we need to remove from sentence i. The size of K_i should be smaller than a threshold t, $|K_i| \leq t$. $f(X_i/K_i)$ is the recomputed humor score for sentence i after removing K_i. Our Maximal Decrement method tries to maximize the following objective by enumerating all possible K_is. The subset K_i that gives the maximal decrement is returned as our extracted humor anchors for sentence i. The system overview is shown in Figure 1.

$$\arg \min_{|K_i \leq t|} f(X_i) - f(X_i/K_i) \quad (1)$$

6 Experiment

In this section, we validate the performance of different semantic structures we extracted on humor recognition and how the combination of the structures contributes to classification. In addition, both qualitative and quantitative results regarding humor anchor extraction performance are explored.

6.1 Humor Recognition

We formulate humor recognition as a traditional text classification problem, and apply Random Forest to perform 10 fold cross validation on two datasets. Random Forest is an ensemble of decision trees [9] for classification (regression) that constructs a multitude of decision trees at training time and outputs the class that is the mode of the classes output by individual trees. Unlike single decision trees, which are likely to suffer from high variance or high bias, random forests use averaging to find a natural balance between the two extremes.

In addition to the four latent structures behind humor, we also design a set of K Nearest Neighbor (KNN) features that uses the humor classes of the K sentences ($K = 5$) that are the closest to this sentence in terms of meaning distance in the training data. We use several methods to act as baselines for comparison with our classier. **Bag of Words** baseline is used to capture a multiset of words in a sentence that might differentiate humor and non-humor. **Language Model** baseline assigns a humor/nonhumor probability to words in a sentence via probability distributions. **Word2Vec** baseline represents the meaning of sentences via Word2Vec (Mikolov et al., 2013) distributional semantic meaning representation. We implemented an earlier work (Mihalcea and Strapparava, 2005) that exploits stylistic features including alliteration, autonomy and adult slang and ensembles with bag of words representations, denoted as **SaC Ensemble**. It is worth mentioning that our datasets are balanced in terms of positive and negative instances, giving a random classification accuracy of 50%.

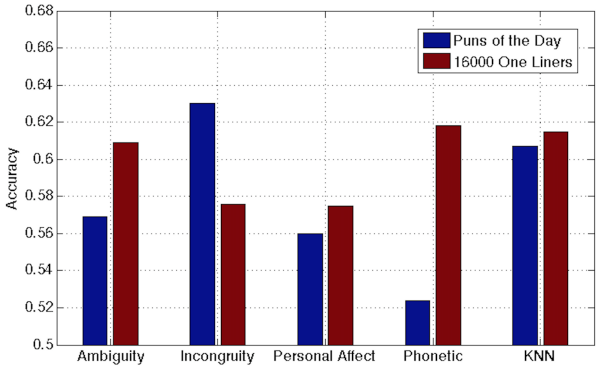

Figure 2: Different Latent Structures' Contribution to Humor Recognition

We first explored how different latent semantic structures affect humor recognition performance and summarize the results in Figure 2. It is evident that *Incongruity* performs the best among all latent semantic structures in the context of Pun of the Day and both *Ambiguity* and *Phonetic* substantially contribute to recognition performance on the 16000 One Liners dataset. The reason behind the differences in performance with *Incongruity* and with *Phonetic* lies in the different nature of the corpus. Most puns are well structured and play with contrasting or incongruous meaning. However, humor sentences in the 16000 One Liners often rely on the reader's awareness of attention-catching sounds (Mihalcea and Strapparava, 2005). This demonstrates that humor characteristics are expressed differently in different contexts and datasets.

We also investigated how the combination of such semantic structures performs compared with our proposed baselines, as shown in Table 2. Here, we denote the combination of four latent structures and KNN features as Human Centric Features (**HCF**). From Table 2, we found that (1) HCF (21 features in total) has a bigger contribution to humor recognition, compared with Bag of Words and Language Model (LM). The

[9] https://www.kaggle.com/wiki/RandomForests

	Pun of the Day				16000 One Liners			
	Accuracy	Precision	Recall	F1	Accuracy	Precision	Recall	F1
HCF	0.705	0.696	0.736	0.715	0.701	0.685	0.746	0.714
Bag of Words	0.632	0.623	0.686	0.650	0.673	0.708	0.662	0.684
Language Model	0.627	0.602	0.762	0.673	0.635	0.645	0.596	0.620
Word2Vec	0.833	0.804	0.880	0.841	0.781	0.767	0.809	0.787
SaC Ensemble	0.763	**0.838**	0.655	0.735	0.662	0.628	0.796	0.701
Word2Vec+HCF	**0.854**	0.834	**0.888**	**0.859**	**0.797**	**0.776**	**0.836**	**0.805**

Table 2: Comparison of Different Methods of Humor Recognition

inadequacy of LM also indicates that we can alleviate the domain differences and capture the real humor. (2) SaC Ensemble is inferior to the combination of Word2Vec and HCF because it does not involve enough latent structures such as Interpersonal Effect and distributional semantics. (3) The combination of Word2Vec and HCF (Word2Vec+HCF) gives the best classification performance because it takes into account both latent structures and semantic word meanings. Such a conclusion is consistent across two datasets. This indicates that our extracted latent semantic structures are effective in capturing humorous meaning.

6.2 Anchor Extraction

Qualitative Evaluation

The above humor recognition classifier provides us with decent accuracy in identifying humor in the text. To better understand which words or semantic units enable humor in sentences, we performed humor anchor extraction as described in Section 5.2. We set the size of the humor anchor set as 3, i.e. $t = 3$. The classifier that is used to predict the humor score is trained on all data instances. Then all predicted humorous instances are collected and input into the humor anchor extraction component. Based on the Maximal Decrement method, a set of humor anchors is extracted for each instance.

Table 3 presents selected extracted humor anchor results, including both successful and unsatisfying extractions. As we can see, extracted humor anchors are quite reasonable in explaining the humor causes or focuses. For example, in the sentence "*I used to be a watchmaker; it is a great job and I made my own hours*", our method selected 'watchmaker', 'made' and 'hours' as humor anchors. It makes sense because each word is necessary and essential to enable humor. Deleting 'watchmaker' will make the combination of 'made' and 'hours' helpless to the comic effect. To sum up, our extracted anchor extraction works fairly well in identifying the focus and meaning of humor language.

Quantitative Evaluation

In addition to the above qualitative exploration, we also conducted quantitative evaluations. For each dataset, we randomly sampled 200 sentences. Then for each sentence, 3 annotators are asked to annotate and label the possible humor anchors. To assess the consistency of the labeling in this context, we introduced an Annotation Agreement Ratio (AAR) measurement as follows:

$$AAR(A, B) = \frac{1}{N_s} \sum_{i=1}^{N_s} \frac{|A_i \cap B_i|}{|A_i \cup B_i|}$$

Here, N_s is the total number of sentences. A_i and B_i are the humor anchor sets of sentence i provided by annotator A and B respectively. The AARs on Pun of the Day and 16000 One Liners datasets are 0.618 and 0.433 respectively, computed by averaging the AAR scores between any two different annotators, which indicate relatively reasonable agreement.

As a further step to validate the effectiveness of our anchor extraction method, we also introduced two baselines. The **Random Extraction** baseline selects humor anchors by sampling words in a sentence randomly. Similarly, **POS Extraction** baseline generates anchors by narrowing down all the words in a sentence to a set of certain POS, e.g. Noun, Verb, Noun Phrase, Verb Phrase, ADVP and ADJP and then sampling words from this set.

To evaluate whether our extracted anchors are consistent with human annotation, we used each annotator's extracted anchor list as the ground truth, and compared with anchor list provided by our method. To identify whether two anchors

Result Category	Representative Sentences
Good	Did you hear about the guy who got **hit** in the head with a can of **soda**? He was lucky it was a **soft drink**.
	I was struggling to figure out how **lightning works** then it **struck** me.
	The one who **invented** the **door knocker** got a **No-bell prize**.
	I used to be a **watchmaker**; it is a great job and I **made** my own **hours**.
Bad	I wanted to lose weight, so I **went** to the **paint store**. I **heard** I could get thinner there.
	I **used** to be a **banker** but I **lost** interest

Table 3: Representative Extracted Humor Anchors. Highlighted parts are the extracted humor anchors in a sentence.

are the same, we introduce two measurements: Exact (EX) Matching and At-Least-One (ALO) Matching. Exact Matching requires the two anchors to be exactly the same. For ALO, two anchors are considered the same if they have at least one word in common. Recall, Precision and F1 Score are act as evaluation metrics. We then average the three annotators' individual scores to get the final extraction performance.

Metrics	Recall	Precision	F1
Pun of the Day Dataset			
MDE EX	0.444	0.446	0.438
POS EX	0.166	0.170	0.165
Random EX	0.121	0.116	0.116
MDE ALO	0.782	0.784	0.756
POS ALO	0.364	0.371	0.360
Random ALO	0.297	0.287	0.285
16000 One Liners Dataset			
MDE EX	0.314	0.281	0.288
POS EX	0.104	0.110	0.104
Random EX	0.087	0.075	0.079
MDE ALO	0.675	0.638	0.616
POS ALO	0.386	0.363	0.356
Random ALO	0.341	0.334	0.319

Table 4: Quantitative Result Comparison of Humor Anchor Extraction

The quantitative evaluation results are summarized in Table 4. Maximal Decrement Extraction is denoted as MDE; POS Extraction is denoted as POS, and Random Extraction is denoted as Random. We report both ALO and EX results for MED, POS and Random. From Table 4, we found that MDE performs quite well under the measurement of human annotation in terms of both ALO and EX settings. This again validates our assumption towards humor anchors and the effectiveness of our anchor extraction method.

6.3 Discussion

The above two subsections described the performance of both humor recognition and humor anchor extraction tasks. In terms of humor recognition, incongruity, ambiguity, personal affect and phonetic style are taken into consideration to assist the identification of humorous language. We focus on discovering generalized structures behind humor, and did not take into account sexual oriented words such as adult slang in modeling humorous language. Based on our results, these four latent structures are effective in capturing humor characteristics and such characteristics are expressed to different extents in different contexts. Note that we can apply any classification methods with our humor latent structures. Once such structures help us acquire high recognition accuracy, we can perform the generalized Maximal Decrement extraction method to identify anchors in humorous text.

Both humor recognition and humor anchor extraction suffer from several common issues. (1) **Phrase Meaning**: For example, a humorous sentence "*How does the earth get clean? It takes a meteor shower*" is predicted as non-humorous, because the recognizer does not fully understand the meaning of 'meteor shower', let alone the comic effect caused by 'earth', 'clean' and 'meteor shower'. For the unsatisfying example in Table 3 "*I used to be a banker but I lost interest*", anchor extraction would work better if it recognizes 'lost interest' correctly as a basic semantic unit. (2) **External Knowledge**: For jokes that involve idioms or social phenomena, or need some external knowledge such as "*Veni, Vidi, Visa: I came, I saw, I did a little shopping*", both humor recognition and anchor extraction fail because a broader and implicit comparison of this sentence and its origin ("*Veni, Vidi, Vici: I came, I*

saw, I conquered... ") is hard to be captured from a sentence. (3) **Humor Categorization**: Moreover, a fine granularity categorization of humor might aid in understanding humorous language, because humor has different types of manifestations, such as irony, sarcasm, creativity, insult and wordplay. Therefore, more sophisticated techniques in modeling phrase meaning, external knowledge, humor types, etc., are needed to better expose and define humor for automatic recognition and extraction.

7 Conclusion

In this work, we focus on understanding humorous language through two subtasks: humor recognition and humor anchor extraction. For this purpose, we first designed four semantic structures behind humor. Based on the designed sets of features associated with each structure, we constructed different computational classifiers to recognize humor. Then we proposed a simple and effective Maximal Decrement method to automatically extract anchors that enable humor in a sentence. Experimental results conducted on two datasets demonstrate the effectiveness of our proposed latent structures. The performances of humor recognition and anchor extraction are superior compared to several baselines. In the future, we would like to step further into the discovery of humor characteristics and apply our findings to the process of humor generation.

Abstract

We compare the multinomial i-vector framework from the speech community with LDA, SAGE, and LSA as feature learners for topic ID on multinomial speech and text data. We also compare the learned representations in their ability to discover topics, quantified by distributional similarity to gold-standard topics and by human interpretability. We find that topic ID and topic discovery are competing objectives. We argue that LSA and i-vectors should be more widely considered by the text processing community as pre-processing steps for downstream tasks, and also speculate about speech processing tasks that could benefit from more interpretable representations like SAGE.

1 Introduction

The text processing and speech processing research communities have similar problems and goals, but the technical approaches in these two communities develop largely independently. In this paper we compare dimensionality reduction techniques on multinomial language data from the text and speech communities. We consider a multinomial formulation of the i-vector model (hereafter "mi-vector" model) from the speech community (Soufifar et al., 2011), the sparse additive generative (SAGE) (Eisenstein et al., 2011) and latent Dirichlet allocation (LDA) (Blei et al., 2003b) topic models from the text community, and latent semantic analysis (LSA) (Deerwester et al., 1990). Both the mi-vector model and the SAGE topic model represent a multinomial parameter vector as the softmax of a sum of vectors, one of which is a background vector representing overall word usage in the corpus, and so we might expect mi-vectors and SAGE to produce similar results on real-world data. We evaluate these two recent models and two more conventional models, LDA and LSA (a term describing a class of methods based on the singular value decomposition, or SVD, which is used broadly in both research communities). We assess the similarity of mi-vectors and SAGE and expose the strengths and weaknesses of all four learned representations by evaluating them on the supervised task of topic identification (topic ID), depicted in Figure 1. We also evaluate the representations on the unsupervised, less easily-measurable task of topic discovery. As a proxy for controlled human annotations, we quantify topic discovery performance by distributional similarity to gold-standard topics.

We use the bag-of-words multinomial representation of text data, i.e., each document is represented by a vector of counts over the word vocabulary. For speech data, we use a modern automatic speech recognition (ASR) system to produce frame-wise triphone state cluster posteriors and we take the sum of these posteriors across all frames in a document to obtain a document-level vector of triphone state cluster soft counts. Modern topic ID systems for speech use ASR output instead of a lower-resource representation like these soft counts to improve performance (Hazen et al., 2007). ASR word counts are high-resource and can be viewed as a noisy version of word counts from text. We wish to assess the relative performance of our learned representations, not the quality of the data pre-processing scheme, and we desire to strengthen our results by evaluating performance on two distinct views of a corpus. Hence we break from convention and use triphone state cluster soft counts as speech data.

While previous work has juxtaposed the mi-vector model against LDA (Chen et al., 2014; Morchid et al., 2014), the current study is the first to provide *cross-community* evaluations of mi-vectors and a contemporaneous model from

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2377–2387,
Lisbon, Portugal, 17-21 September 2015.

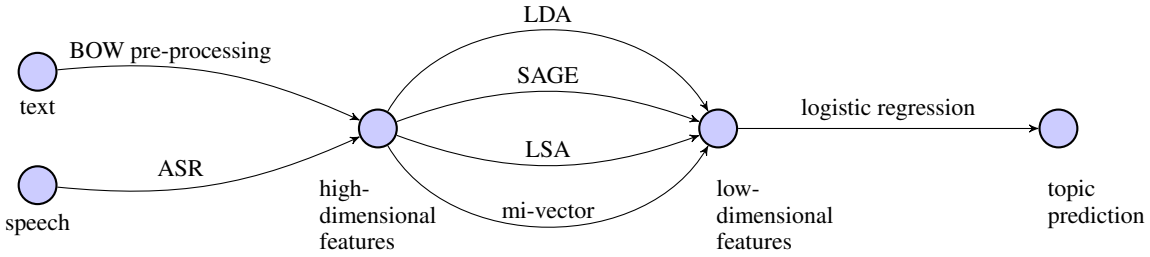

Figure 1: Depiction of the topic ID pipeline. Raw text or speech data is processed into multinomial counts, which are then transformed into a learned representation, and a classifier then predicts the topic of each document based on its representation.

the text community on both text and speech data. This study is also novel in its direct application of the mi-vector model to topic ID and topic discovery, two separate tasks with different motivations and preferring different types of models, and in its use of low-resource triphone state cluster soft counts as speech data for topic ID. The low-resource setting reflects constraints often faced in real-world applications, and we report topic ID performance under limited supervision to better illuminate the practical strengths and weaknesses of the learned representations. Finally, we believe that the centralized comparison herein of several prominent learned representations on two complementary tasks on both text and speech will provide a useful point of reference for future research.

2 Background

Previous work has compared and composed the mi-vector model with older dimensionality reduction techniques, including LDA. Chen et al. (2014) compared a mi-vector language model against LDA and other models on the task of spoken document retrieval, and found the mi-vector model to significantly outperform the other models on words, but not on subwords (syllable pairs), derived from ASR. The syllable pairs are similar in granularity to the triphone state clusters used as multinomial speech data in the current work.

Morchid et al. (2014) improved conversation theme identification by employing LDA and a *Gaussian* i-vector model in a pipeline. They learn LDA models of varying dimensions (numbers of topics) on ASR output and use them to generate a suite of feature vectors. The feature vector for each document-dimension pair is created by marginalizing over topics according to the document's inferred topic proportions. A Gaussian i-vector model is then learned on those feature vectors; the i-vectors are normalized and used to identify document themes via the Bayes decision rule.

Note that we have fundamentally different approaches, goals and methodology from that of Morchid et al. (2014). First, in an effort to provide a scientific comparison of independently created models, we use *multinomial* i-vectors, whereas Morchid et al., focusing on a particular task setting, used traditional *Gaussian* i-vectors. Similarly, while we treat multiple types of topic models as goals in their own rights, directly comparing SAGE and LDA, Morchid et al. use LDA as a pre-processing step to Gaussian i-vectors. Second, we use triphone state cluster soft counts instead of ASR word counts, hence our representation of speech data is significantly lower-resource. Third, we also evaluate performance on text data, and where Morchid et al. limit their vocabulary (from ASR) to 166 task-specific words, we use all 26,606 words present in our training data.

3 Input Representations

Our data is drawn from Part 1 of the Fisher English speech corpus (Cieri et al., 2004c), which contains audio recordings (Cieri et al., 2004a) and manual transcriptions (Cieri et al., 2004b) of telephone conversations. Specifically, we use the topic ID training and evaluation test subsets defined in prior work (Hazen et al., 2007). In each conversation in these subsets of the data, two study participants are prompted to speak on one of a predefined set of forty topics. There are 1374 training conversations and 686 test conversations. We represent each conversation by two documents, one for each side (speaker), resulting in a training set of 2748 documents and a test set of 1372 documents. The deep neural network (DNN) used to infer the triphone state cluster posteriors forming the basis of our speech data was trained on Parts 1 and 2 of the Fisher English speech corpus (Cieri et al., 2004a; Cieri et al., 2005); see the supplement for further

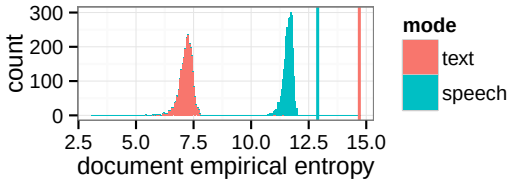

Figure 2: Distributions of the empirical entropy (in bits) of documents under the two multinomial views of our corpus. The vertical lines are the respective upper bounds (entropy of the uniform distributions). The distribution of the entropy of the text documents has median 7.2, over seven bits away from the upper bound of 14.7, thus the text representation is approximately sparse. The speech distribution has median 11.6, within two bits of the upper bound of 12.9, thus the speech representation is nearly uniform.

details about our dataset and ASR system.

To quantify the sparsity of the raw text (word count) and speech (triphone state cluster soft count) representations, we consider the representation density (number of non-zero entries) on our training set. The text representation is sparse, with median density 292 and maximum 500 (out of 26,606 dimensions); the speech representation is dense, with median density 7586 and maximum 7591 (out of 7591 dimensions).

To assess approximate sparsity, we plot histograms of the entropy of the normalized multinomial views of our training set in Figure 2. The median entropy for speech is less than two bits away from the uniform entropy, so the speech data is neither sparse nor approximately sparse.

Finally, we note that topic occurrence in the Fisher English training set is unbalanced, with quartiles (including minimum and maximum) of 6, 18.75, 29.5, 50.25, and 87.

4 Learned Representations

We consider four main dimensionality reduction models: the mi-vector model from the speech community, the SAGE and LDA topic models from the text community, and LSA. The learned representations we consider explain which words appear in a document d via a latent, lower-dimensional representation $\boldsymbol{\theta}^{(d)}$. All representations operate under a bag-of-words assumption. To compare mi-vectors, topic models and LSA, we find it useful to formulate each learned representation as operating on different "areas" or "contexts" a of a document; such a formulation does not negate the fundamental bag-of-words assumption. The four models represent the words that appear in an area a—either the entire document or each token—via multinomial-style parameters $\boldsymbol{\phi}^{(a)}$.[1,2] Each model consists of K *components* (e.g., a K-dimensional affine subspace), and shared parameters $H_{k,v}$ prescribe the amount of weight each component k places on each vocabulary word v. The models construct $\boldsymbol{\phi}^{(a)}$ by combining $\boldsymbol{H}$ and $\boldsymbol{\theta}^{(d)}$; often empirical word statistics $\mathbf{m}$ are also used to stabilize the representations.

4.1 LSA

LSA (Deerwester et al., 1990) factorizes a term-document matrix by truncated SVD, learning the projection of the data onto a linear subspace of fixed rank such that the approximation error of the reconstructed term-document matrix (as measured by the Frobenius norm) is minimized. In the basic version of LSA, SVD is applied to the raw term counts, giving the low-dimensional representation

$$\boldsymbol{\phi}^{(d)} = \boldsymbol{H}\boldsymbol{\theta}^{(d)}, \tag{1}$$

where $\boldsymbol{\phi}^{(d)}$ is the vector of observed multinomial counts in document d, $\boldsymbol{H}$ is the matrix of left singular vectors of the term-document count matrix, and $\boldsymbol{\theta}^{(d)}$ is the inferred representation of $\boldsymbol{\phi}^{(d)}$. In practice, LSA is often applied instead to the term-document matrix weighted by term frequency–inverse document frequency (tf-idf) in order to normalize terms by importance. We can also apply further pre-processing steps, such as term-wise centering by subtracting the column-wise mean $\mathbf{m}$ of the data, in which case LSA finds an affine subspace that approximates the data.

4.2 Mi-vector Model

The original acoustic i-vector model represents continuous, high-dimensional ASR system state (namely, Gaussian mixture model supervectors) in an affine subspace (Dehak et al., 2011). Prior work has found this dense, low-dimensional representation to be effective for a number of tasks, including language recognition (Martínez et al., 2011) and speaker recognition (Dehak et al., 2011; Garcia-Romero and Espy-Wilson, 2011).

Recently the i-vector model was augmented for multinomial observations (Soufifar et al., 2011)

[1] Other efforts have modeled documents with intermediate granularity, e.g., sentence-level (Titov and McDonald, 2008) or entity-level (Newman et al., 2006) granularity.

[2] For brevity, we use the multinomial distribution and its parameter interchangeably throughout.

and applied accordingly to language recognition (Soufifar et al., 2011; McCree and Garcia-Romero, 2015), speaker recognition (Kockmann et al., 2010), and spoken document retrieval (Chen et al., 2014). In this version of the i-vector model the observations are draws from a multinomial and the (unnormalized) natural parameters of that distribution are represented in an affine subspace:

$$\begin{aligned} \boldsymbol{\phi}^{(d)} &= \text{softmax}\left(\mathbf{m} + \boldsymbol{H}\boldsymbol{\theta}^{(d)}\right) \\ \boldsymbol{\theta}^{(d)} &\sim \mathcal{N}(0, \mathbf{I}). \end{aligned} \tag{2}$$

We call this multinomial version of the i-vector model the *mi-vector* model. The latent variable $\boldsymbol{\theta}^{(d)}$ is the *multinomial i-vector*, or *mi-vector*. $\boldsymbol{H}$ is an unconstrained linear transformation. The bias term $\mathbf{m}$ is computed as the log of the l_1-normalized background word count vector. The Gaussian prior on the mi-vector $\boldsymbol{\theta}^{(d)}$ is effectively an l_2 regularizer; mi-vectors are neither non-negative nor sparse in general.

Unlike many Bayesian topic models, word occurrences in the mi-vector model are i.i.d. draws from a document-level multinomial $\boldsymbol{\phi}^{(d)}$; as in LSA, each latent component contributes equally to each word within a given document. Specifically, in the mi-vector model, the natural parameter vector of the multinomial for *all* words in a given document is determined by an additive offset from a background parameter vector.

4.3 Bayesian Discrete Topic Models

Bayesian topic models explain word occurrences via K latent components $\boldsymbol{H}_k$ (topics) each drawn from some prior distribution G. Unlike mi-vectors and LSA, multinomial topic models are admixture models: each token n is drawn from a particular distribution $\boldsymbol{H}_k$. Latent token assignment variables $z_n^{(d)}$, taking integral values between 1 and K, dictate the token's topic choice. A document d controls how often each topic is chosen via the K-dimension multinomial distribution $\boldsymbol{\theta}^{(d)}$. In the parametric settings we consider, Dirichlet priors are often placed on $\boldsymbol{\theta}^{(d)}$, allowing experimentation with the topic representation $\boldsymbol{H}$.[3] A mapping $Q(\boldsymbol{H}_k)$, possibly the identity, ensures $\boldsymbol{\phi}^{(d,n)}$ are probability vectors. A general formulation is then

$$\begin{aligned} \boldsymbol{\phi}^{(d,n)} &= Q\left(\boldsymbol{H}_{z_n^{(d)}}\right) \\ \boldsymbol{H}_k &\sim G\left(\boldsymbol{\eta}\right) \\ z_n^{(d)} &\sim \text{Discrete}\left(\boldsymbol{\theta}^{(d)}\right) \\ \boldsymbol{\theta}^{(d)} &\sim \text{Dirichlet}\left(\boldsymbol{\alpha}\right). \end{aligned} \tag{3}$$

The hyperparameters $\boldsymbol{\alpha}$ and $\boldsymbol{\eta}$ dictate the informativeness of the priors over $\boldsymbol{H}_k$ and $\boldsymbol{\theta}^{(d)}$: often (empirically optimized) symmetric hyperparameters are employed, resulting in a form of Laplace smoothing during topic estimation. In the current work, we follow this strategy, noting that there have been concerted efforts to encode domain or expert knowledge via the hyperparameters (Gormley et al., 2012; Paul and Dredze, 2015).

SAGE Topic Model The Sparse Additive Generative (SAGE) model (Eisenstein et al., 2011) is a generative Bayesian modeling framework in which $\boldsymbol{\phi}^{(d,n)}$ are formed by summing a background vector and one or more sparse vectors generated from appropriate priors. The additive components can reflect the contributions of documents, aspects, topics, or other factors chosen by the modeler. A basic SAGE topic model sets $\boldsymbol{\phi}^{(d,n)} = \text{softmax}\left(\mathbf{m} + \boldsymbol{H}_{z_n^{(d)}}\right)$, and draws $\boldsymbol{H}_k$ from some sparsity-inducing distribution G, e.g., the Laplace distribution. As $\mathbf{m}$ is a shared background frequency vector, $\boldsymbol{H}_k$ is the learned residual frequency vector of topic k.

Replacing the topic assignment in SAGE by its conditional expectation gives

$$\begin{aligned} \tilde{\boldsymbol{\phi}}^{(d,n)} &= \text{softmax}\left(\mathbf{m} + \mathbb{E}_{z_n^{(d)}}\left[\boldsymbol{H}_{z_n^{(d)}} \middle| \boldsymbol{\theta}^{(d)}, \boldsymbol{H}\right]\right) \\ &= \text{softmax}\left(\mathbf{m} + \boldsymbol{H}\boldsymbol{\theta}^{(d)}\right). \end{aligned} \tag{4}$$

This modification of the SAGE topic model is the same as the mi-vector model but with different regularization on the representation vector $\boldsymbol{\theta}^{(d)}$ and l_1 regularization on the basis vectors $\boldsymbol{H}_k$. This "marginal SAGE" model could be useful in future work: the marginalization may mitigate the problem of topic-switching, yielding a more identifiable (but perhaps less interpretable) model and lending to downstream tasks such as topic ID.

LDA Latent Dirichlet Allocation (LDA) (Blei et al., 2003b) is a generative Bayesian topic model similar to SAGE, but in which each topic is drawn

[3] There have been many efforts to provide or induce latent structure among the topics (Blei et al., 2003a; Li and McCallum, 2006; Wallach et al., 2009; Paul and Girju, 2010), but most models ground out to Dirichlet and discrete random variables.

from a Dirichlet prior G rather than a sparsity-inducing distribution. LDA does not explicitly account for the background distribution; to account for this, it is common practice to threshold the vocabulary *a priori* to remove very common and very rare words (though in our experiments, we do not do this). Therefore, $\boldsymbol{\phi}^{(d,n)}$ is exactly $\boldsymbol{H}_{z_n^{(d)}}$, and $\boldsymbol{H}_k \sim \text{Dirichlet}\,(\boldsymbol{\eta})$.

5 Experiments

We compare these four models of learned representations empirically on two distinct tasks, topic ID and topic discovery. The essential implementation details of the models are as follows; further details are provided in the supplement. We learn the **mi-vector** model in a maximum a posteriori framework as in McCree and Garcia-Romero (2015). Our own C++ implementation of **SAGE**, available online,[4] uses approximate mean-field variational inference, as in Eisenstein et al. (2011). We learn the **LDA** model using Gibbs sampling, implemented in MALLET (McCallum, 2002).[5] We perform **LSA** using centered tf-idf–weighted word counts and centered l_2-normalized triphone state cluster soft counts. We implement tf-idf by scaling the raw term count by the log inverse document frequency. We apply l_2 normalization rather than tf-idf weighting to the speech data because it is dense and tf-idf is thus inappropriate. On both text and speech, mean-centering is performed *after* the respective normalization, as this pre-processing recipe performed best of all the variants we tried.[6]

For each of the four models, the low-dimensional real vector $\boldsymbol{\theta}^{(d)}$ represents a given document d in our experiments. We also consider two high-dimensional baseline representations: **raw** (soft) counts on both the text and speech data, and, only on the text data, **tf-idf**–weighted word counts. These tf-idf weights constitute a high-dimensional *learned* representation.

5.1 Topic ID

In our first topic ID experiment we evaluate topic ID error on raw multinomial views of the data. To our knowledge, we are the first to adopt a multinomial view of triphone state clusters and apply it to topic ID. In subsequent experiments we explore the interaction of representation dimension with each model and dataset, and evaluate relative performance when the classifier is only given a fraction of the available data for training. This latter configuration is the most interesting, as it reflects the cost of obtaining supervised data in practice.

Given feature vectors for some representation of the documents in a corpus, topic ID is performed in a one-versus-all framework. We use logistic regression as the per-class binary classifier, implemented using LIBLINEAR (Fan et al., 2008). Results were similar when logistic regression was replaced by support vector machines. All document representations are length-normalized (divided by their l_2 norm) before they are input to the classifier. Performance is measured by topic ID error, the error of multi-class prediction where the class predicted for each document is that of the per-class classifier that gave it the highest weight. Baseline performance on the test set (where the baseline classifier chooses the most prevalent topic in the training set for all test examples) is 96.2% error. Note that this error rate differs from the uniform-at-random classification error rate of 97.5% because of the uneven distribution of topics.

Document Construction Prior work (Hazen et al., 2007; Wintrode and Khudanpur, 2014) treated whole conversations as documents in addition to separating each conversation into its two sides. We perform a small topic ID experiment in this configuration to probe the impact of this design choice. Ten-fold cross-validation (CV) is used to tune the logistic regression regularizers. On the test set, the classifier achieves topic ID error of 12.4% and 15.6% for whole-conversation and individual-side text data, respectively, and 20.1% and 29.5% for whole-conversation and individual-side speech data, respectively. These results correspond roughly to results listed in Table 3 of Hazen et al. (2007), specifically, the topic ID error of 8.2% and 12.4% for whole-conversation and individual-side transcriptions, respectively, and 22.9% and 35.3% for whole-conversation and individual-side triphones derived from ASR lattices, respectively (Hazen et al., 2007). However, we use logistic regression without feature selection instead of Naïve Bayes with feature selection, and we apply our classifier to triphone state cluster soft counts inferred by a DNN instead of triphone

[4] https://github.com/fmof/sagepp

[5] For Gibbs sampling, fractional counts are truncated.

[6] Results for other versions of LSA are provided in the supplement. We did not present the conventional, uncentered tf-idf weighting scheme here because although it performs best in topic ID, it yields extremely variable V-measure.

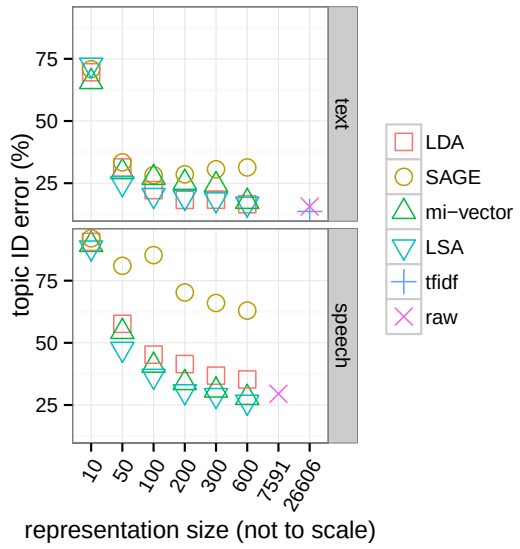

Figure 3: Topic ID error (%) on the test set for raw and tf-idf representations and lower-dimensional learned representations at dimensions $K \in \{10, 50, 100, 200, 300, 600\}$. We see many of the learned representations approach the error rate of the raw representation, but at much lower dimensionality.

counts from ASR lattices. We believe that the discrepancies in performance with respect to prior work are due to these differences in experimental configuration. Our results and those of prior work show that using whole-conversation documents instead of individual-side documents make the topic ID task easier. As a result, we expect that differences in performance between the different learned representations will be more clearly pronounced on individual conversation sides and we restrict the rest of our study to that setting.

Dimensionality Study We perform topic ID on learned representations at dimensions $K \in \{10, 50, 100, 200, 300, 600\}$ on individual conversation sides, using ten-fold cross-validation to tune the logistic regression regularizers. Figure 3 gives topic ID error results on the test set, varying K. (Selected values are listed in Table 1.) In both datasets, as the dimension K increases, topic ID error decreases, approaching (approximately) the raw baseline. On text, tf-idf performs slightly better than the raw representation. LSA is marginally the best-performing lower-dimensional learned representation; LDA and mi-vectors perform well at some representation sizes, depending on the data source, but their performance is less consistent. SAGE performs poorly overall.

speech	raw	7591	29.5

Table 1: Selected topic ID error (%) values from Figure 3.

Limited Data Study The raw text and speech representations (multinomial observations) are very high-dimensional, and the classifier is likely to overfit to specific components (words or triphone state clusters) in these representations. To measure this effect and attempt to separate the predictive power of logistic regression from the quality of the learned representations in our analysis, we experiment with reducing the number of *labeled* training examples the *classifier* can use; we still learn representations on the full (unlabeled) training set. This experiment represents the limited-supervision setting in which supervised data is costly to obtain but unlabeled data abounds.

We run this experiment twice, using $\ell = 2$ and $\ell = 6$ labeled examples per topic, for a total of 80 and 240 classifier training examples, respectively. Ten-fold cross-validation is used to fit the regularizer; per-class loss coefficients are set according to the class prior in the original training set in order to counteract the artificial balancing of the classes in the limited-supervision dataset. We report cross-validation estimates of the topic ID error on the training set for $K = 10$ (Figure 4), $K = 100$ (Figure 5), and $K = 600$ (Figure 6). For $K = 100$ and $K = 600$, LSA dominates in the limited-supervision setting. Mi-vectors perform as well as or better than other low-dimensional learned representations at $K = 10$, and exhibit mixed performance for larger K. SAGE performs poorly overall.[7] LDA performs significantly bet-

[7] We believe that approximately sparse posterior $\boldsymbol{\theta}^{(d)}$ values result in a kind of topic switching, contributing to the poor performance of SAGE. To examine this we "tested on train" and analyzed the top topics inferred for each document: while the highest-weighted topic tended to be consistent, SAGE infers approximately sparse $\boldsymbol{\theta}^{(d)}$ with large variation in the next four highest-weighted topics (the remaining topics are assigned trace mass). Second, a phenomenon known as conversation drift, explained in Section 3 of the supplement, is so pronounced in Fisher that the first 25% percent of words of each conversation side are nearly as predictive as the entire

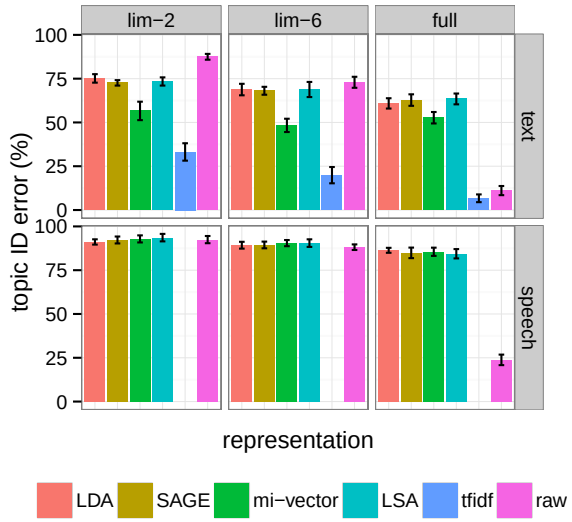

Figure 4: CV topic ID error (%) for raw and tf-idf representations and lower-dimensional learned representations of size $K = 10$. Error bars denote plus and minus one standard deviation according to the CV empirical distribution. We see underparametrized mi-vectors excel at compressing the topic label information for text, particularly in the limited-supervision settings.

ter than SAGE, but not as well as mi-vectors. Finally, tf-idf–weighted word counts perform very well on text, often achieving the best performance of all representations, even under limited supervision (but at the same dimension as the raw data).

5.2 Topic Discovery

To quantitatively assess representations' potential for topic discovery we compute their V-measure against the gold-standard labels. V-measure is an unsupervised measure of similarity between two partitions (Rosenberg and Hirschberg, 2007) and is equivalent to the mutual information normalized by the sum of the entropy (Becker, 2011).

For all representations, we compute V-measure between a partition induced by that representation and the gold-standard topic labels on the test set. A partition is induced on a representation by assigning each document d to the cluster indexed by the coordinate of $\boldsymbol{\theta}^{(d)}$ with highest value (the argmax). Results of this analysis are displayed in Figure 7. (Selected values are listed in Table 2.) On the text data, SAGE dominates the lower-dimensional representations, LSA is next best overall, and LDA and mi-vectors exhibit relatively low performance; the high-dimensional tf-idf weights are surpassed by SAGE for $K > 10$ but beat other representations by a significant margin. On speech, SAGE is best overall, mi-vectors exhibit similar but generally lower performance, LDA performs worse, and LSA is worst.

We also measure the topic discovery potential of the mi-vector and SAGE representations more directly. First, we provide a manual inspection of the learned topics: in Table 3 we show the top-five word lists for five random topics from the 600-dimensional mi-vector and SAGE models (respectively) learned on the text data. In both models, the top five words in a topic are selected according to the five largest positive values in the corresponding vector $\boldsymbol{H}_k$. Qualitatively, the SAGE topics are considerably more interpretable than the mi-vector topics: the SAGE topics represent issues of censorship, foreign relations, coffee fran-

document (Wintrode, 2013). All representations must contend with this drift, but $\boldsymbol{\theta}^{(d)}$ sparsity may make SAGE particularly susceptible. These two issues may make the classification we use much less robust.

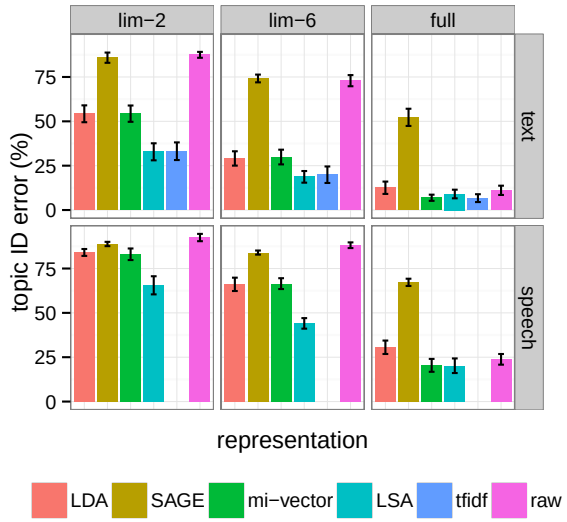

Figure 6: CV topic ID error (%) for raw and tf-idf representations and lower-dimensional learned representations of size $K = 600$. Error bars denote plus and minus one standard deviation according to the CV empirical distribution.

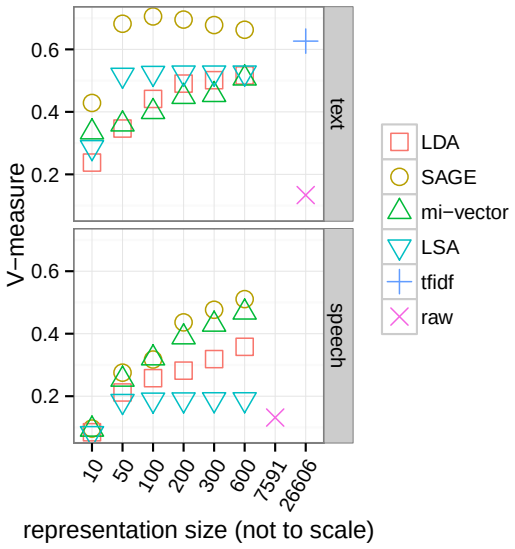

Figure 7: V-measure on the Fisher English text and speech data, respectively, for raw and tf-idf representations and lower-dimensional learned representations at selected dimensions. As in topic ID, we see underparametrized mi-vectors perform well on the text data.

chises, welfare, and professional basketball, while the mi-vector topics are less succinctly characterizable and more polluted by uninformative words.

We complement this qualitative analysis with Mimno et al. (2011)'s intrinsic coherence measure, a standard quantitative method. This scoring function, which correlates well with human quality judgments, averages estimates of the conditional log-likelihoods of each topic's M highest-weighted words across all topics. Using $K = 600$ models on text as before and picking $M = 20$, we compute mi-vector coherence as -453.34 and SAGE coherence (averaged over three runs) as -407.52, indicating that SAGE is more amenable to topic discovery and human interaction.

6 Discussion

We have theoretically and empirically compared several content-bearing representations of text and speech from prior work. We have measured the relative performance of these representations on topic ID, an easy-to-evaluate task familiar to both text and speech research communities. We have also assessed the representations in their ability to discover the topics inherent in a corpus, a task that is more prominent in the text community and more difficult to evaluate. On our subset of the Fisher English data, these tasks appear to have competing objectives: the best representations in one task are not necessarily the best in the other. In particular, while SAGE yields the worst performance as a feature learner for topic ID, it is demonstrably superior to other low-dimensional learned representations in topic discovery. We have evaluated performance in topic discovery by distributional similarity to gold-standard topics as a proxy for human-annotated judgments of topic quality, and briefly compared the interpretability of mi-vectors and SAGE; future work could pursue expert or crowd-sourced human evaluations.

In the full-supervision setting of topic ID, the lower-dimensional learned representations converge in performance to the raw representation as the dimension K increases. However, if only a couple of labeled examples per class are available,

reflecting the expense of obtaining labels in practice, then learned representations generally outperform the raw representation, which is more prone to overfitting. It is surprising that tf-idf performs so well in the limited supervision setting; it is learned from the data, but it should be prone to overfitting due to its high dimensionality. It is also surprising that SAGE performance on text degrades significantly at high dimensions; we suspect this is due to topic switching, but further investigation is warranted. Overall, though, for topic ID on word counts or triphone state cluster soft counts, if labeled data is scarce, we benefit from training on unsupervised learned representations.

In the V-measure experiment, the documents were partitioned according to the heaviest coordinate in their representations. This choice of experimental protocol is a nuisance variable in our results; other partition constructions may yield different conclusions. In particular, the heaviest-coordinate partition may favor topic models, whose representations are probability vectors, and disfavor mi-vectors and LSA, whose representations may have positive and negative coordinates encoding general linear combinations.

Within each task, the ranking of the representations (by performance) is generally consistent between the text and speech data; however, mi-vectors often outperform LDA on the speech data, while LDA often outperforms mi-vectors on the text data. This may be evidence that the two communities have already independently identified appropriate dimensionality reduction techniques for their respective data sources. However, our results support that the speech community can benefit from broader use of sparsity-inducing graphical models such as SAGE in tasks like spoken topic discovery and recommendation, in which human-interpretable representations are desired. The text community may similarly benefit from parsimonious models such as LSA or mi-vectors in downstream tasks; underparametrized mi-vectors perform particularly well on text, and future work may benefit from investigating this setting.

Word counts and triphone state cluster soft counts provide only one view of text and speech (respectively), and other input representations may yield different conclusions. The particular LSA approach we used for text, based on tf-idf weighting, is not as appropriate for our speech data, which is dense. Future work could evaluate other implementations of LSA or use a higher-level view of speech, such as triphone state cluster n-grams, that more naturally exhibits sparsity and lends to tf-idf weighting. In particular, weighting by a likelihood ratio test statistic and applying a log transform has generated better performance in several other tasks (Lapesa and Evert, 2014). Future work could also test our conclusions on higher-resource views of speech, such as ASR word counts, or lower-resource views such as mel-frequency cepstral coefficients (MFCCs).

We have provided a brief cross-community evaluation of learned representations on multinomial text and speech data. Some prior work has evaluated related learned representations on text data alone, surveying parameters and tasks at greater breadth (Lapesa and Evert, 2014; Levy et al., 2015). A similarly comprehensive evaluation spanning the text and speech research communities would demand great effort but provide a large and versatile resource. In complement, a detailed, case-by-case analysis of errors made by the models in our study could illuminate future modeling efforts by exposing exactly how and why each model errs or excels in each task.

7 Conclusion

Topic ID and topic discovery are competing objectives in our setting: we found that the best-performing representations per task were the same whether considering text- or speech-based communications. By evaluating learned representations from both the text and speech communities on a common set of data and tasks, we have provided a framework for better understanding the topic ID and topic discovery objectives, among others. More generally, we hope to encourage cross-community collaboration to accelerate convergence toward comprehensive models of language.

Abstract

Efficient computation of n-gram posterior probabilities from lattices has applications in lattice-based minimum Bayes-risk decoding in statistical machine translation and the estimation of expected document frequencies from spoken corpora. In this paper, we present an algorithm for computing the posterior probabilities of all n-grams in a lattice and constructing a minimal deterministic weighted finite-state automaton associating each n-gram with its posterior for efficient storage and retrieval. Our algorithm builds upon the best known algorithm in literature for computing n-gram posteriors from lattices and leverages the following observations to significantly improve the time and space requirements: i) the n-grams for which the posteriors will be computed typically comprises all n-grams in the lattice up to a certain length, ii) posterior is equivalent to expected count for an n-gram that do not repeat on any path, iii) there are efficient algorithms for computing n-gram expected counts from lattices. We present experimental results comparing our algorithm with the best known algorithm in literature as well as a baseline algorithm based on weighted finite-state automata operations.

1 Introduction

Many complex speech and natural language processing (NLP) pipelines such as Automatic Speech Recognition (ASR) and Statistical Machine Translation (SMT) systems store alternative hypotheses produced at various stages of processing as weighted acyclic automata, also known as lattices. Each lattice stores a large number of hypotheses along with the raw system scores assigned to them. While single-best hypothesis is typically what is desired at the end of the processing, it is often beneficial to consider a large number of weighted hypotheses at earlier stages of the pipeline to hedge against errors introduced by various subcomponents. Standard ASR and SMT techniques like discriminative training, rescoring with complex models and Minimum Bayes-Risk (MBR) decoding rely on lattices to represent intermediate system hypotheses that will be further processed to improve models or system output. For instance, lattice based MBR decoding has been shown to give moderate yet consistent gains in performance over conventional MAP decoding in a number of speech and NLP applications including ASR (Goel and Byrne, 2000) and SMT (Tromble et al., 2008; Blackwood et al., 2010; de Gispert et al., 2013).

Most lattice-based techniques employed by speech and NLP systems make use of posterior quantities computed from probabilistic lattices. In this paper, we are interested in two such posterior quantities: i) n-gram expected count, the expected number of occurrences of a particular n-gram in a lattice, and ii) n-gram posterior probability, the total probability of accepting paths that include a particular n-gram. Expected counts have applications in the estimation of language model statistics from probabilistic input such as ASR lattices (Allauzen et al., 2003) and the estimation term frequencies from spoken corpora while posterior probabilities come up in MBR decoding of SMT lattices (Tromble et al., 2008), relevance ranking of spoken utterances and the estimation of document frequencies from spoken corpora (Karakos et al., 2011; Can and Narayanan, 2013).

The expected count $c(x|A)$ of n-gram x given lattice A is defined as

$$c(x|A) = \sum_{y \in \Sigma^*} \#_y(x) p(y|A) \qquad (1)$$

where $\#_y(x)$ is the number of occurrences of n-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2388–2397,
Lisbon, Portugal, 17-21 September 2015.

gram x in hypothesis y and $p(y|A)$ is the posterior probability of hypothesis y given lattice A. Similarly, the posterior probability $p(x|A)$ of n-gram x given lattice A is defined as

$$p(x|A) = \sum_{y \in \Sigma^*} 1_y(x) p(y|A) \quad (2)$$

where $1_y(x)$ is an indicator function taking the value 1 when hypothesis y includes n-gram x and 0 otherwise. While it is straightforward to compute these posterior quantities from weighted n-best lists by examining each hypothesis separately and keeping a separate accumulator for each observed n-gram type, it is infeasible to do the same with lattices due to the sheer number of hypotheses stored. There are efficient algorithms in literature (Allauzen et al., 2003; Allauzen et al., 2004) for computing n-gram expected counts from weighted automata that rely on weighted finite state transducer operations to reduce the computation to a sum over n-gram occurrences eliminating the need for an explicit sum over accepting paths. The rather innocent looking difference between Equations 1 and 2, $\#_y(x)$ vs. $1_y(x)$, makes it hard to develop similar algorithms for computing n-gram posteriors from weighted automata since the summation of probabilities has to be carried out over paths rather than n-gram occurrences (Blackwood et al., 2010; de Gispert et al., 2013).

The problem of computing n-gram posteriors from lattices has been addressed by a number of recent works (Tromble et al., 2008; Allauzen et al., 2010; Blackwood et al., 2010; de Gispert et al., 2013) in the context of lattice-based MBR for SMT. In these works, it has been reported that the time required for lattice MBR decoding is dominated by the time required for computing n-gram posteriors. Our interest in computing n-gram posteriors from lattices stems from its potential applications in spoken content retrieval (Chelba et al., 2008; Karakos et al., 2011; Can and Narayanan, 2013). Computation of document frequency statistics from spoken corpora relies on estimating n-gram posteriors from ASR lattices. In this context, a spoken document is simply a collection of ASR lattices. The n-grams of interest can be word, syllable, morph or phoneme sequences. Unlike in the case of lattice-based MBR for SMT where the n-grams of interest are relatively short – typically up to 4-grams –, the n-grams we are interested in are in many instances relatively long sequences of subword units.

In this paper, we present an efficient algorithm for computing the posterior probabilities of all n-grams in a lattice and constructing a minimal deterministic weighted finite-state automaton associating each n-gram with its posterior for efficient storage and retrieval. Our n-gram posterior computation algorithm builds upon the custom forward procedure described in (de Gispert et al., 2013) and introduces a number of refinements to significantly improve the time and space requirements:

- The custom forward procedure described in (de Gispert et al., 2013) computes unigram posteriors from an input lattice. Higher order n-gram posteriors are computed by first transducing the input lattice to an n-gram lattice using an order mapping transducer and then running the custom forward procedure on this higher order lattice. We reformulate the custom forward procedure as a dynamic programming algorithm that computes posteriors for successively longer n-grams and reuses the forward scores computed for the previous order. This reformulation subsumes the transduction of input lattices to n-gram lattices and obviates the need for constructing and applying order mapping transducers.

- Comparing Eq. 1 with Eq. 2, we can observe that posterior probability and expected count are equivalent for an n-gram that do not repeat on any path of the input lattice. The key idea behind our algorithm is to limit the costly posterior computation to only those n-grams that can potentially repeat on some path of the input lattice. We keep track of repeating n-grams of order n and use a simple impossibility argument to significantly reduce the number of n-grams of order $n+1$ for which posterior computation will be performed. The posteriors for the remaining n-grams are replaced with expected counts. This filtering of n-grams introduces a slight bookkeeping overhead but in return dramatically reduces the runtime and memory requirements for long n-grams.

- We store the posteriors for n-grams that can potentially repeat on some path of the input lattice in a weighted prefix tree that we construct on the fly. Once that is done, we com-

Table 1: Common semirings.

pute the expected counts for all n-grams in the input lattice and represent them as a minimal deterministic weighted finite-state automaton, known as a factor automaton (Allauzen et al., 2004; Mohri et al., 2007), using the approach described in (Allauzen et al., 2004). Finally we use general weighted automata algorithms to merge the weighted factor automaton representing expected counts with the weighted prefix tree representing posteriors to obtain a weighted factor automaton representing posteriors that can be used for efficient storage and retrieval.

2 Preliminaries

This section introduces the definitions and notation related to weighted finite state automata and transducers (Mohri, 2009).

2.1 Semirings

Definition 1 *A semiring is a 5-tuple* $(\mathbb{K}, \oplus, \otimes, \overline{0}, \overline{1})$ *where* $(\mathbb{K}, \oplus, \overline{0})$ *is a commutative monoid,* $(\mathbb{K}, \otimes, \overline{1})$ *is a monoid,* $\otimes$ *distributes over* $\oplus$ *and* $\overline{0}$ *is an annihilator for* $\otimes$.

Table 1 lists common semirings. In speech and language processing, two semirings are of particular importance. The *log semiring* is isomorphic to the probability semiring via the negative-log morphism and can be used to combine probabilities in the log domain. The *tropical semiring*, provides the algebraic structure necessary for shortest-path algorithms and can be derived from the log semiring using the Viterbi approximation.

2.2 Weighted Finite-State Automata

Definition 2 *A weighted finite-state automaton (WFSA)* A *over a semiring* $(\mathbb{K}, \oplus, \otimes, \overline{0}, \overline{1})$ *is a 7-tuple* $A = (\Sigma, Q, I, F, E, \lambda, \rho)$ *where:* Σ *is the finite input alphabet;* Q *is a finite set of states;* $I, F \subseteq Q$ *are respectively the set of initial and final states;* $E \subseteq Q \times (\Sigma \cup \{\varepsilon\}) \times \mathbb{K} \times Q$ *is a finite set of arcs;* $\lambda : I \to \mathbb{K}$, $\rho : F \to \mathbb{K}$ *are respectively the initial and final weight functions.*

Given an arc $e \in E$, we denote by $i[e]$ its input label, $w[e]$ its weight, $s[e]$ its source or origin state and $t[e]$ its target or destination state. A path $\pi = e_1 \cdots e_k$ is an element of E^* with consecutive arcs satisfying $t[e_{i-1}] = s[e_i]$, $i = 2, \ldots, k$. We extend t and s to paths by setting $t[\pi] = s[e_k]$ and $s[\pi] = t[e_1]$. The labeling and the weight functions can also be extended to paths by defining $i[\pi] = i[e_1] \ldots i[e_k]$ and $w[\pi] = w[e_1] \otimes \ldots \otimes w[e_k]$. We denote by $\Pi(q, q')$ the set of paths from q to q' and by $\Pi(q, x, q')$ the set of paths from q to q' with input string $x \in \Sigma^*$. These definitions can also be extended to subsets $S, S' \subseteq Q$, e.g.

$$\Pi(S, x, S') = \bigcup_{q \in S, q' \in S'} \Pi(q, x, q').$$

An *accepting* path in an automaton A is a path in $\Pi(I, F)$. A string x is accepted by A if there exists an accepting path π labeled with x. A is *deterministic* if it has at most one initial state and at any state no two outgoing transitions share the same input label. The weight associated by an automaton A to a string $x \in \Sigma^*$ is given by

$$[\![A]\!](x) = \bigoplus_{\pi \in \Pi(I, x, F)} \lambda(s[\pi]) \otimes w[\pi] \otimes \rho(t[\pi])$$

and $[\![A]\!](x) \triangleq \overline{0}$ when $\Pi(I, x, F) = \emptyset$.

A weighted automaton A defined over the probability semiring $(\mathbb{R}_+, +, \times, 0, 1)$ is said to be *probabilistic* if for any state $q \in Q$, the sum of the weights of all cycles at q, $\oplus_{\pi \in \Pi(q,q)} w[\pi]$, is well-defined and in $\mathbb{R}_+$ and $\sum_{x \in \Sigma^*} [\![A]\!](x) = 1$.

2.3 N-gram Mapping Transducer

We denote by Φ_n the n-gram mapping transducer (Blackwood et al., 2010; de Gispert et al., 2013)

of order n. This transducer maps label sequences to n-gram sequences of order n. Φ_n is similar in form to the weighted finite-state transducer representation of a backoff n-gram language model (Allauzen et al., 2003). We denote by A_n the n-gram lattice of order n obtained by composing lattice A with Φ_n, projecting the resulting transducer onto its output labels, i.e. n-grams, to obtain an automaton, removing ε-transitions, determinizing and minimizing (Mohri, 2009). A_n is a compact lattice of n-gram sequences of order n consistent with the labels and scores of lattice A. A_n typically has more states than A due to the association of distinct n-gram histories with states.

2.4 Factor Automata

Definition 3 *Given two strings $x, y \in \Sigma^*$, x is a factor (substring) of y if $y = uxv$ for some $u, v \in \Sigma^*$. More generally, x is a factor of a language $L \subseteq \Sigma^*$ if x is a factor of some string $y \in L$. The factor automaton $S(y)$ of a string y is the minimal deterministic finite-state automaton recognizing exactly the set of factors of y. The factor automaton $S(A)$ of an automaton A is the minimal deterministic finite-state automaton recognizing exactly the set of factors of A, that is the set of factors of the strings accepted by A.*

Factor automaton (Mohri et al., 2007) is an efficient and compact data structure for representing a full index of a set of strings, i.e. an automaton. It can be used to determine if a string x is a factor in time linear in its length $O(|x|)$. By associating a weight with each factor, we can generalize the factor automaton structure to weighted automata and use it for efficient storage and retrieval of n-gram posteriors and expected counts.

3 Computation of N-gram Posteriors

In this section we present an efficient algorithm based on the n-gram posterior computation algorithm described in (de Gispert et al., 2013) for computing the posterior probabilities of all n-grams in a lattice and constructing a weighted factor automaton for efficient storage and retrieval of these posteriors. We assume that the input lattice is an ε-free acyclic probabilistic automaton. If that is not the case, we can use general weighted automata ε-removal and weight-pushing algorithms (Mohri, 2009) to preprocess the input automaton.

Algorithm 1 reproduces the original algorithm of (de Gispert et al., 2013) in our notation. Each iteration of the outermost loop starting at line 1 computes posterior probabilities of all unigrams in the n-gram lattice $A_n = (\Sigma_n, Q_n, I_n, F_n, E_n, \lambda_n, \rho_n)$, or equivalently all n-grams of order n in the lattice A. The inner loop starting at line 6 is essentially a custom forward procedure computing not only the standard forward probabilities $\alpha[q]$, the marginal probability of paths that lead to state q,

$$\alpha[q] = \bigoplus_{\pi \in \Pi(I,q)} \lambda(s[\pi]) \otimes w[\pi] \tag{3}$$

$$= \bigoplus_{\substack{e \in E \\ t[e]=q}} \alpha[s[e]] \otimes w[e] \tag{4}$$

but also the label specific forward probabilities $\tilde{\alpha}[q][x]$, the marginal probability of paths that lead to state q and include label x.

$$\tilde{\alpha}[q][x] = \bigoplus_{\substack{\pi \in \Pi(I,q) \\ \exists\, u,v \in \Sigma^*:\ i[\pi]=uxv}} \lambda(s[\pi]) \otimes w[\pi] \tag{5}$$

$$= \bigoplus_{\substack{e \in E \\ t[e]=q \\ i[e]=x}} \alpha[s[e]] \otimes w[e]$$

$$\oplus \bigoplus_{\substack{e \in E \\ t[e]=q \\ i[e]\neq x}} \tilde{\alpha}[s[e]][x] \otimes w[e] \tag{6}$$

Just like in the case of the standard forward algorithm, visiting states in topological order ensures that forward probabilities associated with a state has already been computed when that state is visited. At each state s, the algorithm examines each arc $e = (s, x, w, q)$ and updates the forward probabilities for state q in accordance with the recursions in Equations 4 and 6 by propagating the forward probabilities computed for s (lines 8-12). The conditional on line 11 ensures that the label specific forward probability $\tilde{\alpha}[s][y]$ is propagated to state q only if label y is different from label x, the label on the current arc. In other words, if a label y repeats on some path π leading to state q, then π contributes to $\tilde{\alpha}[q][y]$ only once. This is exactly what is required by the indicator function in Equation 2 when computing unigram posteriors. Whenever a final state is processed, the posterior probability accumulator for each label observed on paths reaching that state is updated by multiplying the label specific forward probability and the final weight associated with that state

Algorithm 1 Compute N-gram Posteriors

```
1  for n ← 1, ..., N do
2      A_n ← Min(Det(RmEps(ProjOut(A ∘ Φ_n))))
3      α[q] ← λ_n(q), ∀ state q ∈ Q_n
4      α̃[q][x] ← 0̄, ∀ state q ∈ Q_n, ∀ label x ∈ Σ_n
5      p(x|A) ← 0̄, ∀ label x ∈ Σ_n
6      for each state s ∈ Q_n do                ▷ In topological order
7          for each arc (s, x, w, q) ∈ E_n do
8              α[q] ← α[q] ⊕ α[s] ⊗ w
9              α̃[q][x] ← α̃[q][x] ⊕ α[s] ⊗ w
10             for each label y ∈ α̃[s] do
11                 if y ≠ x then

13         if s ∈ F_n then
14             for each label x ∈ α̃[s] do
15                 p(x|A) ← p(x|A) ⊕ α̃[s][x] ⊗ ρ_n(s)
16 P ← Min(ConstructPrefixTree(p))
```

and adding the resulting value to the accumulator (lines 13-15). It should be noted that this algorithm is a form of marginalization (de Gispert et al., 2013), rather than a counting procedure, due to the conditional on line 11. If that conditional were to be removed, this algorithm would compute n-gram expected counts instead of posterior probabilities.

The key idea behind our algorithm is to restrict the computation of posteriors to only those n-grams that may potentially repeat on some path of the input lattice and exploit the equivalence of expected counts and posterior probabilities for the remaining n-grams. It is possible to extend Algorithm 1 to implement this restriction by keeping track of repeating n-grams of order n and replacing the output labels of appropriate arcs in Φ_{n+1} with ε labels. Alternatively we can reformulate Algorithm 1 as in Algorithm 2. In this formulation we compute n-gram posteriors directly on the input lattice A without constructing the n-gram lattice A_n. We explicitly associate states in the original lattice with distinct n-gram histories which is implicitly done in Algorithm 1 by constructing the n-gram lattice A_n. This explicit association lets us reuse forward probabilities computed at order n while computing the forward probabilities at order $n+1$. Further, we can directly restrict the n-grams for which posterior computation will be performed.

In Algorithm 2, $\acute{\alpha}[n][q][h]$ represents the history specific forward probability of state q, the marginal probability of paths that lead to state q and include length n string h as a suffix.

$$\acute{\alpha}[n][q][h] = \bigoplus_{\substack{\pi \in \Pi(I,q) \\ \exists\, z \in \Sigma^* \colon\, i[\pi] = zh}} \lambda(s[\pi]) \otimes w[\pi] \tag{7}$$

$$= \bigoplus_{\substack{e \in E \\ t[e] = q \\ g \in \acute{\alpha}[n-1][s[e]] \\ gi[e] = h}} \acute{\alpha}[n-1][s[e]][g] \otimes w[e] \tag{8}$$

$\acute{\alpha}[n][q][h]$ is the analogue of $\alpha[q]$ in Algorithm 1. It splits the forward probability of state q (Equation 3), among length n suffixes (or histories) of paths that lead to state q. We can interpret $\acute{\alpha}[n][q][h]$ as the forward probability of state (q, h) in the n-gram lattice A_{n+1}. Here $(q, h) \in Q_{n+1}$ denotes the unique state corresponding to state q in the original lattice A and state h in the mapping transducer Φ_{n+1}. $\hat{\alpha}[q][h][x]$ represents the history and n-gram specific forward probability of state q, the marginal probability of paths that lead to state q, include length $n-1$ string h as a suffix and

$$\hat{\alpha}[q][h][x] = \bigoplus_{\substack{\pi \in \Pi(I,q) \\ \exists\, z \in \Sigma^*:\ i[\pi] = zh \\ \exists\, u,v \in \Sigma^*:\ i[\pi] = uxv}} \lambda(s[\pi]) \otimes w[\pi] \tag{9}$$

$$= \bigoplus_{\substack{e \in E \\ t[e] = q \\ g \in \acute{\alpha}[|h|][s[e]] \\ gi[e] = x}} \acute{\alpha}[|h|][s[e]][g] \otimes w[e] \;\oplus \bigoplus_{\substack{e \in E \\ t[e] = q \\ g \in \hat{\alpha}[s[e]] \\ gi[e] \neq x}} \hat{\alpha}[s[e]][g][x] \otimes w[e] \tag{10}$$

$\hat{\alpha}[q][h][x]$ is the analogue of $\tilde{\alpha}[q][x]$ in Algorithm 1. $R[n]$ represents the set of n-grams of order n that repeat on some path of A. We start by defining $R[0] \triangleq \{\varepsilon\}$, i.e. the only repeating n-gram of order 0 is the empty string ε, and computing $\acute{\alpha}[0][q][\varepsilon] \equiv \alpha[q]$ using the standard forward algorithm. Each iteration of the outermost loop starting at line 3 computes posterior probabilities of all n-grams of order n directly on the lattice A. At iteration n, we visit the states in topological order and examine each length $n-1$ history g associated with s, the state we are in. For each history g, we go over the set of arcs leaving state s, construct the current n-gram x by concatenating g with the current arc label i (line 11), construct the length $n-1$ history h of the target state q (line 12), and update the forward probabilities for the target state history pair (q, h) in accordance with the recursions in Equations 8 and 10 by propagating the forward probabilities computed for the state history pair (s, g) (lines 14-18). Whenever a final state is processed, the posterior probability accumulator for

each n-gram of order n observed on paths reaching that state is updated by multiplying the n-gram specific forward probability and the final weight associated with that state and adding the resulting value to the accumulator (lines 21-24).

We track repeating n-grams of order n to restrict the costly posterior computation operation to only those n-grams of order $n+1$ that can potentially repeat on some path of the input lattice. The conditional on line 17 checks if any of the n-grams observed on paths reaching state history pair (s, g) is the same as the current n-gram x, and if so adds it to the set of repeating n-grams. At each iteration n, we check if the current length $n-1$ history g of the state we are in is in $R[n-1]$, the set of repeating n-grams of order $n-1$ (line 9). If it is not, then no n-gram $x = gi$ can repeat on some path of A since that would require g to repeat as well. If g is in $R[n-1]$, then for each arc $e = (s, i, w, q)$ we check if the length $n-1$ history $h = g[1:n-1]i$ of the next state q is in $R[n-1]$ (line 13). If it is not, then the n-gram $x = g[0]h$ can not repeat either.

We keep the posteriors $p(x|A)$ for n-grams that can potentially repeat on some path of the input lattice in a deterministic WFSA P' that we construct on the fly. P' is a prefix tree where each path π corresponds to an n-gram posterior, i.e. $i[\pi] = x \implies w[\pi] = \rho(t[\pi]) = p(x|A)$. Once the computation of posteriors for possibly repeating n-grams is finished, we use the algorithm described in (Allauzen et al., 2004) to construct a weighted factor automaton C mapping all n-grams observed in A to their expected counts, i.e. $\forall \pi$ in C, $i[\pi] = x \implies w[\pi] = c(x|A)$. We use P' and C to construct another weighted factor automaton P mapping all n-grams observed in A to their posterior probabilities, i.e. $\forall \pi$ in P, $i[\pi] = x \implies w[\pi] = p(x|A)$. First we remove the n-grams accepted by P' from C using the difference operation (Mohri, 2009),

$$C' = C - \mathrm{RmWeight}(P')$$

then take the union of the remaining automaton C' and P', and finally optimize the result by removing ε-transitions, determinizing and minimizing

$$P = \mathrm{Min}(\mathrm{Det}(\mathrm{RmEps}(C' \oplus P'))).$$

4 Experiments and Discussion

In this section we provide experiments comparing the performance of Algorithm 2 with Algorithm 1 as well as a baseline algorithm based on the approach of (Tromble et al., 2008). All algorithms were implemented in C++ using the OpenFst Library (Allauzen et al., 2007). Algorithm 1 implementation is a thin wrapper around the reference implementation. All experiments were conducted on the 88K ASR lattices (total size: #states + #arcs = 33M, disk size: 481MB) generated from the training subset of the IARPA Babel Turkish language pack, which includes 80 hours of conversational telephone speech. Lattices were generated with a speaker dependent DNN ASR system that was trained on the same data set using IBM's Attila toolkit (Soltau et al., 2010). All lattices were pruned to a logarithmic beam width of 5.

Figure 1 gives a scatter plot of the posterior probability computation time vs. the number of lattice n-grams (up to 5-grams) where each point

Table 2: Runtime Comparison

Max n-gram length	1	2	3	4	5	6	10	all
$\log_{10}(\#n\text{-grams})$	3.0	3.8	4.2	4.5	4.8	5.1	6.3	11.2
Baseline (sec)	5	15	32	69	147	311	5413	-
Algorithm 1 (sec)	0.5	0.6	0.9	1.6	3.9	16	997	-
Algorithm 2 (sec)	0.7	0.8	0.9	1.1	1.2	1.3	1.7	1.0
Expected Count (sec)	0.3	0.4	0.5	0.6	0.7	0.8	1.0	0.5

represents one of the 88K lattices in our data set. Similarly, Figure 2 gives a scatter plot of the maximum memory used by the program (maximum resident set size) during the computation of posteriors vs. the number of lattice n-grams (up to 5-grams). Algorithm 2 requires significantly less resources, particularly in the case of larger lattices with a large number of unique n-grams.

To better understand the runtime characteristics of Algorithms 1 and 2, we conducted a small experiment where we randomly selected 100 lattices (total size: #states + #arcs = 81K, disk size: 1.2MB) from our data set and analyzed the relation between the runtime and the maximum n-gram length N. Table 2 gives a runtime comparison between the baseline posterior computation algorithm described in (Tromble et al., 2008), Algorithm 1, Algorithm 2 and the expected count computation algorithm of (Allauzen et al., 2004). The baseline method computes posteriors separately for each n-gram by intersecting the lattice with an automaton accepting only the paths including that n-gram and computing the total weight of the resulting automaton in log semiring. Runtime complexities of the baseline method and Algorithm 1 are exponential in N due to the explicit enumeration of n-grams and we can clearly see this trend in the 3rd and 4th rows of Table 2. Algorithm 2 (5th row) takes advantage of the WFSA based expected count computation algorithm (6th row) to do most of the work for long n-grams, hence does not suffer from the same exponential growth. Notice the drops in the runtimes of Algorithm 2 and the WFSA based expected count computation algorithm when all n-grams are included into the computation regardless of their length. These drops are due to the expected count computation algorithm that processes all n-grams simultaneously using WFSA operations. Limiting the maximum n-gram length requires pruning long n-grams, which in general can increase the sizes of intermediate WFSAs used in computation and result in longer runtimes as well as larger outputs.

When there is no limit on the maximum n-gram length, the output of Algorithm 2 is a weighted factor automaton mapping each factor to its posterior. Table 3 compares the construction and storage requirements for posterior factor automata with similar factor automata structures. We use the approach described in (Allauzen et al., 2004) for constructing both the unweighted and the expected count factor automata. We construct the unweighted factor automata by first removing the weights on the input lattices and then applying the determinization operation on the tropical semiring so that path weights are not added together. The storage requirements of the posterior factor automata produced by Algorithm 2 is similar to those of the expected count factor automata. Unweighted factor automata, on the other hand, are significantly more compact than their weighted counterparts even though they accept the same set of strings. This difference in size is due to accommodating path weights which in general can significantly impact the effectiveness of automata determinization and minimization.

5 Related Work

Efficient computation of n-gram expected counts from weighted automata was first addressed in (Allauzen et al., 2003) in the context of estimating n-gram language model statistics from ASR lattices. Expected counts for all n-grams of interest observed in the input automaton are computed by composing the input with a simple counting transducer, projecting on the output side, and removing ε-transitions. The weight associated by the resulting WFSA to each n-gram it accepts is simply the expected count of that n-gram in the input automaton. Construction of such an automaton for all substrings (factors) of the input automaton was later explored in (Allauzen et al., 2004) in the con-

Table 3: Factor Automata Comparison

FA Type	Unweighted	Expected Count	Posterior
#states + #arcs (M)	16	20	21
On disk size (MB)	219	545	546
Runtime (min)	5.5	11	22

text of building an index for spoken utterance retrieval (SUR) (Saraclar and Sproat, 2004). This is the approach used for constructing the weighted factor automaton C in Algorithm 2. While expected count works well in practice for ranking spoken utterances containing a query term, posterior probability is in theory a better metric for this task. The weighted factor automaton P produced by Algorithm 2 can be used to construct an SUR index weighted with posterior probabilities.

The problem of computing n-gram posteriors from lattices was first addressed in (Tromble et al., 2008) in the context of lattice-based MBR for SMT. This is the baseline approach used in our experiments and it consists of building a separate FSA for each n-gram of interest and intersecting this automaton with the input lattice to discard those paths that do not include that n-gram and summing up the weights of remaining paths. The fundamental shortcoming of this approach is that it requires separate intersection and shortest distance computations for each n-gram. This shortcoming was first tackled in (Allauzen et al., 2010) by introducing a counting transducer for simultaneous computation of posteriors for all n-grams of order n in a lattice. This transducer works well for unigrams since there is a relatively small number of unique unigrams in a lattice. However, it is less efficient for n-grams of higher orders. This inefficiency was later addressed in (Blackwood et al., 2010) by employing n-gram mapping transducers to transduce the input lattices to n-gram lattices of order n and computing unigram posteriors on the higher order lattices. Algorithm 1 was described in (de Gispert et al., 2013) as a fast alternative to counting transducers. It is a lattice specialization of a more general algorithm for computing n-gram posteriors from a hypergraph in a single inside pass (DeNero et al., 2010). While this algorithm works really well for relatively short n-grams, its time and space requirements scale exponentially with the maximum n-gram length. Algorithm 2 builds upon this algorithm by exploiting the equivalence of expected counts and posteriors for non-repeating n-grams and eliminating the costly posterior computation operation for most n-grams in the input lattice.

6 Conclusion

We have described an efficient algorithm for computing n-gram posteriors from an input lattice and constructing an efficient and compact data structure for storing and retrieving them. The runtime and memory requirements of the proposed algorithm grow linearly with the length of the n-grams as opposed to the exponential growth observed with the original algorithm we are building upon. This is achieved by limiting the posterior computation to only those n-grams that may repeat on some path of the input lattice and using the relatively cheaper expected count computation algorithm for the rest. This filtering of n-grams introduces a slight bookkeeping overhead over the baseline algorithm but in return dramatically reduces the runtime and memory requirements for long n-grams.

Abstract

This paper describes a novel target-side syntactic language model for phrase-based statistical machine translation, bilingual structured language model. Our approach represents a new way to adapt structured language models (Chelba and Jelinek, 2000) to statistical machine translation, and a first attempt to adapt them to phrase-based statistical machine translation. We propose a number of variations of the bilingual structured language model and evaluate them in a series of rescoring experiments. Rescoring of 1000-best translation lists produces statistically significant improvements of up to 0.7 BLEU over a strong baseline for Chinese-English, but does not yield improvements for Arabic-English.

1 Introduction

Many model components of competitive statistical machine translation (SMT) systems are based on rather simplistic definitions with little linguistic grounding, which includes the definitions of phrase pairs, lexicalized reordering, and n-gram language models. However, earlier work has also shown that statistical MT can benefit from additional linguistically motivated models. Most prominent among the linguistically motivated approaches are syntax-based MT systems which take into account the syntactic structure of sentences through CKY decoding and categorial labels (Zollmann and Venugopal, 2006; Shen et al., 2008). On the other hand, the commonly used phrase-based SMT approaches can also reap some of the benefits of using syntactic information by integrating linguistic components addressing specific phenomena, such as Cherry (2008), Carpuat et al. (2010), Crego and Yvon (2010), Ge (2010), Xiang et al. (2011), Lerner and Petrov (2013), Garmash and Monz (2014).

This paper is a contribution to the existing body of work on how syntactically motivated models help translation performance. We work with the phrase-based SMT (PBSMT) (Koehn et al., 2003) framework as the baseline system. Our choice is motivated by the fact that PBSMT is a conceptually simple and therefore flexible framework. It is typically quite straightforward to integrate an additional model into the system. Also, PBSMT is the most widely used framework in the SMT research community, which ensures comparability of our results to other people's work on the topic.

There is a variety of ways syntax can be used in a PBSMT model. Typically a syntactic representation of a source sentence is used to define constraints on the order in which the decoder translates it. For example, Cherry (2008) defines soft constraints based on the notion of syntactic cohesion (Section 2). Ge (2010) captures reordering patterns by defining soft constraints based on the currently translated word's POS tag and the words structurally related to it. On the other hand, target syntax is more challenging to use in PBSMT, since a target-side syntactic model does not have access to the whole target sentence at decoding. Post and Gildea (2008) is one of the few target-side syntactic approaches applicable to PBSMT, but it has been shown not to improve translation. Their approach uses a target side parser as a language model: one of the reasons why it fails is that a parser assumes its input to be grammatical and chooses the most likely parse for it. What we are interested in during translation is how gram-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2398–2408,
Lisbon, Portugal, 17-21 September 2015.

matical the target sentence actually is.

In addition to reordering constraints, source syntax can be used for target-side language modeling. A target side string can be encoded with source-syntactic building blocks and then scored as to how well-formed it is. Crego and Yvon (2010), Niehues et al. (2011), Garmash and Monz (2014) model target sequences as strings of tokens built from the target POS tag and the POS tags of the source words related to it through alignment and the source parse. In this paper, we define a target-side syntactic language model that takes structural constraints from the source sentence, but uses the words from the target side (as 'building blocks'). We do it by adapting an existing monolingual model of Chelba and Jelinek (2000), *structured language models*, to the bilingual setting. Our contributions can be summarized as follows:

- we propose a novel method to adapt monolingual structured language models (Chelba and Jelinek, 2000) (Section 3) to a PBSMT system (Section 4), which does not require an external on-the-fly parser, but only uses the given source-side syntactic analysis to infer structural relations between target words;
- building on the existing literature, we propose a set of deterministic rules that incrementally build up a parse of a target translation hypothesis based on the source parse (Section 4);
- we evaluate our models in a series of rescoring experiments and achieve statistically significant improvements of up to 0.7 BLEU for Chinese-English (Section 5).

Before describing the models, we motivate our method with a common assumption about cross-lingual correspondence (Section 2).

2 Direct correspondence assumption and syntactic cohesion in SMT

Before we apply the syntactic model introduced in Section 3 to the bilingual setting (Section 4), we first explain two widely used assumptions about syntactic correspondence across languages.

We take a *dependency tree* to be a syntactic representation of a sentence and reason about other syntactic assumptions and models in its terms. In this work, we choose a dependency structure over a constituency structure because the former is more primitive.[1] A dependency parse D is a dependency tree analysis of a sentence W, and we will think of it as a relation between words of W, such that $D(w, v)$ if w is a parent (head) of v (v being a child/modifier). D can be generalized to D^* which is an relation between words that are connected by a continuous path in a dependency tree (i.e. $D^*(w, v)$ if $D(w, v)$ or if $\exists u$ s.t. $D(w, u) \wedge D^*(u, v)$). We assume *unlabeled* dependency trees. Finally, we make a projectivity assumption, which is supported by empirical data in many languages (Kuhlmann and Nivre, 2006; Havelka, 2007), and makes a model computationally less expensive. A dependency parse D of a sentence $W = w_1, \ldots, w_n$ is *projective*, if for every word pair $w_i, w_j \in W$ s.t. $D(w_i, w_j)$ it holds that every $w_k \in W$ s.t. $i < k < j$ or $j < k < i$ is a descendant of w_i, i.e., $D^*(w_i, w_k)$; see Figure 1.

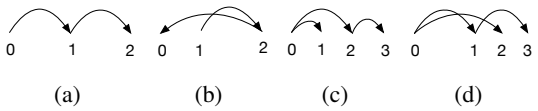

Figure 1: Examples of projective and non-projective parses. (a-b): projective (a) and non-projective (b) parses of the same dependency tree. (b) is non-projective because node 1 is not a descendant of either 0 or 2 (it is the parent of 2). (c-d): projective (c) and non-projective (d) parses of the same dependency tree. Node 2 in (d) is placed between its sibling (node 1) and the child of its sibling (node 3), neither of which is its ancestor.

Most NLP models that address the interaction of two or more languages are based (explicitly or implicitly) on the *direct correspondence assumption* (DCA) (Hwa et al., 2002). It states that close translation equivalents in different languages have the same dependency structure. This is grounded linguistically, as translation equivalence implies semantic equivalence and therefore thematic relations are preserved (Hwa et al., 2002). Thus dependency relations are preserved, as they are defined based on thematic relations between words. On the other hand, there is plenty empirical evidence supporting the violation of DCA under certain conditions (Hwa et al., 2002). For instance, even semantically very close sentences in different languages may have a different number of

[1] A dependency parse (a dependency tree analysis of a sentence) is more primitive because every constituency parse can be formalized as a projective dependency parse with labeled relations, but not vice versa (Osborne, 2008).

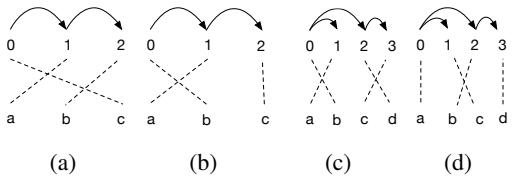

Figure 2: Examples of cohesive and uncohesive translations. (a-b): cohesive (a) and uncohesive (b) translations of the same dependency parse. (b) is uncohesive because words a and c translate the source subtree $\{(1, 2)\}$, but the target word b does not translate this subtree. (c-d): cohesive (c) and uncohesive (d) translations. (d) is uncohesive because a and c translate the source subtree $\{(0, 1)\}$, but b does not translate it.

words. Syntactic divergence increases if the two languages are typologically different.

Even though DCA only holds up to a certain level of precision, it is widely used in NLP. There are models of cross-lingual transfer that define syntactic structure of one language by conditioning it on the structure of semantically equivalent sentences in another language (Naseem et al., 2012). DCA has also been used in SMT. In particular, syntax-based SMT is built implicitly around this assumption (Wu, 1997; Yamada and Knight, 2001). In Quirk and Menezes (2006) DCA is explicitly implemented by defining a translation model in terms of treelet pairs where target-side treelets are produced by projecting source dependencies via word alignments.

Closely related to DCA is the notion of *syntactic cohesion* of translation (Fox, 2002; Cherry, 2008). This is a constraint that does not allow for non-projective reordering: Given a source parse D_S, a translation W is cohesive if all translated target words w_i, w_j do not have any word w_k between them such that there is a source subtree sub in D_S such that some parts of it are translated by w_i and w_j but not by w_k (Figure 2). Cherry (2008) and Bach et al. (2009) define a set of soft constraints based on the syntactic cohesion assumption which are applicable to PBSMT decoding. They only require phrase applications, and not necessarily individual target words, to conform to the cohesion principle. For example, if we imagine a situation where a subtree as in Figure 2(b) is translated as a whole with one phrase application (and not word by word), then it does not violate the cohesion principle, although it is internally uncohesive. Both our approach and Cherry (2008) implement the idea of conforming the target translation to the source syntactic structure, but in different ways. Approaches like Cherry (2008) define principles that constrain the decoder in order to produce better translations. Our goal is to have a model that allows for a more direct way of evaluation of how well-formed the target translation is. In Section 5 we compare translation performance of the two approaches.

3 Structured language models

As discussed in Sections 1 and 2, we would like to test how much a PBSMT can benefit from an additional syntax-based LM. In this section, we describe a syntactic language model, structured LM (SLM) (Chelba and Jelinek, 2000), that we extend to a bilingual setting and apply to SMT in Section 4. SLMs have been applied in SMT before (Yamada and Knight, 2001; Yu et al., 2014), but as we show in Section 4, we provide a much simpler method to integrate it into the system. While a SLM is not the only syntactically defined LM, it is one of the few that models sentence generation sequentially. And due to the way the decoding procedure of PBSMT is defined, it is natural and straightforward to use models whose score can be computed sequentially. Other syntactic language models define sentence generation hierarchically (Shen et al., 2008; Sennrich, 2015), which complicates their integration into a PBSMT system.

The linguistic intuition behind SLMs is that the structural children of a word do not essentially change its distributional properties but just provide additional specification. In Figure 3(a) the word *president* has two modifiers: *the* and *former* and it follows *yesterday* (an adjunct) and precedes *met* (a predicate). This ordering is correct in English. If instead its modifier was *a* or an entire relative clause, it would not make it incorrect.

To capture this observation, (Chelba and Jelinek, 2000) propose a language model where each word w_i of a sentence W is predicted by an ordered subset of the words preceding w_i. This conditioning subset is selected based on the syntactic properties of the preceding sequence W_{i-1}: the strong predictors are kept and the weak ones are left out. The strong predictors are the set of *exposed heads*. Given a subsequence W_{i-1} and its associated parse D_{i-1}, exposed heads are the roots of all the disconnected subtrees in D_{i-1}. Note that

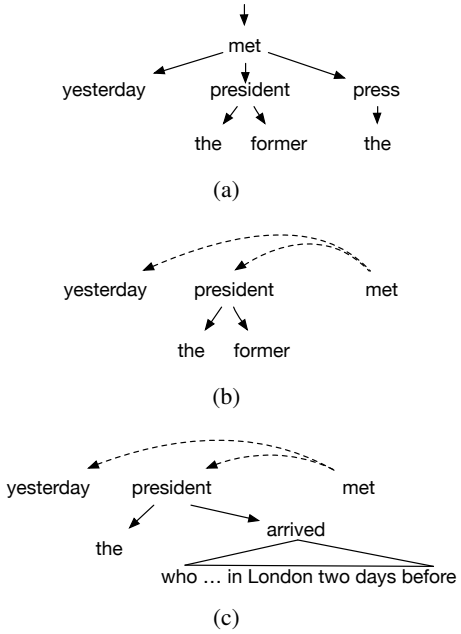

Figure 3: A fully parsed sentence (a) and its partial parse (b) during sequential generation. The partial parse in (b) has two disconnected subtrees with roots *yesterday* and *president*. These roots are the exposed heads for *met*. (c) is an alternative sentence with a similar structure: *president* is still a root of a subtree, and thus and an exposed head.

a parse D_{i-1} is not necessarily fully connected and thus a word can have multiple conditioning words.

For an example, consider again Figure 3(a). In a left-to-right scenario, when *met* is generated, a regular n-gram LM conditions it on *yesterday the former president*, while a SLM conditions it on *yesterday president*, since these two words are the exposed heads with respect to *met* (Figure 3(b)). The words *the* and *former* are modifiers of *president* and they get filtered out. Thus we obtain a less specific conditioning history, which may lead to the resulting model being less sparse. Another potential benefit is that SLMs can capture long-distance reordering: If *president* had as its modifier a relative clause (Figure 3(c)) then a simple n-gram LM would be conditioned on *days before* (assuming $n = 3$), while an SLM would condition *met* on *yesterday president*.

Summarizing the ideas of words being conditioned on a structurally defined subset of the preceding sentence, Chelba and Jelinek (2000) formalize the generation process of W as follows:[2] Each new word w_i is conditioned on a sequence of exposed heads $\mathit{Expos}(W, D)$. Then a tag t_i is predicted, and the parse D_{i-i} of W_{i-1} is extended to D_i incorporating w_i and t_i (where W_{i-1} is the prefix of W preceding w_i):

$$p(W, D) = \prod_{i=1}^{|W|} p(w_i | \mathit{Expos}(W_{i-1}, D_{i-1})) \cdot p(t_i | w_i, \mathit{Expos}(W_{i-1}, D_{i-1})) \cdot p(D_i | w_i, t_i, \mathit{Expos}(W_{i-1}, D_{i-1})). \quad (1)$$

They use a shift-reduce parser with reduce-left, reduce-right, and shift operations.

4 Bilingual structured language models

In this section, we combine the direct correspondence assumption (Section 2) and SLMs (Section 3), and define bilingual structured language models (BiSLMs) for PBSMT. Structured LMs have been successfully applied in SMT before. Yamada and Knight (2001) use SLMs in a string-to-tree SMT system where a derivation of a target-side parse tree is part of the decoding algorithm, and target syntactic representations are obtained 'for free'. Yu et al. (2014) use an on-the-fly shift-reduce parser to build an incremental target parse.

The approaches sketched above rely on resources that a standard PBSMT system does not have access to by default. Phrase-based decoders do not provide us with a parse of the target sentence, and inferring the parse of a target string with an external parser is computationally expensive and potentially unreliable (see Section 1). Our main insight is that in a bilingual setting one does not need an additional probabilistic target parsing model. We assume that the source parse is given (precomputed) and that the DCA (Section 2) holds, and project the parse deterministically onto the target side via word alignments[3]. We obtain the following equation:

$$p(T|S, D_S) = \prod_{i=1}^{|T|} p(t_i | \mathit{Expos}(T_{i-1}, \mathit{ProjP}(D_S, S, T_{i-1}))), \quad (2)$$

where T is a target sentence, T_{i-1} is the sequence in T preceding the i-th target word t_i, S is a

[2]The original model by (Chelba and Jelinek, 2000) is defined in terms of a lexicalized constituency grammar, but as we discussed in Section 2, constituency parses can be transformed into dependency parses.

[3]Phrase-internal word alignments are stored in the phrase table and are available at decoding time, see Section 4.4.

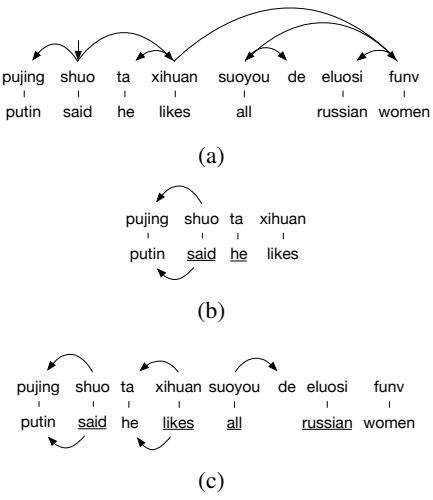

Figure 4: Chinese-English sentence pair (a) and sets of exposed heads (underlined) at different generation (b and c) steps of a bilingual SLM.

source sentence, D_S is a source dependency parse, and *ProjP* is a function that returns a partial target parse D_{Ti-1} by projecting D_S onto T_{i-1}. In words, at each time step i we predict the next word t_i conditioned on the exposed heads of the partial parse of T_{i-1} projected from the source side. We limit *Expos* to returning the four preceding exposed heads.[4] Because the function *ProjP* is deterministic and because we do not have to predict tags for words, Equation 2 is simpler than Equation 1.

We first illustrate Equation 2 with an example in Figure 4. Since word alignment is monotonic in Figure 4(a), it is straightforward to project the source dependencies onto the target side. We aim to imitate a monolingual parser in the way we build up our projected parse: Reduce operations should be invoked whenever both of the subtrees involved in the operation are complete, i.e., are not expected to have any more modifiers (Section 4.2). For example, when the target word *likes* is produced its exposed heads are *said* and *he* (Figure 4(b)), since *Putin* is a modifier of *said*. Likewise, the exposed heads for *women* are *said likes all Russian* (Figure 4(c)).

In what follows we discuss how to define *ProjP*. Compared to projection approaches like (Quirk and Menezes, 2006), we would like our model to project a source parse incrementally, allowing it to be used in a PBSMT decoder. We think of *ProjP* as a function that computes the output in two stages: first, it infers from the source parse the dependency relations between target words (Section 4.1), second, it decides how to parse the target sequence, i.e. in which order to assign these dependencies (Section 4.2). Additionally, in Section 4.3 we propose to use additional labelings of target words, and in Section 4.4 we describe some important implementation details.

4.1 Dependency graph projection

Adoption of DCA (Section 2) allows to build up a target dependency tree from a source tree by projecting the latter through word alignments. The definition of DCA can be rephrased as requiring a one-to-one correspondence *map* between words of a sentence pair, allowing one to unambiguously map dependencies: Given a source parse, if t_1 is the head of t_2, then *map*(t_1) is the head of *map*(t_2). The correspondence relation that we have in PBSMT is the word alignment *align*: in the most general case, it is a many-to-many correspondence, and the straightforward projection described above can lead to incorrect dependency structures. To overcome these problems, we describe a simple ordered set of projection rules, based on the ones specified by (Quirk and Menezes, 2006) (and we point out if otherwise).

The general idea behind this set of rules is to extract a one-to-one function ***align***$_{1-1}$ from source words to target words from *align* and use it to project source dependencies as described in the paragraph above (**R1** below). We then use additional rules (**R2-R4** below) for the target words that are not in *align*$_{1-1}$. Given a source sentence S with a parse D_S, a target sentence T and word alignment *align*, ***align***$_{1-1}$ is extracted as follows: For all $t_i \in T$ with multiple aligned source words $\{s_{i_1}, s_{i_2}, ...\}$ only *align*$_{1-1}(s_{i_1}) = t_i$ (only leftmost source word is kept, the links from the rest of the source words are removed[5]). For all $s_i \in S$ with aligned target words $\{t_{i_1}, t_{i_2}, ...\}$ keep the link only for the leftmost aligned target word: *align*$_{1-1}(s_i) = t_{i_1}$. For example, in Figure 5(b) the link between f_0 and e_1 is not in *align*$_{1-1}$, and in Figure 5(c) the link between f_1 and e_0 is removed (and the arc from f_2 to f_1 is not projected).

[4] As written above, we choose the dependency structures over the lexicalized constituency ones because the latter can be mapped to the former. It is thus more likely that a projected dependency tree is still be a well-formed parse, than a projected constituency tree. We decided to work with structural models that are more flexible, but one may also define BiSLM in terms of the more constraining constituency trees and see if the such model has better generalization power.

[5] This is an ad-hoc solution, other heuristics could be used.

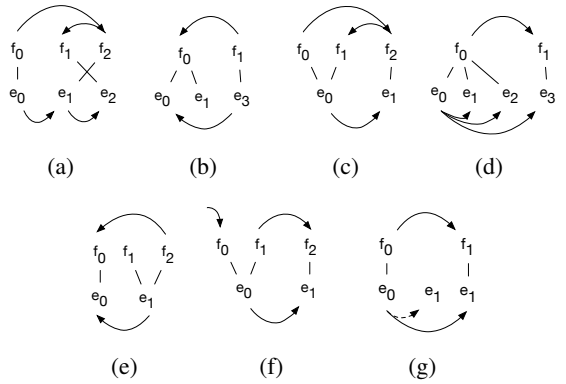

Figure 5: Examples for dependency projection rules. (a): no alignment links get removed (R1). (b): $f_0 - e_1$ link is removed from $align_{1-1}$ (R1). (c): $f_1 - e_0$ link gets removed (R1). (d): e_1 and e_2 get adjoined to e_0 (R2). (e): R3a. (f): R3b. (g) demonstrates two versions of R4: the dashed arrow gets 'realized' only if we adjoin unaligned words to the preceding head.

The following rules should be applied in order (as *else-if* conditions). Given a source sentence S with a parse D_S, a target sentence T and word alignment *align* between them, $t_i \in T$ is a head of $t_j \in T$ (i.e. $D_T(t_i, t_j)$):

(R1) if there are $s_k, s_l \in S$ s.t. $D_S(s_k, s_l)$ and $align_{1-1}(s_k) = t_i$ and $align_{1-1}(s_l) = t_j$; see Figures 5(a)-5(c);

(R2) if $\exists s \in S$ s.t. $align_{1-1}(s) = t_i$ and $(s, t_j) \in align$. This rule deals with one-to-many alignments; see Figure 5(d);

(R3a) if $\exists s_k$ s.t. $align_{1-1}(s_k) = t_i$ and $\exists s_l$ s.t. $(s_l, t_j) \in align$ and and $D_S(s_l, s_k)$, and t_i linearly precedes t_j. In words: if two target words are in $align_{1-1}$ but do not get connected via **R1**, find a source word aligned to the second target word that may get them connected; see Figure 5(e);

(R3b) same as R3a, but in case t_j precedes t_i (i.e., find an additional source word aligned to the first target word; see Figure 5(f)).[6]

(R4) In case $\neg\exists s\ (s, t_j) \in align$ (t_j is unaligned), we consider two strategies: We simplify the rule of Quirk and Menezes (2006) (dealing with the same situation) by adjoining it to the immediately preceding head. We also consider a strategy whereby the word remains unconnected to any word in the sentence; see Figure 5(g).

[6] R3a and R3b differ from the rules proposed in Quirk and Menezes (2006) dealing with the same situation, since we had to adapt it to the left-to-right parsing scenario.

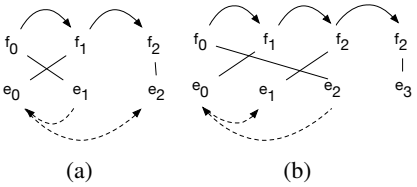

Figure 6: (a): The dashed lines are the dependency arcs that would project through word alignment, resulting in a non-projective projective (impossible under strong source-completeness). (b): The dashed lines are the parse produced under weak source-completeness. Under strong completeness none of the words will get connected.

4.2 BiSLM parsing procedure

Given an inference procedure for dependency relations between target words (Section 4.1), one can specify in which order the corresponding dependency arcs are assigned to the target sentence. We define an incremental parsing procedure in terms of three operations: *shift*, *left-reduce*, and *right-reduce*. The operations are applied as soon as the sufficient conditions hold: We specify the conditions using the following structural properties. A target subtree is *source-complete* if all the descendants of $align^{-1}_{1-1}(root(sub))$ (source correspondent of the root of the current subtree) (Section 4.1) have been translated and reduced. A target subtree is *complete* if it is source-complete and all the target words that are its children through non-projected arcs (through R2 or R4 in Section 4.1) have been translated and reduced. The bilingual parsing operations and the sufficient conditions for them are defined as follows:

Shift: after the word is produced it is shifted onto the stack as an elementary subtree.

Left-reduce: if a disconnected subtree sub_i and a disconnected subtree sub_{i-1} immediately preceding it are both complete and $D_T(root(sub_i), root(sub_{i-1}))$, adjoin sub_{i-1} to sub_i so that $root(sub_{i-1})$ is a modifier of $root(sub_i)$.

Right-reduce: analogous to *left-reduce*, but $D_T(root(sub_{i-1}), root(sub_i))$.

In the case of non-cohesive translation the resulting target dependencies are non-projective. Our definition of left- and right-reduce only produces projective parses. For a non-cohesive translation, certain subtrees will never be source-complete and will never be reduced; see Figure 6(a). Note that this is not a disadvantage

of our model. Cherry (2008) simply assumes that non-cohesive reordering should be penalized, and our model is able to learn this pattern. We also consider an alternative to incorporating non-cohesive alignments by relaxing the definition of completeness for subtrees: A projected subtree sub is *weakly source-complete* if all descendants of all source word(s) which are aligned to the root of sub have been translated and, *only* if the definition of reduce applies, reduced; see Figure 6(b).

4.3 Syntactic labeling of tokens

One of the problems with SLMs in general is that at time steps i and j the sets of exposed heads for t_i and t_j can differ in size, which may imply different predictive power. To this end, we add an additional detail to our model: Each time a reduction occurs, we label the root of the subtree to which another subtree has been adjoined, thus making the conditioning history more specific. We use the following labelings:

Reduction labeling: if a subtree is adjoint to *sub* from the left, then label *root(sub)* with **LR**. If it is adjoint from the right, then label it with **RR**.

Reduction POS-labeling: same as in simple reduction labeling, but add the POS tag of the root of the reduced subtree to the label.

4.4 Implementation and training

To use BiSLM during decoding, one needs access to phrase-internal alignments and target POS tags. We store phrase-internal alignments and target-side POS annotations of each phrase in the phrase table, based on the most frequent internal alignment during training and the most likely target-side POS labeling $\hat{t}$ given the phrase pair: $\hat{t} = \arg\max_{\bar{t}} p(\bar{t}|\bar{e}, \bar{f})$. We train BiSLMs on the parallel training data (Section 5.1) and use the Stanford dependency parser (Chang et al., 2009) for Chinese and and the Stanford constituency parser (Green and Manning, 2010) for Arabic[7]. POS-tagging of the training data is produced with the Stanford POS-tagger (Toutanova et al., 2003). We learn a 5-gram model using SRILM (Stolcke et al., 2011) with modified Kneser-Ney smoothing.

5 Experiments

To evaluate the effectiveness of BiSLMs for PB-SMT, we performed rescoring experiments for Arabic-English and Chinese-English. We compare the resulting 1-best translation lists with an output of the baseline system and the baseline augmented with soft cohesion constraints from Bach et al. (2009).

System	MT06	MT08	MT06+MT08
baseline	32.60	25.94	29.56
cohesion	32.52	25.98	29.54

Table 1: Chinese-English baseline and comparison model (Cherry, 2008; Bach et al., 2009) results.

System	MT08	MT09	MT08+MT09
baseline	45.84	48.61	47.18
cohesion constr.	45.61	48.49	47.02

Table 2: Arabic-English baseline and comparison model (Cherry, 2008; Bach et al., 2009) results.

5.1 Experimental setup

This section provides information about our baseline system. Word-alignment is produced with GIZA++ (Och and Ney, 2003). We use an in-house implementation of a PBSMT system similar to Moses (Koehn et al., 2007). Our baseline has all standard PBSMT features including language model, lexical weighting, and lexicalized reordering. The distortion limit is set to 5. A 5-gram LM is trained on the English Gigaword corpus (1.6B tokens) using SRILM with modified Kneser-Ney smoothing and linear interpolation. Information about the training data for the Arabic-English and Chinese-English systems is in Table 3.[8] Feature weights are tuned using pairwise ranking optimization (Hopkins and May, 2011) on the MT04 benchmark (for both language pairs). For testing, we use MT08 and MT09 for Arabic, and MT06 and MT08 for Chinese. We use case-insensitive BLEU (Papineni et al., 2002) as evaluation metric. Approximate randomization (Noreen, 1989; Riezler and Maxwell, 2005) is used to detect statistically significant differences.

5.2 Baseline and comparison systems

As a comparison model, we implemented six features from Cherry (2008) and Bach et al. (2009)[9] and added them to the log-linear interpolation used

[7] We extract dependency parses from its output based on Collins (1999)

[8] The standard LDC corpora were used for training.

[9] Exhaustive and non-exhaustive interruption check, exhaustive and non-exhaustive interruption count, verb- and noun-dominated subtree interruption count.

Training set	N. of lines	N. of tokens
Source side of Ar-En set	4,376,320	148M
Target side of Ar-En set	4,376,320	146M
Source side of Ch-En set	2,104,652	20M
Target side of Ch-En set	2,104,652	28M

Table 3: Training data for Arabic-English and Chinese-English experiments.

by the baseline system. Since these features are binary or count-based, we cannot use them directly in rescoring. For that reason we integrated the features into the decoder and tuned the corresponding weights. The results for Chinese-English and Arabic-English translation experiments are presented in Table 1 and 2, respectively. We see that adding the cohesion constraints does not improve performance. This finding is different from, for example, Feng et al. (2010), where they get improvement for Chinese-English: however, we note that their training set is smaller than ours, and their baseline is weaker as it does not contain lexicalized distortion models.

5.3 Rescoring experiments

Rescoring with BiSLMs is performed as follows: For the test runs of the baseline system we compute the $n = 1000$ best translation hypotheses for each source sentence and extract their derivations (sequence of phrase pair applications). Each phrase pair in our implementation is associated with a unique phrase-internal alignment and target POS-sequence. We fully reconstruct word-alignment for each pair of a source sentence and its translation hypothesis. We project a precomputed source parse onto the target side and compute representations of the target sentence to be computed by a BiSLM. For each hypothesis, we take its BiSLM score and its score assigned by the baseline system and compute the final score as a weighted sum of the original baseline score and a length-normalized BiSLM score[10], where the weight λ is empirically set to 0.3:

$$\lambda \cdot \frac{score_{\text{BiSLM}}}{length_{\text{Hypothesis}}} + (1 - \lambda) \cdot score_{\text{Baseline}} \quad (3)$$

5.3.1 Chinese-English

Our main focus here is Chinese-English, since it has more instances of longer-distance reordering, at which syntax-based models are typically good.

[10]Normalization is needed to ensure comparability of scores for translation hypotheses of different lengths, since longer translation hypotheses will have lower scores.

labeling	**complete**	**unalign -adjoin**	BLEU	diff.
plain	strong	+	30.09▲	+0.53
		-	30.20▲	+0.64
	weak	+	30.11▲	+0.55
		-	30.22▲	+0.66
reduce	strong	+	29.94△	+0.40
		-	30.19▲	+0.63
	weak	+	30.09▲	+0.53
		-	30.24▲	+0.68
reduce-POS	strong	+	30.09▲	+0.53
		-	30.25▲	+0.69
	weak	+	30.05▲	+0.49
		-	30.25▲	+0.69

Table 4: Rescoring experiments for Chinese MT06+08 1000-best translation sets. Unrescored BLEU is 29.56. The column **labeling** contains information about the kind of labeling used on the target side of a BiSLM: just target words, target words with a reduction label, or target words with a reduction label and a POS of the root of the reduced subtree (Section 4.3). The column **complete** indicates whether we use a strong or weak definition of a complete subtree (Section 4.2). The column **unalign-adjoin** indicates whether we adjoin an unaligned target word to the preceding subtree (Section 4.1). Statistically significant improvements over the baseline are marked ▲ at the $p < .01$ level and △ at the $p < .05$ level. ▼ marks significant decrease at the $p < .01$ level.

SLMs by design are good at capturing longer-distance dependencies. We try out several variations of BiSLM. First, we test whether to use a strong or weak definition of a complete subtree (Section 4.2). Second, we investigate whether to adjoin unaligned target words to a preceding head (Section 4.1; **unalign-adjoin+/-**). Third, we compare several target-side labeling methods (Section 4.3): plain (just target words), reduce (**LR** or **RR**) or reduce-POS (**LR**_POS or **RR**_POS, where POS is the tag of the root of the reduced subtree). The rescoring results are presented in Table 4.

The results show statistically significant improvement over the baseline of up to 0.7 BLEU (for all of the employed BiSLM variants except one). The rescoring experiments also demonstrate the tendency of the **unalign-adjoin-** feature value to produce higher scores than **unalign-adjoin+**. But the other two distinguishing features do not have an effect on BLEU scores. As future work, we are interested in examining if these features produce the same distribution of scores when a BiSLM is fully integrated into the decoder.

labeling	complete	unalign -adjoin	BLEU	diff.
plain	strong	+	47.20	-0.02
		-	47.00▼	-0.18
	weak	+	47.22	+0.04
		-	46.98▼	-0.20
reduce	strong	+	47.15	-0.03
		-	46.99▼	-0.19
	weak	+	47.09	-0.09
		-	46.98▼	-0.20
reduce-POS	strong	+	47.15	-0.03
		-	46.98▼	-0.20
	weak	+	47.17	+0.01
		-	47.00▼	-0.18

Table 5: Rescoring experiments for Arabic MT08+09 n-best translation sets. Unrescored BLEU for is 47.18. For notation see Table 4.

5.3.2 Arabic-English

We also rescore the n-best lists for the output of the Arabic-English baseline system and results are shown in Table 5. Arabic and English are typologically very different, but the range of reordering is much smaller than for Chinese-English. We expect reordering-related models to have lesser effect on Arabic as compared to Chinese (Carpuat et al., 2010). Experimental results on Arabic-English could indicate what kind of translation aspect benefits from BiSLMs. We see that for Arabic-English, just as for the cohesion constraint, BiSLM have little effect on BLEU scores, or even decrease them. This is a weak indication that BiSLMs are better at capturing reordering aspects. As for the varying features defining different BiSLM versions, we again see little effect of the labeling type or subtree completeness definition. On the other hand, we see the opposite pattern for the **unalign-adjoin** feature, where **unalign-adjoin+** is preferred.

To gain further insight into the different effect of BiSLM on the two language pairs, we evaluated our experimental output against a reordering-sensitive metric LRscore (Birch et al., 2010). We use the version of LRscore which is an average of the inverse Kendall's Tau distance and the Hamming distance. In order to compute alignments for test sets which are needed to compute the score we concatenated the parallel text with an additional 250K lines of parallel text from the training data to ensure better generalization of the alignment algorithm (GIZA++). The LRscores of the baseline are compared to the best performing BiSLM system with respect to BLEU, for each of the language pair. The results are provided in Tables 6 and 7.

system	LRscore MT06+08
baseline	0.4736
BiSLM	0.4907

Table 6: LRscores (average inverse Kendall's Tau distance and Hamming distance) for Chinese-English baseline and BiSLM with reduce-labeling, weak completeness, unalign-adjoin-.

system	LRscore MT08+09
baseline	0.6671
BiSLM	0.6719

Table 7: LRscores for Arabic-English baseline and BiSLM with plain-labeling, weak completeness, unalign-adjoin+.

As expected, the scores for Chinese-English are much lower than for Arabic-English, which is consistent with the observation reordering is more difficult for Chinese-English. BiSLM yields larger improvements for Chinese-English suggesting that the proposed model helps addressing difficult reordering problems. While there are also small improvements for Arabic-English the they may be too small to be detectable by BLEU.

6 Conclusions

In this paper we proposed a novel way to adapt structured language models to phrase-based SMT. Our method requires minimal changes to the PB-SMT pipeline. We tried a number of variations of our model and evaluated them in rescoring experiments, resulting in statistically significant improvement for Chinese-English. The model is based on the idea of syntactic transfer (DCA; Section 2) and the positive result indicates its ability to capture syntactic patterns across languages. For Arabic-English, we did not observe any improvements, suggesting that our models indeed mainly improve reordering aspects. Improvements in rescoring are a positive indication that our model may be a strong feature during decoding. As future work, we will fully integrate our model into a PBSMT decoder and evaluate it on other language pairs with different reordering distributions.

Abstract

Efficient methods for storing and querying language models are critical for scaling to large corpora and high Markov orders. In this paper we propose methods for modeling extremely large corpora without imposing a Markov condition. At its core, our approach uses a succinct index – a *compressed suffix tree* – which provides near optimal compression while supporting efficient search. We present algorithms for on-the-fly computation of probabilities under a Kneser-Ney language model. Our technique is *exact* and although slower than leading LM toolkits, it shows promising scaling properties, which we demonstrate through ∞-order modeling over the full Wikipedia collection.

1 Introduction

Language models (LMs) are critical components in many modern NLP systems, including machine translation (Koehn, 2010) and automatic speech recognition (Rabiner and Juang, 1993). The most widely used LMs are $m$gram models (Chen and Goodman, 1996), based on explicit storage of $m$grams and their counts, which have proved highly accurate when trained on large datasets. To be useful, LMs need to be not only accurate but also fast and compact.

Depending on the order and the training corpus size, a typical $m$gram LM may contain as many as several hundred billions of $m$grams (Brants et al., 2007), raising challenges of efficient storage and retrieval. As always, there is a trade-off between accuracy, space, and time, with recent papers considering small but approximate *lossy* LMs (Chazelle et al., 2004; Talbot and Osborne, 2007; Guthrie and Hepple, 2010), or *loss-less* LMs backed by tries (Stolcke et al., 2011), or related compressed structures (Germann et al., 2009; Heafield, 2011; Pauls and Klein, 2011; Sorensen and Allauzen, 2011; Watanabe et al., 2009). However, none of these approaches scale well to very high-order m or very large corpora, due to their high memory and time requirements. An important exception is Kennington et al. (2012), who also propose a language model based on a suffix tree which scales well with m but poorly with the corpus size (requiring memory of about $20\times$ the training corpus).

In contrast, we[1] make use of recent advances in *compressed suffix trees* (CSTs) (Sadakane, 2007) to build compact indices with much more modest memory requirements ($\approx$ the size of the corpus). We present methods for extracting frequency and unique context count statistics for $m$gram queries from CSTs, and two algorithms for computing Kneser-Ney LM probabilities on the fly using these statistics. The first method uses two CSTs (over the corpus and the reversed corpus), which allow for efficient computation of the number of unique contexts to the left and right of an $m$gram, but is inefficient in several ways, most notably when computing the number of unique contexts to both sides. Our second method addresses this problem using a single CST backed by a wavelet tree based FM-index (Ferragina et al., 2007), which results in better time complexity and considerably faster runtime performance.

Our experiments show that our method is practical for large-scale language modelling, although querying is substantially slower than a SRILM benchmark. However our technique scales much more gracefully with Markov order m, allowing unbounded 'non-Markov' application, and enables training on large corpora as we demonstrate on the complete Wikipedia dump. Overall this paper illustrates the vast potential succinct indexes have

for language modelling and other 'big data' problems in language processing.

2 Background

Suffix Arrays and Suffix Trees Let $\mathcal{T}$ be a string of size n drawn from an alphabet Σ of size σ. Let $\mathcal{T}[i..n-1]$ be a *suffix* of $\mathcal{T}$. The *suffix tree* (Weiner, 1973) of $\mathcal{T}$ is the compact labeled tree of $n+1$ leaves where the root to leaf paths correspond to all suffixes of $\mathcal{T}\$$, where \$ is a terminating symbol not in Σ. The *path-label* of each node v corresponds to the concatenation of edge labels from the root node to v. The *node depth* of v corresponds to the number of ancestors in the tree, whereas the *string depth* corresponds to the length of the path-label. Searching for a pattern α of size m in $\mathcal{T}$ translates to finding the *locus* node v closest to the root such that α is a prefix of the path-label of v in $O(m)$ time. We refer to this approach as *forward search*. Figure 1a shows a suffix tree over a sample text. A suffix tree requires $O(n)$ space and can be constructed in $O(n)$ time (Ukkonen, 1995). The children of each node in the suffix tree are lexicographically ordered by their edge labels. The i-th smallest suffix in $\mathcal{T}$ corresponds to the path-label of the i-th leaf. The starting position of the suffix can be associated its corresponding leaf in the tree as shown in Figure 1a. All occurrences of α in $\mathcal{T}$ can be retrieved by visiting all leaves in the subtree of the locus of α. For example, pattern "the night" occurs at positions 12 and 19 in the sample text. We further refer the number of children of a node v as its *degree* and the number of leaves in the subtree rooted at v as the *size* of v.

The *suffix array* (Manber and Myers, 1993) of $\mathcal{T}$ is an array $SA[0 \dots n-1]$ such that $SA[i]$ corresponds to the starting position of the i-th smallest suffix in $\mathcal{T}$ or the i-th leaf in the suffix tree of $\mathcal{T}$. The suffix array requires $n \log n$ bits of space and can also be constructed in $O(n)$ time (Kärkkäinen et al., 2006). Using only the suffix array and the text, pattern search can be performed using binary search in $O(m \log n)$ time. For example, the pattern "the night" is found by performing binary search using SA and $\mathcal{T}$ to determine $SA[18, 19]$, the interval in SA corresponding the the suffixes in $\mathcal{T}$ prefixed by the pattern. In practice, suffix arrays use $4-8n$ bytes of space whereas the most efficient suffix tree implementations require at least $20n$ bytes of space (Kurtz, 1999) which are both much larger than $\mathcal{T}$ and prohibit the use of these structures for all but small data sets.

Compressed Suffix Structures Reducing the space usage of suffix based index structure has recently become an active area of research. The space usage of a suffix array can be reduced significantly by utilizing the compressibility of text combined with succinct data structures. A *succinct* data structure provides the same functionality as an equivalent uncompressed data structure, but requires only space equivalent to the information-theoretic lower bound of the underlying data. For simplicity, we focus on the *FM-Index* which emulates the functionality of a suffix array over $\mathcal{T}$ using $nH_k(\mathcal{T}) + o(n \log \sigma)$ bits of space where H_k refers to the k-th order entropy of the text (Ferragina et al., 2007). In practice, the FM-Index of $\mathcal{T}$ uses roughly space equivalent to the compressed representation of $\mathcal{T}$ using a standard compressor such as `bzip2`. For a more comprehensive overview on succinct text indexes, see the excellent survey of Ferragina et al. (2008).

The FM-Index relies on the duality between the suffix array and the BWT (Burrows and Wheeler, 1994), a permutation of the text such that $\mathcal{T}^{bwt}[i] = \mathcal{T}[SA[i]-1]$ (see Figure 1). Searching for a pattern using the FM-Index is performed in reverse order by performing $\text{RANK}(\mathcal{T}^{bwt}, i, c)$ operations $O(m)$ times. Here, $\text{RANK}(\mathcal{T}^{bwt}, i, c)$ counts the number of times symbol c occurs in $\mathcal{T}^{bwt}[0 \dots i-1]$. This process is usually referred to as *backward search*. Let $SA[l_i, r_i]$ be the interval corresponding to the suffixes in $\mathcal{T}$ matching $\alpha[i \dots m-1]$. By definition of the BWT, $\mathcal{T}^{bwt}[l_i, r_i]$ corresponds to the symbols in $\mathcal{T}$ preceding $\alpha[i \dots m-1]$ in $\mathcal{T}$. Due to the lexicographical ordering of all suffixes in SA, the interval $SA[l_{i-1}, r_{i-1}]$ corresponding to all occurrences of $\alpha[i-1 \dots m-1]$ can be determined by computing the rank of all occurrences of $c = \alpha[i-1]$ in $\mathcal{T}^{bwt}[l_i, r_i]$. Thus, we compute $\text{RANK}(\mathcal{T}^{bwt}, l_i, c)$, the number of times symbol c occurs before l_i and $\text{RANK}(\mathcal{T}^{bwt}, r_i+1, c)$, the number of occurrences of c in $\mathcal{T}^{bwt}[0, r_i]$. To determine $SA[l_{i-1}, r_{i-1}]$, we additionally store the starting positions C_s of all suffixes for each symbol s in Σ at a negligible cost of $\sigma \log n$ bits. Thus, the new interval is computed as $l_{i-1} = C_c + \text{RANK}(\mathcal{T}^{bwt}, l_i, c)$ and $r_{i-1} = C_c + \text{RANK}(\mathcal{T}^{bwt}, r_i+1, c)$.

The time and space complexity of the FM-index thus depends on the cost of storing and pre-

Figure 1: Data structures for the sample text $\mathcal{T}$="#the old night keeper keeps the keep in the town# the night keeper keeps the keep in the night#$" with alphabet Σ={the, old, night, keeper, keeps, keep, in, town, #} and code words *$=0000*, *#=0001*, *i=in=001*, *p=keep=010*, *r=keeper=011*, *s=keeps=1000*, *o=old=101*, *t=the=110*, *n=night=1001* and *T=town=111*.

processing $\mathcal{T}^{bwt}$ to answer RANK efficiently. A *wavelet tree* can be used to answer RANK over $\mathcal{T}^{bwt}$ in $O(\log \sigma)$ time. The wavelet tree reduces RANK over an alphabet Σ into multiple RANK operations over a binary alphabet which can be answered in $O(1)$ time and $o(n)$ bits extra space by periodically storing absolute and relative RANK counts (Munro, 1996). The alphabet is reduced by recursively splitting symbols based on their code words into subgroups to form a binary tree as shown in Figure 1b for $\mathcal{T}^{bwt}$. To answer RANK($\mathcal{T}^{bwt}, i, c$), the tree is traversed based on the code word of c, performing binary RANK at each level. For example, RANK($\mathcal{T}^{bwt}$, 17, 't') translates to performing RANK($WT_{root}, 17, 1$) = 12 on the top level of the wavelet tree, as `t=the=110`. We recurse to the right subtree of the root node and compute RANK($WT_1, 12, 1$) as there were 12 ones in the root node and the next bit in the codeword of 'the' is also one. This process continues until the correct leaf node is reached to answer RANK($\mathcal{T}^{bwt}$, 17, 't') = 5 in $O(\log \sigma)$ time. The space usage of a regular wavelet tree is $n \log \sigma + o(n \log \sigma)$ bits which roughly matches the size of the text.[2] If locations of matches are required, additional space is needed to access $SA[i]$ or the inverse suffix array $SA^{-1}[SA[i]] = i$. In the simplest scheme, both values are periodically sampled using a given sample rate *SAS* (e.g. 32) such that $SA[i] \mod SAS = 0$. Then, for any $SA[i]$ or $SA^{-1}[i]$, at most $O(SAS)$ RANK operations on $\mathcal{T}^{bwt}$ are required to access the value. Different sample rates, bitvector implementations and wavelet tree types result in a wide variety of time-space tradeoffs which can be explored in practice (Gog et al., 2014).

In the same way the FM-index emulates the functionality of the suffix array in little space, *compressed suffix trees* (CST) provide the functionality of suffix trees while requiring significantly less space than their uncompressed counterparts (Sadakane, 2007). A CST uses a compressed suffix array (CSA) such as the FM-Index but stores additional information to represent the shape of the suffix tree as well as information about path-labels. Again a variety of different storage schemes exist, however for simplicity we focus on the CST of Ohlebusch et al. (2010) which we use in our experiments. Here, the shape of the tree is stored using a balanced-parenthesis (BP) sequence which for a tree of p nodes requires $\approx 2p$

[2] However, if code-words for each symbol are chosen based on their Huffman-codes the size of the wavelet tree reduces to $nH_0(\mathcal{T})(1 + o(1))$ bits which can be further be reduced to to $nH_k(\mathcal{T}) + o(n \log \sigma)$ bits by using entropy compressed bitvectors.

bits. Using little extra space and advanced bit-operations, the BP-sequence can be used to perform operations such as string-depth(v), parent(v) or accessing the i-th leaf can be answered in constant time. To support more advanced operations such as accessing path-labels, the underlying CSA or a compressed version of the LCP array are required which can be more expensive.[3] In practice, a CST requires roughly $4 - 6n$ bits in addition to the cost of storing the CSA. For a more extensive overview of CSTs see Russo et al. (2011).

Kneser Ney Language Modelling Recall our problem of efficient $m$gram language modeling backed by a corpus encoded in a succinct index. Although our method is generally applicable to many LM variants, we focus on the Kneser-Ney LM (Kneser and Ney, 1995), specifically the interpolated variant described in Chen and Goodman (1996), which has been shown to outperform other $n$gram LMs and has become the de-facto standard.

Interpolated Kneser-Ney describes the conditional probability of a word w_i conditioned on the context of $m-1$ preceding words, w_{i-m+1}^{i-1}, as

$$P(w_i|w_{i-m+1}^{i-1}) = \frac{\max\left[c(w_{i-m+1}^{i}) - D_m, 0\right]}{c(w_{i-m+1}^{i-1})} + \frac{D_m N^{1+}(w_{i-m-1}^{i-1}\ \bullet)}{c(w_{i-m+1}^{i-1})} \bar{P}(w_i|w_{i-m+2}^{i-1}), \quad (1)$$

where lower-order smoothed probabilities are defined recursively (for $1 < k < m$) as

$$\bar{P}(w_i|w_{i-k+1}^{i-1}) = \frac{\max\left[N^{1+}(\bullet\ w_{i-k+1}^{i}) - D_k, 0\right]}{N^{1+}(\bullet\ w_{i-k+1}^{i-1}\ \bullet)} + \frac{D_k N^{1+}(w_{i-k+1}^{i-1}\ \bullet)}{N^{1+}(\bullet\ w_{i-k+1}^{i-1}\ \bullet)} \bar{P}(w_i|w_{i-k+2}^{i-1})\,. \quad (2)$$

In the above formula, D_k is the $k$gram-specific discount parameter, and the *occurrence count* $N^{1+}(\alpha\ \bullet) = |\{w : c(\alpha w) > 0\}|$ is the number of observed word types following the pattern α; the occurrence counts $N^{1+}(\bullet\ \alpha)$ and $N^{1+}(\bullet\ \alpha\ \bullet)$ are defined accordingly. The recursion stops at unigram level where the unigram probabilities are defined as $\bar{P}(w_i) = N^{1+}(\bullet\ w_i)/N^{1+}(\bullet\ \bullet)$.[4]

[3] See *Supplementary Materials* Table 1 for an overview of the complexities of the functionality of the CST that is used in our experiments.

[4] Modified Kneser-Ney, proposed by Chen and Goodman (1996), typically outperforms interpolated Kneser-Ney through its use of context-specific discount parameters. The implementation of this with our data structures is straightforward in principle, but brings a few added complexities in terms of dynamic computing other types of occurrence counts, which we leave for future work.

3 Using CSTs for KN Computation

The key requirements for computing probability under a Kneser-Ney language model are two types of counts: raw frequencies of $m$grams and occurrence counts, quantifying how many different contexts the $m$gram has occurred in. Figure 2 (right) illustrates the requisite counts for calculating the probability of an example 4-gram. In electing to store the corpus directly in a suffix tree, we need to provide mechanisms for computing these counts based on queries into the suffix tree.

The raw frequency counts are the simplest to compute. First we identify the locus node v in the suffix tree for the query $m$gram; the frequency corresponds to the node's *size*, an $O(1)$ operation which returns the number of leaves below v. To illustrate, consider searching for c(*the night*) in Figure 1a, which matches a node with two leaves (labelled 19 and 12), and thus $c = 2$.

More problematic are the occurrence counts, which come in several flavours: right contexts, $N^{1+}(\alpha\ \bullet)$, left contexts, $N^{1+}(\bullet\ \alpha)$, and contexts to both sides of the pattern, $N^{1+}(\bullet\ \alpha\ \bullet)$. The first of these can be handled easily, as

$$N^{1+}(\alpha\ \bullet) = \begin{cases} \text{degree}(v), & \text{if } \alpha = \text{label}(v) \\ 1, & \text{otherwise} \end{cases}$$

where v is the node matching α, and label(v) denotes the *path-label* of v.[5] For example, *keep in* has two child nodes in Figure 1a, and thus there are two unique contexts in which it can occur, N^{1+}(*keep in* $\bullet$) $= 2$, while *the keep* partially matches an edge in the forward suffix tree in Figure 1a as it can only be followed by *in*, N^{1+}(*the keep* $\bullet$) $= 1$. A similar line of reasoning applies to computing $N^{1+}(\bullet\ \alpha)$. Assuming we also have a second suffix tree representing the *reversed corpus*, we first identify the reversed pattern (e.g., *in keep*$_R$) and then use above method to compute the occurrence count (denoted hereafter N1P(t, v, α)[6], where t is the CST.).

[5] See the *Supplementary Materials* for the explicit algorithm, but note there are some corner cases involving sentinels # and \$, which must be excluded when computing occurrence counts. Such tests have been omitted from the presentation for clarity.

[6] In the presented algorithms, we overload the pattern argument in function calls for readability, and use $\bullet$ to denote the query context.

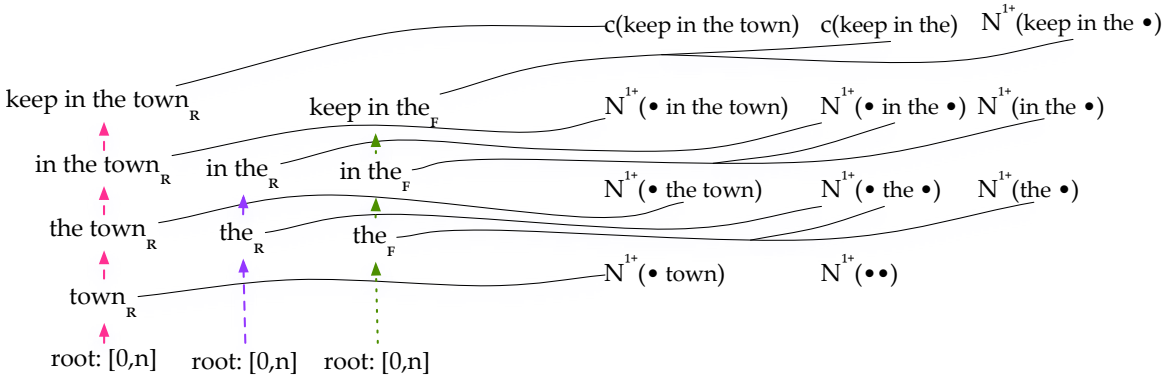

Figure 2: Counts required for computing $P(town|keep\ in\ the)$ (right) and the suffix tree nodes required for computing each value (left). The two left-most columns correspond to $v_{\mathrm{R}}^{\mathrm{all}}$ and v_{R} and are updated using *forward-search* in the reverse CST, while the righter-most column correspond to v_{F} and is updated using *backward-search* in the forward CST. See Algorithm 2 for details.

The final component of the Kneser-Ney LM computation is $N^{1+}(\bullet\ \alpha\ \bullet)$, the number of unique contexts considering symbols on both sides of the pattern. Unfortunately this does not map to a simple suffix tree operation, but instead requires enumeration, $N^{1+}(\bullet\ \alpha\ \bullet) = \sum_{s \in F(\alpha)} N^{1+}(\bullet\ \alpha s)$, where $F(\alpha)$ is the set of symbols that can follow α. Algorithm 1 shows how this is computed, with lines 7 and 8 enumerating $s \in F(\alpha)$ using the *edge* labels of the children of v. For each symbol, line 9 searches for an extended pattern incorporating the new symbol s in the reverse CSA (part of the reverse CST), by refining the existing match v_{R} using a single backward search operation after which we can compute $N^{1+}(\bullet\ \alpha s)$.[7] Line 5 deals with the special case where the pattern does not match a complete edge, in which case there is only only unique right context and therefore $N^{1+}(\bullet\ \alpha\ \bullet) = N^{1+}(\bullet\ \alpha)$.

N1P and N1PFRONTBACK can compute the requisite occurence counts for $m$gram language modelling, however at considerable cost in terms of space and time. The need for twin reverse and forward CSTs incurs a significant storage overhead, as well as the search time to match the pattern in both CSTs. We show in Section 5 how we can avoid the need for the reversed suffix tree, giving rise to lower memory requirements and faster runtime. Beyond the need for twin suffix trees, the highest time complexity calls are *string-depth*, *edge* and *backward-search*. Calling *string-depth* is constant time for internal nodes, but $O(SAS \log \sigma)$ for leaf nodes; fortunately we can avoid this call for leaves, which by definition extend to the end of the corpus and consequently extend further than our pattern.[8] The costly calls to *edge* and *backward-search* however cannot be avoided. This leads to an overall time complexity of $O(1)$ for N1P and $O(F(\alpha) \times SAS \times \log \sigma)$ for N1PFRONTBACK, where $F(\alpha)$ is the number of following symbols and *SAS* is the suffix array value sample rate described in Section 2.

Algorithm 1 Two-sided occ., $N^{1+}(\bullet\ \alpha\ \bullet)$

Precondition: v_{F} in forward CST t_{F} matches α
Precondition: v_{R} in reverse CST t_{R} matches α

```

8:              s ← edge(u_F, d + 1)
9:              u_R ← back-search(v_R, s)
10:             o ← o + N1P(t_R, u_R, • αs)
11:     return o
```

4 Dual CST Algorithm

The methods above for computing the frequency and occurrence counts provide the ingredients necessary for computing $m$gram language model probabilities. This leaves the algorithmic problem

[7] Backward search in the reverse tree corresponds to searching for the reversed pattern appended with one symbol.

[8] We assume search patterns do not extend beyond a single sentence, and thus will always be shorter than the edge labels.

Algorithm 2 KN probability $P\big(w_k|w_{k-(m-1)}^{k-1}\big)$

```
1: function ProbKneserNey(t_F, t_R, w, m)
2:     v_F ← root(t_F)                    ▷ match for suffix of w_{k-(m-1)}^{k-1}
3:     v_R ← root(t_R)                    ▷ match for suffix of w_{k-(m-1)}^{k-1}
4:     v_R^all ← root(t_R)                ▷ match for suffix of w_{k-(m-1)}^{k}
5:     p ← 1
6:     for i ← 1 to m do

24:    return c, N^1, N^{1+}(• •)
```

of efficiently ordering the search operations in forward and reverse CST structures.

This paper considers an interpolated LM formulation, in which probabilities from higher order contexts are interpolated with lower order estimates. This iterative process is apparent in Figure 2 (right) which shows the quantities required for probability scoring for an example $m$gram. Equivalently, the iteration can be considered in reverse, starting from unigram estimates and successively growing to large $m$grams, in each stage adding a single new symbol to left of the pattern. This suits incremental search in a CST in which search bounds are iteratively refined, which has a substantially lower time complexity compared to searching over the full index in each step.

Algorithm 2 presents an outline of the approach. This uses a forward CST, t_{F}, and a reverse CST, t_{R}, with three CST nodes (lines 2–4) tracking the match progress for the full $i$gram ($v_{\text{R}}^{\text{all}}$) and the $(i-1)$gram context ($v_{\text{F}}, v_{\text{R}}$), $i = 1 \ldots m$. The need to maintain three concurrent searches arises from the calls to *size*, $N^{1+}(\bullet\ \alpha)$, $N^{1+}(\alpha\ \bullet)$ and $N^{1+}(\bullet\ \alpha\ \bullet)$ (lines 14, 15; 17; 21; and 18, respectively). These calls impose conditions on the direction of the suffix tree, e.g., such that the edge labels and node degree can be used to compute the number of left or right contexts in which a pattern appears. The matching process is illustrated in Figure 2 where the three search nodes are shown on the left, considered bottom to top, and their corresponding count operations are shown to the right. The $N^{1+}(\bullet\ \alpha)$ calls require a match in the reverse CST (left-most column, $v_{\text{R}}^{\text{all}}$), while the $N^{1+}(\alpha\ \bullet)$ require a match in the forward CST (right-most column, v_{F}, matching the $(i-1)$gram context). The $N^{1+}(\bullet\ \alpha\ \bullet)$ computation reuses the forward match while also requiring a match for the $(i-1)$gram context in the reversed CST, as tracked by the middle column (v_{R}). Because of the mix of forward and reverse CSTs, coupled with search patterns that are revealed right-to-left, incremental search in each of the CSTs needs to be handled differently (lines 7–11). In the forward CST, we perform *backward search* to extend the search pattern to the left, which can be computed very efficiently from the BWT in the CSA.[9] Conversely in the reverse CST, we must use *forward search* as we are effectively extending the reversed pattern to the right; this operation is considerably more costly.

The discounts D on line 12 of Algorithm 2 and $N^{1+}(\bullet\ \bullet)$ (a special case of line 18) are precomputed directly from the CSTs thus avoiding several costly computations at runtime. The precomputa-

[9] See *Supplementary Materials* Table 1 for the time complexities of this and other CSA and CST methods.

tion algorithm is provided in Algorithm 3 which operates by traversing the nodes of the reverse CST and at each stage computing the number of $m$grams that occur 1–2 times (used for computing D_m in eq. 1), or with $N^{1+}(\bullet\ \alpha) \in [1-2]$ (used for computing D_k in eq. 2), for various lengths of $m$grams. These quantities are used to compute the discount parameters, which are then stored for later use in inference.[10] Note that the PRECOMPUTEDISCOUNTS algorithm can be slow, although it is significantly faster if we remove the *edge* calls and simply include in our counts all $m$grams finishing a sentence or spanning more than one sentence. This has a negligible (often beneficial) effect on perplexity.

5 Improved Single CST Approach

The above dual CST algorithm provides an elegant means of computing LM probabilities of arbitrary order and with a limited space complexity ($O(n)$, or roughly n in practice). However the time complexity is problematic, stemming from the expensive method for computing N1PFRONTBACK and repeated searches over the CST, particularly *forward-search*. Now we outline a method for speeding up the algorithm by doing away with the reverse CST. Instead the critical counts, $N^{1+}(\bullet\ \alpha)$ and $N^{1+}(\bullet\ \alpha\ \bullet)$ are computed directly from a single forward CST. This confers the benefit of using only backward search and avoiding redundant searches for the same pattern (cf. lines 9 and 11 in Algorithm 2).

The full algorithm for computing LM probabilities is given in Algorithm 4, however for space reasons we will not describe this in detail. Instead we will focus on the method's most critical component, the algorithm for computing $N^{1+}(\bullet\ \alpha\ \bullet)$ from the forward CST, presented in Algorithm 5. The key difference from Algorithm 1 is the loop from lines 6–9, which uses the *interval-symbols* (Schnattinger et al., 2010) method. This method assumes a *wavelet tree* representation of the *SA* component of the CST, an efficient encoding of the BWT as describes in section 2. The *interval-symbols* method uses RANK operations to efficiently identify for a given pattern the set of preceding symbols $P(\alpha)$ and the ranges $SA[l_s, r_s]$ corresponding to the patterns $s\alpha$ for all $s \in P(\alpha)$

Algorithm 4 KN probability $P(w_k|w_{k-(m-1)}^{k-1})$ using a single CST

```
1: function ProbKneserNey1(t_F, w, m)

6:         v_F^all ← back-search([lb(v_F^all), rb(v_F^all)], w_{k-i+1})
7:         if i > 1 then
8:             v_F ← back-search([lb(v_F), rb(v_F)], w_{k-i+1})
9:         D_i ← discount parameter for igram
10:        if i = m then
11:            c ← size(v_F^all)
12:            d ← size(v_F)
13:        else
14:            c ← N1pBack1(t_F, v_F^all, • w_{k-i+1}^{k-1})
15:            d ← N1pFrontBack1(t_F, v_F, • w_{k-i+1}^{k-1} •)
16:        if i > 1 then
17:            if v_F is valid then
18:                q ← N1p(t_F, v_F, w_{k-i+1}^{k-1} •)
19:                p ← 1/d (max(c − D_i, 0) + D_i q p)
20:        else
21:            p ← c/N^{1+}(• •)
22:    return p
```

Algorithm 5 $N^{1+}(\bullet\ \alpha\ \bullet)$, using forward CST

Precondition: v_F in forward CST t_F matches α

```
1: function N1pFrontBack1(t_F, v_F, α)
2:     o ← 0
3:     if string-depth(v_F) > |α| then
4:         o ← N1pBack1(t_F, v_F, • α)
5:     else
6:         for ⟨l, r, s⟩ ← int-syms(t_F, [lb(v_F), rb(v_F)]) do
7:             l' ← C_s + l
8:             r' ← C_s + r
9:             o ← o + N1p(t_F, node(l', r'), sα •)
10:    return o
```

by visiting all leaves of the wavelet tree of symbols occurring in $\mathcal{T}^{bwt}[l, r]$ (corresponding to α) in $O(|P(\alpha)| \log \sigma)$ time (lines 6-8). These ranges $SA[l', r']$ can be used to find the corresponding suffix tree node for each $s\alpha$ in $O(1)$ time. To illustrate, consider the pattern α = "night" in Figure 1a. From $\mathcal{T}^{bwt}$ we can see that this is preceeded by s ="old" (1^{st} occurrence in $\mathcal{T}^{bwt}$) and s ="the" (3^{rd} and 4^{th}); from which we can compute the suffix tree nodes, namely $[15, 15]$ and $[16 + (3-1), 16 + (4-1)] = [18, 19]$ for "old" and "the" respectively.[11]

N1PBACK1 is computed in a similar way, using the *interval-symbols* method to compute the number of unique preceeding symbols (see *Supplementary Materials*, Algorithm 7). Overall the time complexity of inference for both N1PBACK1

[10] Discounts are computed up to a limit on $m$gram size, here set to 10. The highest order values are used for computing the discount of $m$grams above the limit at runtime.

[11] Using the offsets into the *SA* for each symbol, $C_{\text{old}} = 15$ and $C_{\text{the}} = 16$, while -1 adjusts for counting from 1.

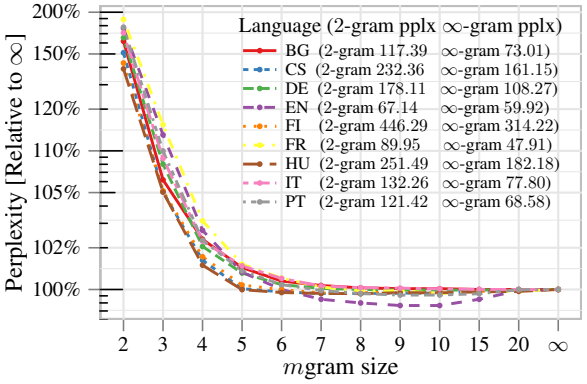

Figure 3: Perplexity results on several Europarl languages for different $m$gram sizes, $m = 2 \ldots 10, 15, 20, \infty$.

and N1PFRONTBACK1 is $O(P(\alpha) \log \sigma)$ where $P(\alpha)$ is the number of preceeding symbols of α, a considerable improvement over N1PFRONTBACK using the forward and reverse CSTs. Overall this leads to considerably faster computation of $m$gram probabilities compared to the two CST approach, and although still slower than highly optimised LM toolkits like SRILM, it is fast enough to support large scale experiments, and has considerably better scaling performance with the Markov order m (even allowing unlimited order), as we will now demonstrate.

6 Experiments

We used Europarl dataset and the data was numberized after tokenizing, splitting, and excluding XML markup. The first $10k$ sentences were used as the test data, and the last 80% as the training data, giving rise to training corpora of between 8M and 50M tokens and uncompressed size of up to 200 MiB (see Table 1 for detailed corpus statistics). We also processed the full 52 GiB uncompressed "20150205" English Wikipedia articles dump to create a character level language model consisting of $72M$ sentences. We excluded $10k$ random sentences from the collection as test data. We use the SDSL library (Gog et al., 2014) to implement all our structures and compare our indexes to SRILM (Stolcke, 2002). We refer to our dual-CST approach as D-CST, and the single-CST as S-CST.

We evaluated the perplexity across different languages and using $m$grams of varying order from $m = 2$ to ∞ (unbounded), as shown on Figure 3. Our results matched the perplexity results from SRILM (for smaller values of m in which SRILM training was feasible, $m \leq 10$). Note that perplexity drops dramatically from $m = 2 \ldots 5$ however the gains thereafter are modest for most languages. Despite this, several large $m$gram matches were found ranging in size up to a 34-gram match. We speculate that the perplexity plateau is due to the simplistic Kneser-Ney discounting formula which is not designed for higher order $m$gram LMs and appear to discount large $m$grams too aggressively. We leave further exploration of richer discounting techniques such as Modified Kneser-Ney (Chen and Goodman, 1996) or the Sequence Memoizer (Wood et al., 2011) to our future work.

Figure 4 compares space and time of our indexes with SRILM on the German part of Europarl. The construction cost of our indexes in terms of both space and time is comparable to that of a 3/4-gram SRILM index. The space usage of D-CST index is comparable to a compact 3-gram SRILM index. Our S-CST index uses only 177 MiB RAM at query time, which is comparable to the size of the collection (172 MiB). However, query processing is significantly slower for both our structures. For 2-grams, D-CST is 3 times slower than a 2-gram SRILM index as the expensive $N^{1+}(\bullet\, \alpha\, \bullet)$ is not computed. However, for large $m$grams, our indexes are much slower than SRILM. For $m > 2$, the D-CST index is roughly six times slower than S-CST. Our fastest index, is 10 times slower than the slowest SRILM 10-gram index. However, our run-time is independent of m. Thus, as m increases, our index will become more competitive to SRILM while using a constant amount of space.

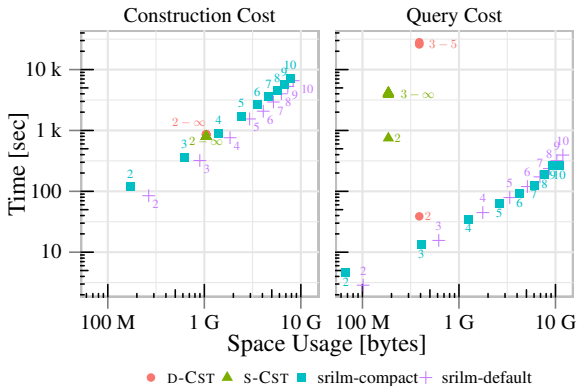

Figure 4: Time versus space tradeoffs measured on Europarl German (de) dataset, showing memory and time requirements.

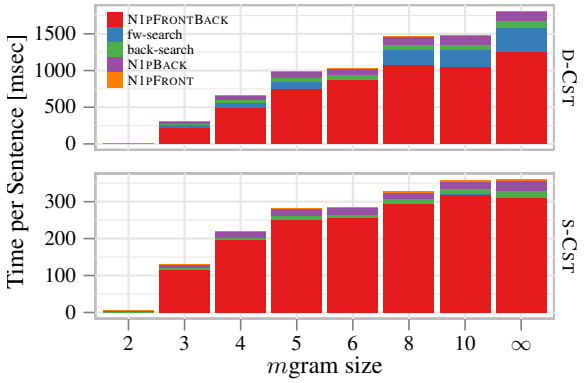

Figure 5: Runtime breakdown of a single pattern averaged over all patterns for both methods over the Wikipedia collection.

Next we analyze the performance of our index on the large Wikipedia dataset. The S-CST, character level index for the data set requires 22 GiB RAM at query time whereas the D-CST requires 43 GiB. Figure 5 shows the run-time performance of both indexes for different $m$grams, broken down by the different components of the computation. As discussed above, 2-gram performance is much faster. For both indexes, most time is spent computing N1PFRONTBACK (i.e., $N^{1+}(\bullet\ \alpha\ \bullet)$) for all $m > 2$. However, the wavelet tree traversal used in S-CST roughly reduces the running time by a factor of three. The complexity of N1PFRONTBACK depends on the number of contexts, which is likely small for larger $m$grams, but can be large for small $m$grams, which suggest partial precomputation could significantly increase the query performance of our indexes. Exploring the myraid of different CST and CSA configurations available could also lead to significant improvements in runtime and space usage also remains future work.

7 Conclusions

This paper has demonstrated the massive potential that succinct indexes have for language modelling, by developing efficient algorithms for on-the-fly computing of $m$gram counts and language model probabilities. Although we only considered a Kneser-Ney LM, our approach is portable to the many other LM smoothing method formulated around similar count statistics. Our complexity analysis and experimental results show favourable scaling properties with corpus size and Markov order, albeit running between 1-2 orders of magnitude slower than a leading count-based LM. Our ongoing work seeks to close this gap: preliminary experiments suggest that with careful tuning of the succinct index parameters and caching expensive computations, query time can be competitive with state-of-the-art toolkits, while using less memory and allowing the use of unlimited context.

Abstract

As a key representation model of knowledge, ontology has been widely used in a lot of NLP related tasks, such as semantic parsing, information extraction and text mining etc. In this paper, we study the task of ontology matching, which concentrates on finding semantically related entities between different ontologies that describe the same domain, to solve the semantic heterogeneity problem. Previous works exploit different kinds of descriptions of an entity in ontology directly and separately to find the correspondences without considering the higher level correlations between the descriptions. Besides, the structural information of ontology haven't been utilized adequately for ontology matching. We propose in this paper an ontology matching approach, named ERSOM, which mainly includes an unsupervised representation learning method based on the deep neural networks to learn the general representation of the entities and an iterative similarity propagation method that takes advantage of more abundant structure information of the ontology to discover more mappings. The experimental results on the datasets from Ontology Alignment Evaluation Initiative (OAEI[1]) show that ERSOM achieves a competitive performance compared to the state-of-the-art ontology matching systems.

[1]The OAEI is an international initiative organizing annual campaigns for evaluating ontology matching systems. All of the ontologies provided by OAEI are described in OWL-DL language, and like most of the other participates our ERSOM also manages the OWL ontology in its current version. OAEI: `http://oaei.ontologymatching.org/`

1 Introductions

In the recent years, it becomes evident that one of the most important directions of improvement in natural language processing (NLP) tasks, like word sense disambiguation, coreference resolution, relation extraction, and other tasks related to knowledge extraction, is by exploiting semantics resources (Bryl et al., 2010). Nowadays, the Semantic Web made available a large amount of logically encoded information (e.g. ontologies, RDF(S)-data, linked data, etc.), which constitutes a valuable source of semantics. However, extending the state-of-the-art natural language applications to use these resources is not a trivial task mainly due to the heterogeneity and the ambiguity of the schemes adopted by the different resources of the Semantic Web. How to utilize these resources in NLP tasks comprehensively rather than choose just one of them has attracted much attention in recent years.

An effective solution to the ontology heterogeneity problem is ontology matching (Euzenat et al., 2007; Shvaiko and Euzenat, 2013), whose main task is to establish semantic correspondences between entities (i.e., classes, properties or instances) from different ontologies.

Ontology matching is usually done by measuring the similarity between two entities from two different ontologies. To effectively calculate the similarities, almost all types of descriptions of an entity should be used. In previous works, given the different nature of different kinds of descriptions, similarities are normally measured separately with different methods and then aggregated with some kind of combination strategy to compute the final similarity score. For example, Mao et al. (2010) defined three single similarities (i.e., *Name similarity*, *Profile similarity* and *Structural similarity*) based on the descriptions of an entity, then they employed a harmony-based method to aggregate

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2419–2429,
Lisbon, Portugal, 17-21 September 2015.

the single similarities to get a final similarity for extracting the final mappings. However, treating different kinds of descriptions of an entity separately suffers from two limitations. First, it limits the capacity of modeling the interactions between different descriptions. For example, entity's label is always a specific substitution of its ID; entity's comment is a semantic definition for its ID; a class can be characterized with its related properties, and a property is usually restricted by its domain and range. These potential correlations of the descriptions are very important to measure the similarity between entities since they can be treated as some potential features describing an entity. Second, it is difficult to estimate how many and which kind of single similarities are needed for an aggregation method to get a satisfactory result.

On the other hand, in order to find more mappings, many structural ontology matching methods are proposed. To the best of our knowledge, previous structural methods are either local methods (Le et al., 2004; Sunna and Cruz, 2007) or global (i.e. iterative) methods but only use part of the structure information of the ontology (Li et al., 2009; Ngo and Bellahsene, 2012). For example, the ontology matching system YAM++ (Ngo and Bellahsene, 2012) utilizes a global structural method but it only uses the structure information of classes and properties to create the propagation graph to find mappings between classes and properties. A large amount of instances and their relations to classes and properties in the ontology haven't been exploited in this system.

To overcome the existing limitations, we propose in this paper a representation learning method to capture the interactions among entity's descriptions; then we present our global structural method which exploits more abundant structure information of the ontology. We summarize our contributions as follows.

- We propose to use the deep neural network model to learn the high-level abstract representations of classes and properties from their descriptions to acquire the potential correlations for the computing of the similarities between classes and properties. Moreover, there is no need to select and aggregate different single similarities in the similarity computation.
- We propose a global similarity propagation method that utilizes more abundant structure information including all kinds of entities and their relations in the ontology, to find more mappings.

To evaluate the effectiveness of our approach, we conduct experiments on the public datasets from OAEI campaign (We select the OAEI data sets mainly because evaluation metrics have been well defined on these data sets and comparision can be easily made). The experimental results show that our matching approach can achieve a competitive matching performance compared to the state-of-the-art systems.

2 Problem Statement

Ontology is a formal, explicit specification of a shared conceptualization in terms of classes, properties and relations (Euzenat et al., 2004). The process of ontology matching is to find mappings (or correspondences) between entities (classes, properties or individuals) from two ontologies. A mapping is defined as a four-tuple as written in Eq.(1), where e^1 and e^2 represent the entity in ontology O^1 and O^2 respectively, r is a kind of matching relation (e.g., equivalent, subsume) and $k \rightarrow [0, 1]$ is the degree of confidence of matching relation between e^1 and e^2 (Mao et al., 2010).

$$m =< e^1, e^2, r, k > \quad (1)$$

Similar with most of the OAEI systems (Li et al., 2009; Ngo and Bellahsene, 2012; Cheatham and Hitzler, 2013b), we focus on discovering only equivalent mappings between classes and properties with cardinality 1:1. That is, one class (property) in ontology O^1 can be matched to at most one class (property) in ontology O^2 and vise versa.

3 ERSOM: Entity Representation and Structure based Ontology Matching

In this paper, we propose a structural ontology matching approach using automatically learned entity representation, which we call ERSOM. Fig.1 shows the architecture of our approach. The details of its major modules are given in the following sections.

3.1 Learning the representation of entity

In this section, we present how to learn the high-level abstract representations for ontology entities. The motivations are: 1) we regard different kinds of the descriptions of an entity as a whole to avoid

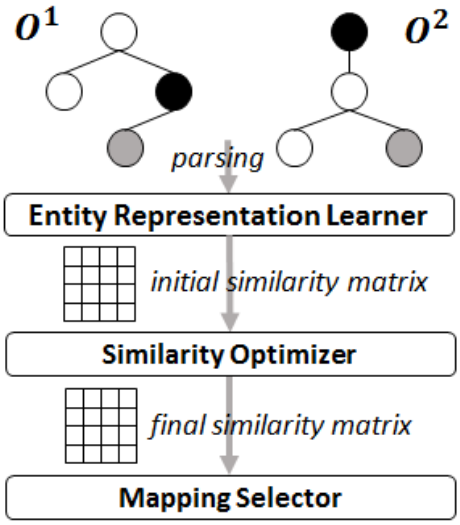

Figure 1: The architecture of ERSOM. Given the two to-be-matched ontologies, we first extract the descriptive information for each entity, then learn the entity's abstract representation based on its descriptions, and finally utilize the representations to compute the similarities between entities to initialize the similarity propagation method to find final mappings.

separatively calculating the similarities and aggregating them later with a combination method; 2) the learned representation can not only express the meaning of the original descriptions of an entity but also captures the interactions among different descriptions.

3.1.1 Creating term vector for entity

We first generate a combination of the entity's descriptions (CDs for short) and then create a term vector for each entity. In particular, the CDs of a class = the class's ID + label + comments + its properties' descriptions + its instances' descriptions. The CDs of a property = the property's ID + label + its domain + its range (or its textual value when the property is a datatype property). And the CDs of an instance = the instance's ID + label + its properties' values. A binary term vector is created for each entity with the pre-processing that consists of tokenizing, removing stop words, stemming and deleting superfluous words. In the binary term vectors, element 1 and 0 refer to the existence and inexistence of a specific word, respectively.

3.1.2 Learning entity representations

In the ontology matching area, training data usually refers to a pair of ontologies with correct mappings created by domain experts between their entities. The acquisition of such dataset is time-consuming and laborious. We state in this section how to learn the abstract representations for entities from their binary term vectors with an unsupervised way. The deep neural network (DNN) (Hinton et al., 2006; Bengio et al., 2007) is a multilayer learning model. It is mainly used for learning the high-level abstract representations of original input data. Given the generalization and the abstraction introduced in the representation learning procedure, DNN allows us to better model the interactions among different kinds of input features, and measure the similarity at a more general level. Inspired by the work in (Hinton, 2007; Bengio et al., 2012; He et al., 2013; Cui et al., 2014), we use auto-encoder (Bourlard and Kamp, 1988; Hinton and Zemel, 1994) to learn the representations for classes and properties. The auto-encoder is one of the neural network variants that can automatically discover interesting abstractions to represent an unlabeled dataset.

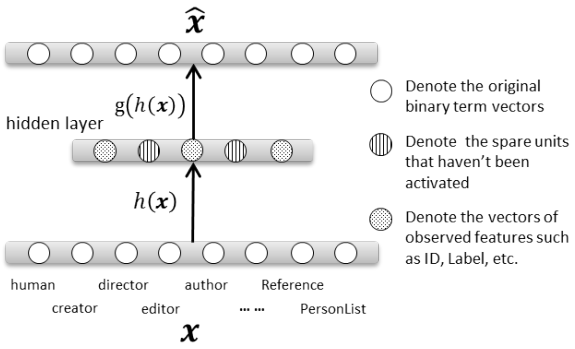

Figure 2: Unsupervised representation learning.

As shown in Fig.2, the input to the auto-encoder is denoted as x, which indicates a binary term vector of a class or a property. Auto-encoder tries to learn an approximation to the identity function $h(x)$, so as to output $\hat{x}$ that is similar to x. More specifically, the auto-encoder consists of an encoding process $h(x) = f(Wx + b_1)$ and a decoding process $g(h(x)) = f(W^T h(x) + b_2)$, where f is a activation function like the sigmoid function $f(x) = 1/(1 + exp(-x))$, W is the weight matrix and b is the bias term. The goal of the auto-encoder is to minimize the reconstruction error $L(x, g(h(x))) = |x - g(h(x))|^2$, thus retaining

maximum information. Through the combination and transformation, auto-encoder learns the abstract representation $h(x)$ of the input binary term vector. The representation is a real vector with values between 0 and 1.

In consideration of the large number of units in the hidden layer (as marked in Fig.2), a sparsity constraint is imposed on the hidden units to hold the capacity to discover interesting structure in the data. We use sparse auto-encoder (Coates et al., 2011) to learn the correlations between descriptions from their binary term vectors. The sparse auto-encoder attempts to minimize the following loss function:

$$J(W,b) = \sum_{i=1}^{m} \left\| x^{(i)} - \widehat{x}^{(i)} \right\|^2 + \lambda \left(\|W_1\|_F + \|W_2\|_F \right) + \beta \sum_{h \in H} KL\left(\rho \| \widehat{\rho}_h\right) \tag{2}$$

where $x^{(i)}$ is the binary term vector of the ith entity (a class or a property), $\widehat{x}^{(i)}$ is the reconstruction of $x^{(i)}$, λ is a regularization parameter, original $\| \cdot \|_F$ is the Frobenius norm, β controls the weight of the sparsity penalty term, H is the set of hidden units, and ρ is the sparsity parameter. Formally, $KL\left(\rho \| \widehat{\rho}_h\right) = \rho \log \frac{\rho}{\widehat{y}_h} + (1-\rho) \log \frac{1-\rho}{1-\widehat{y}_h}$ is the Kullback-Leibler (KL) divergence between a Bernoulli random variable with mean ρ and a Bernoulli random variable with mean $\widehat{y}_h$.

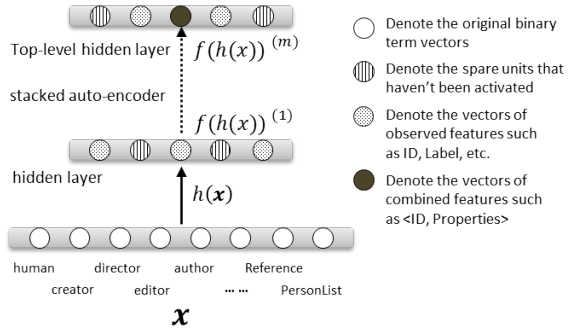

Figure 3: Learning higher level representations.

3.1.3 Learning higher level representations

The auto-encoder which only has one hidden layer may not be enough to learn the complex interactions between input features. Inspired by the work of Vincent et al. (2010) and He et al. (2013), we build multi-layer model to learn more abstract entity representations. To achieve this, we repeatedly stack new sparse auto-encoder on top of the previously learned $h(x)$ (i.e., the higher level representations are formed by combination of lower level representations). This model is called Stacked Auto-Encoder (SAE) by Bengio et al. (2007). In this way, when we input the binary term vector to the network, we can get its abstract representations in different levels. In other words, with the layer-by-layer learning, we obtain different levels of representations. The top-level representation, which models the final interactions of the original descriptions, can be used to measure the similarity between classes and properties.

The prototype of Stacked Auto-Encoder (SAE) is shown in Fig.3, where $f(h(x))^{(m)}$ denotes the final representation learned by the top-level hidden layer and superscript m means the SAE consists of m sparse auto-encoders.

3.2 Optimizing with the ontology structure

The above method can only consider the local descriptions (such as ID, label and comments etc.) of entities in ontology. According to the study in (Melnik et al., 2002), we present our structural method or called Similarity Propagation (SP) method, which exploits more abundant structure information of the ontology to discover more mappings globally. The intuition behind the propagation idea is that the similarity between two entities is not only about their neighbor entities, but it is about all other entities (neighbor entities' neighbor entities) in the ontologies. This idea has also been used in the ontology matching systems RiMOM(Li et al., 2009) and YAM++(Ngo and Bellahsene, 2012) in order to find mappings between classes and properties. But the nodes in their propagation graph are just limited to class pairs and property pairs, and the propagation edges are transformed from relations between two classes, two properties or a class and a property. The difference of our SP method is that we consider the instances and its relations with classes and properties when creating the propagation graph even if we also only find mappings between classes and properties. This is because (1) the similar degree of two classes will be increased if they have some of similar instances; (2) the similar degree of two properties will be increased if the instances that own these properties are similar. The propagation graph in our SP method will be much more complete compared with the previous ones.

Algorithm 1 presents the procedures of our SP method. In the first two steps of it, we represent each to-be-matched ontology to a Directed Labeled Graph (DLG). Each edge in the DLG has format (s, p, o), where s and o are the source and target nodes (each node represents a class, a property or an instance), and the edge's label p comes from one of the seven ontology relations including *HasSubClass*, *HasSubProperty*, *HasObjectProperty*, *HasDataProperty*, *HasInstance*, *HasDomain*, *HasRange*. Then we create a Pairwise Connectivity Graph (PCG) from two DLGs by merging edges having the same labels.

Algorithm 1: Our SP Algorithm

Input: The to-be-matched ontologies, O_R and O_T; The initial similarity matrix, M_0; The edges' weight matrix, W;

Output: The updated similarity matrix, M_1;

$DLG_1 \leftarrow Transform(O_R)$;
$DLG_2 \leftarrow Transform(O_T)$;
$PCG \leftarrow Merge(DLG_1, DLG_2)$;
$IPG \leftarrow Initiate(PCG, M_0, W)$;
$M_1 \leftarrow Propagation(IPG, Normalized)$;

In the fourth step of Algorithm 1, for a PCG, we assign weight values to edges as the inverse of the number of out-linking relationships of its source node (Melnik et al., 2002). For the nodes that consist of two classes or two properties, we assign them values calculated with the cosine similarity between their representations learned in section 2.1.3. For the node consisting of two instances, the similarity value assigned to it is measured with the ScaledLevenstein[2] between the IDs of instances. In this way, we construct an Induced Propagation Graph (IPG) on which the propagation algorithm will run iteratively. Let $\sigma(x, y)$ denotes the similarity score between entities x and y for node (x, y) in the IPG. At the $(i+1)$th iteration, the similarity score is updated as follows:

$$\sigma^{i+1} = \frac{1}{z}\left(\sigma^0 + \sigma^i + \varphi(\sigma^0 + \sigma^i)\right), \quad (3)$$

$$\varphi\left(\sigma^0 + \sigma^i\right) = \sum_{j=1}^{m}\left(\sigma^0 + \sigma_j^i\right) w_j \quad (4)$$

[2] `http://sourceforge.net/projects/secondstring/`. ScaledLevenstein is a good method for computing string similarity (Cheatham and Hitzler, 2013a), of course, it can be replaced by other methods.

where z is the normalization factor defined as $z = \max_{x' \in IPG}\left(\sigma^{i+1}\right)$. σ^0 and σ^i are similarities at the initial time and ith iterations, respectively. $\varphi()$ is the function to compute the similarities propagated from the adjacent node σ_j^i connected to node (x, y) in the $(i+1)$th iteration. And w_j is the weight of edge between the node (x, y) and its jth neighboring node.

During each iteration in the final step of Algorithm 1, only the similarity value between two entities in the node will be updated. At the end of each iteration, all similarity values are normalized by a *Normalized* function to all in range $[0, 1]$. The iteration stops after a predefined number of steps.

3.3 Mapping selection

Similar with the work in (Wang and Xu, 2007; Huang et al., 2007; Ngo and Bellahsene, 2012), we use the Stable Marriage (SM) algorithm (Melnik et al., 2002) to choose the 1:1 mappings from the M rows and N columns similarity matrix, where M and N is the number of classes and properties in ontologies O_1 and O_2, respectively. In addition, before we run the SM algorithm we set the value of cell $[i, j]$ of the similarity matrix to zero if i and j correspond to different types of entities. Thus, we remove lots of redundant data and only find the mappings between classes or properties.

4 Experiments

4.1 Data sets and evaluation criteria

The annual OAEI campaign is an authoritative contest in the area of ontology matching, we choose the data from OAEI in our experiments, because the evaluation metrics have been well defined and the comparision can be easily made. We observe strong structure similarities lies between OAEI ontologies and ontologies used in NLP tasks, such as WordNet and HowNet for WSD (Li et al., 1995; Agirre et al., 2009), and Freebase, YAGO, and knowledge graph for IE, text mining and QA (Yao and Van Durme, 2014; Yao et al., 2014), both describe entities and their relations with class, properties and instances.

Development dataset: the Standard Benchmark 2012 dataset that OAEI provides for developers to test their system before participating in the competition is used as the development dataset in our experiments. This dataset contains one reference ontology and 109 target ontologies. We use

this dataset to test various values for the parameters in our ERSOM and apply the best ones to the experiments on the testing datasets.

Testing dataset: (1) the Benchmark-Biblio 2012 dataset which contains one reference ontology and 94 target ontologies; (2) the Benchmark-Biblioc 2013 dataset which has five sub-datasets and there are one reference ontology and 93 target ontologies in each sub-dataset. We use these two datasets to evaluate the performance of our ERSOM approach.

In the matching scenario, each target ontology should be mapped to the reference ontology. We followed the standard evaluation criteria from the OAEI, calculating the precision, recall and f-measure over each test. The version computed here is the harmonic mean of precision and recall.

4.2 Experimental design and results

4.2.1 Evaluation for representation learning

We first use Jena[3] parsing the ontologies and extract descriptions for entities according to the description in section 2.1.1, then we create a vocabulary based on the dataset and denote each class and property as a binary term vector. We apply the L-BFGS algorithm (Ngiam et al., 2011) to train the stacked auto-encoder described in section 2.1.3. The size of the input layer is equals to the length of the vocabulary created from the dataset. We fix the parameters $\lambda = 1e-4$, $\beta = 3$ and $\rho = 0.25$ in Eq.2, and set the size of the first and second hidden layer of the stacked auto-encoder to 200 and 100, respectively, by experience. The number of iterations of the L-BFGS algorithm is set to 500. We use the learned representations to measure the similarities between classes and properties and apply the strategy presented in section 2.3 to extract final mappings. The matching results of our Unsupervised Representation Learning (URL) method on the development dataset and testing datasets are shown in Table 1 and Table 2, respectively.

Method	Prec.	Rec.	F-m.
TV	0.841	0.715	0.748
URL(1)	0.819	0.822	0.820
URL(2)	0.843	0.846	0.844

Table 1: Representation learning on dev. dataset.

In Table 1, TV denotes the matcher in which the similarities are calculated between binary term vectors of classes and properties by using cosine measure. URL(i), where $i \in \{1, 2\}$, represents that we use the representations learned by the ith hidden layer of the stacked auto-encoder to measure the similarities between classes and properties to find mappings. Table 1 shows that on the development dataset, the F-measure of TV is 0.748 and it is improved 9.6% and 12.8% when we use the representations learned by the single-layer and double-layer auto-encoder to find the mappings, respectively. It illustrates that we have learned some useful information from the term vectors, which can be explained as the interactions between descriptions of entities. From the last two rows in Table 1, we can find that the F-measure improved by 2.9% when we use the representations learned by the second hidden layer (i.e., URL(2)) to measure the similarities.

	Benchmark-Biblio 2012			Benchmark-Biblioc 2013		
	Prec.	***Rec.***	***F-m.***	***Prec.***	***Rec.***	***F-m.***
TV	0.870	0.719	0.761	0.865	0.715	0.757
URL(1)	0.805	0.808	0.806	0.780	0.783	0.786
URL(2)	0.814	0.817	0.815	0.787	0.790	0.793

Table 2: Representation learning on test datasets.

From Table 2 we can see that the F-measures are increased on both of the testing datasets when we use the learned representations to measure similarities between classes and properties compared with using term vectors, but the amount of improvements are less than that on the development dataset. This is because we estimate the parameters of the representation learning model on the development dataset and then apply them on the test tasks directly. The precision is reduced when we use URL method, this may be due to the learned representations of entities are too general. In addition, in the parameter adjustment process, we try to make the F value maximization, but not to care about mapping precision. This is because we usually compare the performance of the systems based on their matching F values.

4.2.2 Comparison with aggregation methods

Aggregating different similarities is pervasive in ontology matching systems that contain multiple single matchers, for example, Falcon-AO(Qu et al., 2006), RiMOM(Li et al., 2009), YAM++(Ngo and Bellahsene, 2012), etc. Since our representation learning method also combines all descriptions of an entity together in an unsu-

[3] https://jena.apache.org/

pervised way, we compare it with previous unsupervised aggregation strategies, that is, Max, Average, Sigmoid, Weighted(Cruz et al., 2010) and Harmony(Mao et al., 2008, 2010). As the work in (Mao et al., 2010; Ngo and Bellahsene, 2012), we first define three context profiles including individual profile, semantic profile and external profile for each class and property (this equivalent to divide the collection of descriptions of a class or a property into three different parts). Then we apply a vector space model with TFIDF weighting scheme and cosine similarity measure to compute similarity scores between profiles. And finally, we aggregate these three single similarities using different aggregation methods.

	Dev.	**Tes.1**	**Tes.2**
Individual Profile	0.668	0.612	0.611
Semantic Profile	0.434	0.472	0.477
External Profile	0.222	0.224	0.224
MAX	0.739	0.705	0.712
Average	0.792	0.786	0.786
Sigmoid	0.763	0.753	0.757
Weighted	0.755	0.716	0.728
Harmony	0.794	0.789	0.785
URL	**0.844**	**0.815**	**0.793**

Table 3: Comparison with aggregation methods.

Table 3 shows the F-measure of the single matchers and aggregation methods on the development dataset (Dev. for short) and two testing datasets (i.e., Tes.1 and Tes.2, which refer to the Benchmark-Biblio 2012 dataset and the Benchmark-Biblioc 2013 dataset, respectively). First, the performance of single matcher is poor, the highest F-measures are 0.668, 0.612 and 0.611 on the datasets Dev., Tes.1 and Tes.2, respectively. And when we use external profile to calculate the similarities, the F-measures are reduced to 22%. Second, the performance is dramatically boosted by aggregation methods and they all achieve F-measures higher than 0.7, so the aggregation methods are very effective in improving the performance of mapping approaches that rely on measuring multiple similarities. And finally, our Unsupervised Representation Learning (URL) method holds the highest F-measure both on the development dataset and on the testing datasets.

4.2.3 Evaluation for our structural method

In this experiment, we compare our Similarity Propagation (SP) method to other structure based methods, that is, ADJACENTS and ASCOPATH in (Le et al., 2004); DSI and SSC in (Sunna and Cruz, 2007); Li's SP (Li et al., 2009) and Ngo's SP (Ngo and Bellahsene, 2012). We first use entity's ID to compute the similarity between classes and properties to provide an unified initial similarity matrix as input (or initialization) for our SP and other structural methods. Then, a new similarity matrix will be created and updated by considering the initial similarities and different structure information. And finally, we extract the mappings from the newly created similarity matrix with the strategy described in section 2.3.

	Dev.	**Tes.1**	**Tes.2**
Initial Matcher	0.616	0.524	0.523
ADJACENTS	0.622	0.569	0.570
ASCOPATH	0.604	0.540	0.552
DSI	0.641	0.576	0.575
SSC	0.642	0.569	0.568
Li's SP	0.747	0.769	0.772
Ngo's SP	0.751	0.768	0.764
Our SP	**0.810**	**0.834**	**0.839**
Our SP with URL	**0.903**	**0.865**	**0.866**

Table 4: Comparison with structural methods.

In ADJACENTS method, the parameter W_k, where $k \in \{1, 2, 3\}$, is set to 1/3. The parameter MCP in the methods DSI and SSC is set to 0.75 as reported in their work. The iterative times to SP algorithm are fixed to 50. Table 4 reports the matching F-measures of these structure based methods on the development dataset (Dev. for short) and testing datasets (Tes.1, Tes.2 for short).

From table 4 we can see that the local-structure based methods (i.e., ADJACENTS, ASCOPATH, DSI and SSC) provide low matching quality. It means that these methods did not discover enough additional correct mappings or even find some incorrect mappings. For example, the F-measure even reduced on the development dataset when use ASCOPATH method. This is because if two entities don't have any common entity in their ancestors, their similarity is equal to 0. Whereas, Li's SP and Ngo's SP are global-structure based methods, and they seem to work well. The F-measure has even improved by 21.9% when using the Ngo's SP compared with the initial matcher. This

is because in the SP method, the similarity score of a pair of entities depends on not only their current status but also on the status of the other pairs. That explains why SP outperforms all other local based structural methods. In our SP, all instances and their relations to other entities in ontology are exploited to help find the mappings between classes and properties, therefore the matching quality is distinctly improved.

The last two rows of Table 4 shows that when we use the learned representations to create the initial similarity matrix to initialize our SP method, the matching quality is significantly improved. For example, the F-measure is improved from 0.810 to 0.903 on the development dataset. This illustrates that the initialization step is very important to the SP method.

4.2.4 Comparison with other ontology matching systems

We compare our ontology matching approach, called ERSOM, with other multi-strategy matching systems on the testing datasets. Fig.4 lists the results of top five matching systems according to their F-measures on the Benchmark-Biblio 2012 dataset and Benchmark-Biblioc 2013 dataset.

As shown in Fig.4, ERSOM outperforms most of the participates except the systems YAM++ and CroMatcher whose F-measures are 0.89 and 0.88 in 2013, respectively. CroMatcher achieves the same level of recall as YAM++ but with consistently lower precision (Grau et al., 2014). Unlike MapSSS, our approach does not use any external resources such as Google queries in its current version. In YAM++ approach, the gold standard datasets that taken from Benchmark dataset published in OAEI 2009 are used to generate training data to train a decision tree classifier. And in the classifying phase, each pair of elements from two to-be-matched ontologies is predicted as matched or not according to its attributes. However, ERSOM is an unsupervised approach, but it does not exclude using external resources and training data to help learning the representations of entities and provide the initial similarity matrix for the SP method to further improve the performance.

5 Related work

There are many studies on Ontology Matching (Euzenat et al., 2007; Shvaiko and Euzenat, 2013). Currently, almost all ontology matching systems exploit various kinds of information provided in

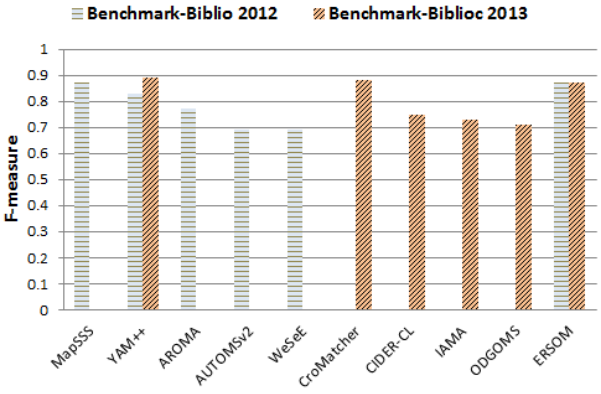

Figure 4: Comparison with other OAEI systems.

ontologies to get better performance. To aggregate the different similarity matrixes, various approaches have been proposed.

Pirró and Talia (2010) is a generic schema matching system. It exploits *Max*, *Min*, *Average* and *Weighted strategies* for the combination. The weighted method assigns a relative weight to each similarity matrix, and calculates a weighted sum of similarity for all similarity matrixes. The *Average method* is a special case of *Weighted*, which considers each similarity matrix equally important in the combination. *Max* and *Min* are two extreme cases that return the highest and lowest similarities in all similarity matrixes respectively. Ji et al. (2011) use the Ordered Weighted Average (OWA) to combine different matchers. It is a kind of ontology-independent combination method which can assign weights to the entity level, i.e., it use a specific ordered position rather than a weight associated with a specific similarity matrix to aggregate multiple matchers. Jean-Mary et al. (2009) combines different matchers by using a weighted sum strategy that adjusts weights empirically, or based on some static rules. This approach cannot automatically combine different matchers in various matching tasks.

There are several works which exploit the supervised machine learning techniques for ontology matching. Eckert et al. (2009), string-based, linguistic and structural measures (in total 23 features) were used as input to train a SVM classifier to align ontologies. CSR (Classification-based learning of Subsumption Relations) is a generic method for automatic ontology matching between concepts based on supervised machine learning (Spiliopoulos et al., 2010). It specifically focusses on discovering subsumption correspon-

dences. SMB (Schema Matcher Boosting) is an approach to combining matchers into ensembles (Gal, 2011). It is based on a machine learning technique called boosting, that is able to select (presumably the most appropriate) matchers that participate in an ensemble.

The difference of our work is that the textual descriptions are not been directly used to measure the similarities between entities. We learn a representation for each ontology entity in an unsupervised way to capture the interactions among the descriptions, which avoid the problem of selecting and aggregating different individual similarities.

6 Conclusions

The successful ontology matching is very important to link heterogeneous ontologies for NLP. In this paper, we have proposed an ontology matching approach, ERSOM, which describes the classes and properties in ontology with abstract representations learned from their descriptions and improves the overall matching quality using an iterative Similarity Propagation (SP) method based on more abundant structure information. Experimental results on the datasets from OAEI demonstrate that our approach performs better than most of the participants and achieves a competitive performance. In our future work, we will consider to use the ontology matching approach to the matching between different NLP-oriented ontologies such as wordnet, Freebase, YAGO, etc.

A Single Word is not Enough: Ranking Multiword Expressions Using Distributional Semantics

Martin Riedl and **Chris Biemann**

Abstract

We present a new unsupervised mechanism, which ranks word n-grams according to their multiwordness. It heavily relies on a new *uniqueness* measure that computes, based on a distributional thesaurus, how often an n-gram could be replaced in context by a single-worded term. In addition with a downweighting mechanism for incomplete terms this forms a new measure called DRUID. Results show large improvements on two small test sets over competitive baselines. We demonstrate the scalability of the method to large corpora, and the independence of the measure of shallow syntactic filtering.

1 Introduction

While it seems intuitive to treat certain sequences of tokens as single terms, there is still considerable controversy about the definition of what exactly such a multiword expression (MWE) constitutes. Sag et al. (2001) pinpoint the need of treating MWEs correctly and classify a range of syntactic formations that could form MWEs and define MWEs as being non-compositional with respect to the meaning of their parts. While the exact requirements on MWEs is bound to specific tasks (such as parsing, keyword extraction, etc.), we operationalize the notion of non-compositionality by using distributional semantics and introduce a new measure that works well for a range of task-based MWE definitions.

Most previous MWE ranking approaches use the following mechanisms to determine multiwordness: part-of-speech (POS) tags, word/multiword frequency and significance of co-occurrence of the parts. In this paper we do not want to introduce "yet another ranking function" but rather an additional mechanism, which performs ranking based on distributional semantics.

Distributional semantics has already been used for MWE identification, but mainly to discriminate between compositional and non-compositional MWEs (Schone and Jurafsky, 2001; Salehi et al., 2014; Hermann and Blunsom, 2014). Here we introduce a new concept to describe the multiwordness of a term by its *uniqueness*. Using the *uniqueness* score we measure how likely a term in context can be replaced by a single word. This measure is motivated by the semiotic consideration that due to parsimony concepts are often expressed as single words. Furthermore, we implement a context-aware punishment, called *incompleteness*, which degrades the score of terms that seem incomplete regarding their contexts. Both concepts are combined into a single score we call DRUID, which is calculated based on a distributional thesaurus. In the following, we show the impact of that new method for French and English and also examine the effect of corpus size on MWE extraction. Additionally, we report on results without using any linguistic preprocessing except tokenization.

2 Related Work

The generation of MWE dictionaries has drawn much attention in the field of Natural Language Processing (NLP). Early computational approaches (e.g. Justeson and Katz (1995)) use POS sequences as MWE extractors. Other approaches, relying on word frequency, statistically verify the hypothesis whether the parts of the MWE occur more often together than would be expected by chance (Manning and Schütze, 1999; Evert, 2005; Ramisch, 2012). One of the first measures that consider context information (co-occurrences) are the C-value and the NC-value introduced by Frantzi et al. (1998). These methods first extract candidates using POS information

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2430–2440,
Lisbon, Portugal, 17-21 September 2015.

and then compute scores based on the frequency of the MWE and the frequency of nested MWE candidates. The method described by Wermter and Hahn (2005) computes a score by multiplying the frequency of a candidate when placing wildcards for each word. A newer method is introduced in Lossio-Ventura et al. (2014), which reranks scores based on an extension of the C-value, which uses a POS-based probability and an inverse document frequency. Using different measures and learning a classifier that predicts the multiwordness was first proposed by Pecina (2010), who, however, restricts his experiments to two-word MWEs for the Czech language only. Korkontzelos (2010) comparatively evaluates several MWE ranking measures. The best MWE extractor reported in his work is the scorer by (Nakagawa and Mori, 2002; Nakagawa and Mori, 2003), who use the un-nested frequency (called marginal frequency) of each candidate and multiply these by the geometric mean of the distinct neighbor of each word within the candidate.

Distributional semantics is mostly used to detect compositionality of MWEs (Salehi et al., 2014; Katz and Giesbrecht, 2006). Most approaches therefore compare the context vector of a MWE with the combined vectors based on the constituent words of the MWE. The similarity between the vectors is then used as degree for compositionality. In machine translation, words are sometimes considered as multiwords if they can be translated as single term (cf. (Bouamor et al., 2012; Anastasiou, 2010)). Whereas this follows the same intuition as our *uniqueness* measure, we do not require any bilingual corpora.

Regarding the evaluation, mostly precision at k ($P@k$) and recall at k ($R@k$) are applied (e.g. (Evert, 2005; Frantzi et al., 1998; Lossio-Ventura et al., 2014)). Another general approach is using the average precision (AP), which is also used in Information Retrieval (IR) (Thater et al., 2009) and has also been applied by Ramisch et al. (2012).

3 Baselines and Previous Approaches

We will evaluate our method by comparing our MWE ranking to multiword lists that have been annotated in corpora. Here, we introduce an upper bound and two baseline methods and give a brief description of the competitive methods used in this paper. Most of these methods require a list of candidate terms T, usually extracted with POS sequences (see Section 5).

3.1 Upper Bound

We use a perfect ranking as upper bound, where we rank all positive candidates before all negative ones.

3.2 Lower Baseline and Frequency Baseline

The ratio between true candidates and all candidates serves as lower baseline, which is also called baseline precision (Evert, 2008). The second baseline is the frequency baseline, which ranks candidate terms $t \in T$ according to their frequency $freq(t)$.

3.3 C-value/NC-value

The commonly used C-value (see Eq. 1) was developed by Frantzi et al. (1998). The first factor, logarithm of the term length in words, favors longer MWEs. The second factor is the frequency of the term reduced by the average frequency of all candidate terms T, which nest the term t, i.e. t is a substring of the terms we denote as T_t.

$$\mathrm{c}(t) = \log_2(|t|)(\mathrm{freq}(t) - \frac{1}{|T_t|}\sum_{b \in T_t}\mathrm{freq}(b)) \quad (1)$$

An extension of the C-value was proposed by Frantzi et al. (1998) as well and is named NC-value. It takes advantage of context words C_t by assigning weights to them. As context words only *nouns*, *adjectives* and *verbs* are considered[1]. Context words are weighted with Equation 2, where k denotes the number of times the context word $c \in C_t$ occurs with any of the candidate terms. This number is normalized by the number of candidate terms.

$$w(c) = \frac{k}{|T|} \quad (2)$$

The NC-value is a weighted sum of the C-value and the product of the term t occurring with each context c which form the term t_c:

$$\mathrm{nc}(t) = 0.8 * \mathrm{c}(t) + 0.2 \sum_{c \in C_t} freq(t_c)w(c). \quad (3)$$

3.4 t-test

The t-test (see e.g. (Manning and Schütze, 1999, p.163)) is a statistical test for the significance of

[1] the context window size is not specified in Frantzi et al. (1998)

co-occurrence of two words. It relies on the probabilities of the term and its single words. The probability of a word $p(w)$ is defined as the frequency of the term divided by the total number of terms of the same length. The *t-test* statistic is computed using Equation 4 with $freq(.)$ being the total frequency of unigrams.

$$t(w_1 \dots w_n) \approx \frac{p(w_1 \dots w_n) - \prod_{i=1}^{n} p(w_i)}{\sqrt{p(w_1 \dots w_n)/freq(.)}} \quad (4)$$

We then use this score to rank the candidate terms.

3.5 FGM Score

Another method inspired by the C/NC-value is proposed in (Nakagawa and Mori, 2002; Nakagawa and Mori, 2003). The method was developed on a Japanese dataset and outperformed a modified C-value[2] measure. The method is composed of two scoring mechanisms for the candidate term t as shown in Equation 5.

$$FGM(t) = GM(t) \times MF(t) \quad (5)$$

The first term in the equation is a geometric mean $GM(.)$ of the number of distinct direct left $l(.)$ and right $r(.)$ neighboring words for each single word t_i within t.

$$GM(t) = \sqrt[2|t|]{\sum_{t_i \in t} (|l(t_i)| + 1)(|r(t_i)| + 1)} \quad (6)$$

The neighboring words are extracted directly from the corpus; the method does neither rely on candidate lists nor POS tags. To the contrary, the marginal frequency $MF(t)$ relies on the candidate list and the underlying corpus. This frequency counts how often the candidate term occurs within the corpus and is not a subset of a candidate. In Korkontzelos (2010) it was shown that while scoring according to Equation 5 leads to comparatively good results, it is consistently outperformed by MF only.

4 Semantic Uniqueness and Incompleteness

We present two new mechanisms relying on a Distributional Thesaurus (DT), which we use to rank terms regarding their multiwordness: A score for the *uniqueness* of a term and a punishing score that conveys the *incompleteness*.

[2]They adjust the logarithmic length in order to be able to use the C-value to detect single worded terms.

4.1 Similarity Computation

The DT is computed based on Biemann and Riedl (2013). First we extract n-grams from text and consider the left and the right neighbor of each n-gram as context feature. Then, we calculate the Lexicographer's Mutual Information (LMI) significance score (Bordag, 2008) between n-grams and features and remove all context features, which co-occur with more than 1000 terms, as these features tend to be to general. In the next step we keep for each n-gram only the 1000 context features, with the highest LMI score. The similarity score is then computed based on the overlap of features between two terms. Due to pruning this overlap-based significance measure is proportional to the Jaccard similarity measure, albeit we do not consider any normalization. After computing the feature overlap between two terms, we keep for each n-gram the 200 most similar n-grams. An example for the most similar n-grams to the terms *red blood cell* and *red blood* including their feature overlap are shown in Table 1.

4.2 Uniqness Computation

The first mechanism of our MWE ranking method is based on the following hypothesis: n-grams, which are MWE, could be substituted by single words, thus they have many single words amongst their most similar terms. This is motivated by semiotic considerations: Because of parsimony, concepts are usually expressed in single words. When a semantically non-compositional word combination is added to the vocabulary, it expresses a concept that is necessarily similar to other concepts. Hence, if a candidate multiword is similar to many single word terms, this indicates multiwordness.

To compute the *uniqueness* score (uq) of an n-gram t, we first extract the n-grams it is similar to using the DT as described in Section 4.1. The function $similarities(t)$ returns the 200 most similar n-grams to the given n-gram t. We then compute the ratio between unigrams and all similar n-grams considered using the formula:

$$uq(t) = \frac{\sum_{s:|s|=1}^{similarities(t)} 1}{|similarities(t)|}. \quad (7)$$

We illustrate the computation of our measure based on the MWE *red blood cell* and the non-MWE *red blood*. When considering only the ten most similar entries for both n-grams as illustrated

in Figure 1, we observe an uniqueness score of $7/10 = 0.7$ for both n-grams. If considering the

red blood cell		*red blood*	
Sim. term	Sc.	Sim. term	Sc.
erythrocyte	133	**red**	148
red cell	129	white blood	111
RBC	95	**Sertoli**	93
platelet	70	**Leydig**	92
red-cell	37	**NK**	86
reticulocyte	34	**mast**	85
white blood	33	**granulosa**	81
leukocyte	29	**endothelial**	81
granulocyte	28	hematopoietic stem	79
the erythrocyte	28	peripheral blood monon	78

Table 1: We show the ten most similar entries for the term *red blood cell* (left) and *red blood* (right). Here, seven out of ten terms are single words.

top 200 similar n-grams, which are also used in our experiments we will obtain 135 unigrams for the candidate *red blood cell* and 100 unigrams for the n-gram *red blood*. We will use these counts for showing the workings of the method in the remainder.

4.3 Incompleteness Computation

Similar to the C/NC-value method, we also assign a context weighting function that punishes incomplete terms, which we call *incompleteness (ic)*. For this function we extract the 1000 most significant context features using the function $context(t)$, which yields tuples of left and right contexts. These context features are the same that are used for the similarity computation in Section 4.1 and have been ranked according to the LMI measure. For the example term *red blood*, some of the contexts are ⟨*extravasated, cells*⟩, ⟨*uninfected, cells*⟩, ⟨*nucleated, corpuscles*⟩. In the next step we split each tuple to its left and right word including its relative position (left/right) to the candidate term. Using the first context feature results in: ⟨*extravasated, left*⟩, ⟨*cells, right*⟩. Then, we sum up the occurrences of for each single context, as shown in Table 2 for the two terms.

We subsequently select the maximal count and normalize it by the counts of features $|context(t)|$ considered, which is 1000. This results into the incompleteness measure $ic(t)$. For our example terms we achieve the values $ic(red\ blood) = 557/1000$ and $ic(red\ blood\ cell) = 48/1000$. Whereas the uniqueness scores for the most similar entries were equal, we now have a measure that indicates the incompleteness of an n-gram, with higher scores indicating more incomplete terms.

Context term	Position	Count
red blood cell		
transfusions	right	48
(	right	42
transfusion	right	33
red blood		
cells	right	557
cell	right	344
corpuscles	right	13

Table 2: Top three most frequent context words for the term *red blood cell* and *red blood* in the Medline corpus.

4.4 Combining Both Measures

As shown in the previous two sections, a high uniqueness score indicates the multiwordness and a high incompleteness score should decrease the overall score. In experiments, we found the best combination if we subtract[3] the incompleteness score from the uniqueness score. This mechanism is inspired by the C-value and motivated as terms that are often preceded/followed by the same word do not cover the full multiword expression and need to be downranked. This leads to Equation 8, which we call **D**ist**R**ibutional **U**niqueness and **I**ncompleteness **D**egree:

$$\texttt{DRUID}(t) = \mathrm{uq}(t) - \mathrm{ic}(t). \quad (8)$$

Applying the DRUID score to our example terms (considering the 200 most similar terms) we will achieve the scores $\texttt{DRUID}(red\ blood\ cell) = 135/200 - 48/1000 = 0.627$ and $\texttt{DRUID}(red\ blood) = 100/200 - 557/1000 = -0.057$. As a higher DRUID score indicates the multiwordness of an n-gram, we can summarize that the n-gram *red blood cell* is a better MWE than the n-gram *red blood*.

5 Experimental Setting

We examine two experimental settings: First, we compute all measures on a small corpus that has been annotated for MWEs, which serves as the gold standard. In the second setting we compute the measures on a larger in-domain corpus. The evaluation is again performed for the same candidate terms as given by the gold standard. Results for the top k ranked entries are reported using the precision at k ($P@k = \frac{1}{k}\sum_{i=1}^{k} x_i$ with x_i equals 1 if the i-th ranked candidate is annotated as MWE and 0 otherwise). For an overall performance we

[3] multiplicative combinations consistently performed worse

use the average precision (AP) as defined in Thater et al. (2009): $AP = \frac{1}{|T_{mwe}|} \sum_{k=1}^{|T|} x_k P@k$, with T_{mwe} beeing the set of positive MWE. When facing tied scores we mix false and true candidates randomly cf. Cabanac et al. (2010).

5.1 Corpora

For the experiments we consider two annotated (small) corpora and two unannotated (large) corpora.

5.1.1 GENIA corpus and SPMRL 2013: French Treebank

In the first experiments we use two small annotated corpora that serve the gold standard MWEs. We use the medical GENIA corpus (Kim et al., 2003)[4] which consists of 1999 abstracts from Medline[5] and encompasses 0.4 million words. This corpus has annotations regarding important and biomedical terms. Also single terms are annotated in this data set, which we ignore.

The second small corpus is based on the French Treebank (Abeillé and Barrier, 2004), which was extended for the SPMRL task (Seddah et al., 2013). This version of the corpus also contains compounds annotated as MWEs. In our experiments we use the training data, which covers 0.4 million words.

Whereas the GENIA MWEs target term matching and medical information retrieval, the SPMRL MWEs mainly focus on improving parsing through compound recognition.

5.1.2 Medline Corpus and Est Républican Corpus (ERC)

In a second experiment the scalability to larger corpora is tested. For this, we make use of the entire Medline[5] abstracts, which consist of about 1.1 billion words. The Est Républican Corpus (ERC) (Seddah et al., 2012)[6] is our large French corpus. It consists of local French news from the eastern part of France and comprises of 150 million words.

5.2 Candidate Selection

In the first two experiments, we use POS filters to select candidates. We concentrate on filters that extract noun MWEs and avoid further preprocessing like lemmatization. We use the filter introduced by Justeson and Katz (1995)[7] for the English medical datasets. Considering only terms that appear more than ten times leads to 1,340 candidates for the GENIA dataset and 29,790 candidates for the Medline dataset. According to Table 3 we observe that most candidates are bigrams. Whereas for both corpora still around 20% of trigrams are contained, the number of 4-grams is only marginally represented. For the French datasets we apply the filter proposed by Daille et al. (1994)[8], which is suited to match nominal MWEs. Applying the same filtering as for the medical corpora leads to 330 candidate terms for the SPMRL and 7,365 candidate terms for the ERC. Here the ratio between bi- and trigrams is more balanced but again the number of 4-grams constitutes the smallest class.

Corpus	Candidates	2-gram	3-gram	4-gram
GENIA	1,340	1,056	243	41
Medline	29,790	22,236	6,400	1,154
SPMRL	330	197	116	17
ERC	7,365	3,639	2,889	837

Table 3: Number of candidates after filtering for the expected POS-tag and their distribution over n-grams with $n \in \{1, 2, 3, 4\}$.

In comparison to the Medline dataset, the ratio of multiwords extracted by the POS filter on the French corpus is much lower. The reason for that property is that in the French data, many adverbial, prepositional MWEs are annotated, which are not covered by the POS filter.

The third experiment shows the performance of the method in absence of language-specific preprocessing. Thus, we only filter the candidates by frequency and do not make use of POS filtering. As most previous methods rely on POS-filtered data we cannot make use of them in this setting.

For the evaluation, we compute the scores of the competitive methods in two settings: First, we compute the scores based on the full candidate list without any frequency filter and prune low-frequent candidates only for the evaluation (post-prune). In the second setting we filter candidates

[4] freely available at `http://www.nactem.ac.uk/genia/genia-corpus/pos-annotation`.

[5] `http://www.nlm.nih.gov/bsd/licensee/access/medline_pubmed.html`

[6] `http://www.cnrtl.fr/corpus/estrepublicain`

[7] A regular expression for matching POS tag sequences is summarized by Korkontzelos (2010): `(([JN]+[JN]?[NP]?[JN]?)N)`. Each letter is a truncated POS tag of length one where J is an adjective N a noun and P a preposition.

[8] Following the same convention as for English the regular expression can be expressed as `N[J]?|NN|NPDN`

according to their frequency before the computation of scores (pre-prune). This leads to differences for context-aware measures, since in the pre-pruned case, a lower number of less noisier contexts is used.

6 Results

6.1 Small Corpora Results

First we show the results based on the GENIA corpus (see Table 4). Almost all competitive methods

Method	P@100	P@500	AP
upper baseline	1.000	1.000	1.0000
lower baseline	0.713	0.713	0.7134
frequency	0.790	0.750	0.7468
t-test	0.790	0.750	0.7573
C-value (pre-pruned)	0.880	0.846	0.8447
NC-value (pre-pruned)	0.880	0.840	0.8405
GM	0.590	0.662	0.6740
MF (pre-pruned)	0.920	0.872	0.8761
FGM (pre-pruned)	0.910	0.840	0.8545
MF (post-pruned)	0.900	0.876	0.8866
FGM (post-pruned)	0.900	0.900	0.8948
DRUID	0.930	0.852	0.8663
log(freq)(DRUID)	**0.970**	0.860	0.8661
MF(post-pruned)DRUID	0.950	0.926	**0.9241**
FGM(post-pruned)DRUID	**0.960**	**0.940**	**0.9262**

Table 4: Results for the GENIA dataset.

beat the lower baseline. The C/NC-value perform best when the pruning is done after a frequency filter. In line with the findings of Korkontzelos (2010) and in contrast to Frantzi et al. (1998) the AP of the C-value is slightly higher than for the NC-value. All the FGM based methods except the GM measure alone outperform the C-value. The results in Table 4 indicate that the best competitive system is the post-pruned FGM system as it has much higher average precision scores and misses only 50 MWEs in the first 500 entries. A slightly different picture is presented in Figure 1 where the $P@k$ scores against the number of candidates are plotted. Here DRUID performs well for the top-k list for small k, i.e. finds many good MWEs with high confidence thus combines well with MF, which extends to larger k, but places too much importance of frequency when used alone. Common errors are frequent chunks such as "in patience", see Table 9 in Section 7. Whereas for the post-pruned case FGM scores higher than MF, the inverse is observed when pre-pruning. Using our DRUID methods can surmount the FGM method only for the first 300 ranked terms (see Figure 1 and Table 4). Multiplying the logarithmic frequency to the DRUID, the results improve

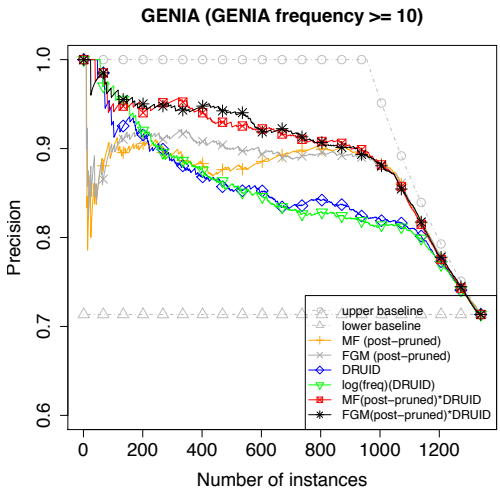

Figure 1: Results for the GENIA corpus.

slightly and the best P@100 with 0.97 is achieved. All FGM results are outperformed when combining the post-pruned FGM scores with our measure. According to Figure 1 this combination achieves high precision for the first ranked candidates and still exploits the good performance of the post-pruned FGM based method for the middle-ranked candidates.

Different results are achieved for the SPMRL dataset as can be seen in Table 5. Whereas the pre-pruned C-value again receives better results than frequency, it scores below the lower baseline. Also the post-pruned FGM and MF method

Scoring	P@100	P@200	AP
upper baseline	1.000	0.860	1.0000
lower baseline	0.521	0.521	0.5212
frequency	0.500	0.480	0.4876
t-test	0.500	0.485	0.4934
C-value (pre-pruned)	0.490	0.540	0.5107
MF (post-pruned)	0.510	0.495	0.5017
FGM (post-pruned)	0.460	0.480	0.4703
DRUID	**0.790**	**0.690**	**0.7794**
log(freq)DRUID	0.770	0.675	0.7631
MF(post-pruned)DRUID	0.700	0.630	0.6850
FGM(post-pruned)DRUID	0.600	0.570	0.5948

Table 5: Results for the French SPMRL dataset

do not exceed the lower baseline. Data analysis revealed that for the French dataset only ten out of the 330 candidate terms are nested within any of the candidates. This is much lower than the 637 terms nested in the 1340 candidate terms for the GENIA dataset. As both the FGM-based methods and the C/NC-value heavily rely on nested candidates, they cannot profit from the candidates of this dataset and achieve similar scores as ordering candidates according to frequency. Comparing the

baselines to our scoring method, this time we obtain the best result for DRUID without additional factors. However, multiplying DRUID with MF or log(frequency) still outperforms the other methods and the baselines.

6.2 Large Corpora Results

Most MWE evaluations have been performed on rather small corpora. Here we want to inspect the performance of the measures for large corpora, so as to realistically simulate a situation where the MWEs should be found automatically for an entire domain.

Using the Medline corpus, all methods except the GM score outperform the lower baseline and the frequency baseline (see Table 6). Regarding the AP the best results are obtained when combining our DRUID method with the MF, whereas for $P@100$ and $P@500$ the log-frequency weighted DRUID scores best. Using solely the DRUID method or the combined variation with the log-frequency lead to the best ranking for the first 1000 ranked candidates and is then outperformed by the MF based DRUID variations. In this experiment the C-value achieves the best performance from the competitive methods for the $P@100$ and $P@500$, followed by the t-test. But the highest AP is reached with the post-pruned MF method, which also outperforms the sole DRUID slightly. Contrary to the GENIA results, the MF scores are consistently higher than the FGM scores.

Scoring	$P@100$	$P@500$	AP
upper baseline	1.000	1.000	1.0000
lower baseline	0.416	0.416	0.4161
frequency	0.720	0.534	0.4331
C-value (pre-pruned)	0.750	0.564	0.4519
t-test	0.720	0.542	0.4483
GM	0.210	0.272	0.3502
MF (pre-pruned)	0.550	0.542	0.4578
FGM (pre-pruned)	0.580	0.478	0.4200
MF (post-pruned)	0.530	0.500	0.4676
FGM (post-pruned)	0.490	0.446	0.4336
DRUID	0.770	0.686	0.4608
log(freq)*DRUID	**0.860**	**0.720**	0.4693
GM*DRUID	0.770	0.634	0.4497
MF(pre-pruned)*DRUID	0.730	0.634	**0.4824**
MF(post-pruned)*DRUID	0.730	0.626	**0.4889**

Table 6: Results computed on the Medline corpus.

When using the French ERC we figured out that no nested terms are found within the candidates. Thus, the post- and pre-pruned settings are equivalent and thus MF equals frequency. The best results are again obtained with our method with and without the logarithmic frequency weighting (see Table 7). Again the AP of the C-value and most of the FGM-based methods are inferior to the frequency scoring. Only the t-test and the MF are slightly higher than the frequency[9]. But in contrast to the results based on the smaller SPMRL dataset, the MF, FGM and C-value can outperform the lower baseline. In comparison to the smaller corpora, the performance for the larger corpora is much lower. Especially low-frequent terms in the small corpora that have high frequencies in the larger corpora have not been annotated as MWEs.

Method	$P@100$	$P@500$	AP
upper baseline	1.000	1.000	1.0000
lower baseline	0.220	0.220	0.2201
frequency	0.370	0.354	0.3105
C-value	0.420	0.366	0.3059
t-test	0.390	0.360	0.3134
GM	0.010	0.052	0.1694
MF	0.370	0.356	0.3148
FGM	0.280	0.260	0.2405
DRUID	0.700	0.568	0.3962
log(freq)DRUID	**0.760**	**0.582**	**0.4075**
MF*DRUID	0.570	0.516	0.3776
FGM*DRUID	0.510	0.418	0.3234

Table 7: Results computed based on the ERC.

6.3 Results without POS Filtering

In the last experiment, we apply our method to candidates without any POS filtering and report results using a frequency threshold of ten. As the competitive methods from the previous section rely on POS tags, we use the t-test for comparison. Analysis revealed that the top-scored candidates according to the t-test begin with stop words.

		Medical		French	
	Method	$P@100$	AP	$P@100$	AP
small corpora	upper baseline	1.000	1.0000	1.000	1.0000

Table 8: Results without linguistic pre-processing.

[9]This is achieved by chance for the MF, as it is equal to the frequency. The different scores are due to the randomly sorted tied scores used during our evaluation and reflect the variance of the randomness.

As an additional heuristic for the t-test, we shift MWEs, which start or end with one of the ten most frequent words, to the last ranks. For the smaller dataset the best results are achieved with the sole DRUID (see Table 8) and the frequency weighting does not seem to be beneficial, as highly frequent n-grams ending with stopwords are ranked higher in absence of POS filtering. This, however, is not observed for larger corpora. Here the best results for Medline are achieved with the frequency weighted DRUID. Whereas for French, the sole DRUID method performs best, the difference between the DRUID and the log-frequency-weighted DRUID is rather small. The low APs throughout can be explained by the large number of considered candidates. The second best scores are achieved with stop word based t-test (t-test + sw). C-value performs en par with frequency.

6.4 Components of DRUID

Here, we show different parameters for DRUID, relying on the English GENIA dataset without POS filtering of MWE candidates and by considering only terms with a frequency of 10 or more. Inspecting the two different components of the DRUID measure (see upper graph in Figure 2), we observe that the uniqueness measure contributes most to the DRUID score. The main effect of the incompleteness component is the downranking of a rather small number of terms with high uniqueness scores, which improves the overall ranking. We can also see that for the top ranked terms the negative incompleteness score does not improve over the frequency baseline but outperforms the frequency in the middle ranked candidates. Used in DRUID we observe a slight improvement for the complete ranking. We achieve a P@500 of 0.474 for the uniqueness scoring and 0.498 for the DRUID score.

When filtering similar entries, used for the uq scoring, by their similarity score (see bottom graph in Figure 2), we observe that the amount of similar n-grams considered seems to be more important then the quality of the similar entries: With the increasing filtering also the quality of extracted candidate MWEs diminishes.

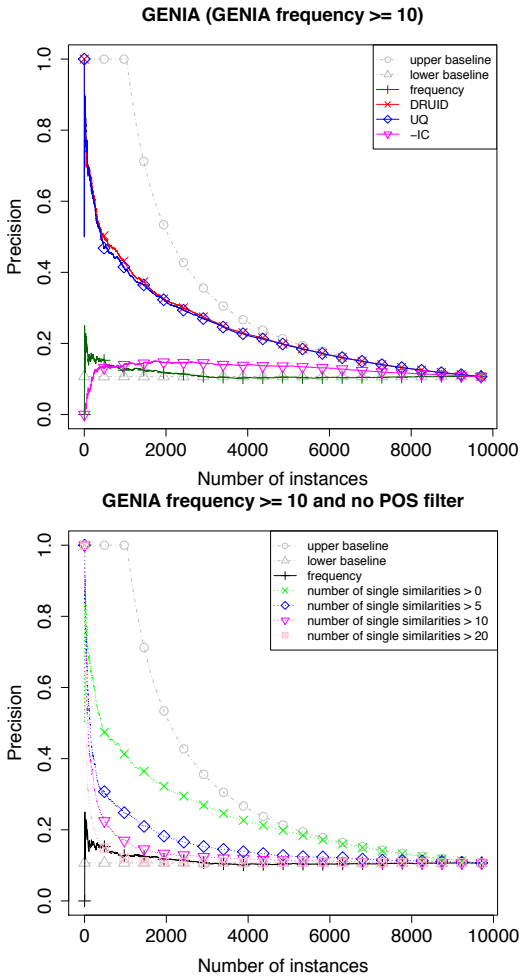

Figure 2: Results for the components of the DRUID measure (top) and for different filtering thresholds of the similar entries considered for the uniqueness scoring (bottom).

7 Discussion and Data Analysis

The experiments confirm that our DRUID measure, either weighted with the MF or alone, works best across two languages and across different corpus sizes. It also achieves the best results in absence of POS filtering for candidate term extraction. The optimal weighting of DRUID depends on the nestedness of the MWEs: Using DRUID with the MF should be used when there are more than 20% of nested candidates and using the log-frequency or no frequency weighting when there are almost no nested candidate terms.

We show the best-ranked candidates obtained with our method and with the best competitive method in terms of P@100 for the two smaller corpora. Using the GENIA dataset, our log-frequency based DRUID (see left column in Table 9) ranks only true MWE within the 15 top-scored candidates.

The right-hand side shows results extracted with the pre-pruned MF method that yields three non-MWE terms. Whereas that could be a POS error,

log(freq)DRUID		MF (pre-pruned)	
NF-kappa B	1	T cells	1
transcription factors	1	NF-kappa B	1
transcription factor	1	transcription factors	1
I kappa B alpha	1	activated T cells	1
activated T cells	1	T lymphocytes	1
nuclear factor	1	human monocytes	1
human monocytes	1	I kappa B alpha	1
gene expression	1	nuclear factor	1
T lymphocytes	1	gene expression	1
NF-kappa B activation	1	NF-kappa B activation	1
binding sites	1	in patients	0
MHC class II	1	important role	0
tyrosine phosphorylation	1	binding sites	1
transcriptional activation	1	in B cells	0
nuclear extracts	1	transcriptional activation	1

Table 9: Top ranked candidates from the GENIA dataset using our method (left) and the competitive method (right). Each term is marked, whether the term is an MWE (1) or not (0).

the MF and also the C-value are not capable to remove terms starting with stop words. The DRUID score alleviates this problem with the uniqueness factor. For the French dataset our method ranks only one false candidate whereas the MF (post-pruned) ranks eight non-annotated candidates in the top 15 list (see Table 10).

DRUID		MF (post-pruned)	
hausse des prix	1	milliards de francs	0
mise en oeuvre	1	millions de francs	0
prise de participation	1	Etats - Unis	1
chiffre d' affaires	1	chiffre d' affaires	1

projet de loi	1	M. Jean	0
système européen	0	an dernier	1
conseil des ministres	1	années	1
Europe centrale	1	% par rapport	0

Table 10: Top ranked candidates from the SPMRL dataset for the best DRUID method (left) and the best competitive method (right). Each term is marked, if it is an MWE (1) or not (0).

Whereas the unweighted DRUID method scores better than its competitors on the large corpora, the best results are achieved when using DRUID with frequency-based weights on the smaller corpora. For a direct comparison we evaluated the small and large corpora using an equal candidate set. We observed that all methods computed on the large corpora achieve slightly inferior results than when computing them using the small corpora. Data analysis revealed that we would consider many of the high ranked "false" candidates as MWE.

Therefore we extracted the top ten ranked terms, which are not annotated as MWE from the methods with the best $P@100$ performance, resulting to the log(freq) DRUID and the pre-pruned C-value methods.

First, we observed that the first 'false' candidate for our method appears at rank 26 and at rank 1 for the C-value. Additionally, only ten out of the top 74 candidates are not annotated as MWEs for our method and 48 for the competitor. When searching the terms within the MeSH dictionary[10], we find seven terms ranked from our method and two for the competitive method.

8 Conclusion

Uniqueness is a new mechanism in MWE modeling. Whereas frequency and co-occurrence have been captured in many previous approaches (see Manning and Schütze (1999), Ramisch et al. (2012) and Korkontzelos (2010) for a survey), we boost multiword candidates t by their grade of distributional similarity with single word terms. We implement such contextual substitutability with a model where the term t can consist of multiword tokens and similarity is measured based on the right and neighboring word between all (single and multiword) terms. Since it is the default to express concepts with single words, a high uniqueness score is given to multiwords that belong to a category just as single words would. E.g. for an English open-domain corpus *hot dog* is most similar to the terms: *food*, *burger*, *hamburger*, *sausage* and *roadside*. Candidates with a low number of single word similarities also serve the same function, but more frequently we observe single n-grams with function words or modifying adjectives concatenated with content words, i.e. *small dog* is most similar to "*various cat*", "*large amount of*", "*large dog*", "*certain dog*", "*dog*". To be able to kick in, the measure requires a certain minimum frequency for candidates in order to find enough contextual overlap with other terms. Additionally, we also demonstrate effective performance on larger corpora and show its applicability when used in a complete unsupervised evaluation setting.

Abstract

Distributed word representations capture relational similarities by means of vector arithmetics, giving high accuracies on analogy detection. We empirically investigate the use of syntactic dependencies on improving Chinese analogy detection based on distributed word representations, showing that a dependency-based embeddings does not perform better than an ngram-based embeddings, but dependency structures can be used to improve analogy detection by filtering candidates. In addition, we show that distributed representations of dependency structure can be used for measuring relational similarities, thereby help analogy mining.

1 Introduction

Relational similarity measures the correspondence between word-word relations (Medin et al., 1990). It is relevant to many tasks in NLP (Turney, 2006), such as word sense disambiguation, information extraction, question answering, information retrieval, semantic role identification and metaphor detection. Typical tasks on relational similarity include *analogy detection*, which measures the degree of relational similarities, and *analogy mining*, which extracts analogous word pairs from unstructured text.

Recently, distributed word representations (i.e. *embeddings*) (Mikolov et al., 2013a; Mikolov et al., 2013b; Levy and Goldberg, 2014b) have been used for unsupervised analogy detection. Mikolov et al. use attributional similarities between words in a relation to compute relational similarities, and show that the method outperforms the best system in the SemEval 2012 shared task on analogy detection. Levy and Goldberg (2014b) further improve Mikolov's relational similarity measure method using novel arithmetic combinations of attributional similarities. For simplicity, we call the method of Mikolov et al. *embedding-based analogy detection*, without stressing the difference between *distributed* and *distributional* (i.e. counting-based) word representations.

Most work on embedding-based analogy detection uses relational similarities as a measure of the quality of embeddings. However, relatively little has been done in the opposite direction, exploring how to leverage embeddings for improving relational similarity algorithms. We empirically study the use of word embeddings for Chinese analogy detection and mining, leveraging syntactic dependencies, which has been shown to be closely associated with semantic relations (Levin, 1993; Chiu et al., 2007). Compared with many other languages, this association is particularly strong for Chinese, which is fully configurational and lacks morphology. To our knowledge, relatively little work has been reported on Chinese relational similarities, compared to other tasks in Chinese NLP, including syntactic parsing, information extraction and machine translation.

We work on three specific problems. First, we study the effect of dependency-based word embeddings for analogy detection. There are two variations of Mikolov et al's *skip-gram* embedding model, one training the distributed word representation of a word using its context words in local ngram window (Mikolov et al., 2013a), and the other training the distributed representation of a word using words in a syntactic dependency context (Levy and Goldberg, 2014b; Bansal et al., 2014). The latter has attracted much recent atten-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2441–2450,
Lisbon, Portugal, 17-21 September 2015.

tion due to its potential in capturing more syntactic regularities. It has been shown to outperform the former in a variety of NLP tasks, and can potentially also improve relation similarity. Our experiments on both English and Chinese show that the dependency-context embeddings consistently under-perform ngram-context embeddings. We give some theoretical justifications to the findings.

Second, we propose to use syntactic dependencies as a context for improving embedding-based analogy detection, pruning the search space and filtering noise using syntactic dependencies. While highly useful for measuring relational similarities, attributional similarities between words are not the only source of information for analogy detection. Traditional methods, such as Turney and Littman (2005), Turney (2006), Chiu et al. (2007) and Ó Séaghdha and Copestake (2009), also leverage context between word pairs in a corpus for better accuracies, which the current embedding-based methods ignore. Results show that our proposed method achieves significant improvements for this task.

Third, we show that a novel distributed representation of syntactic dependencies between word pairs can be used to mine analogous dependencies from a large Chinese corpus. Inspired by the fact that distributed word representations can be used to measure word similarities, we use our distributed dependency representations to measure relation similarities. We propose a bootstrapping algorithm for analogy mining using dependency embeddings, and experiments on a large Chinese corpus show that the method can achieve a precision of 95.2% at a recall of 56.8%.

Our automatically-parsed corpus, trained embeddings and evaluation datasets are released publicly at `http://people.sutd.edu.sg/~yue_zhang/publication.html`. To our knowledge, we are the first to present results on Chinese analogy detection and to release large-scale Chinese word embeddings.

2 Background

2.1 Relational Similarity Tasks

There are three main tasks for relational similarity. This first is *relation classification*, which has been used in Task 2 of SemEval 2012 (Jurgens et al., 2012). In this task, all four words in two word pairs are given, and one needs to judge whether they belong to a same relation type. In order to address this task, various supervised methods have been used (Bollegala et al., 2008; Herdağdelen and Baroni, 2009; Turney, 2013).

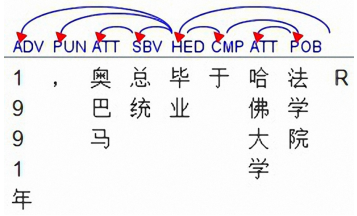

Figure 1: Dependency tree of the sentence "1991年 (in 1991) ， (,) 奥巴马 (Obama) 总统 (President) 毕业 (graduate) 于 (from) 哈佛 (Harvard) 法学院 (Law School)".

The second task is *analogy detection* (Mikolov et al., 2013b), which takes three words in two word pairs, and searches for a most suitable word from the vocabulary to recover the hidden word. This task has been addressed using word embeddings (Mikolov et al., 2013b; Levy and Goldberg, 2014b).

The third task is *analogy mining* (Chiu et al., 2007), which takes one word pair belonging to a certain semantic relation as a seed, and searches for all the word pairs that share the same relation with the seed. Compared with relation classification and analogy detection, analogy mining can be practically more useful because it requires less given information, and provides a large quantity of analogous word pairs automatically.

2.2 Skip-gram Word Embeddings

As a by-product of neural language models (Bengio et al., 2003; Mnih and Hinton, 2007), word embeddings are distributed vector representations of words, trained using local contexts. They capture linguistic regularities in languages (Mikolov et al., 2013b) and have been used in various tasks (Collobert and Weston, 2008; Turian et al., 2010; Socher et al., 2011).

In this paper, we apply the Skip-gram method of Mikolov et al. (2013a) for training embeddings, which works by maximizing the probability of a word given a context of multiple words. Mikolov et al. (2013b) use an ngram window as the context, and observe that the resulting embeddings are highly useful for unsupervised analogy detection.

2.3 Embedding-based Analogy Detection

Formally, the task of analogy detection is to find a word $b*$ given a pair of words *a:b* and a word $a*$ such that *a*:b** is analogous to *a:b*. Mikolov et al. (2013b) show that the task can be solved by finding a word that maximizes:

$$score = sim(b*, b - a + a*) \quad (1)$$

where sim is a similarity measure, typically the $cosine$ function. Levy and Goldberg (2014b) show that the Equation 1 is equivalent to:

$$score = cos(b*, b) - cos(b*, a) + cos(b*, a*) \quad (2)$$

As a result, the goal of analogy detection is to find a word $b*$ which is similar to b and $a*$ but different from a. Levy and Goldberg (2014b) further propose to substitute the addictive functions in Equation 2 with multiplicative functions:

$$score = cos(b*, b)cos(b*, a*)/(cos(b*, a) + \varepsilon) \quad (3)$$

Here $\varepsilon = 0.001$ is used to prevent division by zero. Their experiments show that the use of Equation 3 can improve the state-of-the-art. Following Levy and Goldberg (2014b), we refer to Equation 1 and 2 as 3COSADD and Equation 3 as 3COSMUL, respectively.

2.4 Chinese Relational Similarity

There are various types of relational similarities. Syntactically, inflections can be treated as a type of word-word relation (Mikolov et al., 2013b). For example, the comparative pairs "good:better" and "rough:rougher" are analogous, and the past tense inflections "see:saw" and "return:returned" are analogous. However, such inflectional relations do not apply to Chinese, which is fully configurational and lacks morphology. Consequently, our main focus is semantic similarities, which include antonymy (e.g. (热 (hot):冷 (cold)) VS (快 (fast):慢 (slow))), meronymy (e.g. (车 (car):轮子 (wheel)) VS (熊 (bear):掌 (paw))), gender (e.g. (男人 (man):女人 (woman)) VS (国王 (king):女王 (queen))) and function relations (e.g. (衣服 (clothing):穿 (wear)) VS (帽子 (hat):戴 (wear))), etc.

Chiu et al. (2007) show that English semantic relations are also reflected by syntactic dependencies. Their finding coincides with Levin (1993), who study English verbs. We find that this observation is even more prevalent for Chinese. In our automatically-parsed Chinese corpus of 3.4 billion words (Section 5.1), 86.4% word pairs from the analogy test dataset (Section 5.2) have corresponding dependencies, each of which appearing at least ten times.

The frequent correlation between semantic relations and syntactic dependencies can be due to the lack of morphology and function words in Chinese. In fact, Chinese syntactic ambiguities often need to be resolved by leveraging semantic information (Xiong et al., 2005; Zhang et al., 2014). Although not all occurrences of semantically-related word pairs must also form a syntactic dependency in a corpus, we show that syntactic dependencies can effectively improve analogy detection.

3 Dependency-context Word Embeddings for Analogy Detection

A first use of syntactic dependencies for embedding-based analogy detection is to use them directly for embeddings. Recently, a dependency context has been used for the skip-gram method, for capturing more syntactic regularities. Taking the sentence in Figure 1 for example, a *bi-gram* context for the word "毕业 (graduate)" can be "奥巴马 (Obama), 总统 (President), 于 (from), 哈佛 (Harvard)", while a *dependency context* of the same word can be "1991年/ADV, 总统/SBV, 于/CMP, 法学院/POB_于"[1], where "ADV, SBV, CMP, POB" indicate adverbial modifier, subject, complement and prepositional object, respectively.

It has been shown that a dependency context leads to embeddings that better help parsing (Bansal et al., 2014) and measuring word similarity (Levy and Goldberg, 2014a), compared with ngram contexts. However, little previous work has systematically compared dependency contexts with ngram contexts in analogy detection. We empirically study this problem (c.f Section 6.3), finding that dependency context leads to significantly worse analogy detection results for both Chinese and English using state-of-the-art embedding-based methods (Levy and Goldberg, 2014b). We give analysis in Section 6.4.

[1]The last token is a grand-child of "毕业 (graduate)", via the preposition "于 (at)" (Levy and Goldberg, 2014a).

4 Search Space Pruning Using Syntactic Dependencies

We study an alternative way of making use of syntactic dependencies, by using them to prune the vocabulary-sized search space of analogy detection. Given two word pairs *a:b* and *a*:b**, where *b** is hidden and *a* is the head word, we search for dependencies, taking *a** as the head word. The dependent words in the search candidates need to share the POS tag of *b*. If there are several types of dependencies between *a* and *b*, only the one with highest frequency is used. We rank all resulting dependencies using the 3COSMUL objective, and take the word *b** in the highest-scored dependencies as the answer.

For example, given the word pair (萨拉热窝 *(Sarajevo):*波黑 *(Bosnia and Herzegovina)*), whose most frequency dependency is <萨拉热窝 (Sarajevo), 波黑 (Bosnia and Herzegovina), ATT>, and the unknown pair (伦敦 *(London):b**), we acquire a list of dependencies, including <伦敦 (London), 美国 (USA), ATT>, <伦敦 (London), 巴黎 (Paris), COO>, <伦敦 (London), 加拿大 (Canada), ATT> and <伦敦 (London), 英国 (England), ATT>. Some of these dependencies, such as <伦敦 (London), 巴黎 (Paris), COO>, are parsed as the coordinate relation (COO), and thus pruned because the target syntactic relation is *ATT*. From the resulting list, the 3COSMUL objective successfully ranks the triple <伦敦 (London), 英国 (England), ATT> as the top candidate. In contrast, Levy and Goldberg's method takes "南非 (South Africa)" as the answer, which does not form an attributive-head phrase with "伦敦 (London)".

5 Analogy Mining Using Dependency Embeddings

Formally, *analogy mining* is the task of mining analogous dependencies $<x_1, y_1, r>, <x_2, y_2, r>$ ...$<x_n, y_n, r>$ that share the same relation *r* with a given dependency $<a, b, r>$. We mine analogous dependencies by considering relational similarity and attributional similarity simultaneously using the skip-gram model for embeddings.

5.1 Dependency Embedding

Inspired by the fact that *word* similarities can be measured by using distributed *word* representations, we hypothesize that *relation* similarities can be measured by distributed *relation* representations. Based on the observation in Section 2.4, semantically analogous word pairs typically have syntactic dependencies. We use the skip-gram algorithm to train *distributed representations of syntactic dependencies*, and use them for mining analogous word pairs.

With respect to the skip-gram model, *words* are the most common target for embeddings (Levy and Goldberg, 2014b; Levy and Goldberg, 2014a; Mikolov et al., 2013a), although continuous vector representations can be trained for other structures. For example, Mikolov et al. (2013a) take idiomatic *phrases* as embedding targets. *Dependencies*, which consist of a modifier word, a head word and a syntactic relation between them, can also be represented by continuous embeddings using the same algorithm.

To induce dependency embeddings, we take the union of the dependency context of both the dependent and the head of a dependency as the context. For instance, in the example sentence, the context of the dependency <总统 *(Presiden-*

```
Input  : dependency embedding DT, word
         embedding DW, seed dependency s,
         threshold α and β.
Output: set of ranked dependencies WP.
Function Mine (DT,DW,s,WP,α,β):
begin
    DTSet =∅;
    MScore =0;
    SimDT =GetSimDT (DT,s);
    for each Triple ∈ SimDT do
        MWS =GetMWord (s);
        HWS =GetHWord (s);
        MWD =GetMWord (Triple);
        HWD =GetHWord (Triple);
        ScoreX =Sim (MWS,MWD,DW);
        ScoreY =Sim (HWS,HWD,DW);
        ScoreXY =ScoreX × ScoreY;
        MScore =Max (ScoreXY,MScore);
        TopK (ScoreXY,Triple,DTSet,α)
    end
    MScore =MScore × β ;

        if ScoreXY > MScore and Triple ∉
        WP then
            AddToSet (Triple,WP);
            s =Triple;
            Mine (DT,DW,s,WP,α,β);
        end
    end
end
WP =∅;
Mine (DT,DW,s,WP,α,β);
```

Algorithm 1: Bootstrapping for analogy mining.

t), 毕业 (graduate), SBV> consists of four tokens: "1991年/ADV", "奥巴马/ATT", "于/CMP" and "法学院/POB_于". The same skip-gram algorithm is used to train embeddings for dependency structures.

5.2 Analogy Mining by Bootstrapping

A bootstrapping algorithm is used to mine analogous word pairs based on dependency-context word embeddings and dependency embeddings. Algorithm 1 shows pseudocode of the recursive bootstrapping algorithm.

The recursive function `Mine` (Algorithm 1) contains three steps with six parameters, including the dependency embeddings *DT*, word embeddings *DW*, a seed dependency *s*, and two thresholds α and β. Step 1 (lines 3 to 5) is an initialization process, where the dependency embedding is used to return up to 100 most similar dependencies for the given seed *s*. These dependencies are stored in *SimDT*, and the candidate analogous dependency set *DTSet* is initialized to an empty set.

In Step 2 (lines 6 to 16), an analogous score *ScoreXY* is computed for each dependency *Triple* in *SimDT* by multiplying the similarity scores between the two dependents and the two heads in *Triple* and *s*, respectively. *Triple* is stored into the set *DTSet* if *ScoreXY* is ranked top α. The top 1 score in *DTSet* is referred to as *MScore*. In Step 3 (lines 17 to 24), if the score of a dependency *Triple* in *DTSet* is larger than $\beta \times$*MScore*, it is used as a new seed for mining more analogous dependencies, by calling the function `Mine` recursively.

We take the seed dependency <弹 (play), 钢琴 (piano), VOB> as an example to illustrate the work-flow of the `Mine` function. In Step 1, a set of similar dependencies (e.g., <弹 (play), 吉他 (guitar), VOB>, <弹 (play), 琴 (lyra), VOB>), is calculated using the dependency embeddings *DT* and stored in *SimDT*. Each dependency in *SimDT* is scored in Step 2, and the top α scores are put into the set *DTSet*. Finally, a dependency is used as seed to mine new analogous dependencies if its score is larger than a threshold ($\beta \times$*MScore*). For instance, the dependency <弹 (play), 琴 (lyra), VOB> is used to mine the new dependency <弹 (play), 古筝 (zheng), VOB>, which is then used to mine other dependencies such as <吹 (blow), 葫芦丝 (cucurbit flute), VOB> and <吹 (blow), 萨克斯 (sax), VOB>.

6 Experiments

6.1 Word Embeddings

We train three sets of word embeddings: NG5 (n-gram context with 5 words to the left of the target word and 5 words to the right), NG2 (2 words to the left and right) and DEP (dependency context), and one set of dependency embeddings DT (dependency context), using the Skip-Gram model. WORD2VEC[2] is used to train NG5 and NG2, and WORD2VECF[3] is used to train DEP and DT. The negative-sampling parameter is set to 15 in all the training processes.

All embeddings are trained on a free Chinese news archive[4] that contains about 170 millions sentences and 3.4 billions words. We segment and parse these sentences using the MVT implementation of ZPar 0.7[5] (Zhang and Clark, 2011), which is trained on a large-scale annotated corpus and achieves state-of-the-art analyzing accuracy on contemporary Chinese (Qiu et al., 2014)[6]. Targets and contexts for word and dependency embeddings were filtered with a minimum frequency of 100 and 10, respectively, and all the four types of embeddings are trained with 200 dimensions.

6.2 Datasets and Evaluation Metrics

Three datasets are used for evaluating Chinese embeddings. First, we construct a set of semantic analogy questions. This set contains five types of semantic analogy questions, including capital-country (136 word pairs, and 18354 analogy questions), provincial capital-province (28, 756), city-province (637, 386262), family member (male-female) (18, 306) and currency-country (62, 3782). We collect the five types of word pairs and then produce analogy questions automatically by concatenating two word pairs. The resulting analogy dataset contains 400K analogy questions. We refer to this dataset as the Chinese Analogy Question Set (CAQS).

[2] `http://code.google.com/p/word2vec/`

[3] `https://bitbucket.org/yoavgo/word2vecf`

[4] This dataset contains news articles in 2014 from various news websites, and can be downloaded from `http://pan.baidu.com/s/1o6wRjp4`

[5] `http://people.sutd.edu.sg/\%7Eyue_zhang/doc/doc/multiview.html`

[6] The system achieves 96.1% , 92.6% and 83.28% F1-score for words segmentation, joint POS-tagging and dependency parsing, respectively, on 1493 manually annotated sentences.

Data	Metrics	NG5	NG2	DEP
Cilin	P@1	43.3%	**45.9%**	43.6%
	P@5	31.1%	**33.3%**	32.6%
	P@10	25.5%	**27.5%**	**27.5%**
	P@20	20.5%	22.2%	**22.7%**
	P@50	15.0%	16.2%	**17.0%**
	P@100	11.5%	12.2%	**12.8%**
CWS	Kendall's τ	38.6%	**44.1%**	42.4%
	Spearman's ρ	54.5%	**62.2%**	60.7%

Table 1: Results on *Cilin* and CWS.

Because embeddings are central for analogy detection, yet there is little large-scale evaluation results on Chinese embeddings in the literature, we perform embedding evaluation on two datasets. The first one is the Chinese WordSim (CWS), translated from the English WordSim-353 Set and re-scored by native Chinese speakers (Jin and Wu, 2012). This dataset consists of 297 word pairs.

The second one is the Chinese thesaurus *Tongyicicilin* (Cilin) (Che et al., 2010), which groups 74,000 Chinese words into five-layer hierarchies and has been used for evaluating the accuracy of word similarity by traditional sparse vector space models (Qiu et al., 2011; Jin et al., 2012). The third level of *Cilin*, which contains 1428 classes, is used to evaluate whether two words are semantically similar.

For comparison between Chinese and English, we also use an English analogy question dataset, the Google dataset[7] (Mikolov et al., 2013a), to evaluate the English word embeddings of Levy and Goldberg (2014a)[8] on analogy detection.

On both the CAQS and the Google datasets, the 3COSMUL method (Levy and Goldberg, 2014b) is used to to answer analogy questions based on given embeddings. The results on the CWS dataset are evaluated using the two standard metrics for the task, namely Spearman's ρ and Kendall's τ rank correlation coefficients. The results on *Cilin* are evaluated using Precision@*K*: the percentage of words from the top-*K* candidates that belong to the *Cilin* category of the target word. If one of the top-*K* candidates belongs to the same third-level category in *Cilin* as the target word, the candidate word is taken as correct.

6.3 Dependency-based and Word-based Word Similarity and Analogy Detection

Word Similarity

[7] http://code.google.com/p/word2vec/source/browse/trunk/questions-words.txt

[8] http://levyomer.wordpress.com/2014/04/25/dependency-based-word-embeddings/

	Relation	NG5	NG2	DEP
MUL	capital-country	68.8%	52.7%	9.9%
	capital-province	84.0%	87.7%	50.0%
	city-province	80.9%	80.3%	22.6%
	family	39.7%	45.1%	41.5%
	currency	10.4%	9.9%	2.5%
	All	80.0%	78.8%	22.0%
IMP	capital-country	87.9%	88.0%	87.6%
	capital-province	84.9%	86.8%	84.9%
	city-province	91.8%	92.0%	90.5%
	family	45.3%	48.0%	47.1%
	currency	7.9%	7.0%	25.9%
	All	90.9%	91.1%	89.8%

Table 2: Results on CAQS. MUL and IMP indicate 3COSMUL and our improved method, respectively.

Relation	NG5	NG2	DEP
capital-country	94.6%	84.5%	38.5%
capital-world	71.5%	64.7%	14.2%
city-in-state	53.2%	42.5%	13.1%
family	82.0%	81.2%	81.0%
currency	10.5%	10.7%	6.0%
All	63.7%	60.7%	38.8%

Table 3: English results on the Google set.

Table 1 shows the results of the three Chinese embedding on *Cilin* and CWS, where NG2 performs much better than NG5 on both datasets. This demonstrates that one does not need to use large window sizes in training word-based embeddings for capturing word similarities. The result is similar to the finding of Shi et al. (2010), which indicates that a window size of 2 is better than a window size of 4 for capturing word similarity by using distributional word representations.

DEP performs slightly worse than NG2 on CWS and *Cilin* in P@1 and P@5. However, it achieves better results on *Cilin* in P@10 to P@100 when more candidate similar words are evaluated. In contrast, NG5 and NG2 mix more semantically related words. This finding is consistent with that of Levy and Goldberg (2014a).

Analogy Detection

Table 2 shows the results of the three Chinese embeddings on CAQS. Unlike on *Cilin* and CWS, NG5 outperforms DEP, and is also slightly better than NG2. Similar tendency is shown in Table 3 for the three English embeddings evaluated on the Google dataset. These results show that dependency embeddings are relatively weak for answering analogy questions. On the other hand, the performance also varies across different relation types.

Target	NG5	NG2	DEP
穿 (wear)	短裤 (shorts), 紧身 (slim-fit), 身穿 (wear), 外套 (coat), 裙子 (skirt)	身穿 (wear), 身着 (wear), 短裤 (shorts), 戴 (wear), 紧身 (slim-fit)	身穿 (wear), 身着 (wear), 戴 (wear), 改穿 (change cloths), 外穿 (wear outside)
关羽 (Guan Yu; P)	赵云(Zhao Yun; P), 刘备 (Liu Bei; P), 诸葛亮 (Zhuge Liang; P), 张飞 (Zhang Fei; P), 曹操 (Cao Cao; P)	赵云 (Zhao Yun; P), 刘备 (Liu Bei; P), 张飞 (Zhang Fei; P), 曹操 (Cao Cao; P), 夏侯渊 (Xiahou Yuan; P)	赵云 (Zhao Yun; P), 韩信 (Han Xin; P), 曹操 (Cao Cao; P), 刘备 (Liu Bei; P), 阿修罗 (Asura; P)
郑州 (Zhengzhou; C)	石家庄 (Shijiazhuang; C), 洛阳 (Luoyang; C), 西安 (Xian; C), 许昌 (Xuchang; C), 太原 (Taiyuan)	石家庄 (Shijiazhuang; C), 太原 (Taiyuan; C), 济南 (Ji-nan; C), 合肥 (Hefei; C), 西安 (Xi-an; C)	合肥 (Hefei; C), 济南 (Jinan; C), 武汉 (Wuhan; C), 石家庄 (Shijiazhuang; C), 南宁 (Nanning; C)

Table 4: Comparison between NG2, NG5 and DEP Embeddings. (P: personal name, C: city name)

6.4 Analysis

To analyze the difference between the three Chinese embeddings methods qualitatively, we manually inspect the words "穿 (wear)", "关羽 (Guan Yu, a person name in the novel '三国演义 *(Romance of the three kingdoms)*')", and "郑州 (Zhengzhou, a city)". Their most similar words are shown in Table 4.

Word Similarity

For the word "穿 (wear)", both NG5 and NG2 yield *similar words* such as "身穿 (wear)", "身着 (wear)", "戴 (wear)" and *related words* such as "短裤 (shorts)", "紧身 (slim-fit)", "外套 (coat)", "裙子 (skirt)", although NG5 gives more related words. In contrast, DEP gives only words that are *similar* both syntactically and semantically. This observation holds for other verbs and nouns, and can be explained by the context extraction methods. For instance, the word "穿 (wear)" usually takes one of the words "短裤 (shorts)", "外套 (coat)", "裙子 (skirt)" as its object, and thus shares similar contexts with them in NG5 and NG2. The context extraction method in DEP, on the other hand, yields different context across syntactic roles, such as verbs (e.g. "穿 (wear)") and their objects (e.g. "短裤 (shorts)" and "外套 (coat)").

Observations on the person name "关羽 (Guan Yu)" and location "郑州 (Zhengzhou)" are similar. For "关羽 (Guan Yu)", NG5 and NG2 can yield more person names in the same novel, while DEP yields person names from other novels (i.e. "韩信 (Hanxin)" and "阿修罗 (Asura)"). For "郑州 (Zhengzhou)", the provincial capital of "河南 (Henan)", NG5 and NG2 give more cities in the same province "河南 (Henan)", while DEP yields capitals of other provinces.

Analogy Detection

As mentioned in Section 2.3, both 3COSADD and 3COSMUL seek a word $b*$ that is similar to b and $a*$ but dissimilar to a. Ideally, the two word pairs b:$b*$ and a:$a*$ should be semantically *similar* while the two word pairs a:b and $a*$:$b*$ should be semantically *related*. Therefore, 3COSADD and 3COSMUL require the embeddings to give higher cosine scores for both semantically similar and related words.

Our analysis above shows that word-context embeddings tend to mix semantically *related* and *similar* words, but dependency-context embeddings only capture semantic *similarity*. This partly explains the reason that dependency-context word embeddings are weak for analogy detection.

It has also been shown in Section 6.3 that the performances of analogy detection vary across different types of relations, which indicates that there are more sophisticated underlying factors. One intuitive explanation is that different semantic relations correspond to different syntactic dependency structures. For example, the male-female family member relation is expected to stand less frequently in a syntactic dependency relation, compared with geographic relations such as city-country, which stand frequently in attributional syntactic relations (e.g. "London, England"). As a result, where the coupling between syntactic and semantic relations is weak, our analysis in Section 6.3 and other work based on syntactic relations can find limitations.

6.5 Syntactic Dependencies for Improved Analogy Detection

The results on CAQS using the method in Section 4 are shown in the IMP rows of Table 2. The method achieves significant improvements (from 80.0% to 90.9% using NG5) compared with Levy and Goldberg's method. In addition, DEP also performs significantly better than with MUL, with an increase from 22.0% to 89.8%. The main reason for this improvement is that the filtering process using syntactic dependencies successfully prunes noisy words.

Seed	Count	Prec
吃 (eat), 苹果 (apple), VOB	572	84.70%
弹 (play), 钢琴 (piano), VOB	142	40.49%
穿 (wear), 衣服 (clothing), VOB	452	67.37%
写 (write), 小说 (novel), VOB	441	53.40%
中国 (China), 北京 (Beijing), ATT	2224	95.23%
湖北 (Hubei), 武汉 (Wuhan), ATT	3201	96.34%

Table 5: Main results of Analogy Mining.

Error analysis shows that the main errors by the improved method are quite different from those by the baseline. For instance, the main errors of Levy and Goldberg's method for the city-province relation are caused by giving another province as the answer, while the improved method gives the name of the country as answer. This is because irrelevant provinces do *not* co-occur frequently with the city in syntactic dependencies, and hence can be filtered by our method. On the other hand, both the country name and province name co-occur frequently with the city name in syntactic dependencies, and our method cannot make a choice between them.

6.6 Dependency Structure Embeddings for Analogy Mining

Shown in Table 5, we use six seeds to mine analogous dependencies. The first seed is used for development and the others for test. The first three seeds, the fourth seed and the last two seeds belong to the *Use:Thing, Produce:Thing and Sub-Location:Location* relations, respectively. α and β are set to 20, and 0.6, respectively. Each set of mined dependencies together with the seed dependency and relation type is shown to two human evaluators, who are required to give a Yes/No answer to each dependency in the set. We take the average scores of the two evaluators (the average inter-annotator agreement is 0.95) as the final precision scores.

As shown in the table, the precisions using different seeds are quite different, ranging from 40% to 96%. One possible reason is that different relations have different numbers of analogous dependencies, ranging from dozens to thousands, and thus the fixed thresholds tuned on a development seed does not apply as effectively to all test cases. For instance, "弹 (play)" and its analogous actions, "吹 (blow)" and "拉 (play)", are all human actions on musical instruments, while the actions "吃 (eat)" and "写 (write)" can apply to many patients. For the seed <弹 (play), 钢琴 (piano), VOB>, irrelevant results such as <拿 (use), 剪子 (scissors), VOB> and <拿 (use), 电筒 (flashlight), VOB>, have the verb "拿 (use)", which is also a human action, yet cannot be considered as usage of the patients "剪子 (scissors)" and "电筒 (flashlight)". Because of the stricter selectional preference of "弹 (play)", its precision of analogy mining is lower.

We tentatively measure the recall of the algorithm by taking the first three types of word pairs in CAQS as the gold set, which contains 801 word pairs. All the three types of word pairs belong to the relation *Sub-Location:Location*. The recall is computed as the percentage of the gold word pairs covered by the mined dependencies. When using the two seeds <武汉 (Wuhan), 湖北 (Hubei), ATT> and <北京 (Beijing), 中国 (China), ATT> for analogy mining, the recalls are 50.2% and 11.3%, respectively. Their union recall is 56.8%. When the precision of each seed is similar, we can achieve better recall without precision loss by using more seeds.

7 Related Work

Turney (2006) introduces a latent relational analysis (LRA) model to measure relational similarity, and apply a novel co-occurrence-based method for analogy filtering. The model can be used for both analogy detection and relation classification, yet cannot scale up well to large datasets due to the complexity of Singular Value Decomposition. Recently, distributed word representations using the skip-gram model (Mikolov et al., 2013a) has been shown to give competitive results on analogy detection. Levy and Goldberg (2014a) extends the skip-gram method with dependency-context embeddings. We study the effect of Levy and Goldberg's embeddings on analogy detection, and further extend their embeddings to dependency-context *dependency structure* embeddings for analogy mining.

Chiu et al. (2007) presents a similarity graph tranversal (SGT) method to mine analogous relations from raw English text automatically, using syntactic dependencies to find candidate relations. The method is unsupervised, and can scale up well to large data sets. However, Chiu et al. (2007) mainly focuses on relations between subjects and objects because of its word-pair extraction method. Ó Séaghdha and Copestake (2009) is a supervised method, which combines lexical similarity and relational similarity to classify se-

mantic relations. These methods are based on distributional word representation models and fit for classifying noun-noun word pairs. In contrast, our methods are based on distributed word representation models, and can mine noun-noun word pairs as well as verb-noun word pairs. In addition, our analogy mining method is unsupervised, while the methods of both Turney (2006) and Ó Séaghdha and Copestake (2009) are supervised.

8 Conclusion

We studied several Chinese relational similarity tasks to train embeddings under the context of distributed word representations using the skip-gram model and syntactic dependencies. For Chinese analogy detection, we compared word-context and dependency-context embeddings, finding that the former results in much better accuracies. Observing that common relations in Chinese are frequently represented by syntactic dependencies, we improved Chinese analogy detection using a dependency context. Further, we empirically studied Chinese analogy mining by proposing a bootstrapping algorithm using a novel distributed representation of syntactic dependencies.

Abstract

This paper introduces a novel way to navigate neighborhoods in distributional semantic models. The approach is based on *relative neighborhood graphs*, which uncover the topological structure of local neighborhoods in semantic space. This has the potential to overcome both the problem with selecting a proper k in k-NN search, and the problem that a ranked list of neighbors may conflate several different senses. We provide both qualitative and quantitative results that support the viability of the proposed method.

1 Introduction

Nearest neighbor search is a fundamental operation in data mining, in which we are interested in finding the closest points to some given reference point. Formally, if we have a reference point r and a set of other points P in a metric space M with some distance function d, the nearest neighbor search task is to find the point $p \in P$ that minimizes $d(p, r)$. In k-Nearest Neighbor search (k-NN), we want to find the k closest points to some given reference point. Nearest neighbor search is a well-studied task, and in particular the complexity of the task (a linear search has a running time of $\mathcal{O}(Ni)$ where N is the cardinality of P and i the complexity of the distance function d) has generated a lot of research; suggestions for reducing the complexity of linear nearest neighbor searches include using various types of space partitioning techniques like k-d trees (Bentley, 1975), or various techniques for doing *approximate* nearest neighbor search (Arya et al., 1998), of which one of the most well-known is locality-sensitive hashing (Indyk and Motwani, 1998).

The problem we are concerned with in this paper is not the complexity of nearest neighbor search, but the question of *how to identify the internal structure of neighborhoods defined by the nearest neighbors*. The problem with a normal k-NN is that the result — a sorted list of the k nearest neighbors — does not say anything about the internal structure of the neighborhood. It is quite possible for two neighborhoods with widely different internal structures to produce identical k-NN results. In the context of *Distributional Semantic Models* (DSMs), which collect and represent co-occurrence statistics in high-dimensional vector spaces, such structural differences may carry significant semantic information, e.g. about the different senses of terms. We argue that the inability of standard k-NN to account for structural properties has been misinterpreted as a shortcoming of the distributional representation (Erk and Padó, 2010).

We will demonstrate in this paper that this is *not* a shortcoming of the distributional representation, but of the *mode of querying* the DSM. We argue that information about the different usages (i.e. senses) of a term is encoded in the structural properties of the nearest neighborhoods, and we propose the use of *relative neighborhood graphs* for identifying these structural properties. Relative neighborhood graphs may also be used for finding a relevant k for a given reference point, which we refer to as the *horizon* with respect to the reference point.

2 Distributional Semantics and Nearest Neighbor Search

Collecting and comparing co-occurrence statistics for terms in language has become a standard approach for computational semantics, and is now commonly referred to as *distributional semantics*. There are many different types of models that can be used for this purpose, but their common objective is to represent terms as vectors that record (some function of) their distri-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2451–2460,
Lisbon, Portugal, 17-21 September 2015.

butional properties. The standard approach for generating such vectors is to collect distributional statistics in a *co-occurrence matrix* that records co-occurrence counts between terms and contexts. The co-occurrence matrix is then subject to various types of transformations, ranging from the application of simple frequency filters or association measures to matrix factorization or regression models. The resulting representations are referred to as *distributional vectors* (or *word embeddings*), which are used to compute similarity between terms.

Given a similarity — or distance — measure on such distributional vectors, we can perform a nearest neighbor search. This is a particularly important operation in distributional semantics, since it answers the question "which other terms are similar to this one?" and this is a central question in semantics; lexica and thesauri are built with the main purpose of answering this question. Consequently, nearest neighbor search in a DSM could be seen as a compilation step in a distributional lexicon.

The result of a nearest neighbor search in a DSM is often presented as a list of (the top k) neighbors, sorted by descending similarity with the target term. Table 1 illustrates typical sorted nearest neighbor lists produced with three different DSMs: a standard model based on Pointwise Mutual Information (PMI)[1] that has been reduced to 2,000 dimensions by applying a Gaussian random projection; GloVe, which uses regression to find distributional vectors such that their dot product approximates their log probability of co-occurring (Pennington et al., 2014); and the Skipgram model, which uses stochastic gradient descent and hierarchical softmax combined with negative sampling and subsampling to find distributional vectors that maximize the probability of observed co-occurrence events (Mikolov et al., 2013). We refer to the respective papers for details regarding the various models. The similarity measure used is the cosine similarity: $s(a,b) = \frac{a \cdot b}{\|a\|\|b\|}$.

Table 1 lists the 10 nearest neighbors to *suit* in these three different DSMs using the entire Wikipedia as data. As can be expected, there are both similarities and dissimilarities between these neighborhoods; "suits" and "lawsuit" occur among the 10 nearest neighbors to "suit" in all three models, whereas other terms are specific for one particular model. What is common between the three models is that they all feature neighbors that represent two different usages of "suit": the *law*-sense ("lawsuit") and the *clothes*-sense ("dress", "wearing", "doublebreasted").[2] However, these distinction are not discernible by merely looking at the list of nearest neighbors; the only information it provides is the ranking of the nearest neighbors in descending order of similarity.

Table 1: Sorted list of the nearest neighbors to "suit" in three different distributional models.

PMI	**GloVe**	**Skipgram**
suits	suits	suits
dress	lawsuit	lawsuit
jacket	filed	countersuit
wearing	case	classaction
hat	wearing	doublebreasted
trousers	laiming	skintight
costume	lawsuits	necktie
shirt	alleging	wetsuit
pants	alleges	crossbone
lawsuit	classaction	lawsuits

It has been argued that DSMs that represent terms by a single vector cannot adequately handle polysemy, since they conflate several different usage patterns in one and the same vector (Véronis, 2004; Erk and Padó, 2010). Examples like the one above is often cited as evidence. We argue that this critique is unfounded and misinformed, and that it is *the mode of querying* the DSM that can be susceptible to problems with polysemy. As the above example demonstrates, querying DSMs by k-NN conflates different usages of terms. The reason for this seems quite obvious: simply ranking the nearest neighbors by similarity (or distance) ignores any local structures of the neighborhood. If "suit" has as neighbors both "dress" and "lawsuit", which represent two distinct types of usages of "suit", there will be a *structural* distinction in the neighborhood of "suit" between these different neighbors, since they will be mutually unrelated (i.e. there is a similarity between "suit" and

[1] For observations a and b, PMI$(a,b) = \log \frac{p(a,b)}{p(a)p(b)}$. The probabilities are often replaced in DSMs by co-occurrence counts of a and b and their respective frequency counts.

[2] The Skipgram model also features a *manga*-related sense of "suit" in the neighbor "crossbone," which refers to the mange series "Mobile Suit Crossbone Gundam."

"dress" and between "suit" and "lawsuit", but *not* between "dress" and "lawsuit").

k-NN also gives rise to another problem related to polysemy in DSMs. The problem is that the most frequent senses will populate the top of the nearest neighbor list, while the less frequent senses will not appear until further down the list, and if we set a too restrictive k, we will only see neighbors relating to the most frequent sense. As an example, consider the two different senses of "suit" above. The distributional vector for "suit" can be thought of as a sum $v_{suit} = f_{suit|law}v_{suit|law} + f_{suit|clothes}v_{suit|clothes}$, where $v_{suit|law}$ is an idealized notion of the *true* distributional vector of "suit" in the *law*-sense, and $f_{suit|law}$ is the relative frequency of this sense.[3] From there one can easily argue that a similarity such as $s(v_{suit}, v_{clothes})$ is actually a weighted composite of the similarities $s(v_{suit|law}, v_{clothes})$ and $s(v_{suit|clothes}, v_{clothes})$.[4] If "suit" occurs predominantly in the *law*-sense in our corpus, the k-NN neighborhood of "suit" will be dominated by words pertaining to its *law*-sense, while the less frequent senses might not be present at all. A misguided k may thus obscure any other, less frequent, senses of a term.

3 Word-Sense Induction

Selecting a relevant k for a given term and grouping the neighbors according to which senses they represent is an example of *Word-Sense Induction* (WSI). DSMs are well suited for this task, and there have been a number of different approaches suggested in the literature. One of the earliest approaches is *distributional clustering* (Pereira et al., 1993), which is based on a probabilistic decomposition model that uses maximum likelihood estimation to fit the model to observed data. Another example is *Clustering By Committee* (CBC) (Pantel and Lin, 2002), which first uses average-link clustering to recursively cluster the nearest neighbors of a term into committees, which are then used to define clusters by iteratively adding committees whose similarity to the term exceeds a certain threshold, and that is not too similar to any other added committee. For each added committee, its features are also removed from the distributional representation of the term. This last step ensures that the clusters do not become too similar, and that clusters representing less frequent senses can be discovered.

The idea of iteratively removing features from the distributional vector when a sense cluster as been formed is also present in Dorow and Widdows (2003), who use a graph-based clustering method. Another graph-based approach is the *HyperLex* algorithm (Véronis, 2004), which constructs a graph connecting all pairs of terms that co-occur in the context of an ambiguous term. The resulting graph contains highly connected components, which represent the different senses of the term. Agirre et al. (2006) compare HyperLex to *PageRank* (Brin and Page, 1998) and demonstrates that the two methods perform similarly.

There have also been several attempts to use various types of matrix factorization for WSI. The idea is that the factorization uncovers a set of global senses in the form of the latent factors, and that the sense distribution for a given term can be described as a distribution over these latent factors. Examples of factorization methods that have been used include different versions of *Latent Dirichlet Allocation* ((Brody and Lapata, 2009; Séaghdha and Korhonen, 2011; Yao and Van Durme, 2011; Lau et al., 2012) and *non-negative matrix factorization* (Dinu and Lapata, 2010; Van de Cruys and Apidianaki, 2011).

Tomuro et al. (2007) argue that clustering approaches like distributional clustering or CBC may produce clusters that are themselves polysemous, which may not be a desirable property of a WSI algorithm, and suggests using *feature domain similarity* to solve this problem. The idea is to incorporate similarities between the *features* of items rather than the similarity between the items themselves in a modified version of CBC that enables the algorithm to utilize feature similarities, which inhibit the formation of polysemous clusters.

Koptjevskaja Tamm and Sahlgren (2014) also leverage on the idea of using feature similarity as the basis of sense clustering. The approach, called *syntagmatically labeled partitioning*, relies on a DSM that encodes sequential as well as substitutable relations. The method essentially sorts the k nearest (substitutable) neighbors according to which sequential connections they share. The resulting partitioning of the nearest distributional neighbors does not only constitute a WSI, but it

[3] Weighting schemes muddles this notion quite a bit, but we think the general intuition still holds.

[4] In the case of cosine similarity this follows nicely from the distributive property of dot products: $v = av_1 + bv_2$, $s(v, w) = \frac{v \cdot w}{\|v\|\|w\|} = \frac{a(v_1 \cdot w) + b(v_2 \cdot w)}{\|v\|\|w\|}$

also provides *labels* for the induced senses in the form of the sequential connections the neighbors share.

4 Neighborhood Graphs

Many of the previous WSI approaches operate at a global level, utilizing global structural properties of the semantic spaces, e.g. by matrix factorization techniques. We believe this is as ill-advised as setting a global k or radius for the nearest neighbor search, since it is the *local* structures that are important when analyzing nearest neighbors. Other WSI approaches use various forms of clustering techniques. However, previous studies of the intrinsic dimensionality of distributional semantic spaces using fractal dimensions indicate that neighborhoods in semantic space have a *filamentary* rather than clustered structure (Karlgren et al., 2008).

We therefore propose the use of *topological* models that take the *local* structure of neighborhoods in semantic space into account. The approach discovers different word senses from the local structure of neighborhoods, given nothing but similarities between points. As such it is easy to test on widely different vector models, as long as there exists a well behaved similarity function. The proposed approach not only answers the question which other terms are similar to a given term, but also *how* are they similar.

Relative neighborhoods, first proposed in (Toussaint, 1980), are examples of *empty region graphs* (Cardinal et al., 2009), where points are neighbors if some region between them is empty. For *Relative Neighborhood Graphs* (RNG) this region between two points a and c is defined as the intersection of the two spheres with centers in a and c with radius $d(a, c)$. In other words, a point b lies between points a and c if it is closer to both a and c than a and c are to each other. If no such point b exists, a and c are neighbors. Illustrations of this can be seen in Figure 1.

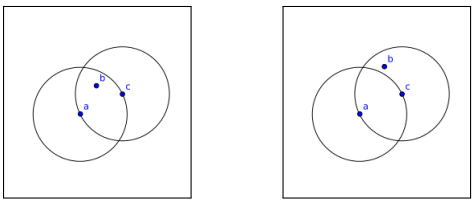

Figure 1: Example of when point b is between point a and c (left), and when it is not (right).

Such neighborhoods have been argued to better preserve local topology (Bremer et al., 2014), and be more robust to deformations of the data than k-NN neighborhoods (Correa and Lindstrom, 2012) as they in some sense contain information about direction whereas k-NN neighborhoods only contain information about distance. Going back to the "suit" example, we can see that if "suit" in the *law*-sense is more similar to the composite "suit" than to its *clothes*-sense, and vice versa, then the composite v_{suit} lies between $v_{suit|law}$ and $v_{suit|clothes}$. This in turn means that out of those two points, both are relative neighbors to "suit", and neither of them lies between the other and "suit".

Formally, the set of points between two points $a, c \in V$ can be characterized and computed in the following way:

$$\text{btw}(V, a, c) = \{b | b \in V, b \text{ is between } a \text{ and } c\}$$

$$\text{rng-nbh}(V, a) = \{c | c \in V, \text{btw}(V, a, c) = \emptyset\}$$

$$E_{\text{rng}}(V) = \{(a, b) | a \in V, b \in \text{rng-nbh}(V, a)\}$$

where E_{rng} is the undirected edge set of the RNG. The function $\text{btw}(V, a, c)$ can be straightforwardly translated to an algorithm taking $\mathcal{O}(|V|)$ time, making the $\text{rng-nbh}(V, a)$ function take $\mathcal{O}(|V|^2)$ time, which in turn makes the computation of the complete graph take $\mathcal{O}(|V|^3)$ time.[5] Clearly unfeasible, but we have not found any alternatives that perform better in the high-dimensional case.[6]

Correa and Lindstrom (2012) note that the intersection of the RNG and the k-NN graph is a more feasible alternative:

$$\text{k-rng-nbh}(V, a) = \text{rng-nbh}(V', a)$$

$$\text{where } V' = k \text{ nearest neighbors of } a.$$

Given a precompiled k-NN lookup, the above takes $\mathcal{O}(k^2)$ time, so using a heap-based $\mathcal{O}(|V| \lg k)$ k-NN algorithm results in an algorithm taking $\mathcal{O}(k^2 + |V| \lg k)$ time.

The same idea can be used to build a tree structure rooted in a reference word a in the following way:

$$\text{rnbh-tree}(V, a) = \{(c, \arg\min_{b \in B_c} d(b, c)) | c \in V\}$$

$$\text{where } B_c = \{a\} \cup \text{btw}(V, a, c)$$

[5] Assuming a constant time distance function.

[6] It should be noted that there are more efficient algorithms for lower-dimensional situations.

which can easily be restricted to the k-nearest neighbors of a in much the same way as above, with the same monotonic behavior.

Computing this for a point a produces a tree where the direct children of a are its relative neighbors, and the parent of a point c further down the tree is the point between a and c that is closest to c. This structure, while similar to a *minimum spanning tree*, differs in some crucial regards: the rnbh-tree(V, a) is rooted in a word a. The difference between rnbh-tree(V, a) and rnbh-tree(V, b) is often quite significant. Furthermore, the restricted k-rnbh-tree is monotonic in k. That property does not hold for a minimum spanning tree of a local neighborhood.

5 Examples of RNGs

To get an intuition of what these neighborhoods look like we present a few examples. The words have been chosen either because they are common examples in similar work — e.g. "heart" and "suit" from Pantel and Lin (2002) — or because they represent different parts-of-speech ("above" is a preposition, "bad" is an adjective, and "service" is a noun) and disparate kinds of ambiguity ("orange" can be both a fruit and a color).

Figure 2 (next page) illustrates what an RNG looks like for the term "heart" and its 100 nearest neighbors in the PMI model. Note that the root "heart" (at the mid-left in the graph) only has two relative neighbors: "cardiac" and "soul," arguably representing a *body*-sense and a *soul*-sense of the term. One advantage of using this type of structure for the neighborhood is that it enables us to examine various depths of the tree. Depth one includes only the direct neighbors ("cardiac" and "soul"), while depth two includes all neighbors two steps away in the graph: "disease," "coronary," "pulmonary," "cardiovascular," "ventricular," and "failure," which are all children to "cardiac." This tree structure can be used to identify neighbors that are themselves polysemous (c.f. the critique mentioned in Section 3 of clustering-based approaches to word-sense induction that they may produce polysemous clusters). One example is the neighbor "disease" at depth two, which has six children that refer to different aspects of disease.

We argue that the RNG can be quite useful for WSI, since the branching structure indicates different usages, and the depth factor enables us to calibrate the granularity of the induced word senses. If we only consider direct neighbors (i.e. depth one), and set $k = V$ (i.e. we do an exhaustive nearest neighbor search), we will extract all terms that have a direct connection to the reference term. We refer to this neighborhood as the *semantic horizon*. At the most coarse level of analysis, this is the neighborhood that represents the main induced senses of a term. Tables 2 and 3 provide examples of 1,000-RNG neighborhoods of depth one.

Table 2: RNG for $k = 1,000$ of the words "suit," "orange," and "heart" in three different semantic models. The numbers in parenthesis indicate the k-NN ranks of the neighbors.

PMI	**GloVe**	**Skipgram**
suit		
suits (1) dress (2) lawsuit (10) dinosaur (53) costly (60) option (76) counterparts (99) predator (107) trump (109) ⋮	suits (1) lawsuit (2) mobile (33) gundam (34) trump (55) zoot (133) rebid (423) serenaders (458) hev (987)	suits (1) lawsuit (2)
orange		
yellow (1) lemon (16)	yellow (1) ktype (12) lemon (14) citrus (17) jersey (21) cherry (24) county (26) peel (42) jumpsuits (57) ⋮	redorange (1)
heart		
cardiac (1) soul (22) hearts (183) ashtray(641) rags(771)	my (1) blood (2) throbs (3) suffering (4) brain (6) cardiac (8) hearts (11) throb (17) lungs (22) ⋮	congestive (1) hearts (2)

These examples demonstrate some interesting similarities and differences between the three models. First of all, there are some direct neighbors that are present in all three models: "suit" has "suits" and "lawsuit" as direct neighbors in all three models, "heart" has "hearts," "service"

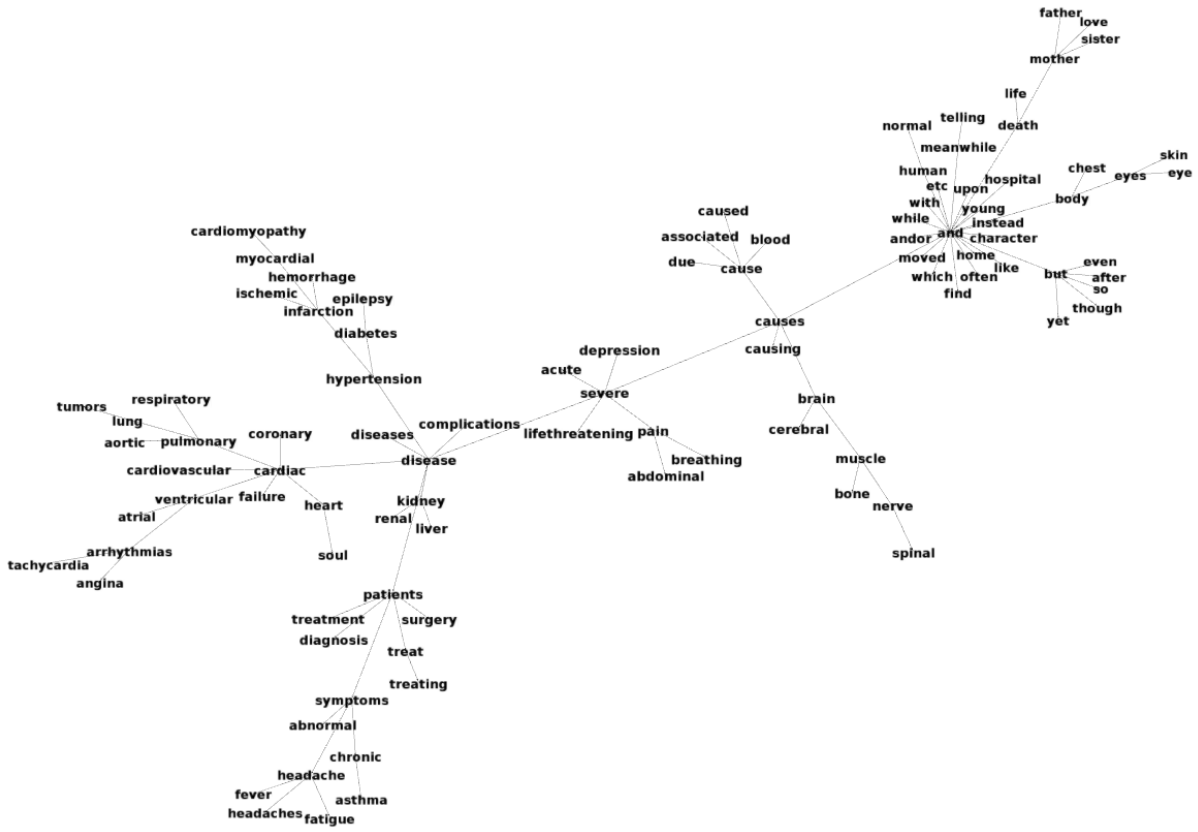

Figure 2: RNG for “heart” in the PMI model, restricted to the 100 nearest neighbors.

has “services,” and “above” has “below”. Plural forms are of course reasonable neighbors of their singular counterparts in a semantic model, but their usefulness for WSI can perhaps be questioned. Taking “suits” to indicate the *clothes*-sense of “suit,” all three models produce both a *clothes*-sense and a *law*-sense. For “orange,” the Skipgram model only represents the *color*-sense, while the PMI and GloVe models also feature a *fruit*-sense. For “heart,” all three models have a *disease*-sense (represented by the neighbors “cardiac” in the PMI and GloVe models, and the neighbor “congestive” in the Skipgram model), and an *organ*-sense (represented by the plural form “hearts”). “Service” is a comparably vague term that has a number of different senses in the PMI and GloVe models, but only one in the Skipgram model. “Bad” produces both a *negativity*-sense and a *German spa town*-sense in all three models, but only the GloVe and Skipgram models have a separate *antonym*-sense (“good” is not a direct neighbor in the PMI model). “Above” has both the antonym and direct neighbors relating to measurements in all three models.

It is interesting to note that GloVe produces a significant amount of sequential relations; “mobile suit gundam”, “cheap suit serenaders”, “orange peel”, and “orange jumpsuit” are just some of many examples of sequential relations found in the relative neighborhood of terms in the GloVe model.

The PMI and GloVe models produce the structurally most similar RNGs in these examples, with on average a handful of direct neighbors, of which some can be very distant. The Skipgram model on the other hand produces very few direct neighbors. This led us to look further into the structural properties of neighborhoods in the Skipgram model. An interesting observation — and possible complication — is that the neighborhoods in the Skipgram model are highly asymmetric: the first neighbor of “information” is “informations”, whereas “information” is the 1,829th neighbor of “informations.” While such asymmetry occurs in all models, it seems much more prevalent in the Skipgram model. Figure 3 confirms this suspicion: each point corresponds to a random word pair (a, b) with x corresponding to where b is in the ordered list of a’s neighbor, and y to where a is in the ordered list of b’s neighbors. The figure

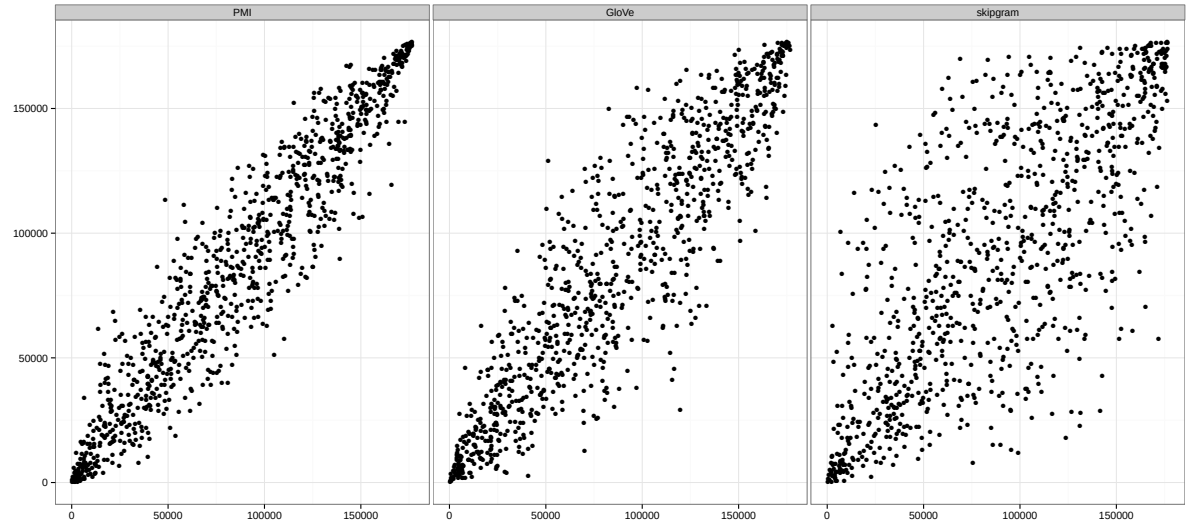

Figure 3: Neighborhood reciprocity in the different models; PMI to the left, GloVe in the middle, and Skipgram to the right.

Table 3: k-RNG for $k = 1,000$ of the words "service," "bad," and "above" in three different semantic models. The numbers in parenthesis indicate the k-NN ranks of the neighbors.

PMI	**GloVe**	**Skipgram**
service		
services (1) network (2) operates (8) launched (18) served (22) intercity(34)	services (1) operated (3) serving (6) military (17) duty (20) passenger (21) dialaride (644) aftersales (759) limitedstop (802)	services (1)
bad		
terrible (1) that (2) luck (39) unfortunate (70) stalling (276) donnersbergkreis (860) rancid (980)	good (1) kissingen (2) ugly (45) nasty (48) dirty (106) omen (328) conkers (360) karma (952)	nauheim (1) good (2) dreadful (5)
above		
below (1) around (2) feet (5) measuring (29) beneath (36) columns (62) atop (102)	below (1) level (2) height (3) just (4) stands (10) lower (11) beneath (12) rise (21) sea (30) ⋮	below (1) 500ft (2)

shows that the local densities vary much more in the Skipgram model than in the others. This is not in itself undesirable, but wild differences in neighborhood reciprocity complicates the choice of k in the k-RNG algorithm, as observed by the particularly sparse neighborhoods of the Skipgram model above.

6 WSI Evaluation

The standard way to evaluate WSI algorithms is to use one the SemEval WSI test collections (Agirre and Soroa, 2007; Manandhar et al., 2010; Navigli and Vannella, 2013; Jurgens and Klapaftis, 2013), which are all designed similarly: systems are expected to first perform WSI and then to assign texts to the induced senses (i.e. in effect doing a word-sense *disambiguation* step). We consider this type of evaluation to be a less useful for our purposes, since the required disambiguation step is a highly non-trivial task in itself. The RNG method proposed in this paper is a pure WSI algorithm, and as such does not offer a solution to the disambiguation problem. We therefore opted to focus solely on the hypothesis that relative neighborhoods cover senses that k-NNs do not. In essence, we investigate whether k-RNG *retrieval* does a better job at covering different senses than k-NN *retrieval*. This was done using *pseudowords*.

Pseudowords are artificially ambiguous words, created by regarding different words as identical. We can, for example, say that the pseu-

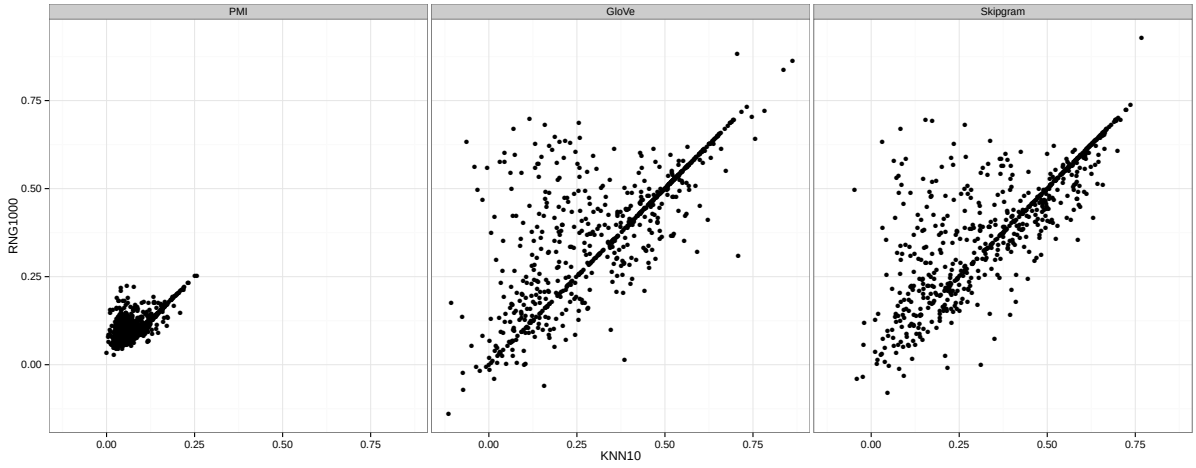

Figure 4: Comparison of minmax pseudosense score for k-RNGs and k-NNs for $k = 1,000$ and $k = 10$ respectively; PMI to the left, GloVe in the middle, and Skipgram to the right.

doword <*deadeye*> is a composite of the two words *marksman* and *loudspeaker*. A corpus with the artificially ambiguous word <*deadeye*> in it can then be created by replacing all occurrences of the words *marksman* and *loudspeaker* with <*deadeye*>.

Using the pseudowords provided by Pilehvar and Navigli (2013) a corpus with 689 non-overlapping pseudowords was created, based on the BNC corpus.[7] Two models were then trained, one on the altered corpus, and one on the unaltered one. To check whether the neighborhood of a pseudoword contains information about its underlying senses we compared each underlying sense to the words in the neighborhood, taking the minimum of all senses' maximum similarity as a score, as demonstrated in Table 4. The similarities were calculated using the model trained on the unaltered corpus, as the one based on the altered corpus will not contain the underlying senses of pseudowords.

Working through the example in Table 4, the neighborhood of the pseudoword <*deadeye* > consists of the three words *shooter*, *stereo*, and *sport*. The pseudoword in itself is made up of the two underlying senses *marksman* and *loudspeaker*. The similarities between the words in the neighborhood of the model trained on the unaltered data and the words of the underlying senses are as presented in Table 4. The closest word to *marksman* is *shooter*, with a similarity score of 0.7. The closest word to *loudspeaker* is *stereo*, with a score of 0.3. So the scoring would, in total, be 0.3. It should be noted that the upper bound for this score is oftentimes significantly lower than 1: The neighborhood could not possibly contain the words *marksman* or *loudspeaker*, as those words are not present in the corpus. This means that the scores are bounded by the similarity of the least similar closest neighbor to the underlying senses.

Table 4: Example scoring of a neighborhood of the word <*deadeye*>.

<*deadeye*>	*shooter*	*stereo*	*sport*	**max**
marksman	0.7	0.04	0.4	0.7
loudspeaker	0.01	0.3	0.05	0.3
min: 0.3				

This score was chosen because of its simplicity and intuitive interpretation: a low score implies that at least one word sense was not represented in the neighborhood whereas a high score means that all senses are represented in the neighborhood. One can then plot these scores for both relative neighborhoods and k-NN neighborhoods for each pseudoword as is done in Figure 4. Each

[7] www.natcorp.ox.ac.uk

point (x, y) represents a pseudoword, with x and y being the score of the k-NN neighborhood and the k-RNG neighborhood respectively.

Figure 5 shows an aggregate of Figure 4, plotting the distribution of $y - x$, i.e. the difference between the scores achieved by the k-RNG and the k-NN. As seen in Figure 4, a lot of points lie on the line $y = x$, meaning both methods achieved the same score. However, when this is not the case, there is a clear bias for the k-RNG to outperform the k-NN, as demonstrated in Figure 5. Here, using the BNC instead of Wikipedia as training data, the GloVe and Skipgram models yielded sparse relative neighborhoods — both with an average of about 8 neighbors — but the PMI model produced quite dense neighborhoods averaging 63 neighbors. Since the scoring function does not penalize neighborhood size there is good reason to be skeptical of its viability, and specifically the performance of the PMI-model based on these figures.

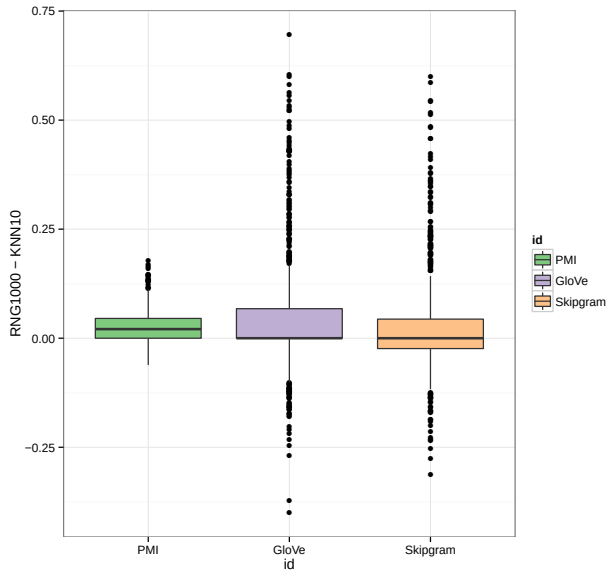

Figure 5: Distribution of difference between scores for k-RNGs and k-NNs. Positive scores means that the k-RNG scored higher than the k-NN

7 Conclusions

This paper has discussed the question how to query semantic models, which is a question that has been long neglected in research on computational semantics. Nearest neighbor search (or k-NN) is often treated as the only available option, which leads to misunderstandings regarding how semantic models represent and handle vagueness and polysemy. We have argued that the structure — or topology — of the local neighborhoods in semantic models carry useful semantic information regarding the different usages — or senses — of a term, and that such topological properties therefore can be used to analyze polysemy and do WSI.

We have introduced relative neighborhood graphs (RNG) as an alternative to standard k-NN, and we have exemplified k-RNG in three different well-known semantic models. The examples demonstrate that k-RNG manages to retrieve disparate and relevant neighbors in all three models, yet the kind of neighbors returned and the nature of the neighborhoods differ. Quantitatively, The k-RNG method consistently outperformed k-NN on underlying sense retrieval.

We have also illustrated how k-RNG can be used as a tool to gain insight into the topological properties of different models. The GloVe model, for example, makes no difference between sequential and substitutable relations, leading to neighborhoods that contain n-grams instead of senses. This can clearly be seen in for example Table 2. Skipgram uses more sophisticated tokenization, which alleviates this issue.

Another interesting result of the paper is that the RNG uncovers otherwise unseen differences between the models, which manifest not as scoring differences but as properties of the word representations themselves. One example is the differences in neighborhood reciprocity observed between the different models.

Abstract

Multi-modal semantics has relied on feature norms or raw image data for perceptual input. In this paper we examine grounding semantic representations in raw auditory data, using standard evaluations for multi-modal semantics, including measuring conceptual similarity and relatedness. We also evaluate cross-modal mappings, through a zero-shot learning task mapping between linguistic and auditory modalities. In addition, we evaluate multi-modal representations on an unsupervised musical instrument clustering task. To our knowledge, this is the first work to combine linguistic and auditory information into multi-modal representations.

1 Introduction

Although distributional models (Turney and Pantel, 2010; Clark, 2015) have proved useful for a variety of NLP tasks, the fact that the meaning of a word is represented as a distribution over other words implies that they suffer from the *grounding problem* (Harnad, 1990); i.e. they do not account for the fact that human semantic knowledge is grounded in the perceptual system (Louwerse, 2008). Motivated by human concept acquisition, multi-modal semantics enhances linguistic representations with extra-linguistic perceptual input. These models outperform language-only models on a range of tasks, including modelling semantic similarity and relatedness, and predicting compositionality (Silberer and Lapata, 2012; Roller and Schulte im Walde, 2013; Bruni et al., 2014). Although feature norms have also been used, raw image data has become the de-facto perceptual modality in multi-modal models.

However, if the objective is to ground semantic representations in perceptual information, why stop at image data? The meaning of *violin* is surely not only grounded in its visual properties, such as shape, color and texture, but also in its sound, pitch and timbre. To understand how perceptual input leads to conceptual representation, we should use as many perceptual modalities as possible. A recent preliminary study by Lopopolo and van Miltenburg (2015) found that it is possible to derive uni-modal semantic representations from sound data. Here, we explore taking multi-modal semantics beyond its current reliance on image data and experiment with grounding semantic representations in the auditory perceptual modality.

Multi-modal models that rely on raw image data have typically used "bag of visual words" (BoVW) representations (Sivic and Zisserman, 2003). We follow a similar approach for the auditory modality and construct bag of audio words (BoAW) representations. Following previous work in multi-modal semantics, we evaluate these models on measuring conceptual similarity and relatedness, and inducing cross-modal mappings between modalities to perform zero-shot learning. In addition, we evaluate on an unsupervised musical instrument clustering task. Our findings indicate that multi-modal representations enriched with auditory information perform well on relatedness and similarity tasks, particularly on words that have auditory assocations. To our knowledge, this is the first work to combine linguistic and auditory representations in multi-modal semantics.

2 Related Work

Information processing in the brain can be roughly described to occur on three levels: perceptual input, conceptual representation and symbolic reasoning (Gazzaniga, 1995). While research in AI has made great progress in understanding the first and last of these, understanding the middle level is still more of an open problem: how is it that per-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2461–2470,
Lisbon, Portugal, 17-21 September 2015.

ceptual input leads to conceptual representations that can be processed and reasoned with?

A key observation is that concepts are, through perception, *grounded* in physical reality and sensorimotor experience (Harnad, 1990; Louwerse, 2008), and there has been a surge of recent work on perceptually grounded semantic models that try to account for this fact. These models learn semantic representations from both textual and perceptual input, using either feature norms (Silberer and Lapata, 2012; Roller and Schulte im Walde, 2013; Hill and Korhonen, 2014) or raw image data (Feng and Lapata, 2010; Leong and Mihalcea, 2011; Bruni et al., 2014) as the source of perceptual information. A popular approach in the latter case is to collect images associated with a concept, and then lay out each image as a set of keypoints on a dense grid, where each keypoint is represented by a robust local feature descriptor such as SIFT (Lowe, 2004). These local descriptors are subsequently clustered into a set of "visual words" using a standard clustering algorithm such as k-means and then quantized into vector representations by comparing the descriptors with the centroids. An alternative to this bag of visual words (BoVW) approach is transferring features from convolutional neural networks (Kiela and Bottou, 2014).

Various ways of aggregating images into visual representations have been proposed, such as taking the mean or the elementwise maximum. Ideally, one would jointly learn multi-modal representations from parallel multi-modal data, such as text containing images (Silberer and Lapata, 2014) or images described with speech (Synnaeve et al., 2014), but such data is hard to obtain, has limited coverage and can be noisy. Hence, image representations are often learned independently. Aggregated visual representations are subsequently combined with a traditional linguistic space to form a multi-modal model. This mixing can be done in a variety of ways, ranging from simple concatenation to more sophisticated fusion methods (Bruni et al., 2014).

Cross-modal semantics, instead of being concerned with improving semantic representations through grounding, focuses on the problem of reference. Using, for instance, mappings between visual and textual space, the objective is to learn which words refer to which objects (Lazaridou et al., 2014). This problem is very much related to the object recognition task in computer vision, but instead of using just visual data and labels, these cross-modal models also utilize textual information (Socher et al., 2014; Frome et al., 2013). This allows for *zero-shot learning*, where the model can predict how an object relates to other concepts just from seeing an image of the object, but without ever having previously encountered an image of that particular object (Lazaridou et al., 2014). Multi-modal and cross-modal approaches have outperformed state-of-the-art text-based methods on a variety of tasks (Bruni et al., 2014; Silberer and Lapata, 2014).

MEN	score	SimLex-999	score

guitar-piano	0.86	music-melody	0.70

Table 1: Examples of pairs in the datasets where auditory is relevant, with the similarity score.

3 Evaluations

Following previous work in multi-modal semantics, we evaluate on two standard similarity and relatedness datasets: SimLex-999 (Hill et al., 2014) and the MEN test collection (Bruni et al., 2014). These datasets consist of concept pairs together with a human-annotated similarity or relatedness score, where the former dataset focuses on genuine similarity (e.g., *teacher-instructor*) and the latter focuses more on relatedness (e.g., *river-water*). In addition, following previous work in cross-modal semantics, we evaluate on the zero-shot learning task of inducing a cross-modal mapping to the correct label in the auditory modality from the linguistic one and vice-versa.

3.1 Multi-modal Semantics

Evidence suggests that the inclusion of visual representations only improves performance for certain concepts, and that in some cases the introduction of visual information is detrimental to performance on similarity and relatedness tasks (Kiela et al., 2014). The same is likely to be true for other perceptual modalities: in the case of comparisons such as *guitar-piano*, the auditory modal-

Dataset	MEN	AMEN	SLex	ASLex
Linguistic	3000	258	999	296
Auditory	2590	233	534	216

Table 2: Number of concept pairs for which representations are available in each modality.

ity is certainly meaningful, whereas in the case of *democracy-anarchism* it is probably less so. Therefore, we had two graduate students annotate the datasets according to whether auditory perception is relevant to the pairwise comparison. The annotation criterion was as follows: if both concepts in a pairwise comparison have a distinctive associated sound, the modality is deemed relevant. Inter-annotator agreement was high: $\kappa = 0.93$ for MEN and $\kappa = 0.92$ for SimLex-999. Some examples of relevant pairs can be found in Table 1. Hence, we now have four evaluation datasets: the MEN test collection **MEN** and its auditory-relevant subset **AMEN**; and the SimLex-999 dataset **SLex** and its auditory-relevant subset **ASLex**. Due to the nature of the auditory data sources, it is not possible to build auditory representations for all concepts in the test sets. Hence, unless stated otherwise, we report results for the covered subsets (using the same subsets when comparing across modalities, to ensure a fair comparison). Table 2 shows how much of the test sets are covered for each modality.[1]

3.2 Cross-modal Semantics

In addition to evaluating our models on the MEN and SimLex tasks, we evaluate on the cross-modal task of zero-shot learning. In the case of vision, Lazaridou et al. (2014) studied the possibility of predicting from "we found a cute, hairy wampimuk sleeping behind the tree" that a "wampimuk" will probably look like a small furry animal, even though a wampimuk has never been seen before. We evaluate zero-shot learning, using partial least squares regression (PLSR) to obtain cross-modal mappings from the linguistic to auditory space and vice versa.[2] Thus, given a linguistic representation for e.g. *guitar*, the task is to map it to the appropriate place in auditory space without ever having heard a guitar; or map it to the appropriate place in linguistic space without ever having read about a guitar (having only heard it).

4 Approach

One reason for using raw image data in multi-modal models is that there is a wide variety of resources that contain tagged images, such as ImageNet (Deng et al., 2009) and the ESP Game dataset (Von Ahn and Dabbish, 2004). However, such resources do not exist for audio files, and so we follow a similar approach to Fergus et al. (2005) and Bergsma and Goebel (2011), who use Google Images to obtain images. We use the online search engine Freesound[3] to obtain audio files. Freesound is a collaborative database released under Creative Commons licenses, in the form of snippets, samples and recordings, that is aimed at sound artists. The Freesound API allows users to easily search for audio files that have been tagged using certain keywords.

For each of the concepts in the evaluation datasets, we used the Freesound API to obtain samples encoded in the standard open source OGG format[4]. Because the database contains variable numbers of files, with varying duration per individual file, we restrict the search to a maximum of 50 files and a maximum of 1 minute duration per file. The Freesound API allows for various degrees of keyword matching: we opted for the strictest keyword matching, in that the audio file needs to have been purposely tagged with the given word (the alternative includes searching the text description for matching keywords). For example, if we are searching for audio files of cars, we retrieve up to 50 files with a maximum duration of 1 minute per file that have been tagged with the label "car".

4.1 Linguistic Representations

For the linguistic representations we use the continuous vector representations from the log-linear skip-gram model of Mikolov et al. (2013). Specifically, we trained 300-dimensional vector representations trained on a dump of the English Wikipedia plus newswire (8 billion words in total).[5] These types of representations have been found to yield the highest performance on a variety of semantic similarity tasks (Baroni et al., 2014).

[1] To facilitate further work in multi-modal semantics beyond vision, our code and data have been made publicly available at http://www.cl.cam.ac.uk/~dk427/audio.html.

[2] To avoid introducing another parameter, we set the number of latent variables in the cross-modal PLSR map to a third of the number of dimensions of the perceptual representation.

[3] http://www.freesound.org.

[4] http://www.vorbis.com.

[5] We used the demo-train-big-model-v1.sh script from http://word2vec.googlecode.com to obtain this corpus.

4.2 Auditory Representations

A common approach to obtaining acoustic features of audio files is the Mel-scale Frequency Cepstral Coefficient (MFCC) (O'Shaughnessy, 1987). MFCC features are abundant in a wide variety of applications in audio signal processing, ranging from audio information retrieval, to speech and speaker recognition, and music analysis (Eronen, 2003). Such features are derived from the mel-frequency cepstrum representation of an audio fragment (Stevens et al., 1937). In MFCC, frequency bands are spaced along the mel scale, which has the advantage that it approximates human auditory perception more closely than e.g. linearly-spaced frequency bands. Hence, MFCC takes human perceptual sensitivity to audio frequencies into consideration, which makes it suitable for e.g. compression and recognition tasks, but also for our current objective of modelling auditory perception. We obtain MFCC descriptors for frames of audio files using librosa, a popular library for audio and music analysis written in Python.[6] After having obtained the descriptors, we cluster them using mini-batch k-means (Sculley, 2010) and quantize the descriptors into a "bag of audio words" (BoAW) (Foote, 1997) representation by comparing the MFCC descriptors to the cluster centroids. This gives us BoAW representations for each of the audio files. Auditory representations are obtained by taking the mean of the BoAW representations of the relevant audio files, and finally weighting them using positive point-wise mutual information (PPMI), a standard weighting scheme for improving vector representation quality (Bullinaria and Levy, 2007). We set $k = 300$, which equals the number of dimensions for the linguistic representations.

4.3 Multi-modal Fusion Strategies

Since multi-modal semantics relies on two or more modalities, there are several ways of combining or *fusing* linguistic and perceptual cues (Bruni et al., 2014). When computing similarity scores, for instance, we can either jointly learn the representations; learn them independently, combine (e.g. concatenate) them and compute similarity scores; or learn them independently, compute similarity scores independently and combine the scores. We call these possibilities *early*, *middle* and *late* fusion, respectively, and evaluate multi-modal models in each category.

[6] http://bmcfee.github.io/librosa.

4.3.1 Early Fusion

A good example of early fusion is the recently introduced multi-modal skip-gram model (Lazaridou et al., 2015). This model behaves like a normal skip-gram, but instead of only having a training objective for the linguistic representation, it includes an additional training objective for the visual context, which consists of an aggregated representation of images associated with the given target word. The skip-gram training objective for a sequence of training words $w_1, w_2, ..., w_T$ and a context size c is:

$$\frac{1}{T}\sum_{t=1}^{T} J_\theta(w_t)$$

where J_θ is the log-likelihood $\sum_{-c\leq j\leq c} \log p(w_{t+j}|w_t)$ and $p(w_{t+j}|w_t)$ is obtained via the softmax:

$$p(w_{t+j}|w_t) = \frac{\exp^{u_{w_{t+j}}^\top v_{w_t}}}{\sum_{w'=1}^{W} \exp^{u_{w'}^\top v_{w_t}}}$$

where u_w and v_w are the context and target vector representations for the word w respectively, and W is the vocabulary size. The objective for the multi-modal skip-gram has an additional visual objective J_{vis} (in this case a margin criterion):

$$\frac{1}{T}\sum_{t=1}^{T} J_\theta(w_t) + J_{vis}(w_t)$$

Here, we take a similar but more straightforward approach by making the auditory context a part of the initial training objective, which is possible because linguistic and auditory representations have the same dimensionality. That is, we modified word2vec to predict additional auditory contexts that have been set to the corresponding BoAW representation. We jointly learn linguistic and audio representations by taking the aggregated mean μ_w^a of the auditory vectors for a given word w, and adding this mean vector to the context:

$$\frac{1}{T}\sum_{t=1}^{T} J_\theta(w_t) + \log p(\mu_{w_t}^a|w_t)$$

The intuition is that the induced vector for the target word now has to predict an auditory vector as part of its context, as well as the linguistic ones. As an alternative, we also investigate re-

placing the mean $\mu^a_{w_t}$ with an auditory vector obtained by uniformly sampling from the set of auditory representations for the target word. We refer to these two alternatives as MMSG-MEAN and MMSG-SAMPLED, respectively. For this model, auditory BoAW representations are built for the ten thousand most frequent words in our corpus, based on 10 audio files retrieved from FreeSound for each word (or fewer when 10 are not available).

4.3.2 Middle and Late Fusion

Whereas early fusion requires a joint training objective that takes into account both modalities, middle fusion allows for individual training objectives and independent training data. Similarity between two multi-modal representations is calculated as follows:

$$sim(u, v) = g(f(u^l, u^a), f(v^l, v^a))$$

where g is some similarity function, u^l and v^l are linguistic representations, and u^a and v^a are the auditory representations. A typical formulation in multi-modal semantics for $f(x, y)$ is $\alpha\, x \| (1-\alpha) y$, where $\|$ is concatenation (see e.g. Bruni et al. (2014) and Kiela and Bottou (2014)).

Late fusion can be seen as the converse of middle fusion, in that the similarity function is computed first before the similarity scores are combined:

$$sim(u, v) = h(g(u^l, v^l), g(u^a, v^a))$$

where g is some similarity function and h is a way of combining similarities, in our case a weighted average: $h(x, y) = \frac{1}{2}(\alpha\, x + (1-\alpha) y)$; and we use $g = \frac{x \cdot y}{|x||y|}$ (cosine similarity). Since cosine similarity is the normalized dot-product, and the uni-modal representations are themselves normalized, middle and late fusion are equivalent if $\alpha = 0.5$, which we call MM. However, when $\alpha \neq 0.5$, we distinguish between the two models, calling them MM-MIDDLE and MM-LATE respectively.

5 Results

5.1 Conceptual Similarity and Relatedness

We evaluate performance by calculating the Spearman ρ_s correlation between the ranking of the concept pairs produced by the automatic similarity metric (cosine between the derived vectors) and that produced by the gold-standard similarity scores. To ensure a fair comparison, we evaluate on the common subsets for which there are representations in both modalities (see Table 2).

Modality	MEN	AMEN	SLex	ASLex
Linguistic	0.687	0.603	0.320	0.314
Auditory	0.325	0.510	0.161	0.201
MMSG-MEAN	0.612	0.537	0.274	0.266
MMSG-SAMPLED	**0.690**	0.602	**0.321**	0.314
MM	0.680	**0.662**	0.314	**0.345**

Table 3: Spearman ρ_s correlation comparison of uni-modal and multi-modal representations. The MMSG models perform early fusion, MM represents middle and late fusion with $\alpha = 0.5$ (see Section 4.3.2).

The results are reported in Table 3. We find that, while performance decreases for linguistic representations on the auditory-relevant subsets of the two datasets, performance increases for the uni-modal auditory representations on those subsets. This indicates that our auditory representations are better at judging auditory-relevant comparisons than they are at non-auditory ones, as we might expect.

For all datasets, the accuracy scores for multi-modal models are at least as high as those for the purely linguistic representations. In the case of the full datasets this difference is only marginal, which is to be expected given how few of the words in the datasets are auditory-relevant. However, the results indicate that adding auditory input even for words that are not directly auditory-relevant is not detrimental to overall performance.

In the case of the auditory-relevant subsets, we see a large increase in performance when using multi-modal representations. It is also interesting that this performance increase is found in the simple MM model, compared to the more complicated MMSG models, which seems to indicate that the latter models are still too reliant on linguistic information, which harms their performance when performing auditory-specific comparisons. The model which performs consistently well across the four datasets is MM, the middle-late fusion model with $\alpha = 0.5$.

5.2 Cross-modal Zero-shot Learning

We learn a cross-modal mapping between the linguistic and auditory spaces using partial least squares regression, taking out each concept, training on the others, and then projecting from one

Mapping	P@1	P@5	P@20	P@50
Chance	0.00	0.93	4.01	8.49
Auditory ⇒ Ling.	0.77	6.48	17.54	31.33
Ling. ⇒ Auditory	0.73	6.71	22.16	37.32

Table 4: Cross-modal zero-shot learning accuracy.

space into the other. Zero-shot performance is evaluated using the average percentage correct at N (P@N), which measures how many of the test instances were ranked within the top N highest ranked nearest neighbors. Results are shown in Table 4, with the chance baseline obtained by randomly ranking a concept's nearest neighbors. Insofar as it is possible to make a direct comparison with linguistic-visual zero-shot learning (which uses entirely different data), it appears that the current task may be more difficult: Lazaridou et al. (2014) report a P@1 of 2.4 and P@20 of 33.0 for their linguistic-visual model.

5.3 Qualitative Analysis

We also performed a small qualitative analysis of the BoAW representations for the words in MEN and SLex. As Table 5 shows, the nearest neighbors are remarkably semantically coherent. For example, the model groups together sounds produced by machines, or by water. It even finds that dinner, meal, lunch and breakfast are closely related. In contrast, nearest neighbors for the linguistic model tend to be of a more abstract nature: where we find *mouth* and *throat* as auditory neighbors for *language*, the linguistic model gives us concepts like *word* and *dictionary*; while auditory *gossip* sounds like *maids* and is something you might do in the *corridor*, it is linguistically associated with more abstract concepts like *news* and *newspaper*.

6 Parameter Tuning

There are many parameters that were left fixed in the main results that could have been adjusted to improve performance, particularly in the middle and late fusion models. It is useful to investigate some of the parameters that are likely to have an impact on performance: what the effect of the α mixing parameter is, whether a different k would have yielded better auditory representations, and whether the number and duration of the audio files from FreeSound has any effect.

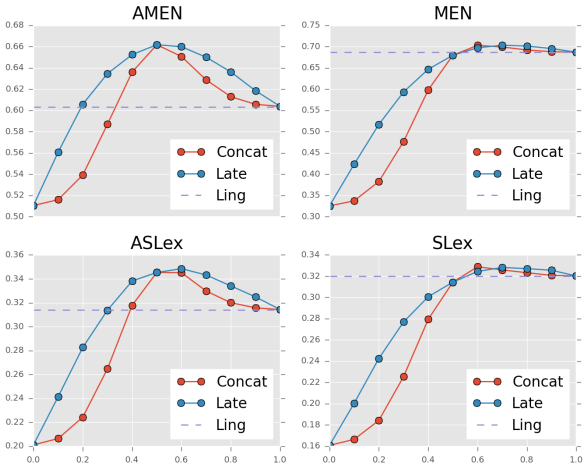

Figure 1: Performance of middle and late multimodal fusion models compared to linguistic representations on the four datasets when varying the α mixing parameter on the x-axis.

6.1 Mixing with α

The mixing parameter α plays an important role in the middle and late fusion models. We kept it fixed at 0.5 for the MM model above, but here we experiment with varying the parameter, yielding results for two different models, MM-MIDDLE and MM-LATE. The results are shown in Figure 1, where moving to the right on the x-axis uses more linguistic input and moving to the left uses more auditory input. The late model consistently outperforms the middle fusion model, which is probably because it is less susceptible to any noise in the auditory representation. Optimal performance seems to be around $\alpha = 0.6$ for both fusion strategies on all four datasets, indicating that it is better to include a little more linguistic than auditory input. It appears that any $0.5 \leq \alpha < 1$ (i.e., where we have more linguistic input but still some auditory signal), outperforms the purely linguistic representation, substantially in the case of the auditory-relevant subsets.

6.2 Number of Auditory Dimensions

We experimented with different values for the number of audio words k (i.e. the number of clusters in the k-means clustering that determines the number of "audio words"). As Figure 2 shows, the quality of the uni-modal auditory representations is highly robust to the number of dimensions. In fact, any choice of k in the range shown provides similar results across the datasets.

Auditory				Linguistic			
navy	language	gossip	dinner	navy	language	gossip	dinner
army	mouth	maid	meal	army	word	news	lunch
aviation	man	guest	lunch	military	words	newspaper	wedding
plane	father	elevator	writer	vessel	literature	cute	meal

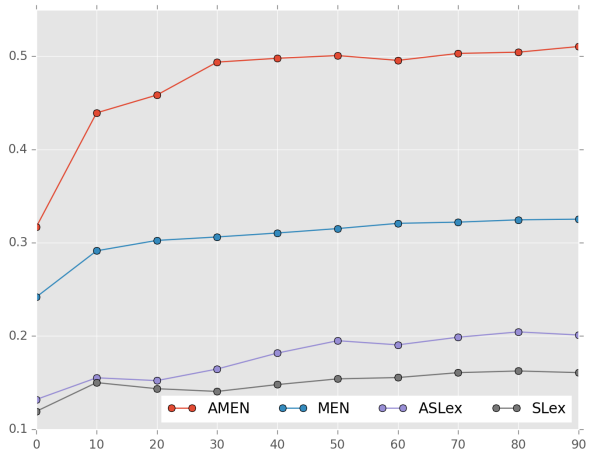

Figure 3: Performance of uni-modal auditory representations on the four datasets when varying the number of audio files per target word.

6.3 Number and Duration of Audio Files

We experimented with the number of audio files by querying FreeSound for up to 100 audio files per search word, while keeping $k = 300$. The results are shown in Figure 3. It appears that "the more the better", although performance does not increase significantly after around 40 audio files.

In order to examine the effect of audio file duration, we experimented with specifying the duration of audio files when querying the database, either taking very short (up to 5 seconds), medium length (up to 1 minute) or files of any duration. The results can be found in Figure 4, showing that performance generally increases as the files get longer (except on AMEN where a duration of 1 minute provides optimal performance).

7 Case Study: Musical Instruments

To strengthen the finding that multi-modal representations perform well on the auditory-relevant subsets of the datasets, we evaluate on an altogether different task, namely that of musical instrument classification. We used Wikipedia to collect a total of 52 instruments and divided them into 5 classes: brass, percussion, piano-based, string and woodwind instruments. For each of the instruments, we collected as many audio files from FreeSound as possible, and used the MM-MIDDLE model with parameter settings that yielded good results in the previous experiments ($k = 300$ and $\alpha = 0.6$). We then performed k-means clustering with five cluster centroids and compared results between auditory, linguistic and multi-modal, evaluating the clustering quality using the standard V-measure clustering evaluation metric (Rosenberg and Hirschberg, 2007).

This is an interesting problem because instrument classes are determined somewhat by conven-

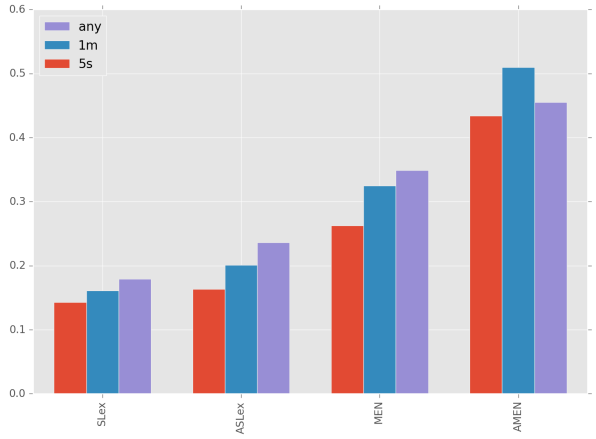

Figure 4: Performance of uni-modal auditory representations on the four datasets when varying the maximum duration.

Model	Auditory	Linguistic	MM-MIDDLE
V-measure	0.39	0.47	0.54

	Linguistic
1	baritone
2	lute, zither, xylophone, lyre, cymbals
3	piano, trombone, clarinet, cello, violin
4	castanets, tambourine, claves, maracas
5	trumpet, horn, bugle, cowbell, carillon

	Multi-modal
1	drum, claves, bongo, bass, conga
2	xylophone, glockenspiel, tambourine, cymbals
3	cello, piano, clarinet, trombone, violin,
4	chimes, bell
5	mandolin, banjo, harmonica, guitar, sitar

Table 6: V-measure performance for clustering musical instruments, together with instruments closest to cluster centroid for linguistic and multi-modal.

tion (is a saxophone a brass or a woodwind instrument?). What is more, how instruments actually sound is rarely described in detail in text, so corpus-based linguistic representations cannot take this information into account. The results are in Table 6, clearly showing that the multi-modal representation which utilizes both linguistic information and auditory input performs much better on this task than the uni-modal representations. It is interesting to observe that the linguistic representations perform better than the auditory ones: a possible explanation for this is that audio files in FreeSound are rarely samples of a single individual instrument, so if a bass is often accompanied by a drum this will affect the overall representation. The table also shows, for the 5 clusters under both models, the nearest instruments to the cluster centroids, qualitatively demonstrating the greater cluster coherence for the multi-modal model.

8 Conclusions

We have studied grounding semantic representations in raw auditory perceptual information, using a bag of audio words model to obtain auditory representations, and combining them into multi-modal representations using a variety of fusion strategies. Following previous work in multi-modal semantics, we evaluated on conceptual similarity and relatedness datasets, and on the cross-modal task of zero-shot learning. We presented a short case study showing that multi-modal representations perform much better than auditory or linguistic representations on a musical instrument clustering task. It may well be the case that the auditory modality is better suited for other evaluations, but we have chosen to follow standard evaluations in multi-modal semantics to allow for a direct comparison.

In future work, it would be interesting to investigate different sampling strategies for the early fusion joint-learning approach and to investigate more sophisticated mixing strategies for the middle and late fusion models, e.g. using the "audio dispersion" of a word to determine how much auditory input should be included in the multi-modal representation (Kiela et al., 2014). Another interesting possibility is to improve auditory representations by training a neural network classifier on the audio files and subsequently transferring the hidden representations to tasks in semantics. Lastly, now that the perceptual modalities of vision, audio and even olfaction (Kiela et al., 2015) have been investigated in the context of distributional semantics, the logical next step for future work is to explore different fusion strategies for multi-modal models that combine various sources of perceptual input into a single grounded model.

Automatic recognition of habituals: a three-way classification of clausal aspect

Annemarie Friedrich **Manfred Pinkal**
Department of Computational Linguistics
Saarland University, Saarbrücken, Germany
{afried,pinkal}@coli.uni-saarland.de

Abstract

This paper provides the first fully automatic approach for classifying clauses with respect to their aspectual properties as habitual, episodic or static. We bring together two strands of previous work, which address only the related tasks of the episodic-habitual and stative-dynamic distinctions, respectively. Our method combines different sources of information found to be useful for these tasks. We are the first to exhaustively classify *all* clauses of a text, achieving up to 80% accuracy (baseline 58%) for the three-way classification task, and up to 85% accuracy for related subtasks (baselines 50% and 60%), outperforming previous work. In addition, we provide a new large corpus of Wikipedia texts labeled according to our linguistically motivated guidelines.

1 Introduction

In order to understand the function of a clause within a discourse, we need to know the clause's aspectual properties. The distinction between *dynamic* and *stative* lexical aspect, as in examples (1a) and (1b) respectively, is fundamental (Vendler, 1957). Its automatic prediction has been addressed previously (Siegel and McKeown, 2000; Zarcone and Lenci, 2008; Friedrich and Palmer, 2014).

(1) (a) Bill drank a coffee after lunch. (**dynamic**)
(b) Bill likes coffee. (**stative**)

In this work, we focus on *habituality* as another fundamental aspectual property. While example (1a) is an *episodic* sentence, i.e., a sentence expressing information about a particular event, the same dynamic verb can be used to characterize the default behavior of an individual or of a kind in a certain type of situation (2).

(2) (a) Bill usually drinks coffee after lunch. (**habitual**)
(b) Italians drink coffee after lunch. (**habitual**)

The entailment properties of episodic and habitual (or *characterizing*) sentences differ substantially. Also, they have different functions in discourse. The episodic event expressed by (1a) is typically embedded in the temporal structure of a narration. The habitual sentence (2a) can be used, e.g., as an explanation (why Bill is still sitting at the table), or in a contrastive context (today, he ordered a grappa instead). *Generic* sentences with *kind-referring* subjects (2b) can also be habitual, generalizing at the same time over typical members of this kind and over situations in which they typically carry out some action.

Habitual sentences do not move narrative time, similar to stative clauses such as (1b). Carlson (2005) considers habituals to be aspectually stative. Since there are clear differences between ordinary statives such as (1b) and habituals, we apply a three-way distinction for *clausal aspect* in this work. We classify clauses as one of the three categories **habitual**, **episodic** and **static**.[1]

Through its impact on entailment properties and temporal discourse structure, the determination of clausal aspect is relevant to various natural language processing applications requiring text understanding, such as novelty detection (Soboroff and Harman, 2005), knowledge extraction from text (Van Durme, 2010) or question answering (Llorens et al., 2015). Using aspectual information has been shown to improve temporal relation identification (Costa and Branco, 2012).

Some languages (e.g., Czech or Swahili) have systematic morphological markers of habituality

[1]For clarity, we use the label *static* for the clausal aspect of non-episodic and non-habitual sentences. We reserve *stative*, which is more common in the literature, for the lexical aspectual class.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2471–2481,
Lisbon, Portugal, 17-21 September 2015.

(Dahl, 1985). In other languages, there are cues for habituality, such as the simple present in English, and the use of certain adverbials (Dahl, 1995). The automatic recognition of habitual sentences for the latter languages is non-trivial. The work in this paper targets the English language; we leave recognition of habituality in other languages to future work.

The only previous work on categorizing sentences as episodic or habitual we know of is by Mathew and Katz (2009). They do not attempt to categorize arbitrary sentences in 'free text', however, but work with a corpus of selected sentences and use gold standard parse information for their experiments. In particular, they consider clauses containing lexically dynamic verbs only.

In this work, we address the task of an exhaustive classification of all clauses of a text into the three aspectual classes **habitual**, **episodic**, and **static**. Static sentences include lexically stative clauses as well as negated or modalized clauses containing a dynamic main verb. A computational model for identifying episodic and habitual clauses clearly needs to address this third class as well if it is to be applied in a realistic setting. Linguistically, the determination of clausal aspect depends on the recognition of the verb's lexical aspectual class (stative or dynamic), and on the recognition of any aspectual markers or transformations, such as use of the perfect tense, negations or modals. Our work builds on results for the related subtasks (Mathew and Katz, 2009; Siegel and McKeown, 2000; Friedrich and Palmer, 2014), using both context-based and verb-type based information.

Our major contributions are: (i) We create a corpus of 102 Wikipedia texts whose about 10,000 clauses are annotated as episodic, static or habitual with substantial agreement. This corpus allows for studying the range of linguistic phenomena related to the clause types as defined above (compared to previous work which uses only a small set of verbs and sentences), and provides a basis for future research. (ii) We provide the first fully automatic approach for this classification task, combining two classification tasks (lexical aspectual class and habituality) that have been treated separately in previous work. For an exhaustive classification of clauses of free text, these two classification tasks need to be addressed jointly. We show two different feature sets (verb-type based features and context-based features) to have different impact on the two subtasks, and to be complementary for our full three-way task.

We reach accuracies of nearly 85% for the two subtasks of identifying static clauses and distinguishing episodic and habitual clauses (majority class baselines are 60% and 50% respectively). A joint model for the three-way classification task reaches an accuracy of 80% (baseline 60%). In addition, we show that the verb-type based linguistic indicator features generalize well across verb types on our tasks: for verbs unseen in the training data, accuracies drop only by 2-5%.

2 Theoretical background and annotation guidelines

In this section, we give an overview of the semantic theory related to habituals, at the same time introducing our annotation guidelines for marking clauses as **habitual**, **episodic** or **static**.

2.1 Habituality

Habitual sentences express regularities in terms of generalizations over events and activities. In semantic theory, habituals are formally represented using a quantifier-like operator GEN (Krifka et al., 1995):

(3) GEN[s](s **is an after-dinner situation** & Bill **is involved in** s; Bill **drinks a coffee in** s)

In the semi-formal representation (3) of sentence (2a) above, GEN binds a variable s ranging over situations, the first argument restricts the situation type, and the second argument provides the activity that is typically carried out by the protagonist in the respective situations. The GEN operator is similar to the universal quantifier of predicate logic. However, habitual sentences tolerate exceptions: (2a) is true even if Bill does not drink a coffee after every lunch. Also note that habituals are not restricted to what one would consider a matter of habit; they can also have inanimate subjects, as illustrated by (4).

(4) Glass breaks easily. (**habitual**)

2.2 Clausal and lexical aspectual class

Clausal aspect is dependent on the lexical aspectual class (stative or dynamic), but the two levels are essentially different. Dynamic verbs express events or activities (e.g., *kill, fix, walk, forget*), while stative verbs express states (e.g., *be,*

like, know, own). The *fundamental aspectual class* (Siegel and McKeown, 2000) of a verb in context describes whether it is used in a stative or dynamic sense before any aspectual markers or transformations (such as use of the past/present perfect or modals) have been applied. It is a function of the main verb and a select group of complements (it may differ per verb which ones are important). For example, the fundamental lexical aspectual class of the verb *make* with the subject *Mary* and the object *cake* in (5) is dynamic. English clauses in past or present perfect such as (5) are static, as they focus on the post-state of an event rather than the event itself (Katz, 2003).

(5) Mary has made a cake. (**static**)

Habituals with verbs of dynamic aspectual class are by far more frequent in our corpus,[2] but there are also instances of stative verbs used in a habitual way, as for example (6).

(6) Sloths sometimes sit on top of branches. (**habitual**, *stative* lexical aspectual class)

2.3 Modality and negation

Modalized (7) and negated sentences (8) tend to be static: they do not express information about a particular event, but refer to actual or possible states of the world.

(7) Mary can swim. (**static**)

(8) Mary didn't go swimming yesterday. (**static**)

The above definitions of habituality and stativity are generally agreed upon in literature. However, the interaction of these phenomena is by no means trivial (Hacquard, 2009), and required making some decisions during the design of our annotation guidelines. Here, we explain these decisions, which are all motivated by a clause's entailment properties.

One difficult issue is how to interpret and mark negated sentences such as (9a) whose positive version (9b) is habitual.

(9) (a) John does not smoke. (**habitual**)
(b) John smokes. (**habitual**)

[2]The distribution of lexical aspectual class of verbs is generally skewed towards dynamic (Friedrich and Palmer, 2014).

Sentence (9a) can be considered either **static** because of the negation (*It is not the case that John smokes*), or as **habitual** because it characterizes John's behavior (*In any relevant situation, John does not smoke*). Both decisions are possible (Garrett, 1998), we decide for the latter possibility. This decision is supported by the observation that (9a) is similar in its entailment properties to (10), which due to the frequency adverbial *never* clearly generalizes over relevant situations (though note that this is not a linguistic test).

(10) John never smokes. (**habitual**)

Likewise, we mark modalized sentences as habitual if they have a strong implicature that an event has actually happened regularly (Hacquard, 2009), as in (11). In contrast, (7) is static as it does not imply that Mary actually swims regularly.

(11) I had to eat an apple every day. (**habitual**)

The above example shows that modality and habituality are interweaved and sometimes hard to identify. Nevertheless, we reach substantial agreement in the annotation of our corpus (see Section 4.2).

Finally, some habituals have a *dispositional* reading, indicating ability/capability (Menéndez-Benito, 2012). Example (12) can be paraphrased by (13), as it does not indicate that the car is actually driven this fast regularly, it only states its maximum speed.

(12) This car goes 200 kph.

(13) This car can go 200 kph.

3 Related work

The task of predicting *fundamental aspectual class* aims to determine whether the verb is used in a stative or dynamic sense. This task predicts the aspectual class of a verb in context before any aspectual markers or transformations (such as use of the perfect or modals) have been applied. Siegel and McKeown (2000) propose the use of linguistic indicators (explained in Section 5.2); Friedrich and Palmer (2014) show the importance of using context-based features in addition. Zarcone and Lenci (2008) classify occurrences of 28 Italian verbs according to Vendlers classes state, process, accomplishment and achievement.

Mathew and Katz (2009) address the problem of 'supervised categorization for habitual versus

episodic sentences' . The authors randomly select 1052 sentences for 57 verbs from the Penn TreeBank (Marcus et al., 1993) and manually mark them with regard to whether they are **habitual** or **episodic**. They focus on verbs that are lexically dynamic and discuss a variety of syntactic features, which they extract from gold standard parse trees. Their aim is to study the ability of syntactic features alone to identify habitual sentences.

Xue and Zhang (2014) annotate verbs with the four event types *habitual event*, *state*, *on-going event* and *episodic event* with the aim of improving tense prediction for Chinese. Recent related work (Williams, 2012; Williams and Katz, 2012) extracts typical durations (in term of actual time measures) for verb lemmas from Twitter. They distinguish episodic and habitual uses of the verbs, using the method of Mathew and Katz (2009).

4 Data

In this section, we describe the data sets used in our experiments.[3]

4.1 Penn TreeBank (M&K) data set

Mathew and Katz (2009) randomly select sentences for several verbs from the WSJ and Brown corpus sections of the Penn Treebank. They require the verb to be lexically dynamic. Sentences are marked as **habitual** or **episodic**, further details on the annotation guidelines are not specified. Their data set contains 2743 annotated sentences for 239 distinct verb types. Mathew and Katz remove verb types with highly skewed distributions of labels, but their filtered data set is not available. We follow their filtering approach, but we could not replicate their filtering step. Our final data set contains 1230 sentences for 54 distinct verb types. Mathew and Katz (2009) state that their data set comprises 1052 examples for 57 verb stems. We aimed at producing a similar distribution of labels: our data set contains 73.3% episodic cases, M&K's version has 73.1%.

4.2 Wikipedia corpus

We select 102 texts from a variety of domains from Wikipedia, as we expect an encyclopedia to contain many habitual sentences. We use the discourse parser SPADE (Soricut and Marcu, 2003) to automatically segment the first 70 sentences of each article into clauses. A clause is approximately defined as a finite verb phrase. Each clause is then labeled as **static**, **episodic** or **habitual**. Details on our annotation scheme have been given in Section 2. Annotators are allowed to skip non-finite clauses (e.g., headlines only containing a noun phrase). This happened in about 14% of all pre-segmented clauses. The final Wikipedia data consists of 10355 labeled clauses. Table 1 gives statistics for the distribution of labels.

Label	#	%
static	6184	59.7
episodic	2114	20.4
habitual	2057	19.9
total	10355	-

Table 1: Wikipedia data, distribution of labels for clausal aspect.

The data set was labeled by three paid annotators, all students of computational linguistics. Annotators were given a written manual and a short training on documents not included in the corpus. Agreement on the Wikipedia data is 0.61 in terms of Fleiss' κ, which indicates substantial agreement (Landis and Koch, 1977). The gold standard that we use in our experiments is constructed via majority voting. The gold standard contains the cases where at least two annotators agreed on the label. We found only 86 cases where all annotators disagree, and manual inspection shows that most of these cases are related to disagreements on the lexical aspectual class that coincide with an attention slip by one of the annotators.

5 Method

In this section, we describe our computational models for determining clausal aspect.

5.1 CONTEXT-BASED features

Table 2 shows the syntactic-semantic features, which we call CONTEXT-BASED as they are extracted from the context of each verb occurrence that we classify. This feature set comprises the features proposed by Mathew and Katz (2009) and the ones proposed by Friedrich and Palmer (2014). In addition, we use the features *modal* and *negated*. We extract these features from syntactic dependency parses created using the Stanford parser (Klein and Manning, 2002). Tense and voice are extracted following the rules pro-

[3] All data sets are freely available from `www.coli.uni-saarland.de/projects/sitent`. We thank Thomas A. Mathew and Graham Katz for allowing us to publish their data set.

Feature		Values
verb	tense*† pos† voice†	past, present, infinitive VB, VBG, VBN, ... active, passive
aspect	progressive*† perfect*†	true, false true, false
subject	bare plural* definite* indefinite*	true, false true, false true, false
object	absent* bare plural* definite* indefinite*	true, false true, false true, false true, false
grammatical dependents†		WordNet lexname/POS
sentence	modal	*would, can,...*
	negated	true, false
	conditionals*	presence of clause starting with if/when/ whenever
	temporal modifiers*	specific, quantificational, including *used to* and *would* (where no if)
	prepositions*	at / in / on (3 features, true/false)

Table 2: CONTEXT-BASED features. Used by: *Mathew and Katz (2009), †Friedrich and Palmer (2014).

vided by Loaiciga et al. (2014). The values of the grammatical dependents' features are the WordNet (Miller, 1995) lexical filename of the dependent's lemma, or, if not available, the dependent's part-of-speech tag. Quantificational adverbs are temporal modifiers such as *always*, *occasionally* or *weekly*.[4] Specific temporal adverbs are, according to a heuristic proposed by Mathew (2009), phrase children marked with the part-of-speech tag TMP and whose child is a prepositional phrase. Noun phrases with one of the determiners *the, this, that, these, those, each, every, all*, as well as possessives, pronouns, proper names and quantified phrases are definite. NPs with determiners *a, an, many, most, some*, and cases of modifying adjectives without determiners (e.g., *few*) or cardinal numbers (part-of-speech tag CD) are indefinite. Mathew (2009) describes their features in detail.

5.2 TYPE-BASED features

This feature set consists of the verb-type based linguistic indicator features of Siegel and McKeown (2000). The computation of these features is based on a large parsed, but otherwise unannotated background corpus. For each verb type (i.e., lemma), these features count how often the verb occurs with each of the linguistic indicators as listed in Table 3. Except for the frequency feature, these values are normalized by the number of occurrences of the verb type. For example, if the verb type *win* occurs 1000 times in the parsed background corpus, of which 100 times with perfect aspect, the value of the linguistic indicator feature `perfect` is 0.1 for the verb type *win*. For any instance whose verb's lemma is *win*, 0.1 will be the value of the feature `perfect`, in other words, all instances of the same verb type receive the same TYPE-BASED feature values. Linguistic indicator features have recently been applied successfully on the related task of classifying the lexical aspectual class of verbs by Friedrich and Palmer (2014), who extract the linguistic indicators from an automatically parsed version of the AFE and XIE parts of Gigaword. We use their database of linguistic indicator values.[5]

Feature	Example
frequency	-
present	*says*
past	*said*
future	*will say*
perfect	*had won*
progressive	*is winning*
negated	*not/never*
particle	*up/in/...*
no subject	-

Feature	Example
continuous adverb	*continually endlessly*
evaluation adverb	*better horribly*
manner adverb	*furiously patiently*
temporal adverb	*again finally*

for-PP	*for an hour*

Table 3: TYPE-BASED feature set (**linguistic indicators**) and examples for lexical items associated with each indicator, following Siegel and McKeown (2000).

5.3 Algorithm

In order to investigate in which circumstances the task of predicting a clause's label (**habitual**, **episodic** or **static**) can be addressed jointly, or whether a pipelined approach is better, we apply the following methods. Our JOINT model learns the decision boundaries for the three classes jointly, i.e., as a three-way classification task. In addition, we present a CASCADED model, which uses two models learned for the two different subtasks: (a) identifying static clauses and (b) distinguishing episodic and habitual clauses.

First, we train a model to distinguish the **static** class from the other two. In this learning step, we simply map all the clauses labeled as **episodic** and

[4] The complete list of quantificational adverbs used is given by Mathew (2009), page 36.

[5] `www.coli.uni-saarland.de/projects/sitent`

habitual to the class **non-static** and learn the decision boundary between the two classes **static** and **non-static**. Second, we train a model to distinguish the **episodic** from the **habitual** class. This model is trained on the subset of examples labeled with either of these two classes.

In the CASCADED model, first, the **static** vs. **non-static** model is applied. The CASCADED model labels all instances automatically labeled as **static** in this first step, and then applies the second model (**episodic** vs. **habitual**) on all remaining instances.

We train Random Forest classifiers (Breiman, 2001) using Weka (Hall et al., 2009) for each step and also for the JOINT model. Besides providing a robust performance, Random Forest classifiers can easily deal with both categorical and numeric features. This is relevant as our CONTEXT-BASED features are categorical while the TYPE-BASED features are numeric. In our experiments, we will compare the impact of the different feature sets on each subtask and on the JOINT model.

5.4 Baseline: Mathew and Katz (2009)

As a baseline, we also report results for the subset of our CONTEXT-BASED features used by Mathew and Katz (2009) and call this subset MK. Mathew and Katz (2009) find a J48 decision tree and a Naive Bayes classifier to work best. We replicate their results for the decision tree in Section 6.2.

6 Experiments and discussion

This section describes our experiments. First, we reproduce the experiments of Mathew and Katz (2009), who use manually created syntactic parses, in a purely automatic setting.

The data set and experiments of Mathew and Katz (2009) focus on the episodic-habitual distinction using a set of sentences selected for a small set of verbs, and their feature design focuses on syntactic properties of the clauses found in this annotated data set. In the further experiments, we turn to the Wikipedia data, which contains annotations for full texts. We expect the Wikipedia data to cover the range of habitual and episodic expressions more fully, and in addition, allows for studying the task of separating static sentences from the other two classes. As we will show, this latter task profits from including features relevant to the stative-dynamic distinction on the lexical level.

We first present experimental results for the two subtasks (described in Section 5.3). Our CASCADED model first identifies static clauses, and then classifies the remaining clauses as episodic or habitual. For reasons of readability, we first report on our experiments for the episodic-habitual distinction using both the M&K and Wikipedia data sets. Using the Wikipedia data, we then report on the results for the static vs. non-static distinction. Finally, we turn to the full task of the three-ways distinction.

6.1 Experimental setting

We report results for 10-fold cross validation (CV) with two different settings: In the RANDOM CV setting, we randomly distribute the instances over the folds, putting all instances of one document into the same fold. In the UNSEEN VERBS CV setting, we simulate the case of not having labeled training data for a particular verb type by putting all instances of one verb type into the same fold.

We compute the information retrieval statistics of precision (P), recall (R) and F1-measure per class, where F1 is the harmonic mean of P and R, $F1 = \frac{2*P*R}{P+R}$. Macro-average P is computed as the (unweighted) average of the P scores of the classes, and macro-average R is computed likewise. Macro-average F1 is the harmonic mean of macro-average P and macro-average R. We use McNemar's test with $p < 0.01$ to compute statistical signficance of differences in accuracies. In our tables, we indicate that two results differ significantly by marking them with the same symbols (we only show this when scores are close).

6.2 M&K data: episodic vs. habitual

We use Weka's 10-fold stratified cross validation and a J48 decision tree in the experiments reported in this section in order to replicate their experimental setting. Results are shown in Table 4. For the sake of completeness, we also show the results as presented in the original paper. F1-scores are computed from P and R as reported in the original paper. Note that their experiments are performed on a different subset of the data and so these numbers are not directly comparable to ours, but our subset has a very similar class distribution (see Section 4.1). Our accuracies based on automatic parses rather than gold standard parses are about 3% lower when using the original feature set (MK). We conclude that our results are in the expected range. Also, we do not find any significant improvements on this data set when using any

other feature sets or combinations thereof (the table shows the results for our CONTEXT-based feature set); the M&K feature set designed for this corpus captures its variation well.

We have used a J48 decision tree in this section for comparability with previous work. In all following sections, we present results using Random Forest classifiers as described in Section 5.3.

	F1-score			Acc.
System	epis.	habit.	*macro*	
majority class*	84.5	0.0	42.2	73.1
MK*	91.1	70.5	80.8	86.1
MK	89.6	63.5	76.5	83.8
CONTEXT	90.0	64.7	77.3	84.4

Table 4: Results for **episodic** vs. **habitual**, J48 decision tree, data from Mathew and Katz (2009). *Numbers from original paper.

6.3 Wikipedia: episodic vs. habitual

We study the classification task of distinguishing **episodic** and **habitual** sentences using the subset of the Wikipedia data having one of these two labels (4171 instances). This task parallels the experiment of Mathew and Katz (2009) described above. We conduct two experiments, once using the RANDOM CV setting and once using the UNSEEN VERBS setting. Table 5 shows the results. The distribution of instances is nearly 50:50 in the gold standard (see Section 4, Table 1), and the majority classes in the respective training folds differ (this is the reason for the different baseline scores). For reasons of space we do not show the other scores here; macro-average F1-scores have (almost) the same values as accuracy, the F1-scores for episodic and habitual are similar to each other in each case.

Our findings are as follows: TYPE-BASED features outperform the majority class baseline,

Features	RANDOM CV	UNSEEN VERBS
majority class	42.1	46.3
lemma	65.4	46.3
TYPE	68.1	53.9
MK	82.3	‡81.4
CONTEXT	*†82.8	‡**83.8**
+ lemma	*84.3	
CONTEXT + TYPE	†**85.1**	83.1
+ lemma	84.0	

Table 5: **Wikipedia**: **Accuracy** of **episodic** vs **habitual**, 4171 instances, 10-fold cross validation, *†‡differences statistically significant.

	RANDOM CV		UNSEEN VERBS	
Features	**F1**	**Acc.**	**F1**	**Acc.**
majority class	37.4	59.7	37.4	59.7‡
MK	67.5	*69.5	59.2	62.7‡
CONTEXT	70.3	*71.7	62.8	64.9‡
+ lemma	81.9	†82.8		
TYPE	78.8	79.3	72.2	73.2‡
CONTEXT + TYPE	83.6	†84.1	**78.4**	**79.2**‡
+ lemma	**83.8**	**84.4**		

Table 6: **Wikipedia**: **static** vs **non-static**. All 10355 instances, 10-fold cross validation.*†‡ differences statistically significant.

which means that some verbs have a preference for being used as either episodic or habitual. The CONTEXT-BASED features work remarkably well. If training data of the same verb type is available, adding the TYPE-BASED features or the lemma to the CONTEXT-BASED features results in improvements; this is not the case in the UNSEEN VERBS setting. The latter setting shows that the additional contextual features (compared to the MK subset) are important: our corpus indeed covers a broader range of phenomena than the M&K data set.

6.4 Wikipedia: static vs. non-static

We evaluate the task of classifying **static** versus **non-static** clauses using all 10355 instances of the Wikipedia data set. Any instance labeled **episodic** or **habitual** receives the label **non-static** both in training and testing. Results of this task are shown in Table 6. For this subtask, the CONTEXT-BASED features are less informative than the TYPE-BASED features. Again, using lemma information approximates the use of type-based information, but this is not an option in the UNSEEN VERBS setting. A combination of the CONTEXT-BASED and TYPE-BASED features achieves the best results. Friedrich and Palmer (2014) find that TYPE-BASED features generalize well across verb types when predicting the aspectual class of verbs in context, the same is true here. They achieve small improvements by adding context-based features. Predicting the lexical aspectual class of the clause's main verb is only part of our classification task, the **static** class includes not only lexically stative clauses but also clauses with lexically dynamic verbs that are stativized, e.g., modals, negation or perfect tense. Hence, as expected, in our task, adding the CONTEXT-BASED features results in a considerable performance improvement (5-7% absolute in accuracy).

	RANDOM CROSS VALIDATION					UNSEEN VERB TYPES EXPERIMENT				
	F1-score				Acc.	F1-score				Acc.
Features	stat.	epis.	habit.	*macro*		stat.	epis.	habit.	*macro*	
majority class baseline	74.8	0	0	24.9	59.7	74.8	0.0	0.0	24.9	‡59.7
JOINT: MK	76.6	65.4	26.1	57.5	*67.0	76.3	41.7	0.8	49.0	‡63.8
JOINT: CONTEXT	77.5	65.8	36.4	60.5	*68.4	74.7	57.1	12.0	51.7	⋆63.9
+ lemma	85.5	75.0	51.6	71.8	†78.0					
JOINT: TYPE	81.9	52.7	49.7	61.5	69.9	74.9	4.2	2.8	40.7	⋆60.0
JOINT: CONTEXT + TYPE	86.1	75.8	58.8	73.8	†79.0	81.2	69.5	31.3	63.6	**72.1
+ lemma	86.8	75.0	59.9	74.2	79.6					
CASCADED	**86.9**	**76.1**	**62.2**	**75.1**	**79.9**	**82.6**	**72.0**	**50.2**	**68.4**	****74.3**

Table 7: **Wikipedia**: **static** vs. **episodic** vs. **habitual**. 10355 instances, 10-fold cross validation. The CASCADED model uses the best models from Table 6 and Table 5. *† ‡ ⋆** differences statistically significant.

It is worth noting that even for verbs not seen in the training data, high accuracies and F1-scores of almost 80% can be reached.

6.5 Wikipedia: combined task

In this section, we describe our experiments for the three-way classification task of **static**, **episodic** and **habitual** clauses, as in a realistic classification setting, a clause may belong to either of these *three* classes. We investigate whether a pipelined CASCADED approach is better, or whether the JOINT model profits from learning the decision boundaries between all three classes jointly. The results for this task are presented in Table 7. Both the CONTEXT-BASED and the TYPE-BASED features when used alone improve over the majority class baseline by about 10% in accuracy in the RANDOM CV setting, and only by about 4% in the UNSEEN VERBS setting. In the latter setting, all feature sets when used alone are ineffective for identifying habituals. This indicates that the CONTEXT-BASED features only 'pick up' on some type-based information in the RANDOM CV case. The best models for this JOINT classification task use both the CONTEXT-BASED and the TYPE-BASED feature sets: F1-scores and accuracy increase remarkably. Again, in the RANDOM CV setting, using the lemma results in a large performance gain, though using the TYPE-BASED features is beneficial, and, in the UNSEEN VERBS setting, essential.

We apply the CASCADED model as described in Section 5.3, training and testing the models for the subtasks in each fold. In the RANDOM CV setting, the accuracy of the CASCADED approach is not significantly better than the one of the JOINT approach, though F1-scores for the less frequent **episodic** and **habitual** classes both increase. In the UNSEEN VERBS setting, however, the difference is remarkable: macro-average F1-score increases by almost 5% (absolute) and accuracy increases by 2.2%. Most notably, the F1-score for the habitual class increases from 0.31 to 0.50 (due to an increase in recall). To conclude, the CASCADED approach is favorable as it works more robustly both for verb types seen or unseen in the training data.

6.6 Feature ablation

In the above sections, we have compared the two major feature groups of CONTEXT-BASED and TYPE-BASED features. In addition, we ablate each single feature from the best results for each experiment. For all classification tasks, we found features reflecting tense and grammatical aspect to be most important, both for the CONTEXT-BASED and TYPE-BASED features. In general, we observe that no single feature has a big impact on the results, accuracy drops only by at most 1-2%. This shows that our feature set is quite robust and some of the features (e.g., part-of-speech tag of the verb and tense) reflect partially redundant information. However, using only the best features results in a significant performance drop by several percentage points in the various settings, which means that though single features may not have a large impact, overall, the models for this classification task profit from including many diverse features.

For the **episodic-habitual** distinction in the UNSEEN VERBS setting, the definiteness of the object was an important CONTEXT-BASED feature. In the **static vs. non-static** task, the subject also plays an important role, as well as the TYPE-BASED feature for *continuous adverbs*. In the UNSEEN VERBS setting, many TYPE-BASED features

are important, including those indicating how often the verb type occurs with *adverbs of manner*, *negation* and *in-PPs* in the background corpus. For the **combined** three-way task, we found the main verb's lemma and the direct object to have most impact. Of the TYPE-BASED features, the *for-PP*, *present* and *temporal adverbial* were most important. In the UNSEEN VERBS setting, many linguistic indicator features (among others *past*, *progressive*, *negation*) play a greater role, as well as information about the object, subject and tense.

7 Conclusion

In this paper, we have presented an approach for classifying the aspect of a clause as **habitual**, **episodic** or **static**. Clearly, when exhaustively classifying all clauses of a text, the **static** class cannot be ignored; we have shown that we can separate these instances from episodic and habitual instances, most of which are lexically dynamic, with high accuracy. Our model for distinguishing episodic and habitual sentences integrates a wide range of contextual information and outperforms previous work. Previous work has only addressed the classification of lexical aspectual class and the automatic distinction of episodic and habitual sentences. Our work is the first bringing together two strands of work relevant to classifying clausal aspect, and we have shown that sources of information relevant to these two underlying aspectual distinctions are relevant for our three-way classification task.

We have shown that for distinguishing static sentences from the other two, TYPE-BASED *and* CONTEXT-BASED information is needed; for distinguishing episodic and habitual clauses, CONTEXT-BASED features are most important. Our experimental results show that the three-way classification task is most effectively approached by combining both contextual and verb-type based information. Especially for verbs unseen in the training data, we found the CASCADED approach to work better. It is hard for the JOINT approach to identify habitual clauses; while in the CASCADED approach, performance for both steps is high and adds up.

We found the overall performance of this task to be about 80% accuracy, and 75% macro-average F1-score. These scores suggest that this method may be usable as a preprocessing step for further temporal processing.

8 Future work

Our models do not yet take discourse information into account. Consider example (14) by Mathew and Katz (2009): The second sentence is habitual, but the only indicator for this is sentence-external.

(14) John rarely ate fruit. He just ate oranges. (**habitual**)

In some preliminary experiments, we tried to leverage the discourse context of a clause for its classification by means of incorporating the gold standard label of the previous clause as a feature. This did not result in significant performance improvements. However, further experiments trying to incorporate discourse information are due, and, due to our new corpus of fully annotated texts, now possible.

Another related research direction is the classification of the different types of static clauses, e.g., the different senses of modality (Ruppenhofer and Rehbein, 2012). As mentioned before, a finer classification of the temporal structure of clauses is needed, among others identifying the lexical aspectual class as well as *viewpoint aspect* as *perfective* vs. *imperfective* (Smith, 1997).

Finally, the next steps in this line of research are to integrate the aspectual information attributed to clauses by our model into models of temporal discourse structure, which in turn are useful for information extraction and text understanding tasks in general. Costa and Branco (2012) are the first to show that aspectual information is relevant here; we hope to show in the future that temporal processing profits from integrating more fine-grained aspectual information.

Acknowledgments

We thank the anonymous reviewers, Alexis Palmer, Alessandra Zarcone and Andrea Horbach for their helpful comments related to this work, Graham Katz for providing us with their data set, and our annotators Christine Bocionek, Kleio-Isidora Mavridou and Melissa Peate Sørensen. Distributed Representations for Unsupervised Semantic Role Labeling

Abstract

We present a new approach for unsupervised semantic role labeling that leverages distributed representations. We induce embeddings to represent a predicate, its arguments and their complex interdependence. Argument embeddings are learned from surrounding contexts involving the predicate and neighboring arguments, while predicate embeddings are learned from argument contexts. The induced representations are clustered into roles using a linear programming formulation of hierarchical clustering, where we can model task-specific knowledge. Experiments show improved performance over previous unsupervised semantic role labeling approaches and other distributed word representation models.

1 Introduction

In recent years, an increasing body of work has been devoted to learning distributed word representations and their successful usage in numerous tasks and real-world applications. Examples include language modeling (Collobert et al., 2011; Mikolov et al., 2013c; Mnih and Kavukcuoglu, 2013), paraphrase detection (Socher et al., 2011a), sentiment analysis (Socher et al., 2011b; Kalchbrenner et al., 2014), and most notably machine translation (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Auli et al., 2013). Distributed word representations (also known as word embeddings) are trained by predicting the contexts in which the words or phrases occur.

In this paper, we present a new approach for *unsupervised* semantic role labeling that leverages distributed representations. The goal of semantic role labeling is to discover the relations that hold between a predicate and its arguments in a given input sentence (e.g., "who" did "what" to "whom", "when", "where", and "how").

1. [The burglar]$_{\text{A0}}$ [broke]$_{\text{V}}$ [the window]$_{\text{A1}}$.
2. [The window]$_{\text{A1}}$ [broke]$_{\text{V}}$.

In sentence (1), A0 represents the *Agent* of the breaking event, A1 represents the *Patient* (i.e., the physical object affected by the breaking event) and V determines the boundaries of the predicate. The semantic roles in the example are labeled in the style of PropBank (Palmer et al., 2005), a broad-coverage human-annotated corpus of semantic roles and their syntactic realizations. In the unsupervised case, the model must induce such labels from data without access to a predefined set of semantic roles.

Role induction is commonly treated as a clustering problem (Titov and Klementiev, 2012; Lang and Lapata, 2014). The input to the model are instances of arguments (e.g., *window*, *the burglar* in sentence (1)) and the output is a grouping of these instances into clusters such that each cluster contains arguments corresponding to a specific semantic role and each role corresponds to exactly one cluster. In other words, the syntactic representations of verbal predicates, and argument positions are observable, whereas the associated semantic roles are latent and need to be inferred.

The task is challenging due to its unsupervised nature — it is difficult to define a learning objective function whose optimization will yield an accurate model — but also because each predicate can allow several alternate mappings or linkings between its semantic roles and their syntactic realization. Despite occupying different syntactic positions (subject in sentence (1) and object in sentence (2)), the noun phrase *the window* expresses the same role in both sentences. To learn such linkings, previous work has made use of syntactic and semantic features (e.g., whether two arguments are in the same position in the parse tree,

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2482–2491,
Lisbon, Portugal, 17-21 September 2015.

whether they have the same POS-tags, whether they are lexically similar). These features are typically defined on argument instances, without taking the predicate into account, and do not interact but instead are sequentially applied.

In this work we propose to learn these features and their complex interactions (e.g., selectional restrictions) automatically from data. Specifically, we induce embeddings to represent a predicate *and* its arguments. Argument embeddings are learned from surrounding contexts involving the predicate and neighboring arguments. Analogously, predicate embeddings are learned from contexts representing their arguments. Our model learns a rich feature space which can serve as input to any clustering algorithm. We use a linear programming formulation of hierarchical clustering which is advantageous for two reasons. Firstly, expressing clustering as a global optimization problem with an explicit objective function can potentially yield higher quality output compared to greedy algorithms (such as agglomerative clustering). Secondly, through the use of constraints, we can model task-specific knowledge (e.g., semantic roles are unique within a frame). Experimental results show improved performance over both previous unsupervised semantic role labeling approaches and other distributed word representation models.

2 Related Work

Our model is inspired by recent work in learning distributed representations of words (Bengio et al., 2006; Mnih and Hinton, 2008; Collobert et al., 2011; Turian et al., 2010; Mikolov et al., 2013a). In this framework, a neural network is used to predict a word taking into account its context. Words are represented by vectors which are concatenated or averaged in order to form a representation of the context. We induce vector representations to represent each predicate and its argument. As a learning objective, vectors are required to contribute to a prediction task about the target argument in the sentence, given the predicate and a small window of surrounding arguments. Similarly, predicate vectors are learned from the contexts of preceding arguments, and are required to contribute to the prediction of upcoming arguments. Our vectors encode the semantics of arguments, predicates, and their interdependence.

Approaches to unsupervised semantic role labeling follow two main modeling paradigms. Under the the first variant, semantic roles are modeled as latent variables in a (directed) graphical model that relates a verb, its semantic roles, and their possible syntactic realizations (Grenager and Manning, 2006; Lang and Lapata, 2010; Garg and Henderson, 2012). Role induction here corresponds to inferring the state of the latent variables representing the semantic roles of arguments. The second approach is similarity-driven and based on clustering. For instance, Lang and Lapata (2014) induce semantic roles via graph partitioning: each vertex in a graph corresponds to an argument instance of a predicate and edges represent features expressing syntactic or semantic similarity. The graph partitioning problem is solved using task-specific adaptations of label propagation and agglomerative clustering. Titov and Klementiev (2012) propose a Bayesian clustering algorithm based on the Chinese Restaurant Process. Their model encourages similar verbs to have similar linking preferences using a distance-dependent Chinese Restaurant Process prior.

More recently, Titov and Khoddam (2015) propose a reconstruction-error minimization framerwork for unsupervised semantic role induction. Their model consists of two componenets: the encoder (implemented as a log-linear model) predicts roles given syntactic and lexical features, whereas the reconstruction component (implemented as a probabilistic tensor factorization model) recovers argument fillers based on the role predictions, the predicate and other arguments. The two components are estimated jointly to minimize errors in argument reconstruction.

Our work follows the similarity-driven modeling paradigm. Rather than engineering relevant features, we learn them using a neural network and a task-appropriate training objective. We are thus able to model complex interactions between arguments and their predicates without making simplifying assumptions (e.g., that arguments are conditionally independent of each other given the predicate). Our embeddings are largely independent of the clustering algorithm used to induce the semantic roles. We advocate the use of linear programming, which supports the incorporation of linguistic and structural constraints during cluster formation. ILP techniques have been previously applied to several *supervised* NLP tasks, including semantic role labeling (Punyakanok et al., 2008), how-

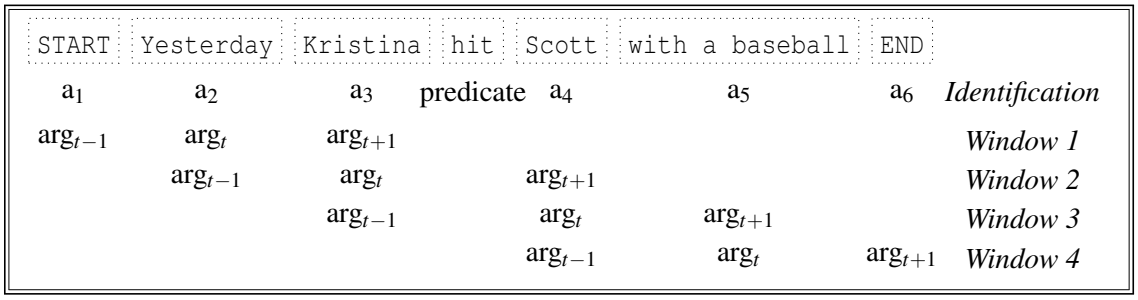

Figure 1: Symmetric context window from the list of arguments

ever their application to *unsupervised* role induction is novel to our knowledge.

3 Model

Unsupervised role induction is commonly modeled after supervised semantic role labeling (Màrquez et al., 2008) and follows a two-stage approach. Given a sentence and a designated verb, the goal is to identify the arguments of the verbal predicate (argument identification) and label them with semantic roles (role induction). The model is first given a syntactically analyzed sentence (e.g., in the form of a dependency parse) with the aim of determining all constitutents that fill a semantic role. Argument identification is performed heuristically using a small number of rules which take into account syntactic relations encountered when traversing the dependency tree from predicate to argument (Lang and Lapata, 2014; Titov and Klementiev, 2012). An alternative which we follow here is to use a supervised classifier trained on a small amount of data using non-lexicalized features.

As mentioned earlier, we treat role induction as a type-level clustering problem: argument instances are assigned to clusters such that these represent semantic roles. We induce a separate set of clusters for each verb, and each cluster thus represents a verb-specific role. Clustering algorithms commonly take a matrix of pairwise similarity scores between instances as input and produce a set of output clusters, often satisfying some optimality criterion. In our case, instances are type-level arguments represented by embeddings whose similarity is quantified using a distance measure such as cosine (see Section 3.1) and clusters are formed using a linear programming formulation of hierarchical clustering (see Section 3.2).

3.1 Predicate and Argument Embeddings

Our approach for learning predicate and argument vectors is inspired by recent methods aimed at learning high-quality vector representations of words from large amounts of unstructured text data (Mikolov et al., 2013a). In this framework, vectors of the surrounding words within a fixed-sized window (the *context*) are summed into a single vector v_c, which is useful in predicting the output vector v_0 representing the current or *target* word. Longer-range context information can also be captured (Le and Mikolov, 2014), specifically words within the current paragraph but outside of the target word context window.

In contrast to previous word-based approaches, our model induces vector representations for each predicate and its semantic arguments. As a learning objective, vectors are required to contribute to a prediction task about the target argument in the sentence, given the predicate and a small window of surrounding arguments. So despite the fact that the argument vectors and weightings are initialized randomly, they can eventually capture semantics as an indirect result of the prediction task. Similarly, predicate vectors are learned from the many contexts sampled from sentences involving that predicate, and are required to contribute to the prediction task of the next argument. One way to consider the role of the predicate token is as another argument. It acts as a memory (similar to the paragraph memory of Le and Mikolov, 2014) that remembers what is missing from the current context, and so captures something of the core nature of the predicate.

Figure 1 illustrates our approach for building the context, for the example sentence *Yesterday, Kristina hit Scott with a baseball.* As a preprocessing step, (verbal) predicates and arguments are identified based on a dependency parse, to give a full list of arguments for the sentence. Boxes show

the span of each argument. In our model, contexts are symmetric and of fixed length ($c = 1$ in the Figure), sampled from a sliding window over the argument list. To enable the first and last arguments within the sentence to be predicted from the context, we augment the argument list with *START* and *END* arguments. Meanwhile, the predicate is associated with all contexts generated from the sliding window approach.

More formally, given a training set comprising a predicate b and a sequence of its semantic arguments $a_1, a_2, a_3, \ldots, a_T$, the objective of the model is to maximize the average log probability:

$$\frac{1}{T}\sum_{t=1}^{T} \log p\left(a_t | b, a_{t+j}, -c \leq j \leq c, j \neq 0\right) \quad (1)$$

where c is the size of the training context around the center argument a_t. We define probability using the softmax function:

$$p\left(a_t | b, a_{\text{context}}\right) \propto \exp\left(v_c^T v_0\right), \quad (2)$$

where v_0 is the target argument vector and v_c the context vector formed from predicate and context arguments vectors. Vectors are trained using stochastic gradient descent where the gradient is obtained via back-propagation. After the training converges, predicates and arguments with similar meaning are mapped to a similar position in the vector space.

Every predicate is mapped to a unique vector v_{pred}, with the vocabulary of vectors shared across the data set. For the arguments, we generate feature vectors f_{-1} and f_{+1} from syntactic information (dependency relations and POS-tags), concatenated with a distributional vector to represent the head word token in each argument. The representation vectors v_{-1} and v_{+1} are calculated from the feature vectors using $v_j = W_{\text{context}} f_j$, where the matrix W_{context} is also updated as part of the learning process. W_{context} is common for all arguments. In a similar manner, the representation vector v_0 for the target argument is calculated using $v_0 = W_{\text{argument}} f_0$. The predicate and argument vectors are concatenated to predict the middle argument in a context. Other ways of dividing the argument window between context and predicted argument, and of combining context vectors, are possible. As the full list of arguments in a sentence is known, we use a symmetric window. The advantage of concatenating the vectors is that information on the sequence of arguments is preserved. An illustration of our model is given in Figure 2.

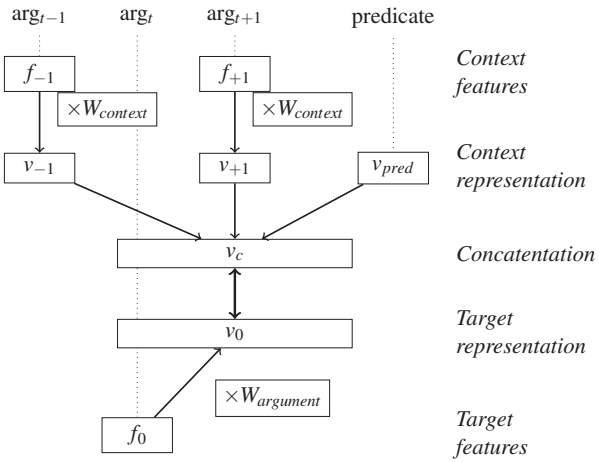

Figure 2: Distributional model for learning representations of predicates and semantic arguments.

Through a context window of arguments rather than neighboring tokens, our model captures a semantic representation of each verbal predicate. Furthermore, the arguments themselves are positioned in vector space as a result of the selectional preferences of the predicates. In the next section, we use the induced semantic space to cluster arguments into semantic roles.

3.2 Argument Clustering

Hierarchical clustering is a method of clustering which seeks to build a hierarchy of clusters, often presented in a dendrogram. In such a representation, all possible pairs of clusters are merged at some level. It is typically implemented as a greedy heuristic algorithm with no explicit objective function. Instead, it requires a measure of dissimilarity between sets of observations, typically through a measure of distance between pairs of observations. An example is the agglomerative clustering technique used in Lang and Lapata (2014). Their algorithm starts from seed clusters based on shared syntactic information, and then repeatedly merges pairs of clusters "bottom up" to form a hierarchy.

It is possible to formalize hierarchical clustering as an integer linear programming (ILP) problem with the dendrogram properties enforced as linear constraints (Gilpin et al., 2013). Although exact solvers exists for ILP, their performance is highly dependent on the number of variables involved, and we found it necessary to develop a linear programming (LP) relaxation to provide approximate solutions faster. Dynamic programming is an al-

ternative approximation technique that could be explored; it has recently been used successfully in the context of supervised semantic role labeling (Täckström et al., 2015).

But first, we consider the exact formalization of agglomerative clustering as an ILP. In order to generate a legal dendrogram, it is necessary for the model to enforce the following partition properties:

Reflexivity A seed cluster is always in the same merged cluster as itself.

Symmetry If seed cluster a is merged into the same cluster as seed cluster b, then b is also in the same cluster as a.

Transitivity If a and b are merged at a certain level, and b and c are also merged at the same level, then a is in the same cluster as c at that level.

To model hierarchical clustering as an ILP problem, we consider all pairs of clusters a and b, and introduce variables $\mathcal{M}_{ab}$ to represent the merge level between clusters a and b. Reflexivity is enforced by the constraint:

$$\mathcal{M}_{aa} = 0, \tag{3}$$

Meanwhile the symmetry requirement is captured by the constraint:

$$\mathcal{M}_{ab} = \mathcal{M}_{ba}. \tag{4}$$

The transitivity requirement and the objective to find the hierarchy that minimizes pair-wise distances are modeled in the objective of the ILP using auxiliary variables O_{abc} that represent the merge order of pairs (a,b) and (a,c), and coefficients w_{abc} that are set equal to the difference between distance metrics D between those pairs:

$$\arg\max_{\mathcal{M},O} \sum_{a,b,c \in \text{Instances}} w_{abc} O_{abc}$$

subject to:

$$\begin{aligned} &\mathcal{M}_{ab} \text{ is a merge function} \\ &O_{abc} = \begin{cases} 1 & \text{if } \mathcal{M}_{ab} < \mathcal{M}_{ac} \\ 0 & \text{otherwise} \end{cases} \\ &w_{abc} = D(a,c) - D(a,b). \end{aligned}$$

Although exact solutions can be found using ILP solvers, for the problems we consider there are typically over 100 seed clusters. This generates in the order of 10^6 transitivity constraints, and it is this in particular that results in combinatorial complexity from off-the-shelf ILP solvers.

An LP relaxation provides approximate solutions faster. A maximum merge level L is first defined as a parameter, although as this is not an integer problem and fractional levels are possible, this does not represent the number of levels. Auxiliary variables $Z_{ab \geq ac}$ capture the merge hierarchy, and T_{abc} rewards transitivity by a factor α:

$$\arg\max_{\mathcal{M},O,Z} \sum_{a,b,c \in \text{Instances}} w_{abc} O_{abc} + \alpha T_{abc}$$

subject to:

$$\begin{aligned} 0 \leq T \leq 1 \\ 0 \leq O \leq 1 \\ 0 \leq Z \leq 1 \\ 0 \leq \mathcal{M} \leq L \\ -L \leq \mathcal{M}_{ac} - \mathcal{M}_{ab} - (L+1) O_{abc} \leq 0 \\ -L \leq \mathcal{M}_{ab} - \mathcal{M}_{ac} - (L+1) Z_{ab \geq ac} + 1 \leq 0 \\ -L \leq \mathcal{M}_{bc} - \mathcal{M}_{ac} - (L+1) Z_{bc \geq ac} + 1 \leq 0 \\ Z_{ab \geq ac} + Z_{bc \geq ac} \geq T_{abc} \end{aligned} \tag{5}$$

To capture the linguistic principles involved in semantic role labeling (Lang and Lapata, 2014), our formulation includes additional constraints. These are expressed explicitly through the construction of the linear programme:

Role Uniqueness Semantic roles are unique within a particular frame. This principle is captured by constraining the merge level of two seed clusters a and b to be at the top level L of the hierarchy, where a and b are roles that occur within the same frame, with the constraint:

$$\mathcal{M}_{ab} = L \qquad \forall (a,b) \text{ in frame.} \tag{6}$$

Syntactic Position Arguments occurring in a specific syntactic position within a specific linking all bear the same semantic role. This is handled by construction of the problem, where all arguments of a particular predicate occurring in a specific syntactic position are collected into a seed cluster at the beginning of the merging problem.

Argument Head Distribution The distribution over argument heads is the same for two clusters that represent the same semantic role. The distribution of arguments is captured in vector space by the model described in Section 3.1. We calculate

centroid vectors from the instances in each cluster. To measure similarity between clusters a and b, we use cosine similarity between centroids:

$$D(a,b) = \frac{v_a^T v_b}{\|v_a\|\|v_b\|} \quad (7)$$

Equations (3)–(7) comprise the LP model.

4 Experimental Setup

In this section we present our experimental setup for assessing the performance of the model presented above. We explain how it was trained and tested, and also briefly introduce the models used for comparison with our approach.

4.1 Training

To obtain distributed representations, we used text from a subset of the English Gigaword corpus (Parker et al., 2011), comprising almost 64 million tokens (2.7 million sentences). The training corpus was pre-processed using `MATE` (Björkelund et al., 2009) to lemmatize the words, provide POS-tags and a dependency parse, identify verbal predicates and the position of arguments.

The neural network model described in Section 3.1 was trained using Matlab. We restricted the predicate vocabulary to use the 5,000 most frequent verbs in the training corpus, and the verbal predicates found in the CoNLL-2008 shared task data set (Surdeanu et al., 2008). Predicates were represented as vectors of size 80, while vectors of length 50 were used for arguments. We used a symmetric context window of size $c = 1$. As the mechanism to prevent all vectors from having the same value, we used "negative-sampling" (Mikolov et al., 2013b), where there are $k = 5$ randomly sampled negative examples of (context, target) pairs for each data sample. This technique has the advantage that we do not need to provide numerical probabilities for the noise distribution. Model parameters were updated during training using stochastic gradient descent over 5 epochs, decreasing the update step size at each epoch.

4.2 Argument clustering

Following common practice in unsupervised role induction (Titov and Klementiev, 2012; Lang and Lapata, 2014), we evaluated our model on the complete CoNLL-2008 shared task data set. We used the clustering metrics of purity, collocation and their harmonic mean F1. In addition, we used V-measure (Rosenberg and Hirschberg, 2007), an entropy-based measure which explicitly evaluates how successfully the criteria of homogeneity and completeness have been satisfied.

In previous work on unsupervised role induction, the results for each predicate were weighted in proportion to the number of times the predicate appeared in the CoNLL-2008 test set. In addition to this measure, we evaluate clustering where predicates are uniformly weighted. In a data set where the top 10 predicates account for almost 20% of the samples, these metrics give a view of performance on the other 3,000-plus predicates where less predicate-specific data is available.

4.3 Comparison Models

We compared our model against a baseline that assigns arguments to clusters based on their syntactic functions (SYNTF; Lang and Lapata, 2014). Specifically, the baseline forms clusters from the syntactic position of an argument using four cues: the verb's voice, the argument's position relative to the predicate, its syntactic relation, and any realizing preposition.[1]

To assess whether our *argument*-based model has any advantages over other *word*-based distributed representations we compared the following variants: (a) the `arg2vec` model presented in Section 3.1 trained on the subset of Gigaword; (b) the continuous bag-of-words model trained using `word2vec` on the same Gigaword corpus; and (c) 300–dimensional vectors pre-trained on part of the Google News dataset[2] (about 100 billion words), again using `word2vec`. In all three instances, we performed argument clustering using the LP of Section 3.2. We also compare against Agglomerative-cosine (AGGLOM), the best performing model of Lang and Lapata (2014).[3] Where applicable, we also refer to the models presented in Titov and Klementiev (2012).

5 Results

Our results on the semantic role induction task are summarized in Tables 1 and 2. Table 1 presents results using the gold standard parses and argu-

[1] Differences in the results compared to Lang and Lapata (2014) are due to our re-implementation of the predicate labeling stage, to be consistent with the preprocessing we used for the other comparison systems.

[2] `http://code.google.com/p/word2vec/`

[3] Differences from published results are again due to changes at the predicate labeling stage.

Table 2: Purity, collocation and F1 measures, and homogeneity, completeness and V1 measures for CoNLL-2008 data set using automatic parse syntax information.

ments available in the CoNLL 2008 data set. Notice that our embeddings are still learned using automatically identified arguments. Table 2 uses automatic parses with automatically identified arguments which is a more realistic evaluation setting.

As can be seen in Table 1, when gold standard information is used the syntactic function baseline (SYNTF) is very effective. When considering F1 (weighted by the number of instances), arg2vec performs on the same par with graph-based agglomerative clustering (AGGLOM). Interestingly, word2vec performs worse when trained either on Gigaword or the Google News corpora. According to (weighted) V1, arg2vec outperforms all other comparison models. When predicates are weighted uniformly, arg2vec is the best performing model using F1 or the more information-centric V-measure. This suggests that our model performs well on the the less-frequent predicates and rarer semantic roles. The results also show that our model captures semantic information useful for this task more successfully than the word-based distributional models. Both word2vec models have similar performance, despite significant differences in the size of their training data.

Table 2 shows similar trends. The poorer performance of SYNTF and AGGLOM can partly be ascribed to the heuristics used for argument identification: DEPREL+MATE gives the baseline performance of our dependency parser and argument identification. Nevertheless, when comparing systems that have access to the same preprocessing, our arg2vec model gives the best performance particularly in the information-centric V-measures. Also note, that it seems robust to noise incurred by the automatic parsing and argument identification procedures.

Titov and Klementiev (2012) report a (weighted) F1 of 83.0 on the gold standard CoNLL-2008 dataset, using a coupled model where parameters are shared across verbs and a form of smoothing which replaces argument fillers by lexical cluster ids stemming from Brown et al.'s (1992) algorithm (trained on the RCV1 corpus, about 63 millions words). Our model would presumably benefit from a similar coupling mechanism which we could enforce as a constraint in the ILP. However, we leave this to future work. When tested on automatic parses and gold arguments, their model yields a weighted F1 of 78.8. For comparison, arg2vec obtains an F1 of 80.6 on automatic parses and arguments. Figure 4 shows visualizations of the argument semantic space as captured by the arg2vec-GIGAWORD model, for the predicates *eat* and *win*. Dimensionality reduction was performed by the t-SNE library.[4] The visualization suggests that the model learns similarities beyond simple word contexts.

The evaluation presented so far assesses the quality of the argument representations learned by our model. We also wanted to see whether the predicate embeddings capture meaningful semantic content. Figure 3 shows a visualization

[4] http://lvdmaaten.github.io/tsne/

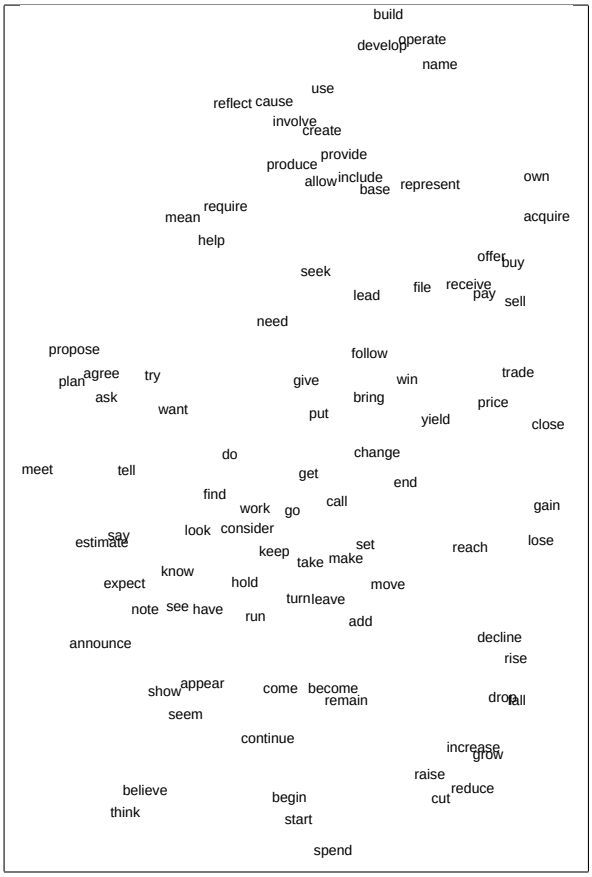

Figure 3: 2-D representation of the induced predicate space for the 100 most frequent predicates in CoNLL-2008.

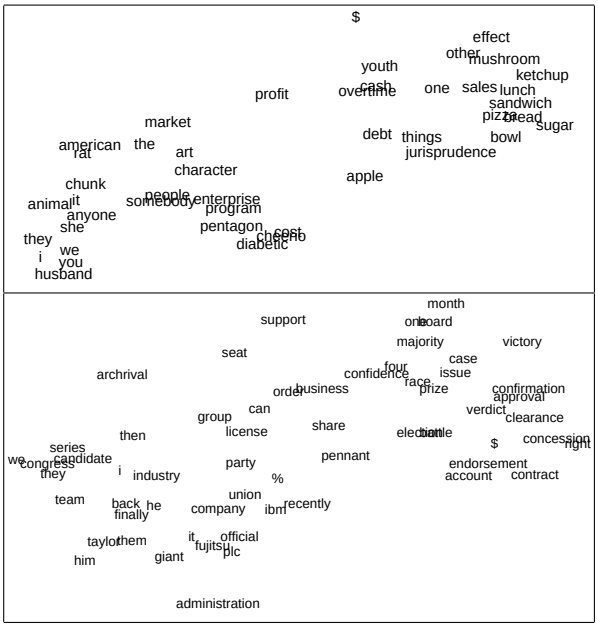

Figure 4: 2-D representation of the induced argument space for the predicates *eat* (top) and *win* (bottom). In both representations, A0 arguments are clustered bottom left, while A1 arguments are found top right.

of the predicate semantic space as captured by `arg2vec` when it is trained on the Gigaword corpus. It shows a projection of the 100 most frequent verbs in CoNLL-2008, with dimensionality reduction again performed by `t-SNE`. The visualization suggests that the model captures non-trivial predicate similarities. Verbs relating to buying and selling lie close together (e.g., *offer, buy, receive, pay, sell*). Verbs denoting growth or decrease are also grouped together (*drop, fall, increase, grow, reduce, cut*). Interestingly, verbs with similar argument structure share regions of the space (e.g., *say, estimate*, or *believe, think* or *seem, appear*). Usefully, verbs are represented in a continuous space rather than discrete clusters (e.g., *acquire* is somewhere between *buy* and *own*).

In order to quantitatively evaluate the quality of the predicate representations induced by our model, we compared the cosine distances between vectors to the hierarchy of VerbNet (Schuler, 2005). VerbNet is a hierarchical domain-independent broad-coverage verb lexicon for English, organizing verbs into classes. The evaluation task was, for all pairs of predicates, to predict whether they would be in the same cluster at the top layer of the hierarchy of VerbNet. To form the top layer of VerbNet, we took the first integer of each VerbNet class number. As an example, the verbs *believe* (VN class conjecture-29.5), *think* (consider-29.9), *expect* (conjecture-29.5-1), and *adopt* (appoint-29.1) would all be in the same class 29. According to this reduction of VerbNet, there are 101 classes. The prediction was based on whether the cosine distance between the pair of vectors was above a threshold value. We measured area under the precision-recall curve (AUC) which captures performance at all thresholds, and F1-score at the best threshold. `arg2vec` does better in both measures than a baseline of random vectors of the same dimension, scoring 0.637 for AUC compared to a baseline of 0.505, and 29.5 against 22.9 for F1.

6 Conclusion

In this paper we presented a new approach for learning distributed representations for predicates and their arguments which we show is useful for unsupervised semantic role labeling. Rather than creating a task-specific algorithm for role induction, we learn a task-specific representation. We

thus decouple feature learning from clustering inference, which results in a conceptually simpler model. Through a formulation of the clustering problem as a linear programme, we are able to perform clustering efficiently and incorporate task-specific constraints. In the future, we would like to investigate how our approach generalizes across languages and tasks.

A Tableau Prover for Natural Logic and Language

Lasha Abzianidze
TiLPS, Tilburg University, the Netherlands
L.Abzianidze@uvt.nl

Abstract

Modeling the entailment relation over sentences is one of the generic problems of natural language understanding. In order to account for this problem, we design a theorem prover for Natural Logic, a logic whose terms resemble natural language expressions. The prover is based on an analytic tableau method and employs syntactically and semantically motivated schematic rules. Pairing the prover with a preprocessor, which generates formulas of Natural Logic from linguistic expressions, results in a proof system for natural language. It is shown that the system obtains a comparable accuracy ($\approx 81\%$) on the unseen SICK data while achieving the state-of-the-art precision ($\approx 98\%$).

1 Introduction

A problem of recognizing textual entailments (RTE)—given two text fragments T (for a text) and H (for a hypothesis), determine whether T entails, contradicts or is neutral to H—is considered as a complex and, at the same time, fundamental problem for several NLP tasks (Dagan et al., 2005). For more than a decade, RTE challenges have been held, where systems are competing to each other with respect to human annotated RTE test data; but there are few systems that try to solve RTE problems by computing meanings of linguistic expressions and employing inference engines similar to proof procedures of formal logics. Moreover, those few systems are usually used in combination with shallow classifiers since the systems' performances alone are poor.

The current paper advocates that purely deductive inference engines over linguistic representations backed up with a simple lexical knowledge base could be solely and successfully used for the RTE task. Our work builds on the theory of an analytic tableau system for Natural Logic (Natural Tableau) introduced by Muskens (2010). The theory offers to employ a tableau method—a proof procedure used for many formal logics—for the version of Natural Logic that employs Lambda Logical Forms (LLFs)—certain terms of simply typed λ-calculus—as Logical Forms (LFs) of linguistic expressions. The merits of the current approach are several and they can be grouped in two categories: virtues attributed to the tableau prover are (i) the high precision for the RTE task characteristic to proof procedures, (ii) the transparency of the reasoning process, and (iii) ability for solving problems with several premises; and those concerning LLFs are (iv) an evidence for LFs that are reminiscent of Surface Forms but still retaining complex semantics, and (v) an automatized way of obtaining LLFs from wide-coverage texts.

The rest of the paper is organized as follows. First, Natural Tableau is introduced, and then a method of obtaining LLFs from raw text is described. We outline the architecture of an implemented theorem prover that is based on the theory of Natural Tableau. The power of the prover is evaluated against the SICK data; the results are analyzed and compared to related RTE systems. The paper concludes with future work.

2 Natural Tableau for Natural Logic

Natural Logic is a vague notion and refers to logics that account for valid inferences of natural languages, where reasoning and the grammar are strongly related to each other and LFs resemble surface forms (Lakoff, 1972). On the other hand, a tableau method (Beth, 1955) is a popular proof procedure and nowadays many formal logics have their own version of it (D'Agostino et al., 1999). A combination of these two devices is offered by Muskens (2010), where the language of Natural Logic is considered to be a part of simply typed

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2492–2502,
Lisbon, Portugal, 17-21 September 2015.

$$\frac{X\ A\ B:\ [\,]:\ \mathbb{F}}{\begin{array}{c}A:\ [c]:\ \mathbb{T}\\ B:\ [c]:\ \mathbb{F}\\ \text{s.t. } X \in \{\texttt{all}, \texttt{every}\}\\ \text{and } c \text{ is a } \textit{fresh} \text{ term}\end{array}}\forall_F \qquad \frac{A\ B:\ [\vec{C}]:\ \mathbb{X}}{A:\ [B,\vec{C}]:\ \mathbb{X}}\text{PUSH} \qquad \frac{A:\ [B,\vec{C}]:\ \mathbb{X}}{A\ B:\ [\vec{C}]:\ \mathbb{X}}\text{PULL}$$

$$\frac{\begin{array}{c}A:\ [\vec{C}]:\ \mathbb{T}\\ B:\ [\vec{C}]:\ \mathbb{F}\end{array}}{\begin{array}{c}\times\\ \text{s.t. } A \leq B\end{array}}\leq\!\times \qquad \frac{X\ A\ B:\ [\,]:\ \mathbb{F}}{\begin{array}{c}A:\ [d]:\ \mathbb{F} \qquad B:\ [d]:\ \mathbb{F}\\ \text{s.t. } X \in \{\texttt{some}, \texttt{a}\} \text{ and } d \text{ is an } \textit{old} \text{ term}\end{array}}\exists_F$$

$$\frac{\texttt{not}\ A:\ [\vec{C}]:\ \mathbb{X}}{A:\ [\vec{C}]:\ \overline{\mathbb{X}}}\text{NOT}$$

Figure 1: Tableau rules for quantifiers ($\forall_F$ and $\exists_F$), Boolean operators (NOT), formatting (PUSH and PULL) and inconsistency ($\leq\!\times$). The relation $\leq$ stands for entailment, $\vec{C}$ and $\mathbb{X}$ are meta-variables over sequences of terms and truth signs ($\mathbb{T}$ and $\mathbb{F}$), respectively; the bar operator $\overline{\mathbb{X}}$ negates a sign.

λ-terms that are built up from variables and lexical constant terms with the help of application and lambda abstraction. The terms of the language are called LLFs and resemble linguistic surface forms:[1]

$$\texttt{a}_{(et)(et)t}\ \texttt{bird}_{et}\ \texttt{fly}_{et}$$

$$\texttt{some}_{(et)(et)t}\ \texttt{bird}_{et}\ (\texttt{not}_{(et)et}\ \texttt{fly}_{et})$$

$$\texttt{not}_{((et)(et)t)(et)(et)t}\ \texttt{all}_{(et)(et)t}\ \texttt{bird}_{et}\ \texttt{fly}_{et}$$

Note that common nouns and intransitive verbs are typed as properties (i.e. functions from entities to truth values) and quantifiers as binary relations over properties; the latter typing treats quantified noun phrases (QNPs) as generalized quantifiers (GQs)—a term of type properties over properties $(et)t$.

A Natural Tableau entry is a tuple containing a term, a sequence of terms representing an argument list, and a truth sign. The entries are such that when a term is applied to all arguments from an argument list in the order of the list, the resulted term is of type truth value. For example, $A_{eet}c_e : [d_e] : \mathbb{T}$ is a valid tableau entry (i.e. a node) since it consists of a term $A_{eet}c_e$, an argument list $[d_e]$ and a truth sign $\mathbb{T}$ standing for *true*, and additionally, $A_{eet}c_e d_e$ is a term of type t.

A tableau method is a refutation method and it proves an argument by searching a counterexample. The search process is guided by applications of certain set of rules. A tableau rule is a schema with a set of antecedent nodes above a line and a set of precedent branches below a line, where each branch consists of (precedent) nodes. A rule is applicable if all its antecedent nodes match to some nodes in a tableau, and after the rule is applied, precedent nodes of the rule are introduced in the tableau. A tableau consists of branches where each branch models a situation and is either closed (i.e., inconsistent) or open (i.e., consistent) depending whether it contains a closure $\times$ sign (i.e., an obvious contradiction). A tableau is closed if all its branches are closed, otherwise it is open.

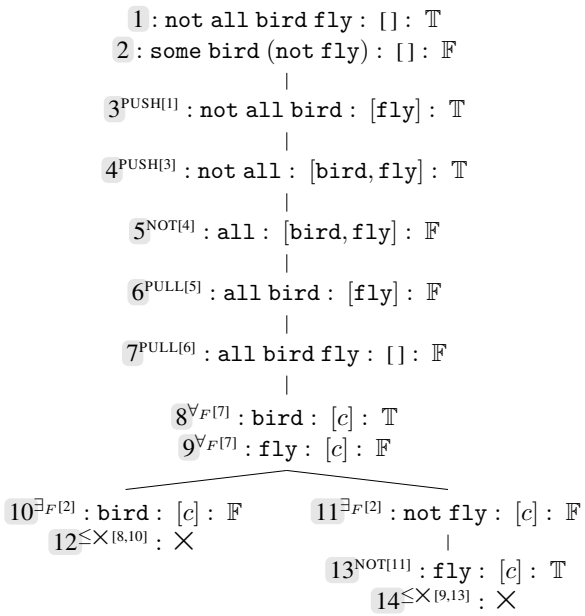

Figure 2: The closed tableau serves as a proof for: *not all birds fly → some bird does not fly*

In Figure 2, a tableau proof, which employs the rules of (Muskens, 2010) from Figure 1, is presented. In order to show a way the tableau is developed, the nodes are enumerated and annotated with a source rule and IDs of nodes from which a current node is obtained. For example, 3 is obtained from 1 by the PUSH rule. In order to prove an argument, the tableau starts with a counterexample of the argument, i.e. a premise being true and a conclusion false. After several rule applications, all the branches of the tableau close meaning

[1]Since modeling intensionality is beyond the scope of the paper, we present LLFs typed with extensional semantic types, i.e. types are built up from basic e (for entities) and t (for truth values) types. We use the comma as a type constructor, e.g., (e, t) stands for a functional type from entities to truth values. The comma is omitted when types are denoted by single letters, e.g., et stands for (e, t). Taking into account right-associativity of the type constructor we often drop parentheses for better readability. Terms are optionally annotated with their types in a subscript.

that none of the situations for the counterexample were consistent.

An advantage of Natural Tableau is that it treats both single and multi-premised arguments in the same fashion and represents a deductive procedure in an intuitive and transparent way.

3 Obtaining LLFs for Natural Tableau

3.1 CCG and the C&C Parser

Combinatory Categorial Grammar (CCG) is a lexicalized grammar formalism that assigns a syntactic category and a semantic interpretation to lexical items, where the items are combined via combinatory rules (Steedman, 2000; Steedman and Baldridge, 2011). The CCG category A/B (or $A\backslash B$) is a category of an item that becomes of category A when it is combined with an item of category B on its right (or left, respectively) side. In the example below, the sentence *every man walks* is analyzed in the CCG formalism, where lexical items are combined via the *forward application* rule and unspecified semantic interpretations are written in a boldface:

$$\dfrac{\dfrac{\dfrac{\text{every}}{(S/(S\backslash NP))/N : \mathbf{every}} \quad \dfrac{\text{man}}{N : \mathbf{man}}}{S/(S\backslash NP) : \mathbf{every\ man}} \quad \dfrac{\text{walks}}{S\backslash NP : \mathbf{walk}}}{S : (\mathbf{every\ man})\ \mathbf{walk}}$$

The CCG derivation trees are suitable structures for obtaining LLFs for at least two reasons. First, the CCG framework is characterized by a transparent interface between syntactic categories and semantic types; second, there exist efficient and robust CCG parsers for wide-coverage texts.

During obtaining LLFs, we employ the C&C CCG parser of Clark and Curran (2007) and EasyCCG of Lewis and Steedman (2014). While the C&C parser is a pipeline of several NLP systems: POS-tagger, chunker, named entity recognizer (NER), lemmatizer (Minnen et al., 2001) supertagger and sub-parser, EasyCCG is an extremely simple but still comparably accurate CCG parser based on A* parsing.[2] These two parsers use different settings for supertagging and parsing; therefore, it is interesting to test both parsers for our application.

In Figure 3, there is a CCG derivation by the C&C parser displayed in a tree style: terminal nodes are annotated with tokens, syntactic categories, lemmas and POS-tags while non-terminal nodes are marked with combinatory rules and resulted categories; some basic categories are subcategorized by features.

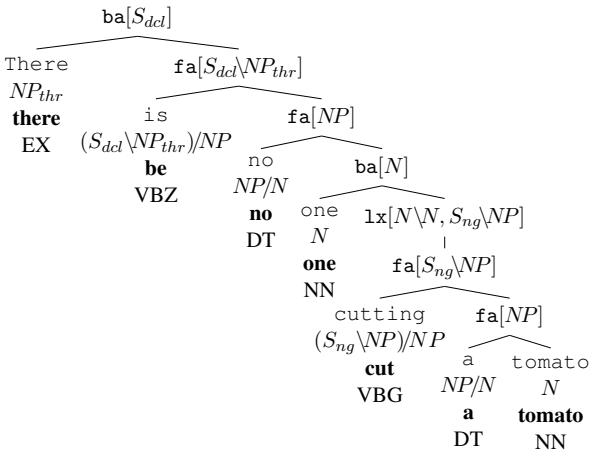

Figure 3: The CCG tree by the C&C parser for *there is no one cutting a tomato* (SICK-2404), where *thr, dcl, ng* category features stand for an expletive *there*, declarative and present participle, respectively.

3.2 From CCG Trees to LLFs

Initially, it may seem easy to obtain fine-grained LLFs from CCG trees of the parsers, but careful observation on the trees reveals several complications. The transparency between the categories and types is violated by the parsers as they employ lexical (i.e. type-changing) rules—combinatory rules, *non-native* ones for CCG, which changes categories. Lexical rules were initially introduced in CCGbank (Hockenmaier and Steedman, 2007) to decrease the total number of categories and rules. In the tree of Figure 3, a lexical rule changes a category $S_{ng}\backslash NP$ of a phrase *cutting a tomato* with $N\backslash N$. In addition to this problem, the trees contain mistakes from supertaggers (and from the other tools, in case of the C&C parser).

The first step in processing CCG trees is to remove directionality from the categories. This step is the same as obtaining unspecified semantic interpretation of a phrase in the CCG framework. While converting categories $A\backslash B$ and A/B into a non-directional type $(\mathtt{b}, \mathtt{a})$, the arrangement of nodes must be changed in a corresponding way. For instance, in case of the top backward application rule ($\mathtt{ba}[S_{dcl}]$ in Figure 3), the order of

[2] The employed C&C parser is trained on *rebanked* CCGbank (Honnibal et al., 2010)—an updated version of CCGbank (Hockenmaier and Steedman, 2007) with improved analyses for predicate-argument structures and nominal modifiers. For EasyCCG, input sentences are already processed by the POS-tagger and the NER of the C&C parser.

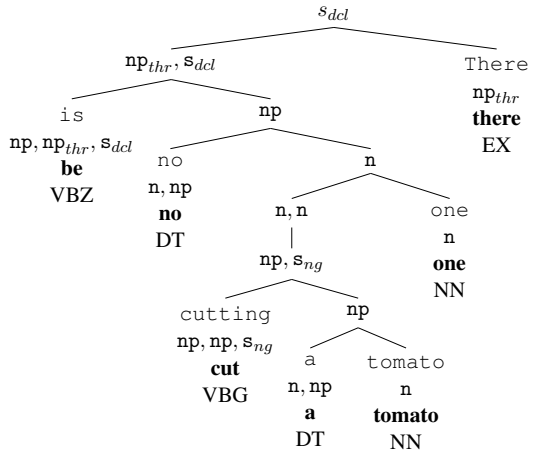

Figure 4: A CCG term obtained from the CCG tree of Figure 3. Categories are converted into types.

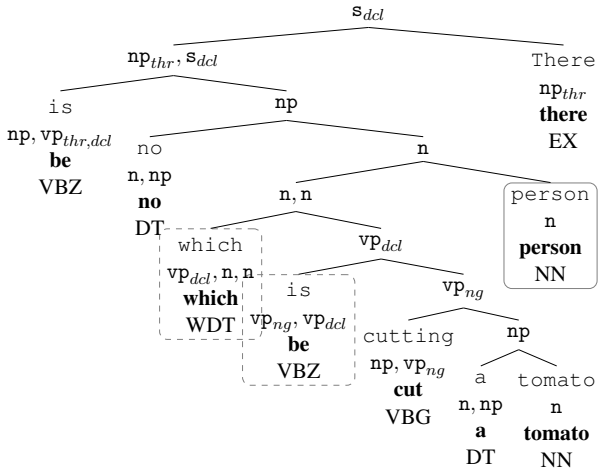

Figure 5: A fixed CCG term that is obtained from the CCG term of Figure 4. A node with a dashed (solid) frame is inserted (substituted, respectively). A type $\mathtt{vp}_{a,b}$ abbreviates $(\mathtt{np}_a, \mathtt{s}_b)$.

nodes is reversed to guarantee that the function category $(\mathtt{s}_{dcl}, \mathtt{np}_{thr})$ precedes its argument category $\mathtt{np}_{thr}$. There are about 20 combinatory rules used by the parsers and for each of them we design a way of reordering subtrees. In the end, the order of nodes coincides with the order according to which semantic interpretations are combined. The reordering recipes for each combinatory rule is quite intuitive and can be found in (Steedman, 2000) and (Bos, 2009), where the latter work also uses the C&C parser to obtain semantic interpretations. Trees obtained after removing the directionality from the categories are called CCG terms since they resemble syntactic trees of typed λ-terms (see Figure 4).

$$\mathtt{on}_{\mathtt{np},\mathtt{pp}}(\mathtt{ice}_{\mathtt{n}})_{\mathtt{np}} \longrightarrow \mathtt{on}_{\mathtt{np},\mathtt{pp}}(\mathtt{a}_{\mathtt{n},\mathtt{np}}\mathtt{ice}_{\mathtt{n}}) \quad (1)$$

$$\mathtt{run}_{\mathtt{np},\mathtt{s}}(\mathtt{dogs}_{\mathtt{n}})_{\mathtt{np}} \longrightarrow \mathtt{run}_{\mathtt{np},\mathtt{s}}(\mathtt{s}_{\mathtt{n},\mathtt{np}}\mathtt{dog}_{\mathtt{n}}) \quad (2)$$

$$(\mathtt{Dow}^{\mathtt{PER}}_{\mathtt{n},\mathtt{n}}\ \mathtt{Jones}^{\mathtt{PER}}_{\mathtt{n}})_{\mathtt{np}} \longrightarrow \mathtt{Dow\_Jones}_{\mathtt{np}} \quad (3)$$

$$(\mathtt{two}_{\mathtt{n},\mathtt{n}}\ \mathtt{dogs}_{\mathtt{n}})_{\mathtt{np}} \longrightarrow \mathtt{two}_{\mathtt{n},\mathtt{np}}\ \mathtt{dogs}_{\mathtt{n}} \quad (4)$$

$$\mathtt{her}_{(\mathtt{pp},\mathtt{n}),\mathtt{np}}\ \mathtt{car}_{\mathtt{pp},\mathtt{n}} \longrightarrow \mathtt{her}_{\mathtt{n},\mathtt{np}}\ \mathtt{car}_{\mathtt{n}} \quad (5)$$

$$\mathtt{who}_{\mathtt{w}}V(Q_{\mathtt{n},\mathtt{np}}N) \longrightarrow Q_{\mathtt{n},\mathtt{np}}(\mathtt{who}_{\mathtt{w}'}VN) \quad (6)$$

$$\mathtt{nobody} \longrightarrow \mathtt{no}_{\mathtt{n},\mathtt{np}}\ \mathtt{person}_{\mathtt{n}} \quad (7)$$

Lexical rules are the third most commonly used combinatory rules (7% of all rules) by the parsers on the SICK data (Marelli et al., 2014b), and therefore, they deserve special attention. In order to compositionally *explain* several category changes made by lexical rules (represented with $(.)_\alpha$ operator in terms), either types of constant terms are set to proper types or lexical entries are inserted in CCG terms. For explaining a lexical rule $\mathtt{n} \rightsquigarrow \mathtt{np}$, mainly used for bare nouns, an indefinite determiner is inserted for singular nouns (1) and a plural morpheme *s* is used as a quantifier for plurals (2). Also identifying proper names with the feature assigned by the C&C NER tool helps to eliminate $\mathtt{n} \rightsquigarrow \mathtt{np}$ change (3). Correcting the type of a quantifier that is treated as a noun modifier is another way of eliminating this lexical rule (4). In case of $(\mathtt{s}, \mathtt{np}) \rightsquigarrow (\mathtt{n}, \mathtt{n})$ change, *which is* phrase is inserted and salvages the category-type transparency of CCG (see Figure 5). As a whole, the designed procedures explain around 99% of lexical rules used in CCG terms of the SICK sentences. Note that explaining lexical rules guarantees a well-formed CCG term in the end.

Apart from the elimination of lexical rules, we also manually design several procedures that fix a CCG term: make it more semantically adequate or simplify it. For example, the C&C parser assigns a category *N/PP* of relational nouns to nouns that are preceded by possessives. In these cases, a type $\mathtt{n}$ is assigned to a noun and a type of possessive is changed accordingly (5). To make a term semantically more adequate, a relative clause is attached to a noun instead of a noun phrase (6), where a type $\mathtt{w} \equiv (\mathtt{vp}, \mathtt{np}, \mathtt{s})$ of a wh-word is changed with $\mathtt{w}' \equiv (\mathtt{vp}, \mathtt{n}, \mathtt{s})$. CCG terms are simplified by substituting terms for *no one, nobody, everyone*, etc. with their synonymous terms (see (7) and Figure 5). These substitutions decrease a vocabulary size, and hence, decrease the number of tableau rules.

The final operation is to convert a fixed CCG term into an LLF, meaning to convert QNPs into GQs of (Montague, 1974; Barwise and Cooper, 1981). In this procedure, a type $(\mathtt{n}, \mathtt{np})$ of a quan-

tifier is replaced with $(\mathtt{n},(\mathtt{np},\mathtt{s}),\mathtt{s})$, and the resulted new NP is applied to the smallest clause it occurs in; but if there are other QNPs too, then it also applies to the clauses where other QNPs are situated. This operation is not deterministic and can return several terms due to multi-options in quantifier scope ordering. As an example, two λ-terms, (9) and (10), are obtained from the CCG term (8) of Figure 5.[3]

$$\mathbf{b}(\mathbf{no}(\mathbf{w}(\mathbf{b}(\mathbf{c}(\mathbf{a}\,\mathbf{t})))\mathbf{p}))\mathbf{th} \quad (8)$$

$$\mathbf{no}\left(\mathbf{w}(\mathbf{b}(\lambda x.\,\mathbf{a}\,\mathbf{t}(\lambda y.\,\mathbf{c}yx)))\mathbf{p}\right)\left(\lambda z.\,\mathbf{b}\,z\,\mathbf{th}\right) \quad (9)$$

$$\mathbf{a}\,\mathbf{t}(\lambda x.\,\mathbf{no}\left(\mathbf{w}(\mathbf{b}(\mathbf{c}x))\mathbf{p}\right)\left(\lambda z.\,\mathbf{b}\,z\,\mathbf{th}\right)) \quad (10)$$

Eventually the final λ-terms, analogous to (9) and (10), obtained from CCG trees will be considered as LLFs that will be used in the wide-coverage theorem prover. It has to be stressed that generated LLFs are theory-independent abstract semantic representation. Any work obtaining semantic representations from CCG derivations can combine its lexicon with (already corrected) LLFs and produce more adequate semantics in this way.

3.3 Extending the Type System

An obvious and simple way to integrate the LLFs, obtained in Subsection 3.2, in Natural Tableau is to translate their types into semantic types built up from e and t.[4] We will not do so, because this means the information loss since the information about syntactic types are erased; for example, usually syntactic types $\mathtt{pp}$, $\mathtt{n}$ and $(\mathtt{np},\mathtt{s})$ are translated as et type. Retaining syntactic types also contributes to fine-grained matching of nodes during rule application in the prover. For instance, without syntactic types it is more complex to determine the context in which a term $\mathbf{game}$ occurs and find an appropriate tableau rule when considering the following LLFs, $\mathbf{game}_{\mathtt{n},\mathtt{n}}\mathbf{theory}$ and $\mathbf{game}_{\mathtt{pp},\mathtt{n}}(\mathbf{of}\ X)$, as both $(\mathtt{n},\mathtt{n})$ and $(\mathtt{pp},\mathtt{n})$ are usually translated into $(et)et$ type, like it is done by (Bos, 2009).

In order to accommodate the LLFs with syntactic types in LLFs of (Muskens, 2010), we extend the semantic type system with $\mathtt{np},\mathtt{n},\mathtt{s},\mathtt{pp}$ basic syntactic types corresponding to basic CCG categories. Thus complex types are now built up from the set $\{e,t,\mathtt{np},\mathtt{n},\mathtt{s},\mathtt{pp}\}$ of types. The extension automatically licenses LLFs with syntactic types as terms of the extended language.

We go further and establish interaction between semantic and syntactic types in terms of a subtyping $\sqsubseteq$ relation. The relation is defined as a *partial order* over types and satisfies the following conditions for any $\alpha_1,\alpha_2,\beta_1,$ and β_2 types:

(a) $e\sqsubseteq\mathtt{np},\quad \mathtt{s}\sqsubseteq t,\quad \mathtt{n}\sqsubseteq et,\quad \mathtt{pp}\sqsubseteq et;$

(b) $(\alpha_1,\alpha_2)\sqsubseteq(\beta_1,\beta_2)$ iff $\beta_1\sqsubseteq\alpha_1$ and $\alpha_2\sqsubseteq\beta_2;$

Moreover, we add an additional typing rule to the calculus: a term is of type β if it is already of type α and $\alpha\sqsubseteq\beta$. According to this typing rule, now a term can be of multiple types. For example, both $\mathbf{walk}_{\mathtt{np},\mathtt{s}}$ and $\mathbf{man}_{\mathtt{n}}$ terms are also of type et, and all terms of type $\mathtt{s}$ are of type t too. From this point on we will use a boldface style for lexical constants of syntactic types.

Initially it may seem that the lexicon of constant terms is doubled in size, but this is not the case as several syntactic constants can mirror their semantic counterparts. This is achieved by *multiple typing* which enables to put semantic and syntactic terms in the same term. For instance, $\mathbf{love}_{\mathtt{np},\mathtt{np},\mathtt{s}}\,c_e\,\mathbf{john}_{\mathtt{np}}$ and $\mathbf{at}_{\mathtt{np},\mathtt{pp}}\,c_e\,d_e$ are well-formed LLFs of type t that combine terms of syntactic and semantic types, and there is no need of introducing semantic terms (e.g., $\mathtt{at}_{\mathtt{eet}}$ or $\mathtt{love}_{\mathtt{eet}}$) in order to have a well-formed term. In the end, the extension of the language is conservative in the sense that LLFs and the tableau proof of Section 2 are preserved. The latter is the case since the tableau rules are naturally extensible to match new LLFs.

4 Implementation of the Prover

In order to further develop and evaluate Natural Tableau, we implement the prover, LangPro, based on the extended theory. Its general architecture is based on the first-order logic (FOL) prover of Fitting (1990). The prover also contains a module for λ-calculus that roughly follows (Blackburn and Bos, 2005).

Setup of the inventory of rules is a crucial for efficiency of the prover. There is a priority order for the categories of rules according to their computational efficiency. The prover most prefers to employ non-branching rules that introduce no fresh terms and antecedents of which can be ignored af-

[3] We use initial letters of lemmas to abbreviate a term corresponding to a lexical entry. Note that (9) represents a reading with *no one* having a wide scope while, in (10), *a tomato* has a wide scope.

[4] The similar translation is carried out in (Bos, 2009) for Boxer (Bos, 2008), where basic CCG categories are mapped to semantic types and the mapping is isomorphically extended to complex categories.

ter the application (e.g., NOT). Less preferred and inefficient rules are the ones that branch, produce new terms or antecedents of which are kept after the application (e.g., $\forall_F$ and $\exists_F$). In order to encourage finding short proofs, *admissible* rules representing shortcuts of several rule applications are also introduced (e.g., FUN$\uparrow$ and ARG in Figure 9). The inventory consists of about 50 rules, where most of them are manually designed based on RTE problems (see Section 5.1) and the rest represents the essential part of the rules found in (Muskens, 2010).

The LLF generator (LLFgen) is a procedure that generates LLFs from a CCG derivation in the way described in Subsection 3.2. We also implement an LLF-aligner that serves as an optional preprocessor between LLFgen and the prover itself; it aligns identical chunks of LLFs and treats them as a constant (i.e. having no internal structure). This treatment often leads to smaller tableau proofs. The example of aligned LLFs is given in Figure 8.

LangPro uses only the antonymy relation and a transitive closure of the hyponymy/hypernymy relations from WordNet 3.0 (Fellbaum, 1998) as its knowledge base (KB). The entailment $\leq$ (contradiction $\perp$) relation between lexical constants of the same type $A \leq B$ ($A \perp B$) holds if there exists a WordNet sense of A that is a transitive hyponym (an antonym) of some WordNet sense of B. Note that there is no word sense disambiguation (WSD) used by the prover; therefore, adopting these interpretations of entailment and contradiction amounts to considering all senses of the words. For example, *a man is crying* entails *a man is screaming* as there are senses of *cry* and *scream* that are in the entailment relation.

All in all, chaining a CCG parser, LLFgen, the LLF-aligner, the prover and KB results in an automatized tableau prover LangPro which operates directly over natural language text.

5 Learning and Evaluation

5.1 Learning

For learning and evaluation purposes, we use the SICK data (Marelli et al., 2014b). The data consists of problems that are rich in the lexical, syntactic and semantic phenomena that compositional distributional semantic models (Mitchell and Lapata, 2010) are expected to account for.[5] The SICK data contains around 10K text-hypothesis pairs that are classified in three categories: entailment, contradiction, and neutral.

During learning we used only the trial portion of the data, SICK-trial, including 500 problems. The learning process consists of improving the components of the prover while solving the RTE problems: designing fixing procedures of LLFgen, adding new sound rules to the inventory, and introducing valid relations in KB that were not found in WordNet (e.g., *woman*$\leq$*lady*, *note*$\leq$*paper* and *food*$\leq$*meal*). During learning, each RTE problem is processed as follows:

input: $(T, H, \texttt{answer})$;
1: $t =$ the first LLF of $\texttt{llf}(T)$;
2: $h =$ the first LLF of $\texttt{llf}(H)$;
3: **case** answer, $\texttt{tab}\{t{:}\mathbb{T}, h{:}\mathbb{F}\}$, $\texttt{tab}\{t{:}\mathbb{T}, h{:}\mathbb{T}\}$
ENTAILMENT, CLOSED, OPEN: HALT;
CONTRADICTION, OPEN, CLOSED: HALT;
NEUTRAL, OPEN, OPEN: HALT;
4: **otherwise**
5: **if** t or h is incorrect **then** try to amend llf; go to 1
6: **else if** a rule is missing **then** add it; go to 3
7: **else if** a relation is missing **then** add it; go to 3
8: **else** HALT;

A function llf denotes the combination of LLFgen and a CCG parser; for learning we use only the C&C parser. A function $\texttt{tab} : S \rightarrow \{\text{CLOSED}, \text{OPEN}\}$ returns CLOSED if one of the tableaux initiated with aligned or non-aligned set S of nodes closes; otherwise it returns OPEN. For instance, while checking a problem (T, H) on entailment (contradiction), tableau starts with a counterexample: T being true and H false (true, respectively). Note that 5-7 procedures are carried out manually while the phase is significantly facilitated by graphical proofs produced by LangPro.[6]

As a result, there were collected around 30 new rules where about a third of them are admissible ones; the new rules cover phenomena like noun and adverbial modifiers, prepositional phrases, passive constructions, expletive sentences, verb-particle constructions, auxiliaries, light verb constructions, etc. Most of the new rules are discussed in more details in (Abzianidze, 2015).

[5] SICK is partitioned in three parts (trail, train and test) and used as a benchmark for RTE14 (Marelli et al., 2014a). The data and the system results of RTE14 are available at http://alt.qcri.org/semeval2014/task1/

[6] Automating a tableau rule extraction is quite hard for the following reasons: it is unclear how to determine automatically whether a CCG derivation is wrong, a tableau rule is missing, or lexical knowledge is lacking; and the general format of a rule makes search procedure extremely inefficient.

ID	Gold/LP	Problem (premise ? conclusion)
3670	E/N	It is raining on a walking man ? A man is walking in the rain
219	E/N	There is no girl in white dancing ? A girl in white is dancing
5248	N/E	Someone is playing with a toad ? Someone is playing with a frog
8490	N/C	A man with a shirt is holding a football ? A man with no shirt is holding a football
7402	N/C	There is no man and child kayaking through gentle waters ? A man and a young boy are riding in a yellow kayak
1431	C/C	A man is playing a guitar ? A man is not playing a guitar
8913	N/C	A couple is not looking at a map ? A couple is looking at a map

Table 1: Problems from SICK-trial and SICK-train with gold and LangPro judgments.

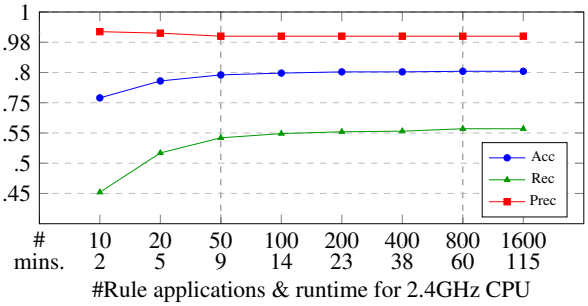

Figure 6: Performance of LangPro on SICK-train (4500) using CCG derivations of the C&C parser.

LangPro \ SICK	test (4927 problems)		
	Prec%	Rec%	Acc%
Baseline (majority)	-	-	56.36
+C&C+50	98.03	53.75	79.52
+EasyCCG+50	98.03	51.41	78.53
LangPro Hybrid-50	97.99	57.03	80.90
+C&C+800	97.99	54.73	79.93
+EasyCCG+800	98.00	52.67	79.05
LangPro Hybrid-800	97.95	58.11	**81.35**

Table 2: Evaluation of the versions of LangPro

LangPro was unable to prove several problems requiring complex background knowledge (e.g., SICK-3670 in Table 1) or having wrong CCG derivations from the C&C parser (e.g., in SICK-219, *white dancing* is a noun constituent).

5.2 Development

The part of the SICK data, SICK-train, issued for training at RTE14 was used for development. After running LangPro on SICK-train, we only analyzed false positives, i.e. neutral problems that were identified either as entailment or contradiction by the prover. The analysis reveals that the parsers and WordNet are responsible for almost all these errors. For example, in Table 1, SICK-5248 is classified as entailment since *toad* and *frog* might have synonymous senses; this problem shows the advantage of not using WSD, where a proof search also searches for word senses that might give rise to a logical relation. SICK-7402 was falsely identified as contradiction because of the wrong analyses of the premise by both CCG parsers: *no man* and *child...* are in coordination, which implies *there is no man*, and hence, contradicts the conclusion. SICK-8490 is proved as contradiction since the prover considers LLFs where *shirt* takes a wide scope. With the help of LangPro, we also identified inconsistency in the annotations of problems, e.g., SICK-1431, 8913 are similar problems but classified differently; it is also surprising that SICK-5248 is classified as neutral.

During this phase, also the effective (800) and efficient (50) upper bounds for the rule application number were determined (see Figure 6). Moreover, 97.4% of proofs found in 1600 rule applications are actually attainable in at most 50 rule applications; this shows that the rule application strategy of LangPro is quite efficient.

5.3 Evaluation

We evaluate LangPro on the unseen portion of the SICK data, SICK-test, which was used as a benchmark at RTE14; the data was also held out from the process of designing LLFgen. The prover classifies each SICK problem as follows:

input: (T, H);
try t = the first LLF of `llf`(T);
h = the first LLF of `llf`(H)
if no error **then**
case `tab`$\{t{:}\mathbb{T}, h{:}\mathbb{F}\}$, `tab`$\{t{:}\mathbb{T}, h{:}\mathbb{T}\}$
CLOSED, OPEN: classify as `ENTAILMENT`;
OPEN, CLOSED: classify as `CONTRADICTION`;
OPEN, OPEN: classify as `NEUTRAL`;
CLOSED, CLOSED: classify as `ENTAILMENT`; report it;
else classify as `NEUTRAL`; report it;

The results, in Table 2, show evaluation of LangPro on SICK-test using both parsers separately with the efficient and effective rule application upper bounds. Slightly better results with the C&C parser is explained by employing the parser in the learning phase. The difference of .5% in

System \ Measure+	Prec%	Rec%	Acc% (+LP)
Illinois-LH	81.56	**81.87**	**84.57** (+0.55)
ECNU	84.37	74.37	83.64 (+1.69)
UNAL-NLP	81.99	76.80	83.05 (+1.44)
SemantiKLUE	85.40	69.63	82.32 (+**2.78**)
The Meaning Factory	93.63	60.64	81.59 (+2.72)
LangPro Hybrid-800	**97.95**	58.11	81.35
UTexas	97.87	38.71	73.23 (+8.97)
Prob-FOL	-	-	76.52
Nutcracker	-	-	78.40
Baseline (majority)	-	-	56.69

Table 3: Comparing LangPro to the top or related RTE systems and combining their answers[7]

accuracy between the C&C-based and EasyCCG-based provers show that LLFgen was not fitted to the C&C parser's output during the learning phase.

In order to eliminate at some extent errors coming from the parsers, hybrid provers are designed that simply combine answers of two systems—if one of the systems proves a relation then it is an answer. Both hybrid versions of LangPro show more than 80% of accuracy while only 5 systems were able to do so at RTE14, where 77.1% was a median accuracy. The prover turns out to be extremely reliable with its state-of-the-art precision being almost 98%. A high precision is conditioned by the formal deductive proof nature of LangPro and by the sound rules it employs.

In Table 3, we compare the best version of hybrid LangPro to the top 5 systems of RTE14 on SICK-test and show the improvement it gives to each system when blindly adopting its positive answers (i.e. entailment and contradiction).

The decision procedure of the prover is completely rule-based and easy to comprehend since it follows the intuitive deductive rules. Tableaux proofs by LangPro for SICK-247 (in Figure 7) and SICK-2895 (in Figure 8) show step by step how T contradicts and entails, respectively, H.[8] Several new rules employed in these tableaux are given in Figure 9. Note that the both problems, SICK-247, 2895, were wrongly classified by all the top 7 systems of the RTE14. Taking into account that solving SICK-247 requires a sort of De Morgan's law for negation and disjunction, this demonstrates where LangPro, a purely logic-based system, outperforms non-logic-based systems.[9] The another problem, SICK-2895, is an evidence how unreliable the state-of-the-art and non-logic-based RTE systems might be since solving the problem only requires a lexical knowledge $barbell \leq weight$, which is available in WordNet.

6 Related Work

Using formal logic tools for a wide-coverage RTE task goes back to the Nutcracker system (Bos and Markert, 2005), where a wide-coverage semantic processing tool Boxer (Bos, 2008), in combination with the C&C tools, first produces discourse representation structures of (Kamp and Reyle, 1993) and then FOL semantic representations (Curran et al., 2007). Reasoning over FOL formulas is carried by off-the-shelf theorem provers and model builders for FOL.[10] Our approach differs from the latter in several main aspects: (i) the underling logic of LLFs (i.e. higher-order logic) is more expressive than FOL (e.g., it can properly model GQs and subsective adjectives), (ii) LLFs are cheap to get as they are easily obtained from CCG derivations, and (iii) we develop a completely new proof procedure and a prover for a version of Natural Logic.

The other related works are (MacCartney and Manning, 2008) and (Angeli and Manning, 2014). Both works contribute to Natural Logic and are based on the same methodology.[11] The approach has two main shortcomings compared to Natural Tableau; namely, it is unable to process multi-premised problems, and its underling logic is weaker (e.g., according to (MacCartney, 2009), it cannot capture the entailment in Figure 2).

[7]The top 5 systems of RTE14 are Illinois-LH (Lai and Hockenmaier, 2014), ECNU (Zhao et al., 2014), UNAL-NLP (Jimenez et al., 2014), SemantiKLUE (Proisl et al., 2014) and The Meaning Factory (Bjerva et al., 2014).

[8]In the tableaux, due to lack of space, several constants are denoted with initial characters of their lemmas and some intermediate nodes are omitted. Some of the nodes are annotated with a sequence of source rule applications.

[9]Even a shallow heuristic—if H has a named entity that does not appear in T, then there is no entailment—is not sufficient for showing that SICK-247 is contradiction. We thank our reviewer for mentioning this heuristic w.r.t. SICK-247.

[10]Nutcracker obtains 3% lower accuracy on SICK than our prover (Pavlick et al., 2015). The Meaning Factory (Bjerva et al., 2014) that is a brother system of Nutcracker, instead of solely relying on decisions of theorem provers and model builders, uses machine learning methods over the features extracted from these tools; this method results in a more robust system. RTE systems UTexas (Beltagy et al., 2014) and Prob-FOL (Beltagy and Erk, 2015) also use Boxer FOL representations but employ probabilistic FOL. For comparison purposes, the results of these systems on the SICK data are given in Table 3.

[11]They relate two sentences by a sequence of string edits; the final logical relation between the sentences is computed by composing logical relations associated with these edits.

7 Conclusion and Future Work

We made Natural Tableau of Muskens (2010) suitable for the wide-coverage RTE task by extending it both in terms of rules and language. Based on the extended Natural Tableau, the prover LangPro was implemented, which has a modular architecture consisting of the inventory of rules, KB and the LLF generator. As a whole, the prover represents a deductive model of natural reasoning with the transparent and naturally interpretable decision procedure. While learning only from the SICK-trial data, LangPro showed the comparable accuracy and the state-of-the-art precision on the unseen SICK data.

For future work, we plan to explore the FraCaS (Consortium et al., 1996) and newswire RTE (Dagan et al., 2005) data sets to further improve the LLF generator and enrich the inventory of tableau rules. These tasks are also interesting for two reasons: to find out how much effort is required for adapting the LLF generator to different data, and which rules are to be added to the inventory for tackling the new RTE problems. Incorporating more WordNet relations (e.g., similarity, derivation and verb-group) and the paraphrase database (Ganitkevitch et al., 2013) in KB is also a part of our future plans.

Acknowledgments

I thank Reinhard Muskens for helpful discussions on this work, Jan Sprenger for his feedback on an early version of this paper, the authors of (Honnibal et al., 2010) for sharing a recent parser model, and anonymous reviewers for useful comments. This work is a part of the project "Towards Logics that Model Natural Reasoning" and supported by the NWO grant (project number 360-80-050).

JEAM: A Novel Model for Cross-Domain Sentiment Classification Based on Emotion Analysis

Kun-Hu Luo, Zhi-Hong Deng*, Liang-Chen Wei, Hongliang Yu

Abstract

Cross-domain sentiment classification (CSC) aims at learning a sentiment classifier for unlabeled data in the target domain based on the labeled data from a different source domain. Due to the differences of data distribution of two domains in terms of the raw features, the CSC problem is difficult and challenging. Previous researches mainly focused on concepts mining by clustering words across data domains, which ignored the importance of authors' emotion contained in data, or the different representations of the emotion between domains. In this paper, we propose a novel framework to solve the CSC problem, by modelling the emotion across domains. We first develop a probabilistic model named JEAM to model author's emotion state when writing. Then, an EM algorithm is introduced to solve the likelihood maximum problem and to obtain the latent emotion distribution of the author. Finally, a supervised learning method is utilized to assign the sentiment polarity to a given online review. Experiments show that our approach is effective and outperforms state-of-the-art approaches.

1 Introduction

Cross-domain sentiment classification (CSC) is the task that learns a sentiment classifier for unlabeled data in the target domain based on the labeled data from the source domain. With the increasing amount of opinion information available on the Internet, CSC has become a hot spot in recent years. Traditional machine learning algorithms often train a classifier utilizing the labeled data for CSC. However, in some practical cases, we may have many labeled data for some domains (source domains) but very few or no labeled data for other domains (target domains). Due to the differences of the distribution of two domains in terms of raw features, e.g. raw term frequency, the classifier trained from the source domain often performs badly on the target domain. To overcome this issue, several feature-based studies have been proposed to improve the sentiment classification domain adaptation [Zhuang et al., 2013; He et al., 2011; Gao and Li, 2011; Li et al., 2012; Dai et al., 2007; Zhuang et al., 2010; Pan et al., 2010; Wang et al., 2011; Long et al., 2012; Lin and He, 2009].

Existing studies build various generative models to solve the domain adaptation problems for CSC. In most cases, the models are trained by using the whole corpora without specifying on the sentiment of the texts. For example, [Zhuang et al., 2013] propose a general framework HIDC to mine high-level concepts (e.g. word clusters) across various domains. However, their learned concepts contain many topics not restricted to the sentiment. On the other hand, some researchers focus on the usage of the sentiment in CSC study [Mitra et al., 2013a; Mitra et al., 2013b; He et al., 2011]. [He et al., 2011] modify JST model [Lin and He, 2009] by incorporating word polarity priors through adjusting the topic-word Dirichlet priors. However, they fail to consider the expression differences among various domains.

To overcome the above issues, we employ "emotion", for its ubiquity among domains. The sentiment words in different domains might vary

* Corresponding author

Lisbon, Portugal, 17-21 September 2015.

significantly, but the emotion can be effectively transferred. For example, when expressing the emotion "happiness", one uses "bravo" in the domain of sport, while "yummy" in the domain of food. Therefore, we propose an EA framework to model the latent emotions which are commonly contained in subjective articles and expressed by "emotional words". We infer the sentiment polarity of a document based on the emotion state. The hierarchy of EA is composed by four layers:

(1) Sentiment Layer

Normally, the sentiment of a document is the general opinion towards a certain event or object. For example, a movie review in IMDB might voice the feeling about the movie by a reviewer [Yu et al., 2013].

(2) Emotion Layer

Based on the emotion classification theories in psychology [Plutchik, 2002], the emotion can be classified into the basic ones influenced by the physiological factors, e.g. happiness, sadness, anger, etc., and dozens of complicated ones formed under some specific social conditions, e.g. shame, guilt, abashment, etc. Additionally, the emotion can be classified as positive and negative (similar to the sentiment classification) based on dimensional models of emotion [Schlosberg, 1954; Plutchik, 2002; Rubin and Talerico, 2009]. Intuitively, we assume that a document tends to contain the emotions of similar polarity.

(3) Lexicon Layer

To build the connection between words and the emotion, we introduce emotional words instead of raw word features into our model. By utilizing the emotional lexicon MPQA [Wiebe et al., 2005], we select groups of strong polar words, which get high scores in the emotional lexicon. These words are considered highly correlated to the certain emotion of the same polarity. And these strong polar words have invariant polarity across domains. Therefore, the emotion can be substantialized by a series of emotional words drawn from corresponding probability distribution.

(4) Expression Layer

In many practical cases, data come from different domains. We suppose that the correlation between emotion state and sentiment orientation is stable over domains, but one emotion may have different expressions when domain varies. E.g., "satisfaction" may be expressed as "interesting" or "attractive" for a book; meanwhile, it may be expressed "efficient" for an electronics device. Formally, we have

$$p(e|y,r1) = p(e|y,r2) = p(e|y) \quad (1)$$

$$p(w_e|e,r1) \neq p(w_e|e,r2) \quad (2)$$

where e denotes the emotion, y denotes the author's sentiment orientation, $r1$ and $r2$ denotes two different domains, and w_e denotes the emotional words.

Along this line, we propose the Joint Emotion Analysis Model (named JEAM for abbreviation) utilizing the probabilistic methods. See details in the next section.

2 Proposed Model

2.1 Problem Formulation

The CSC problem can be formulated as follows: Suppose we have two sets of data, denoted as D_s and D_t, which represent the source domain data and the target domain data respectively. In the CSC problem, the source domain data consist of labeled instances, denoted by $D_s = \{\left(x_i^{(s)}, y_i^{(s)}\right)\}|_{i=1}^{n_s}$, where $x_i^{(s)} \in \mathbb{R}^k$ is an input vector, $y_i^{(s)} \in \{0,1\}$ is the output label, and n_s is the number of documents in D_s. Unlike that of the source domain, the target domain data consists of samples without any label information, denoted by $D_t = \{x_i^{(t)}\}|_{i=1}^{n_t}$, where $x_i^{(t)} \in \mathbb{R}^k$ is an input vector, and n_t is the number of documents in D_t. The task of CSC is to leverage the training data of source domain D_s to predict the label $y_i^{(t)}$ corresponding to input vector $x_i^{(t)}$ of target domain D_t.

2.2 The JEAM Model

To model the author's emotion state contained in the document, we propose the JEAM model based on the probabilistic graphical principle. Note that all the factors and edges in JEAM are derived from the specific concepts and relations in EA, e.g., Eq(1) and Eq(2). We draw the graphical representation of JEAM in Figure 1, and show the notations of this paper in Table 1.

In Figure 1, y denotes the sentiment orientation of the author, which is a latent variable in this model. e denotes any emotion (topic) generated by y from a conditional probability $p(e|y)$. e is also a latent variable in this model. r denotes any data domain, e.g., books, dvd, kitchen, and electronics etc. d denotes any document chosen from domain r with label y. For documents from the source domain, the conditional probability $p(d|r,y)$ is known, which can be used to supervise the modeling process. u denotes the prior sentiment polarity of the corresponding emotional word. In practice, u can be obtained from the emotional lexicon,

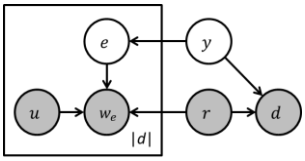

Figure 1. The Graphical representation of JEAM. All the latent variables are marked in white, and all the observed variables are marked in gray.

e	Emotion
w_e	Emotional word
r	Domain
d	Document
u	Prior sentiment polarity of the emotional word
y	Sentiment polarity of the document
X	All the observed variables
θ	All the model parameters

Table 1. Means of Symbols

which classifies a series of words into positive and negative categories. w_e denotes any emotional word with polarity u, which is chosen over words conditioned on emotion e and domain r from conditional probability $p(w_e|e,r,u)$. In this paper, we only select emotional words with strong sentiment polarities to represent the vector of the document. Therefore, we rebuild the data with the help of emotional lexicon cutting out the non-emotional words. As a result, any word chosen from the rebuilt data will be an emotional word, which is supposed not to change its polarity in different domains. Additionally, the joint probability over all the observed variables can be defined as follows based on the hidden variables:

$$p(w_e,d,r,u) = \sum_{e,y} p(e,y,w_e,d,r,u) \quad (3)$$

Based on the graphical model, we have:

$$p(e,y,w_e,d,r,u) = p(w_e|e,r,u)p(d|r,y)p(e|y)p(r)p(y)p(u) \quad (4)$$

We need to learn the unobservable probabilities (e.g., $p(w_e|e,r,u), p(d|r,y), p(e|y), p(y)$) to infer the hidden emotion distribution. Therefore, we develop an Expectation-Maximization (EM) algorithm to maximize the log likelihood of generating the whole dataset and obtain the iterative formula in E-step as follows:

$$p(e,y|w_e,d,r,u) = \frac{p(w_e|e,r,u)p(d|r,y)p(e|y)p(r)p(y)p(u)}{\sum_{e,y} p(w_e|e,r,u)p(d|r,y)p(e|y)p(r)p(y)p(u)} \quad (5)$$

where all the factors are calculated in M-step similar to PLSA and HIDC (Hoffman, 1999; Zhuang et al., 2013).

2.3 CSC via JEAM

To use JEAM to solve CSC problems, we adopt two optimizations:

First, we supervise the EM optimization with the polarity information of emotional words and instances respectively in the source domain. On the one hand, we estimate $p(e,y|w_e,d,r,u)$ utilizing the polarity label of the emotional words. Let the emotion set E be divided into positive set E_p and negative set E_n. We set $p(e_i,y|w_e,d,r,u_{w_e}) = 0$ during the whole EM process when the polarities of the emotion and current emotional word are different. On the other hand, we estimate the probability $p(d|r,y)$ with the label information of instances in the source domain. When the document is from the source domain, we set $p(d|r,y) = 0$ if y is different with the ground truth.

Second, we reconstruct the document as follows,

$$d^* = [e_1,e_2,\dots e_m], e_i = \begin{cases} 1 + \frac{|W_{e_i}^r|}{\sum_{j=1}^m |W_{e_j}^r|}, if\ W_{e_i}^r \neq \emptyset \\ 0, others \end{cases} \quad (6)$$

where $[e_1,e_2,\dots e_m]$ is the distribution over emotions, $W_{e_i}^r = \{w_e|e_{w_e}^r = i\}$, $e_{w_e}^r = argmax_e\, p(e|w_e,r)$, and $p(e|w_e,r)$ can be computed based on $p(w_e|e,r,u)$, $p(e|y), p(u)$ and $p(r)$ obtained after EM algorithm. The main function of this step is to process a new given document faster, avoiding training JEAM again with the new input. Finally, a machine learning method Support Vector Machine (SVM) is introduced to train a classifier with the labeled data from the source domain and assign polarities to documents from the target domain based on our reconstructed data.

3 Experiments

3.1 Experimental Setup

We demonstrate the effectiveness of JEAM on the Multi-Domain sentiment data set [Blitzer et al., 2007] which contains four types (domains) of real-world product documents taken from Amazon.com, which are books, dvd, electronics and kitchen. We randomly select 1800 documents from the one domain (source domain) and 200 documents from another domain (target domain). Then, we train a sentiment classifier using documents selected from the source domain and

assign labels to documents selected from the target domain, which generates 12 classification tasks. We preform 10 random selections and report the average results over 10 different runs. We use MPQA subjective lexicon [1] as the emotional lexicon. In our experiments, only strongly subjective clues are considered as emotional words, consisting of 1717 positive and 3621 negative words. We rebuild the dataset by cutting out the non-emotional words. For experiment parameters, we set $p = 25$, $n = 25$, and $T = 100$ after plenty of experiments. Considering the data in practice, the sentiment orientation y has only two forms, positive or negative. Note that we do neither instance selection nor complicated feature selection (only filter the low-frequency words) to our proposed method and other methods in comparison.

3.2 Experimental Result

Performance of Emotional Words

We show the effectiveness of introducing emotional words to solve the CSC problem. In JEAM, we reconstruct the documents by cutting out the non-emotional words. To compare the classification accuracy on the original documents and the reconstructed (emotional) documents, we choose two common classification algorithms, linear SVM and PLSA (topic size=10) for experiment respectively. The experiment results shows that both SVM and PLSA perform better on the emotional documents (60.43% and 60.48%) than on the original documents (57.73% and 56.69%) for the average accuracy over 12 classification tasks.

Effectiveness of using domain information and word polarity

We show the effectiveness of using domain information and word polarity, which are employed in our approach. For this purpose, we repeat the experiment without introducing domain and word polarity (node u and node r) into the model. Figure 2 shows the results. As it is clear, the highest performance can be achieved when domain information and word polarity are both used, while the lowest performance is obtained when neither of them is used.

Comparison with the Baselines

We compare our proposed approach with PLSA, SVM, SFA [Pan et al., 2010], JST [He et al., 2011] and HIDC [Zhuang et al., 2013]. The experimental results of the 12 classification tasks are shown in Figure 3. It can be observed that our proposed approach outperforms all the other approaches in general. Note that in order to obtain a more precise comparison of the algorithms, we do neither the instance selection nor the complicated feature selection. The result of our proposed approach can possibly be improved with the help of these selection strategies.

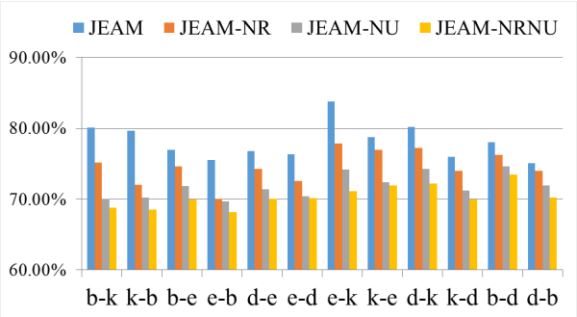

Figure 2: Effectiveness of using domain information and word polarity

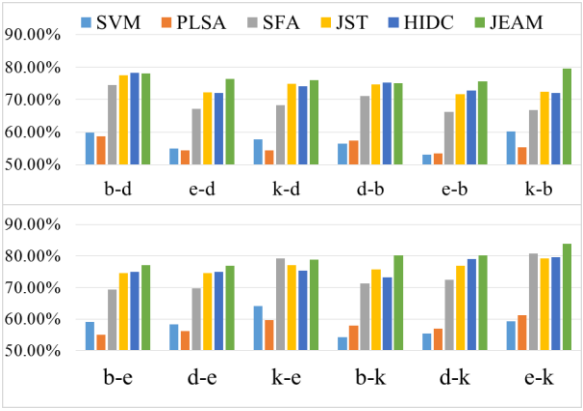

Figure 3: Comparison with the Baselines

4 Conclusion

In this paper, we propose a novel framework to solve the CSC problem, by modelling emotions across domains. We deeply analyze the relation between the author and the document based on the emotion theories in the field of psychology. Along this line, we propose a framework named EA, which takes the emotions and domains into account. Based on EA, we propose a novel model named JEAM to model the author's emotion state for Cross-domain sentiment classification. We conduct extensive experiments on real datasets to evaluate JEAM. The experiment results show that emotion plays an important role in CSC and JEAM outperforms existing state-of-the-art methods on the task of CSC.

Abstract

This paper presents a new method to identify sentiment of an aspect of an entity. It is an extension of RNN (Recursive Neural Network) that takes both dependency and constituent trees of a sentence into account. Results of an experiment show that our method significantly outperforms previous methods.

1 Introduction

Aspect-based sentiment analysis (ABSA) has been found to play a significant role in many applications such as opinion mining on product or restaurant reviews. It is a task to determine an attitude, opinion and emotions of people toward aspects in a sentence. For example, given a sentence "Except the design, the phone is bad for me", the system should classify positive and negative as the sentiments for the aspects 'design' and 'phone', respectively.

The simple approach is to calculate a sentiment score of a given aspect as the weighted sum of opinion scores, which are defined by a sentiment lexicon, of all words in the sentence (Liu and Zhang, 2012; Pang and Lee, 2008). This method is further improved by identifying the aspect-opinion relations using tree kernel method (Nguyen and Shirai, 2015a).

Other researches have attempted to use unsupervised topic modeling methods. To identify the sentiment category of the aspect, topic models which can simultaneously exploit aspect and sentiment have been proposed, such as TSLDA (Nguyen and Shirai, 2015b), ASUM (Jo and Oh, 2011), JST (Lin and He, 2009) and FACTS model (Lakkaraju et al., 2011).

Recursive Neural Network (RNN) is a kind of deep neural network. Using distributed representations of words (aka word embedding) (Bengio et al., 2003; Hinton, 1986), RNN merges word representations to represent phrases or sentences. It is one of the best methods to predict sentiment labels for the phrases (Socher et al., 2011; Socher et al., 2012; Socher et al., 2013). AdaRNN (Adaptive Recursive Neural Network) is an extension of RNN for Twitter sentiment classification (Dong et al., 2014a; Dong et al., 2014b).

This paper proposes a new method PhraseRNN for ABSA. It is an extended model of RNN and AdaRNN, which are briefly introduced in Section 2. The basic idea is to make the representation of the target aspect richer by using syntactic information from both the dependency and constituent trees of the sentence.

2 Recursive Neural Networks for ABSA

In RNN and AdaRNN, given a sentence containing a target aspect, "binary dependency tree" is built from a dependency tree of the sentence. Intuitively, it represents syntactic relations associated with the aspect. Each word (leaf) or phrase (internal node) in the binary dependency tree is represented as a d-dimensional vector. From bottom to up, the representations of a parent node v is calculated by combination of left and right child vector representations (v_l and v_r) using a global function g in RNN:

$$g(v_l, v_r) = W \begin{bmatrix} v_l \\ v_r \end{bmatrix} + b \quad (1)$$

where $W \in \Re^{d \times 2d}$ is the composition matrix and $b \in \Re^d$ is the bias vector. Then $v = f(g(v_l, v_r))$ where f is a nonlinear function such as $tanh$.

Instead of using only a global function g, AdaRNN employed n compositional functions $G = \{g_1, \cdots, g_n\}$ and selected them depending on the linguistic tags and combined vectors as follows:

$$v = f\left(\sum_{i=1}^{n} P(g_i|v_l, v_r, e) g_i(v_l, v_r)\right) \quad (2)$$

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2509–2514,
Lisbon, Portugal, 17-21 September 2015.

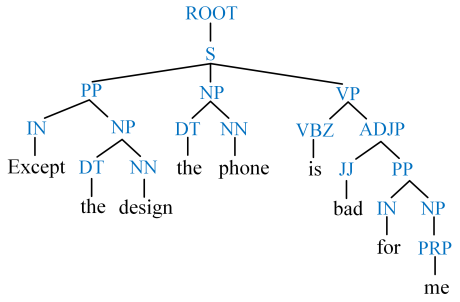

Figure 1: Example of a Constituent Tree

where $P(g_i|v_l, v_r, e)$ is the probability of function g_i given the child vectors v_l, v_r and external feature vector e. The probabilities are estimated as Equation (3).

$$\begin{bmatrix} P(g_1|v_l, v_r, e) \\ \cdots \\ P(g_n|v_l, v_r, e) \end{bmatrix} = softmax\left(\beta R \begin{bmatrix} v_l \\ v_r \\ e \end{bmatrix}\right) \quad (3)$$

where $\beta \in \Re$ is a hyper-parameter, and $R \in \Re^{n\times(2d+|e|)}$ is the parameter matrix.

The vector of the root node of the binary dependency tree is regarded as a representation of the target aspect. It is fed to a logistic regression to predict the sentiment category of the aspect.

3 PhraseRNN: Phrase Recursive Neural Network

In this model, a representation of an aspect will be obtained from a "target dependent binary phrase dependency tree" constructed by combining the constituent and dependency trees. In addition, instead of using a list of global functions G as in AdaRNN, two kinds of composition functions G in inner-phrase and H in outer-phrase are used.

3.1 Building Hierarchical Structure

First, the basic phrases (noun phrases, verb phrases, preposition phrases and so on) are extracted from the constituent tree of the sentence. For example, a list of phrases P = {PP[Except the design], NP[the phone], VP[is bad for me]} is extracted from the constituent tree in Figure 1.

Given a dependency tree and a list of phrases, a phrase dependency tree is created by Algorithm 1. The input is a dependency tree $T = (V, E)$ consisting of a set of vertices $V = \{v_1, \cdots, v_{|V|}\}$ and a set of relation edges $E = \{(r_{ji}, v_i, v_j)\}$ between two vertices, and a list of phrases $P = \{p_1, \cdots, p_K\}$ extracted from the constituent tree. The output is a phrase dependency tree $pT = (pV, pE)$ where $pV = \{T_1, \cdots, T_K\}$ ($T_i = (V_i, E_i)$ is a subtree) and $pE = \{(r_{ji}, T_i, T_j)\}$ (a set of relations between two subtrees). With the dependency tree and the phrase list in Figure 2(a), the algorithm will output a phrase dependency tree in Figure 2(b).

Algorithm 1: Convert to Phrase Dependency Tree

Input: dependency tree $T = (V, E)$, phrase list $P = \{p_1, \cdots, p_K\}$
Output: phrase dependency tree: $pT = (pV, pE)$ where $pV = \{T_1, \cdots, T_K\}, T_i = (V_i, E_i)$ and $pE = \{(r_{ji}, T_i, T_j)\}$

```
for each phrase p_i ∈ P do
    V_i ← {v_j | v_j ∈ p_i}
end
for each edge (r_nm, v_m, v_n) ∈ E do
    v_m ∈ p_k, v_n ∈ p_l
    if k = l then
        E_k ← E_k ∪ {(r_nm, v_m, v_n)}
    else
        pE ← pE ∪ {(r_nm, T_k, T_l)}
    end
end
```

The phrase dependency tree is transformed into a target dependent binary phrase dependency tree bpT by Algorithm 2. The input of the algorithm is a phrase dependency tree $pT = (pV, pE)$ and a target word v_t (the aspect word we want to predict the sentiment category). The output is the binary tree bpT. Note that the leaves of the binary tree bpT are binary subtrees $bT_1, \cdots, bT_K$ which are the binary versions of subtrees $T_1, \cdots, T_K$. On the other hand, the leaves of binary subtree bT_i are the words in phrase p_i. bpT and bT_i are obtained by *convert* function defined as Algorithm 3. It can convert an arbitrary tree to a binary tree [1]. Figure 2(c) and Figure 3 show the outputs for the aspect 'design' and 'phone', respectively.

3.2 Constructing the Aspect Representation

Each node in the binary tree is represented as a d-dimensional vector. In this research, we use the pre-trained Google News dataset [2] by word2vec algorithms (Mikolov et al., 2013). Each word is

[1] Note that *convert* function returns a tree represented by nested brackets such as [PP,[NP,VP]].

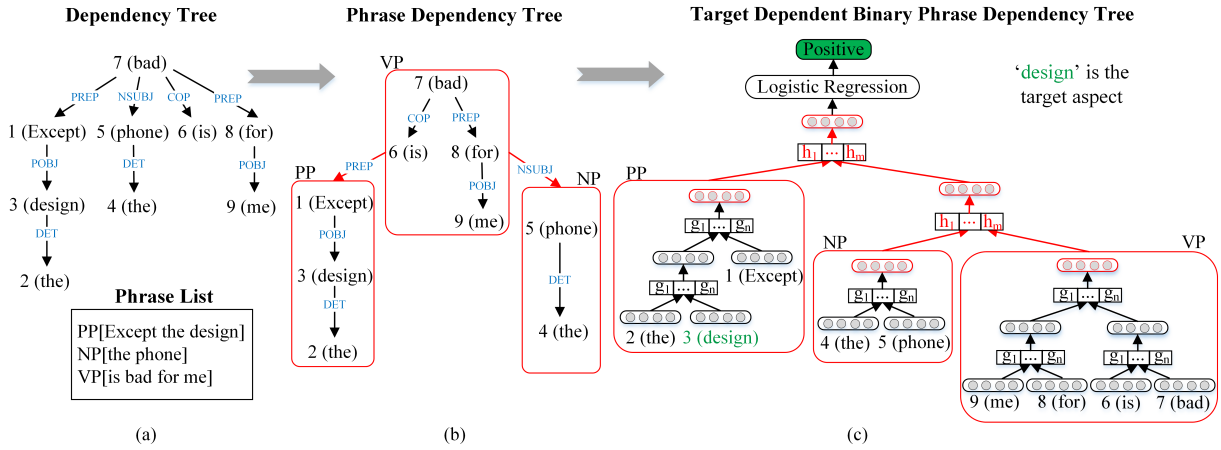

Figure 2: Hierarchical Structures in PhraseRNN: (a) Dependency Tree, (b) Phrase Dependency Tree and (c) Target Dependent Binary Phrase Dependency Tree

Algorithm 2: Convert to Target Dependent Binary Phrase Dependency Tree

Input: phrase dependency tree: $pT = (pV, pE)$, target v_t
Output: target dependent binary phrase dependency tree: bpT

for $T_i = (V_i, E_i) \in pV$ **do**
  if $v_t \in V_i$ **then**
    $h \leftarrow v_t$
  else
    $h \leftarrow$ vertex having no head in E_i
  end
  $bT_i \leftarrow convert(E_i, h)$
end
$T_{v_t} \leftarrow T_i$ that contains v_t
$bpT \leftarrow convert(pE, T_{v_t})$
Replace all T_i in bpT with bT_i

Algorithm 3: Convert to a Binary Tree

Function *convert*(E, v_t)**:**
  $v \leftarrow v_t$
  for $v_i \rightarrow v_t$, $v_t \rightarrow v_i$ *in* E **do**
    if $v_t \rightarrow v_i$ **then**
      $E' \leftarrow E \setminus \{v_t \rightarrow v_i\}$
      $w \leftarrow [convert(E, v_i), v]$
    else
      $E' \leftarrow E \setminus \{v_i \rightarrow v_t\}$
      $w \leftarrow [v, convert(E, v_i)]$
    end
    $v \leftarrow w$
  end
  return v
end

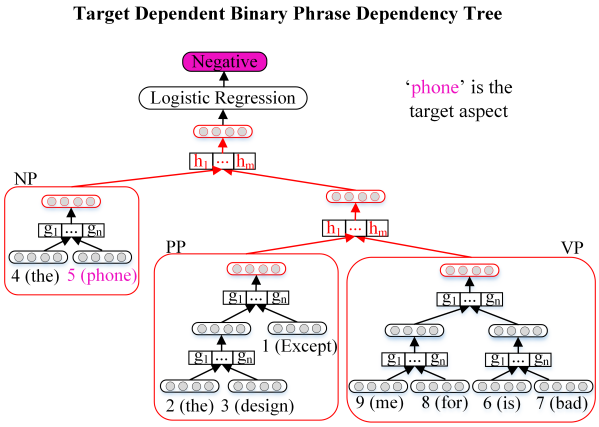

Figure 3: Another Target Dependent Binary Phrase Dependency Tree (Target Aspect 'phone')

represented as a 300-dimensional vector in this pre-trained dataset.

PhraseRNN uses two kinds of composition function $G = \{g_1, \cdots, g_n\}$ for inner-phrase and $H = \{h_1, \cdots, h_m\}$ for outer-phrase. n and m are the number of functions in G and H, respectively.

The vector of the parent node v_{in} in the binary subtree bT_i, where v_l and v_r are the vectors of the left and right children, is computed as:

$$v_{in} = f\left(\sum_{i=1}^{n} P(g_i|v_l, v_r, e_{in}) g_i(v_l, v_r)\right) \quad (4)$$

where e_{in} is the external feature vector. $P(g_i|v_l, v_r, e_{in})$ is the probability of function g_i given the child vectors v_l, v_r and e_{in}. It is

defined as Equation (5).

$$\begin{bmatrix} P(g_1|v_l, v_r, e_{in}) \\ \cdots \\ P(g_n|v_l, v_r, e_{in}) \end{bmatrix} = softmax\left(\beta R \begin{bmatrix} v_l \\ v_r \\ e_{in} \end{bmatrix}\right) \quad (5)$$

where $\beta \in \Re$ is a hyper-parameter, and $R \in \Re^{n\times(2d+|e_{in}|)}$ is the parameter matrix.

In the target dependent binary phrase dependency tree bpT, the vector of the parent node v_{out}, where the vectors of the left and right children are v_l and v_r, is computed as:

$$v_{out} = f\left(\sum_{i=1}^{m} P(h_i|v_l, v_r, e_{out}) h_i(v_l, v_r)\right) \quad (6)$$

$P(h_i|v_l, v_r, e_{out})$ is the probability of function h_i given the child vectors v_l, v_r and external feature vector e_{out} as shown in Equation (7).

$$\begin{bmatrix} P(h_1|v_l, v_r, e_{out}) \\ \cdots \\ P(h_m|v_l, v_r, e_{out}) \end{bmatrix} = softmax\left(\beta S \begin{bmatrix} v_l \\ v_r \\ e_{out} \end{bmatrix}\right) \quad (7)$$

where $S \in \Re^{m\times(2d+|e_{out}|)}$ is the parameter matrix.

The external features e_i (e_{in} and e_{out}) of the node v_i consists of three types of features: $Label_l$, $Label_r$ and $DepType_i$. $Label_l$ and $Label_r$ are the labels of the left and right child nodes, respectively. If node v_l is a leaf word, $Label_l$ is the POS of the word v_l. Otherwise, it is the non-terminal symbol of the lowest common parent of descendants of v_l in the constituent tree. For example, the $Label$ of the node combined from 'the' and 'design' in Figure 2(c) is 'NP' which is the lowest common parent of these two words in the constituent tree in Figure 1. $DepType_i$ is the dependency relation for node v_i. If the left and right children of v_i are leaf nodes, it is the direct relation in the dependency tree between them. Otherwise, $DepType_i$ is the relation between head words of the left and right nodes. For instance, in Figure 2(c), let a be the parent of 'is' and 'bad', b is the parent of 'for' and 'me', c is the parent of a and b. $DepType$ of a and b are 'COP' and 'POBJ' that are direct relations between two child nodes in the dependency tree in Figure 2(a). While, $DepType$ of c is 'PREP' that is the dependency relation between two head words 'bad' and 'for'. e_i is a binary vector where the weight of the vector represents the presence of each feature.

We suppose a batch training data consisting of B instances $\{(x^{(1)}, t^{(1)}), \cdots, (x^{(B)}, t^{(B)})\}$, where $x^{(b)}$ and $t^{(b)}$ are the aspect and its sentiment category of b-th instance. Let $y^{(b)}$ be the predicted sentiment category for aspect $x^{(b)}$ by PhraseRNN. The goal is to minimize the loss function which is the sum of the mean of negative log likelihood and L2 regularization penalty in a batch training set as in Equation (8).

$$L = -\frac{1}{B}\sum_{b=1}^{B} log(P(y^{(b)} = t^{(b)}|x^{(b)}, \theta)) + \lambda \sum_{\theta_i \in \theta} \| \theta_i \|^2 \quad (8)$$

where λ is a constant controlling the degree of penalty, θ is all the parameters in the model.

Stochastic gradient descent is used to optimize the loss function. Backpropagation is employed to propagate the errors from the top node to the leaf nodes. The derivatives of parameters are used to update the parameters.

4 Evaluation

We use the restaurant reviews dataset in SemEval2014 Task 4 consisting of over 3000 English sentences. For each aspect, "positive", "negative" or "neutral" is annotated as its polarity. Dataset is divided into three parts: 70% training, 10% development and 20% test.

We compare the following methods:

ASA w/o RE: It defines a sentiment score of a given aspect as the weighted sum of opinion scores of all words in the sentence, where the weight is defined by the distance from the aspect (Liu and Zhang, 2012; Pang and Lee, 2008).

ASA with RE: It improves "ASA w/o RE" by firstly identifying the aspect-opinion relations using tree kernel, then integrating them to the sentiment calculation (Nguyen and Shirai, 2015a).

RNN: It uses only one global function g_1 over the binary dependency tree.

AdaRNN: It uses multi-composition functions $G = \{g_1, \cdots, g_n\}$ over a binary dependency tree (Dong et al., 2014a).

PhraseRNN-1: our PhraseRNN with only one global function: $G = H = g_1$

PhraseRNN-2: our PhraseRNN with two global functions. One for inner-phrase, the other for outer-phrase: $G = g_1$ and $H = h_1$

PhraseRNN-3: our PhraseRNN with multiple global functions: $G = H = \{g_1, \cdots, g_n\}$

PhraseRNN-4: our PhraseRNN with two lists of global functions. One for inner-phrase, the other for outer-phrase: $G = \{g_1, \cdots, g_n\}$ and $H = \{h_1, \cdots, h_m\}$

Stanford CoreNLP (Manning et al., 2014) is used to parse the sentence and obtain constituent and dependency trees. For RNN, AdaRNN and PhraseRNN, the optimal parameters, which minimize the error in the development set, are used for the sentiment classification of the test set. We set $\beta = 1$ for AdaRNN and PhraseRNN since it is reported that $\beta = 1$ is the best parameter (Dong et al., 2014a). The optimized number of composition functions n and $m = \frac{n}{2}$ are selected by grid search with $n = \{2, 4, 6, 8, 10\}$ on the development set. $\lambda = 0.0001$ is employed. Accuracy (**A**), Precision (**P**), Recall (**R**) and F-measure (**F**) are used as evaluation metrics [3].

Table 1 shows the results of the methods. Differences of PhraseRNN and RNN are verified by statistical significance tests. We use the paired randomization test because it does not require additional assumption about distribution of outputs (Smucker et al., 2007). The results indicate that four variations of our PhraseRNN outperform "ASA w/o RE", "ASA with RE", RNN and AdaRNN methods from 5.35% to 19.44% accuracy and 8% to 16.48% F-measure. Among four variations, PhraseRNN-2 and PhraseRNN-3 achieved the best performance. By using different global functions in the inner and outer phrases, PhraseRNN-2 improves PhraseRNN-1 by 2.54% F-measure while keeping the comparable accuracy. Using multi-composition functions is also effective since PhraseRNN-3 was better than PhraseRNN-1 by 1.55% accuracy. PhraseRNN-4 improved PhraseRNN-3 by 6.38% precision while keeping comparable in other metrics.

Since our PhraseRNN-1 and PhraseRNN-3 outperform RNN and AdaRNN (the models relying on the binary dependency tree) respectively, we can conclude that our target dependent binary phrase dependency tree is much effective than binary dependency tree for ABSA.

In the data used in (Dong et al., 2014a), one sentence contains only one aspect. On the other hand, two or more aspects can be appeared in one sentence in SemEval 2014 data. It is common in the real text. To examine in which cases our method is better than the others, we conduct an additional experiment by dividing the test set into three disjoint subsets. The first subset (**S1**) contains sentences having only one aspect. The second subset (**S2**) and third subset (**S3**) have two or more aspects in each sentence. All aspects in a sentence in S2 have the same sentiment category, while different sentiment categories in S3. The number of aspects in S1, S2 and S3 are 200, 323 and 187, respectively.

[3] Precision, Recall and F-measure are the average for three polarity categories weighted by the number of true instances.

Table 1: Results of ABSA

Methods	A	P	R	F
ASA w/o RE	46.76	54.63	46.76	48.06
ASA with RE	52.39	53.91	52.39	52.54
RNN	60.85	53.59	60.85	54.21
AdaRNN	60.42	36.78	60.42	45.73
PhraseRNN-1	64.65†	58.59†	64.65†	59.67*
PhraseRNN-2	63.94†	**62.40***	63.94†	**62.21***
PhraseRNN-3	**66.20***	53.88	**66.20***	59.32*
PhraseRNN-4	65.92*	60.26†	65.92*	59.80*

Notes: Statistical significance test of PhraseRNN comparing to RNN.
* Significant at the 1 percent level.
† Significant at the 5 percent level.

Table 2: The Number of Correctly Identified Aspects in Subsets S1, S2 and S3

Methods	S1	S2	S3
ASA w/o RE	98 (49.00)	156 (48.30)	78 (41.71)
ASA with RE	111 (55.50)	176 (54.49)	85 (45.45)
RNN	123 (61.50)	226 (69.97)	83 (44.39)
AdaRNN	117 (58.50)	234 (72.45)	78 (41.71)
PhraseRNN-1	**129** (**64.50**)	248 (76.78)	82 (43.85)
PhraseRNN-2	125 (62.50)	247 (76.47)	82 (43.85)
PhraseRNN-3	125 (62.50)	**257** (**79.57**)	88 (47.06)
PhraseRNN-4	128 (64.00)	250 (77.40)	**90** (**48.13**)

Table 2 shows the number of aspects where their sentiments are correctly identified by the methods in the subsets S1, S2 and S3. The accuracies are also shown in parentheses. Among three subsets, S3 is the most difficult and ambiguous case. In all methods, the performance in S3 is worse than S1 and S2. Comparing with other methods in each subset, PhraseRNN improves the accuracy in S2 more than in S1 and S3.

5 Conclusion

We proposed PhraseRNN to identify the sentiment of the aspect in the sentence. Propagating the semantics through the binary dependency tree in RNN and AdaRNN could not be enough to represent the sentiment of the aspect. A new hierarchical structure was constructed by integrating the dependency relations and phrases. The results indicated that our PhraseRNN outperformed "ASA w/o RE", "ASA with RE", RNN and AdaRNN.

Abstract

This paper introduces **ASTD**, an Arabic social sentiment analysis dataset gathered from Twitter. It consists of about 10,000 tweets which are classified as objective, subjective positive, subjective negative, and subjective mixed. We present the properties and the statistics of the dataset, and run experiments using standard partitioning of the dataset. Our experiments provide benchmark results for 4 way sentiment classification on the dataset.

1 Introduction

Arabic sentiment analysis work is gaining large attention nowadays. This is mainly due to the need of a product that can utilize natural language processing technology to track and analyze the public mood through processing social data streams. This calls for using standard social sentiment analysis datasets. In this work we present **ASTD** (**A**rabic **S**entiment **T**weets **D**ataset) an Arabic social sentiment analysis dataset gathered from Twitter. We discuss our method for gathering and annotating the dataset, and present its properties and statistics through the following tasks: (1) 4 way sentiment classification (2) Two stage class classification; and (3) sentiment lexicon generation. The contributions in this work can be summarized as:

1. We present an Arabic social dataset of about 10k tweets for subjectivity and sentiment analysis gathered from.
2. We investigate the properties and the statistics of the dataset and provide standard splits for balanced and unbalanced settings of the dataset.
3. We present a set of benchmark experiments to the dataset to establish a baseline for future comparisons.
4. We make the dataset and the used experiments publicly available[1].

2 Related Work

The detection of user sentiment in texts is a recent task in natural language processing. This task is gaining a large attention nowadays due to the explosion in the number of social media platforms and the number of people using them. Some Arabic sentiment datasets have been collected (see Table 1). (Abdul-Mageed et al., 2014) proposed the SAMAR system that perform subjectivity and sentiment analysis for Arabic social media where they used different multi-domain datasets collected from Wikipedia TalkPages, Twitter, and Arabic forums. (Aly and Atiya, 2013) proposed LABR, a book reviews dataset collected from GoodReads. (Rushdi-Saleh et al., 2011) presented an Arabic corpus of 500 movie reviews collected from different web pages. (Refaee and Rieser, 2014) presented a manually annotated Arabic social corpus of 8,868 Tweets and they discussed the method of collecting and annotating the corpus. (Abdul-Mageed and Diab, 2014) proposed SANA, a large-scale, multi-domain, and multi-genre Arabic sentiment lexicon. The lexicon automatically extends two manually collected lexicons HUDA (4,905 entries) and SIFFAT (3,325 entries). (Ibrahim et al., 2015) built a manual corpus of 1,000 tweets and 1000 microblogs and used it for sentiment analysis task. (ElSahar and El-Beltagy, 2015) introduced four datasets in their work to build a multi-domain Arabic resource (sentiment lexicon). (Nabil et al., 2014) and (El-Sahar and El-Beltagy, 2015) proposed a semi-supervised method for building a sentiment lexicon that can be used efficiently in sentiment analysis.

Total Number of conflict free tweets	10,006
Subjective positive tweets	799
Subjective negative tweets	1,684
Subjective mixed tweets	832
Objective tweets	6,691

Table 2: Twitter dataset statistics

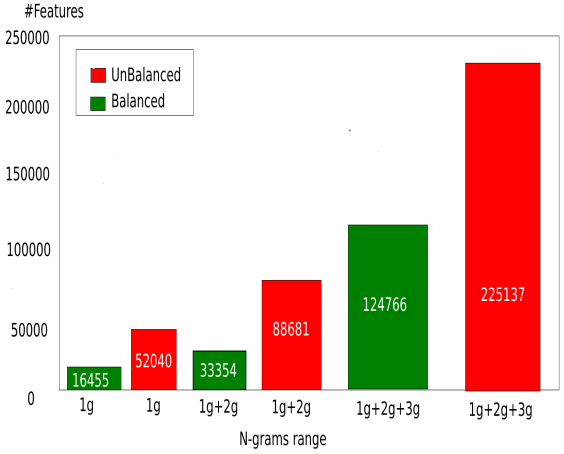

Figure 3: **Feature Counts.** Number of unigram, bigram, and trigram features per each class category.

3 Twitter Dataset

3.1 Dataset Collection

We have collected over 84,000 Arabic tweets. We downloaded the tweets over two stages: In the first stage we used SocialBakers [2] to determine the most active Egyptian Twitter accounts. This gave us a list of 30 names. We got the recent tweets of these accounts till November 2013, and this amounted to about 36,000. In the second stage we crawled EgyptTrends [3], a Twitter page for the top trending hash tags in Egypt. We got about 2500 distinct hash tags which are used again to download the tweets. We ended up obtaining about 48,000 tweets. After filtering out the non-Arabic tweets, and performing some pre-processing steps to clean up unwanted content like HTML, we ended up with 54,716 Arabic tweets.

3.2 Dataset Annotation

We used Amazon Mechanical Turk (**AMT**) service to manually annotate the data set through an API called Boto[4]. We used four tags: objective, subjective positive, subjective negative, and subjective mixed. The tweets that are assigned the same rating from at least two raters were considered as conflict free and are accepted for further processing. Other tweets that have conflict from all the three raters were ignored. We were able to label around 10k tweets. Table 2 summarizes the statistics for the conflict free ratings tweets.

3.3 Dataset Properties

The dataset has 10,006 tweets. Table 2 contains some statistics gathered from the dataset. The histogram of the class categories is shown in Fig. 1,

Avg. tokens per tweet	16
Number of tokens	160,206
Number of vocabularies	38,743

Table 3: **Twitter Dataset Statistics**..

where we notice the unbalance in the dataset, with much more objective tweets than positive, negative, or mixed. Fig. 2 shows some examples from the data set, including positive, negative, mixed ,and objective tweets.

4 Dataset Experiments

In this work, we performed a standard partitioning to the dataset then we used it for the sentiment polarity classification problem using a wide range of standard classifiers to perform 4 way sentiment classification.

4.1 Data Preparation

We partitioned the data into training, validation and test sets. The validation set is used as a mini-test for evaluating and comparing models for possible inclusion into the final model. The ratio of the data among these three sets is 6:2:2 respectively.

Fig. 4 and Table 4 show the number of tweets for each class category in the training, test, and validation sets for both the balanced and unbalanced settings. Fig. 3 also shows the number of n-gram counts for both the balanced and unbalanced settings.

4.2 4 Way Sentiment Classification

We explore using the dataset for the same set of experiments presented in (Nabil et al., 2014) by applying a wide range of standard classifiers on the balanced and unbalanced settings of the dataset. The experiment is applied on both the token counts and the Tf-Idf (token frequency inverse document frequency) of the n-grams. Also we used the same accuracy measures for evaluating our results which are the weighted accuracy and the weighted F1 measure.

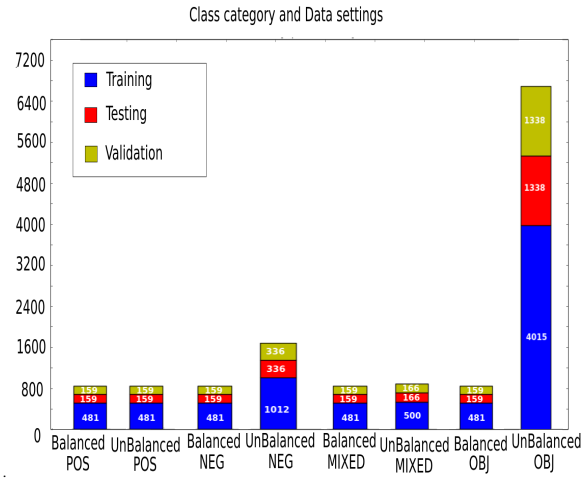

Figure 4: **Dataset Splits.** Number of tweets for each class category for training, validation, and test sets for both balanced and unbalanced settings.

Table 5 shows the result for each classifier after training on both the training and the validation set and evaluating the result on the test set (i.e. the train:test ratio is 8:2). Each cell has numbers that represent **weighted accuracy / F1 measure** where the evaluation is performed on the test set. All the experiments were implemented in Python using Scikit Learn[5]. Also the experiments were performed on a machine with Intel® Core™ i5-4440

Table 5: **Experiment 1: 4 way Classification Experimental Results**. *Tf-Idf* indicates whether tf-idf weighting was used or not. *MNB* is Multinomial Naive Bayes, *BNB* is Bernoulli Naive Bayes, *SVM* is the Support Vector Machine, SGD is the stochastic gradient descent and KNN is the K-nearest neighbor. The numbers represent weighted accuracy / F1 measure where the evaluation is performed on the test set. For example, 0.558/0.560 means a weighted accuracy of 0.558 and an F1 score of 0.560.

CPU @ 3.10GHz (4 cores) and 16GB of RAM.

From table 5 we can make the following observations:

1. The 4 way sentiment classification task is more challenging than the 3 way sentiment classification task. This is to be expected, since we are dealing with four classes in the former, as opposed to only three in the latter.

2. The balanced set is more challenging than the unbalanced set for the classification task. We believe that this because the the balanced set contains much fewer tweets compared to the unbalanced set. Since having fewer training examples create data sparsity for many n-grams and may therefore leads to less reliable classification.

3. SVM is the best classifier and this is consistent with previous results in (Aly and Atiya, 2013) suggesting that the SVM is reliable choice.

5 Conclusion and Future Work

In this paper we presented **ASTD** an Arabic social sentiment analysis dataset gathered from twitter. We presented our method of collecting and annotating the dataset. We investigated the properties and the statistics of the dataset and performed two set of benchmark experiments: (1) 4 way sentiment classification; (2) Two stage classification. Also we constructed a seed sentiment lexicon from the dataset. Our planned next steps include:

1. Increase the size of the dataset.

2. Discuss the issue of unbalanced dataset and text classification.

3. Extend the generated method either automated or manually.

Adjective Intensity and Sentiment Analysis

Raksha Sharma, Mohit Gupta, Astha Agarwal, Pushpak Bhattacharyya
Dept. of Computer Science and Engineering
IIT Bombay, Mumbai, India
{raksha,mohitgupta,astha11,pb}@cse.iitb.ac.in

Abstract

For fine-grained sentiment analysis, we need to go beyond zero-one polarity and find a way to compare adjectives that share a common semantic property. In this paper, we present a semi-supervised approach to assign intensity levels to adjectives, *viz. high, medium* and *low*, where adjectives are compared when they belong to the same semantic category. For example, in the semantic category of EXPERTISE, *expert, experienced* and *familiar* are respectively of level *high, medium* and *low*. We obtain an overall accuracy of 77% for intensity assignment. We show the significance of considering intensity information of adjectives in predicting star-rating of reviews. Our intensity based prediction system results in an accuracy of 59% for a 5-star rated movie review corpus.

1 Introduction

Sentence intensity becomes crucial when we need to compare sentences having the same polarity orientation. In such scenarios, we can use intensity of words to judge the intensity of a sentence. Words that bear the same semantic property can be used interchangeably to upgrade or downgrade the intensity of the expression. For example, *good* and *outstanding* both are positive words from the QUALITY category, but the latter can be used to intensify positive expression in a sentence.

There are several manually or automatically created lexical resources (Liu, 2010; Wilson et al., 2005b; Wilson et al., 2005a; Taboada and Grieve, 2004) that assign a fixed positive (+1) or negative (−1) polarity to words, making no distinction among them in terms of their intensity. This paper presents a semi-supervised approach to assign intensity levels to adjectives, *viz. high, medium* and *low*, which share the same semantic property. We have used the semantic frames of FrameNet-1.5 (Baker et al., 1998) to obtain these semantic categories. Our approach is based on the idea that the most intense word has higher contextual similarity with *high* intensity words than with *medium* or *low* intensity words. We use the intensity annotated movie review corpus to obtain the most intense word for a semantic category. Then, cosine similarity between word vectors of the most intense word and other words of the category is used to assign intensity levels to those words. Our approach with the used resources is shown in figure 1.

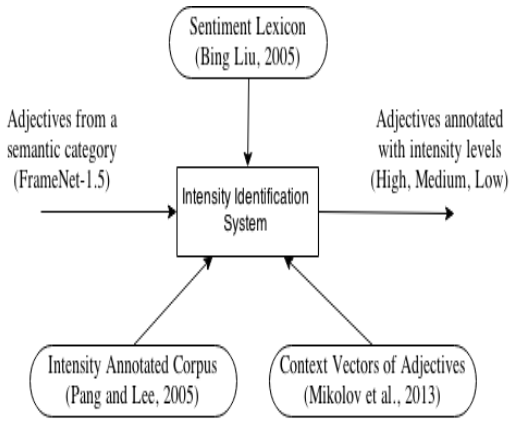

Figure 1: Intensity Analysis System

Our Contribution: Corpus based approaches suffer from the data sparsity problem. Our approach tackles this problem by using word vectors for intensity assignment (Section 2.3). It also provides a better overall accuracy (77%) than current state of the art when compared with gold-standard intensity levels (Section 6.2). In addition to this, we show that accuracy of the star rating prediction task improves when we incorporate our intensity levels as features in addition to standard features such as unigrams (Section 6.3).

Lisbon, Portugal, 17-21 September 2015.

2 Idea Used for Deriving Adjectival Scale

In this paper, we dealt with 52 semantic (polar) categories of the FrameNet data and derived the polarity-intensity ordering among adjectives for each category. Examples of these semantic categories with a few words that belong to the category are as follows.

- INTELLIGENCE: *Brainy, brainless, intelligent, smart, dim etc*.
- CANDIDNESS: *Honest, dishonest, trustworthy, reliable, gullible etc*.
- EMOTION: *Sad, upset, appalled, tormented, gleeful, happy, pleased etc*.

Our algorithm to assign intensity levels to adjectives is based on the following ideas:

2.1 What Does Intensity Annotated Corpus Tell About The Intensity of Words?

Rill et al. (2012) showed that an intensity annotated polar corpus can be used to derive the intensity of the adjectives. A high intensity word will occur more frequently in high intensity reviews. For example, the word *excellent* is found 118 times, while *average* is found only 16 times in 5-star rated movie reviews (Section 3). Based on this distribution, we use a weighted mean formula to find intensity of the words from the corpus. We call it **Weighted Normalized Polarity Intensity (WNPI)** formula. For a 5-star intensity rating corpus, the $WNPI$ formula is as follows:

$$WNPI(word) = \frac{\sum_{i=1}^{5} i * C_i}{5 * \sum_{i=1}^{5} C_i} \quad (1)$$

where C_i is the count of the $word$ in i-star reviews.

2.2 Need Significant Occurrence of A Word

The $WNPI$ formula gives a corpus based result, hence can give biased scores for words which occur less frequently in the corpus. For example, in our movie review data-set, the word *substandard* occurs only 3 times in the corpus, and these occurrences happen to be in 1-star and 2-star reviews only. Hence, the $WNPI$ formula assigns a higher score to *substandard*. To avoid such a bias, we integrate $WNPI$ formula with Chi-Square test. Sharma and Bhattacharyya (2013) used Chi-Square test to find significant polar words in a domain. We use the same categorical Chi-Square test in our work.

2.3 How to Get Intensity Clue for All Words?

A combination of $WNPI$ formula and Chi-Square test cannot assign intensity scores to adjectives, which are not present in the corpus. To overcome this data sparsity problem, we restrict the use of $WNPI$ formula to identify the most intense word in each category. We explore precomputed context vectors of words, presented by Mikolov et al. (2011) (Section 3), to assign intensity levels to remaining words of the semantic category:

Case-1 Words which have less number of senses: These words will have a limited set of context words. Hence, their context vectors will also be based on these limited words. Example: *excellent, extraordinary, amazing, superb, great etc.*

Case-2 Words which have many senses: These words will have a large set of context words. Hence their context vectors will be based on a set of large number of words. Example: *good, fair, fine, average etc.*

Inferences:

1. Two words expressing similar meaning, and satisfying case-1 will have similar context. Hence, their word vectors will exhibit high cosine similarity. Whereas a word satisfying case-2 will be less similar to a word satisfying case-1.

2. The classical *semantic bleaching theory*[1] states that a word which has less number of senses (possibly one) tends to have higher intensity in comparison to a word having more senses. Considering *semantic bleaching* phenomenon as a base, we deduce that words which satisfy case-1 tend to be *high* intensity words while words satisfying case-2 are *low* intensity words.

Hence, we conclude that *high* intensity words (case-1) have higher *cosine similarity* with each other than with *low* or *medium* intensity words (case-2). Therefore, cosine similarity with a *high* intensity word can be used to obtain intensity ordering for remaining words of the category.

3 Data and Resources

This section gives an overview of the corpus and lexical resources used in our approach.

Semantic Categories: We worked with frames of FrameNet-1.5 (Baker et al., 1998). A frame

[1]The *semantic bleaching phenomenon* in words was reported in US edition of *New York Times*: `http://www.nytimes.com/2010/07/18/magazine/18onlanguage-anniversary.html?\_r=0`

Rating	Definition	Size
0	Totally painful, unbearable picture	179
1	Poor Show (dont waste your money)	1057
2	Average Movie	888
3	Excellent show, look for it	1977
4	A must see film	905

Table 1: Review ratings with their definitions and number of reviews.

represents a semantic property and contains words bearing the property. We explored the FrameNet data manually and found 52 frames (semantic categories) with polar semantic properties.

Intensity Annotated Corpus: To identify a *high* intensity word for a semantic category, we use a movie review corpus[2] (Pang and Lee, 2005) of 5006 files. Each review is rated on a scale of 0 to 4, where 0 indicates *an unbearable movie* and 4 represents *a must see film*. Table 1 describes the meanings of the rating scores with the count of reviews in each rating. We can infer that increase in rating corresponds to increase in positive intensity and decrease in negative intensity.

Sentiment Lexicon: To identify the polarity orientation of words, we use a list of positive (2006) and negative (4783) words[3] (Liu, 2010). We manually assign polarities to universally polar words like *enduring, creditable* and *nonsensical*, which are missing in this lexicon, using other standard lexicons. We found a total of 218 such missing words.

Context Vectors: We use the precomputed context vectors of words generated using Recurrent Neural Network Language Model (RNNLM) (Mikolov et al., 2013). The RNN is trained with $320M$ words from the broadcast news data.

4 Gold Standard Data Preparation

We asked five annotators to assign words to different intensity levels: *high, medium*, and *low*. Annotators were given positive and negative words of each category separately. The level chosen by a majority of annotators is selected as the gold standard intensity level for the word. To compute agreement among five annotators, we used *fleiss' kappa*, and obtained a score of **0.61**.

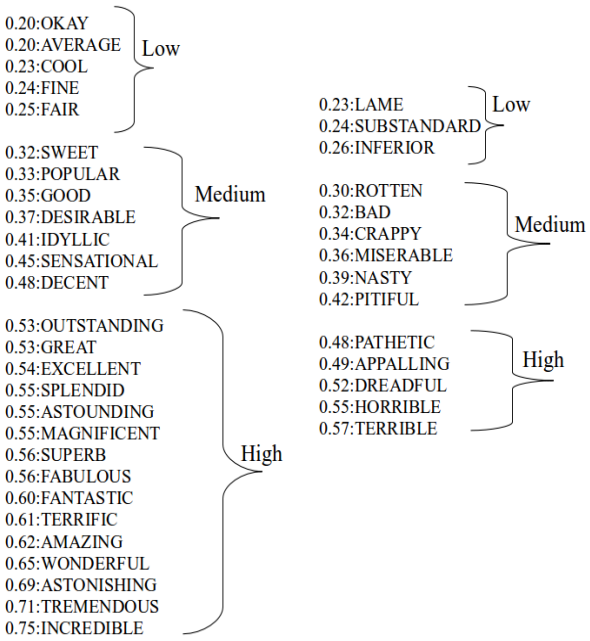

Figure 2: Intensity scale for QUALITY category, where *extraordinary* was found as *Pos-pivot* and *awful* as *Neg-pivot*.

5 Identification of Intensity of Adjectives

In this section, we give a step-by-step description of our approach.

Step 1: Find Intensity of Words

We calculate polarity-intensity of each word of a semantic category using $WNPI$ formula (eq. 1). Based on the polarity orientation of a word, the $WNPI$ formula uses intensity interpretation of star-rating as shown in table 2. The variable i of the $WNPI$ formula refers to these star ratings (intensity levels). The polarity orientation of an observed word is obtained using Bing Liu's lexicon.

Star-Rating / Word-Orientation	0	1	2	3	4
Positive	1	2	3	4	5
Negative	5	4	3	2	1

Table 2: Interpretation of star rating as intensity scores of reviews for positive and negative words.

Step 2: Find Pivot Using Chi-Square Test

The word which gives the highest Chi-Square

[2]Written and rated by four authorized movie critics. Available at: `http://www.cs.cornell.edu/people/pabo/movie-review-data/`

[3]Available at: `http://www.cs.uic.edu/~liub/FBS/sentiment-analysis.html\#datasets`

score with the highest intensity score as per $WNPI$ is set as *pivot* (*Pos-pivot* and *Neg-pivot*). The Chi-Square test helps us to exclude the biased words, which are getting high intensity scores by the $WNPI$ formula, just by chance (Section 2.2).

Step 3: Obtain Similarity Scores with Pivot Further, we compute the *cosine similarity* between the context vectors of the pivot and the other words of the category. We use *Pos-pivot*, if the observed word is positive and *Neg-pivot*, if the observed word is negative.

Step 4: Assign Intensity Level to Words Finally, we arrange similarity scores obtained above in decreasing order, and place 2 break points in the sequence where consecutive similarity scores differ the most. We set these breakpoints as the thresholds for intensity levels.

Figure 2 shows the intensity scale obtained by our approach for the QUALITY category, where *extraordinary* was found as *Pos-pivot* and *awful* as *Neg-pivot*.

6 Experiments And Results

To evaluate the performance of our approach, we consider three measures: accuracy with the gold-standard data, comparison with state of the art and accuracy for the *star rating prediction task*.

6.1 Evaluation Using Gold Standard Data

We compute accuracy as the fraction of adjectives for which the predicted intensity level is the same as the gold standard level. We obtained an overall accuracy of 77% across 52 polar categories, containing a total of 697 adjectives.

6.2 Comparison with State of The Art

Ruppenhofer et al. (2014) showed that a corpus based method called MeanStar approach performs the best for intensity ordering task among existing approaches (De Melo and Bansal, 2013; Kim and de Marneffe, 2013; Fahrni and Klenner, 2008; Dragut et al., 2010) for polar semantic categories. Figure 3 shows the comparison between MeanStar and our approach for four semantic categories[4]. For first three categories, our approach performs better than MeanStar and for EXPERTISE we obtain the same level of accuracy. MeanStar approach gives an overall accuracy of 73% across 52 polar categories, which is significantly lesser than the accuracy obtained with our approach. MeanStar approach does not assign intensity score to words missing from the corpus. While, 88 out of 122 missing words are assigned correct intensity levels by our approach.

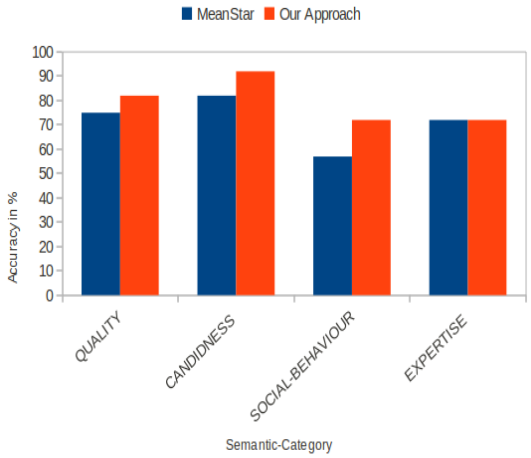

Figure 3: Accuracy obtained with MeanStar and our approach

6.3 Evaluation Using Star Rating Prediction

There have been several successful attempts at sentiment polarity detection in the past (Turney, 2002; Pang et al., 2002; Pang and Lee, 2004; Mohammad et al., 2013; Svetlana Kiritchenko and Mohammad, 2014). However, prediction of star ratings still considered as a challenging task (Qu et al., 2010; Gupta et al., 2010; Boteanu and Chernova, 2013). We implemented three systems to evaluate the significance of intensity annotated adjectives in star rating prediction task.

System 1: A rule based system based on the concept that *negatively high intense* words will occur more frequently in the *low star reviews* and *positively high intense* words will occur more frequently in the *high star reviews*. This system uses the following function I to assign intensity score to a review r:

$$I(r) = \frac{\sum_{i=1}^{3} i * C_i^P - \sum_{i=1}^{3} i * C_i^N}{3 * (\sum_{i=1}^{3} C_i^P + \sum_{i=1}^{3} C_i^N)} \quad (2)$$

where C_i^P and C_i^N respectively represent sum of the term-frequencies of positive and negative adjectives with intensity i.

Eq. 2 gives us an intensity score between -1 and $+1$ for each review. We need four breakpoints on these intensity scores to map intensity scores

[4]We have used the same semantic categories and intensity annotated movie review corpus in our work as used by Ruppenhofer et al. (2014).

into 5-star ratings. We learn these breakpoints by maximizing accuracy for the training data[5] over all possible breakpoints.

System 2: In this system, we consider intensity of each adjective as $+1$ or -1 as per its polarity, and then uses eq. 2 to find review intensity.

System 3: This is an SVM based system which uses four different types of features: (a) unigrams, (b) unigrams with the modification that if adjective belongs to our intensity annotated adjective list, then feature value is intensity of the adjective, (c) and (d) use the scores coming from eq. 2 as an additional feature over those in (a) and (b) respectively.

System	Accuracy(%)	MSE	MAE
1	42.28	0.94	0.69
2	27.33	1.12	0.86
3(a)	55.81	0.63	0.50
3(b)	57.21	0.56	0.47
3(c)	58.71	0.57	0.46
3(d)	**59.21**	**0.54**	**0.45**

Table 3: Comparison of rating prediction systems, where MSE is the Mean Squared Error and MAE is the Mean Absolute Error

Table 3 shows the results obtained with the above systems. System 3(d) achieves the maximum accuracy depicting that inclusion of intensity information with the standard features improves the star rating prediction significantly.

7 Related Work

Sentiment analysis on adjectives has been extensively explored in NLP literature. However, most of the works addressed the problem of finding polarity orientation of adjectives (Hatzivassiloglou and McKeown, 1997; Wiebe, 2000; Fahrni and Klenner, 2008; Dragut et al., 2010). The first work in the direction of adjectival scale was done by Hatzivassiloglou and McKeown (1993). They exploited linguistic knowledge available in the corpora to compute similarity between adjectives. However, their approach did not consider polarity orientation of adjectives, they provided ordering among non-polar adjectives like, *cold, lukewarm, warm, hot*.

[5]We use 80% of the star-rated movie review corpus as training data and 20% as test data. The results reported in table 3 are based on the 20% test data.

The task of ordering adjectives according to their polarity-intensity has recently received much attention due to the vital role of intensity analysis in several real world tasks. Kim et al. (2013) interpreted the continuous space word representation by demonstrating that vector off-set can be used to derive scalar relationship amongst adjectives. Their approach provided relationship among all the adjectives independent of their semantic property. De Melo and Bansal (2013) used a pattern based approach to identify intensity relation among adjectives, but their approach had a severe coverage problem. They also did not consider the semantic property of adjectives, assuming one single intensity-scale for all adjectives.

Ruppenhofer et al. (2014) provided ordering among polar adjectives that bear the same semantic property. Their approach was completely corpus dependent, it was not able to derive intensity of those adjectives which were not found in the corpus. We have used the same star-rated movie review corpus in our work as used by Ruppenhofer et al. (2014) and found 122 polar adjectives which are absent from the corpus. Our system is able to identify intensity levels for these missing adjectives. Moreover, we obtained an improvement of 4% in overall accuracy.

8 Conclusion

In this paper, we have proposed an approach that assigns intensity levels to domain independent adjectives, *viz. high, medium* and *low*. The important feature of our approach is that it is not fully corpus dependent, hence is able to assign intensity to adjectives that are absent in the corpus. We have reported that the overall results are better than the recently reported corpus based approach and fairly close to human agreement on this challenging task.

The use of adjectives with their intensity information can enrich existing sentiment analysis systems. We have shown the significance of considering intensity information of adjectives in predicting the intensity of movie reviews.

The Rating Game: Sentiment Rating Reproducibility from Text

Lasse Borgholt, Peter Simonsen, Dirk Hovy
Center for Language Technology
University of Copenhagen
{fkr838|cbl123}@alumni.ku.dk, dirk.hovy@hum.ku.dk

Abstract

Sentiment analysis models often use ratings as labels, assuming that these ratings reflect the sentiment of the accompanying text. We investigate *(i)* whether human readers can infer ratings from review text, *(ii)* how human performance compares to a regression model, and *(iii)* whether model performance is affected by the rating "source" (i.e. original author vs. annotator). We collect IMDb movie reviews with author-provided ratings, and have them re-annotated by crowdsourced and trained annotators. Annotators reproduce the original ratings better than a model, but are still far off in more than 5% of the cases. Models trained on annotator-labels outperform those trained on author-labels, questioning the usefulness of author-rated reviews as training data for sentiment analysis.

1 Introduction

Machine learning approaches have become the dominant paradigm for sentiment analysis since introduced by Pang et al. (2002). While these approaches produce good results, they need to be trained on sufficiently large labeled data sets. Since human annotation can be both slow and expensive, many studies use data with an inherent subjectivity indicator, such as movie or product reviews with user ratings (Dave et al., 2003; Pang and Lee, 2005; Snyder and Barzilay, 2007; Elming et al., 2014, i.a.). While it is a fair assumption that the *rating* expresses the author's attitude towards the subject, it is less obvious to what extent the review *text* reflects this attitude, and hence what the relation between text and rating is. In this study, we ask

(i) whether readers are able to infer the author's numerical rating based on the author's review text,

(ii) how well learning algorithms perform on the task compared to human readers, and

(iii) whether model performance is affected by the rating source used for labeling (i.e. how the numerical rating is obtained) .

In order to investigate these questions, we compile a data set of user-generated movie reviews with *author ratings* and collect both *crowdsourced annotator ratings* and *trained annotator ratings*. This setup allows us to evaluate the reproducibility of ratings for both humans and models.

We address *(i)* by comparing author ratings to crowdsourced and trained annotator ratings. Author ratings supposedly capture the essence of the author's sentiment, but we do not expect annotators to perfectly reproduce these ratings based on text alone.

We investigate *(ii)* by evaluating a linear regression model on author-labeled data. Sentiment analysis models supposedly emulate the cognitive process of text-based rating inference. The gap between human and model performance is interesting, because if human annotators are unable to consistently infer author ratings, we cannot expect learning algorithms to achieve this goal.

Finally, we address *(iii)* by comparing regression models trained on data labeled with crowdsourced and author ratings. Existing work treats both labeling sources as ontologically interchangeable. That is, it does not matter whether a text was labeled by the author in the process of writing said text, or by an annotator who has been paid to label the text a posteriori. This is not at all self-evident.

To the best of our knowledge, no previous study has investigated the assumption that the sentiment of a text can be objectively inferred. Since sentiment analysis is still far from being solved, investigating this core bias can help address current limitations.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2527–2532,
Lisbon, Portugal, 17-21 September 2015.

2 Data

We collect 2,000 user-generated IMDb movie reviews and randomly sample 200 authors, each contributing 10 reviews of a length between 800 and 2,000 characters. All reviews are rated on a 10-point scale. Some authors mention their rating in the review text. This mention is of course an unwanted clue for the annotators, why we remove these reviews.

We pay annotators on CrowdFlower to rate the semantic orientation of reviews on a scale from 1 (negative) to 10 (positive). Each review is labeled by five experienced annotators. Overall, 171 annotators participated in the task. We incorporate control items in the annotation task, and each annotator starts by completing eight of these test questions. Further test questions are inserted randomly throughout the annotation tasks. We define a range of permitted ratings (within two steps of the original author rating). If annotators fall below an accuracy of 70%, they are removed from the project. Reviews used as test questions (10% of the initial data) are not part of the final data set.

We use three trained annotators to rate a 20% subset of the reviews: two authors of this study, and a student. All three annotate the full subset. We use stratified sampling to select the subset, considering each rating as a stratum. The distribution of author ratings in our subset thus matches the distribution of author ratings in the full data set. The subset contains 317 reviews, the full data set 1,629 reviews. Notice that only the subset is used to answer *(i)*, whereas the full data set is used for the regression-based tasks *(ii)* and *(iii)*.

3 Experiments

We want to establish the reproducibility of author ratings from text by human annotators and statistical models. In order to measure performance of the different methods, we use *mean absolute error (MAE)* and *root mean squared error (RMSE)*. While RMSE is more common, MAE is more directly interpretable, as it does not emphasize outliers. For this reason, we focus on MAE in our analysis.

MAE and RMSE measure the proximity between two sets of observations, but we also need a measure of the *relative* movement between observations. For this purpose, we use mainly Spearman's ρ, but also report Krippendorff's α and Cohen's κ. The latter is a standard agreement measure, but does not work as well for ordinal ratings such as these, since it assumes a uniform distribution to compute chance agreement.

We have two sources of human annotations, namely three trained annotators and five crowdsource annotators per review. In order to obtain our final ratings, we average over each of those annotation sources.[1] This result is more robust towards individual biases and misinterpretations. This effect is known as *wisdom of the crowd* and well-documented in the literature, e.g. Steyvers et al. (2009). However, we also wish to investigate how well individual annotators perform. Therefore, we also compute error and pairwise correlation for each individual annotator with the authors or other annotators, and then average over the pairwise comparisons for each annotator type.

This measure is equivalent to a *macro*-score and captures the average influence of individual annotators. When comparing across the two groups of annotators, we use all possible 3x5 combinations.

We use the same measures as outlined above to compare the different annotators to each other within the two groups. Hence, we compute both MAE, RMSE and correlation calculated between the individual crowdsource and trained annotators, respectively.

In order to control for different levels variance in the rating distributions, we *align* the crowdsource annotator and author distribution by sub-sampling. The number of reviews per rating is determined by the distribution with fewer reviews for the given rating. The resulting two data sets contain the same number of reviews per rating, and a total of 1,319 reviews. The main implication of aligning the distributions, is that variance for both distributions will be identical, thus making the comparison more appropriate.

3.1 Model

We use a linear least-squares model with L_2 regularization *(ridge regression)* to reduce overfitting.[2] L_2 imposes a term α, which penalizes the parameters w of the model if they grow too large. Formally, w can be calculated by

$$\min_w \|Xw - y\|_2{}^2 + \alpha \|w\|_2{}^2$$

We also experiment with incorporating a prior,

[1] Aggregating with an item-response model like MACE (Hovy et al., 2013) results in worse estimates, since it requires nominal data.

[2] Experimenting with support vector regression did not yield better results, so we chose the simpler model.

to model the tendency of authors to use the extremes more than predicted by a Gaussian distribution. We use a beta distribution with shape parameters $(0.8, 0.8)$.

We use 10-fold cross validation for robust results, and 5-fold cross validation on each of the then training folds in order to determine the optimal α.

We use bag-of-words features, including all unigrams appearing more than twice in the training data. [3]

4 Results

As baselines, we use the average rating over each of the *entire* rating distributions. Since the distributions differ between author and annotator ratings, the baseline differs from task to task.

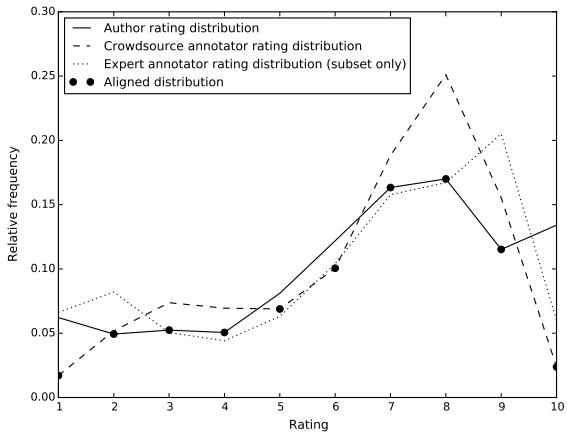

Figure 1. Rating distributions for authors, crowdsourced, and trained annotator ratings. Dots indicate aligned distribution.

Human Rating Inference *(i)* Figure 1 shows the rating distributions of the three human sources. Note the more peaked distributions of both annotator types, as compared to the author distribution. Especially crowdsource annotators have a smaller variance. Furthermore, the author distribution includes more extreme ratings, while the annotator distributions show no such "flaps".

[3]To rule out that the lack of any syntactic information (which human annotators use) disadvantages the model, we also experimented with including dependency triples (*dobj* and *nsubj*, the most frequent dependencies) using the Stanford Parser (Klein and Manning, 2003). However, performance did not improve, so due to limited space, we did not further explore this option.

Trained annotators are more correlated with one another ($\rho = 0.90, \alpha = 0.67, \kappa = 0.34$) than the crowdsource annotators ($\rho = 0.75, \alpha = 0.52, \kappa = 0.09$). Likewise, we see a lower MAE among trained annotators (0.75) than among crowdsource annotators (1.13), indicating a more diverse set of ratings for the latter.

		aut - cs	aut - tr	tr - cs
Corr. (ρ)	Mean	0.84	0.85	0.94
	Ind.	0.71	0.83	0.80
MAE	Mean	0.96	0.96	0.71
	Ind.	1.15	1.05	1.07
RMSE	Mean	1.31	1.30	1.01
	Ind.	1.61	1.44	1.48

Table 1. Pairwise comparisons between author (aut), trained (tr), and crowdsource (cs) ratings.

Table 1 compares the different rating sources. We find a higher correlation and lower error between the two sets of annotator ratings than between the author ratings and any of the annotator ratings. However, when comparing the individual rating correlations, author ratings are highly correlated with trained, but not with crowdsource annnotators, showing the uncertain nature of crowdsource annotators.

There is no discernible difference between the two annotator groups in terms of error margins. 80% of mean annotator ratings, regardless of source, are correctly inferred or one step off. Slightly more than 5% of ratings are more than two steps off. However, comparing *individual* annotator ratings instead of mean ratings, some crowdsource annotators are a full nine steps off, and in a single case, even one of the trained annotators was eight steps off.

	Ridge	+Prior	Aligned
Aut	1.66 / 2.14	1.70 / 2.21	1.52 / 1.95
Base	2.15 / 2.62	2.15 / 2.62	1.85 / 2.24
Ann	1.31 / 1.69	-	1.34 / 1.72
Base	1.85 / 2.23	-	1.85 / 2.24
Ann/Aut	1.60 / 2.05	-	-
Base	2.15 / 2.62	-	-

Table 2. MAEs/RMSEs for baselines and regressors trained and tested on Aut=authors; Ann=crowdsource annotators; Ann/Aut=trained on annotators and tested on authors.

In the next section, we compare the MAE be-

tween author ratings and the two sets of annotator ratings with the performance of the linear model. Conveniently, the numbers for the two types of annotators are equal (0.96), making it unnecessary to distinguish between them.

Human vs. Machine ***(ii)*** Table 2 shows the regression results. Since we want to compare the ability of people and regressors to infer *author ratings* from text, we only look at the *Author* row. Both the full rating distributions and the aligned distribution(s) are presented in Figure 1. All settings easily outperform the baseline.

The regression model achieves an MAE of 1.66, whereas both sets of human annotators achieve a MAE of 0.96 (see Table 1). This is an absolute difference of 0.70 in favor of the annotators. Or, in relative terms: the MAE of the learning algorithm is 72.6% larger than the human MAE.

Author vs. Annotator Labels ***(iii)*** In order to test whether the model is influenced by the label source, we compare the results in the *Author* and *Annotator* rows of Table 2. The regressor performs noticeably better on the annotator ratings than on the author ratings when using the full data set. Just as human annotators, the regressor under-estimates the extreme ratings (i.e., the "flaps"). Even incorporating a prior to address this shortcoming does not increase performance.

The performance difference between the models trained on the aligned distributions is smaller, but still noticeable. This is an important result, indicating that the model's performance drop when trained on authors is not solely due to the variance in the underlying distribution, but to the *quality* of the ratings.

The Ann/Aut row indicates that even if the goal is to predict author ratings, it could still be advantageous to train on annotator-labeled data.

5 Related Work

Since Pang et al. (2002) used author-labeled IMDb user reviews in their seminal study, author-labeled data has been used for a wide range of domains, like user-generated product reviews (Dave et al., 2003), restaurant reviews with several aspect ratings (Snyder and Barzilay, 2007), movie reviews from experienced film critics (Pang and Lee, 2005), business reviews (Hardt and Wulff, 2012; Elming et al., 2014; Hovy, 2015), and many more.

Pang and Lee (2005) also argue that it is unreasonable to expect a learning algorithm to predict ratings on a fine-grained scale if humans are not able to do so. To test this, they presented pairs of movie reviews from a single author rated on a 10-point Likert scale to two subjects (the authors themselves). Subjects had to decide whether one review was more, less, or equally positive than the other. Subjects correctly discerned reviews separated by more than three steps, but accuracy dropped when relative difference decreases. Pang and Lee (2005) also identify three obstacles for humans to accurately infer author ratings, namely *lack of calibration*, *author inconsistency* and *textually unsupported ratings*.

While suitable for their purposes, the study does not answer our research questions. First of all, the experiment is rather small (178 instances), which limits general validity and reliability. Second, the study tests the human ability to discern *relative*, not *absolute differences*. If two reviews rated 7 and 8 are judged a 3 and a 4, the *relative* difference will be correctly identified, even though the guess is far off in absolute terms. Furthermore, single-author reviews dilute the effects of the three aforementioned obstacles. Inconsistencies within a single author are undoubtedly smaller than inconsistencies between multiple authors. Single-author use also affects lack of calibration, since subjects can adjust to the writing style of one author better than that of several. Finally, we expect experienced authors to be less prone to producing reviews that do not support their ratings.

Annotator labels are typically used for phrase-level semantics (Wilson et al., 2005; Wiebe et al., 2005; Socher et al., 2013). Alternatively, labels can be induced from salient sentiment-related features like emoticons (Pak and Paroubek, 2010; Go et al., 2009; Tang et al., 2014) or hashtags (Kouloumpis et al., 2011). Often, the label source tends to be a matter of convenience, rather than theoretical reflection. The lack of considerations regarding potential differences between author and annotator labels implies that these are often perceived as ontologically equivalent. We do not believe this to be the case.

6 Discussion

Human rating inference ***(i)*** We observe some interesting differences between the three rating distributions. First, the "flaps" in the extreme

ratings in the author ratings are not present in the annotator rating distributions. This phenomenon might be explained by the observation that *"the propensity to post online reviews is higher for movies that are perceived by consumers to be exceptionally good or exceptionally bad"* (Dellarocas and Narayan, 2006). However, this tendency does not explain why the flaps are not present in the annotator distributions. One possible explanation is *risk aversion*. An annotator might estimate a review to be between 6 and 10. She might also estimate 10 to be the most likely rating and 6 the least. However, in order to minimize the margin of error, picking 8 is a better option than 6 or 10, since it will ensure the annotator is within two steps of the author's rating. This behavior is especially prevalent with crowdsourced annotators, who have a monetary incentive to minimize their error, which could explain the lack of flaps in *their* distribution. Indeed, the trained annotators show *some* evidence of flaps, but are still less extreme than the authors (i.e. their mean is closer to the center of the scale).

We also want to stress the role of *wisdom of the crowd*. Individual annotators perform worse (with regard to both correlation and MAE) than the mean over all annotators. This holds for both annotator types. Human ability to infer author ratings should thus be seen in light of these results. No individual annotator performed better than the mean of all annotators. The wisdom-of-the-crowd effect might also explain why crowdsource annotators perform as well as trained annotators: using five crowdsourced (vs. three trained) annotators provides more robust estimates to counter sloppy annotators.

We might expect a simple answer to our initial research question whether humans are able to infer author ratings. Of course, this is not the case. Most annotator ratings were within two steps of the original author rating. Only slightly more than 5% were further off. These results indicate that humans in *most* cases are able to infer the original author rating with decent accuracy, if allowed to "work together".

Human vs. Machine ***(ii)*** Based on our results, learning algorithms are *still* worse than humans in detecting semantic orientation of text. This difference holds even though humans, too, fail in a considerable number of cases. Overall, our results provide an upper bound for the performance we can expect from learning algorithms.

Author vs. Annotator Labels ***(iii)*** As hypothesized, using annotator labels lowered the MAE more than using author labels. Presumably, annotator labels follow a more regular, and thus predictable, pattern than author labels, since the former are generated by the reader's interaction with the text.

The aligned-distribution results support this theory. Aligning the distributions controls for different levels of rating variation in the distributions, thus ruling it out as confounder for the MAE difference. The aligned-distribution results also indicate that the model is biased towards mean ratings: MAE improves for author labels, since the relatively high variation is eliminated, but worsens for the annotator labels, as variance increases.

However, alignment also creates problems. First, the reviews contained in the author and annotator data sets differ in 18.6 % of the cases, although this should not be of significant advantage to either set. Second, aligned distributions do not evaluate the natural rating distributions. However, results follow the same trend as when using unmodified distributions (and hence the exact same reviews): annotator labels outperform author labels. All this suggests that annotator labels are more aligned with the text than author labels.

7 Conclusion

We find that readers infer author ratings from the review text fairly accurately (on average less than one step off on a 10-point scale). However, in more than 5% of the cases, the annotators were off by at least three points.

Human annotators outperform a linear regression model, even when adding a prior. We believe that no trivial adjustments can bridge this gap. However, the model achieves better results using annotator rather than author ratings, even when controlling for rating variance as a confounding factor. This suggests that author ratings are *not* optimal data labels for text-based sentiment analysis models.

Abstract

We present the Trip-MAML dataset, a Multi-Lingual dataset of hotel reviews that have been manually annotated at the sentence-level with Multi-Aspect sentiment labels. This dataset has been built as an extension of an existent English-only dataset, adding documents written in Italian and Spanish. We detail the dataset construction process, covering the data gathering, selection, and annotation. We present inter-annotator agreement figures and baseline experimental results, comparing the three languages. Trip-MAML is a multi-lingual dataset for aspect-oriented opinion mining that enables researchers (i) to face the problem on languages other than English and (ii) to the experiment the application of cross-lingual learning methods to the task.

1 Introduction

Reviews of products and services that are spontaneously produced by customers represent a source of unquestionable value not only for marketing strategies of private companies and organizations, but also for other users since their purchasing decisions are likely influenced by other customers' opinions (Chevalier and Mayzlin, 2006).

Overall ratings (e.g., in terms of a five stars rating scale), and also aspect-specific ratings (e.g., the Cleanliness or Location of a hotel), are the typical additional information expressed by customers in their reviews. Those ratings help to derive a number of global scores to facilitate a first screening of the product or service at hand. Notwithstanding, users who pay more attention to a particular aspect (e.g., the Rooms of a hotel) remain constrained to manually inspect the entire text of reviews in order to find out the reasons other users argued in that respect. Methods for automatic analysis of the aspect-oriented sentiment expressed in reviews would enable highlighting aspect-relevant parts of the document, so as to allow users to perform a faster and focused inspection of them.

Previous work on opinion mining (Pang and Lee, 2008) has already faced the overall sentiment prediction (Pang et al., 2002), multiple aspect-oriented analysis (Hu and Liu, 2004), and fine-grained phrase-level analysis (Wilson et al., 2009). Most of the available opinion mining datasets contain only documents written in English, as this language is the most used on the Internet and the one for which more NLP tools and resources are available. (Hu and Liu, 2004) worked on the summarization of reviews by means of weakly supervised feature mining. (Täckström and McDonald, 2011) used a finer-grained dataset in which global polarity annotation is applied also to each sentence composing the document. Similarly did (Socher et al., 2013) with the Stanford Sentiment Treebank, which annotates each syntactically plausible phrase in thousands of sentences using annotators from Amazon's Mechanical Turk, annotating the polarity of phrases on a five-level scale. (Lazaridou et al., 2013) performed a single-label polarity annotation of elementary discourse units of TripAdvisor reviews, adopting ten aspect labels. (Marcheggiani et al., 2014) did a similar annotation work, using sentences as the annotation elements and adopting a multi-label polarity annotation, i.e., each sentence can be assigned to zero, one, or more than one aspect.

Cross-lingual sentiment classification (Wan, 2009; Prettenhofer and Stein, 2011) explores the scenario in which training data are available for

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2533–2538,
Lisbon, Portugal, 17-21 September 2015.

a language that is different from the language of the test documents. Cross-lingual learning methods have important practical applications, since they allow to build classifiers for many languages reusing the training data produced for a single language (typically English), probably giving up a bit of accuracy, but compensating it with a large save in terms of human annotation costs.

Multi-lingual datasets are beneficial to the research community both as a benchmark to explore cross-lingual learning and also as resources on which to develop and test new NLP tools for languages other than English. Prettenhofer and Stein (2010) used a multi-lingual dataset focused on full-document classification at the global polarity level. Denecke (2008) used a dataset of 200 Amazon reviews in German to test cross-lingual document polarity classification using an English training set. Klinger and Cimiano (2014) produced a bi-lingual dataset (English and German), named USAGE, in which aspect expressions and subjective expressions are annotated in Amazon product reviews. In (Klinger and Cimiano, 2014) aspect expressions can be any piece of text that mentions a relevant property of the reviewed entity (e.g., *washer, hose, looks*) and are not categorical label, as in our dataset. The USAGE dataset is thus more oriented at information extraction rather than at text classification applications. Banea et al. (2010) used machine translation to create a multilingual version of the information-extraction oriented MPQA dataset (Wiebe et al., 2005) on six languages (English, Arabic, French, German, Romanian and Spanish).

In this paper we present Trip-MAML, which extends the Trip-MA[1] dataset of Marcheggiani et al. (2014) with Italian and Spanish annotated reviews. We describe Trip-MAML and report experiments aimed at defining a first baseline. Both the dataset and the software used in experiments are publicly available at `http://hlt.isti.cnr.it/trip-maml/`.

2 Annotation Process

We recall the annotation process adopted by Marcheggiani et al. (2014) for Trip-MA and the procedure we employed to extend it into Trip-MAML. We will use the national codes EN, ES, and IT, to denote the English, Spanish, and Italian parts of the Trip-MAML dataset, respectively. Note that EN coincides with Trip-MA.

2.1 English Reviews

The Trip-MA dataset was created by Marcheggiani et al. (2014) by annotating a set of 442 reviews, written in English, randomly sampled from the publicly available TripAdvisor dataset of Wang et al. (2010), composed by 235,793 reviews. Each review comes with an overall rating on a discrete ordinal scale from 1 to 5 "stars". The dataset was annotated according to 9 recurrent aspects frequently involved in hotel reviews: Rooms, Cleanliness, Value, Service, Location, Check-in, Business, Food, and Building. The last two are not officially rated by TripAdvisor but were added because they are frequently commented in reviews. Two "catch-all" aspects, Other and NotRelated, were also added, for a total of 11 aspect. Aspect Other denotes opinions that are pertinent to the hotel being reviewed, but not relevant to any of the former nine aspects (e.g., generic evaluations like *Pulitzer exceeded our expectations*). Aspect NotRelated denotes opinions that are not related to the hotel (e.g., *Tour Eiffel is amazing*).

If a sentence is relevant to an aspect, the possible sentiment label values are three: Positive, Negative, and Neutral/Mixed[2]. Neutral/Mixed annotates subjective evaluations that are not clearly polarized (e.g., *The hotel was fine with some exceptions*).

2.1.1 Annotation protocol

Marcheggiani et al. (2014) relied on three human annotators to annotate each sentence of the 442 reviews with respect to polarities of opinions that are relevant to any of the 11 aspects. 73 reviews, out of 442, were independently annotated by all the annotators in order to measure the inter-annotator agreement, while the remaining 369 reviews were partitioned into 3 equally-sized sets, one for each annotator. Bias in the estimation of inter-annotator agreement was minimized by sorting the list of reviews of each annotator so that every eighth review was common to all annotators; this ensured that each annotator had the same amount of coding experience when labeling the same shared review.

[1] Marcheggiani et al. (2014) gave no name to their dataset, here we name it Trip-MA to identify its source and its multi-aspect nature.

[2] Marcheggiani et al. (2014) initially distinguished between implicit and explicit opinions but the human agreement was so low they removed this distinction from the schema.

	# Reviews	# Sentences	# Opinion-laden sentences
EN	442	5799	4810
ES	500	2620	2400
IT	500	2593	2392

Table 1: Number of reviews, sentences, and sentences with at least one opinion annotation.

2.2 Spanish and Italian Reviews

For the creation of ES and IT parts of the Trip-MAML dataset we followed the same annotation protocol of Marcheggiani et al. (2014), employing teams of three native speakers as annotators for each language. We crawled the Spanish and Italian reviews from TripAdvisor by accessing its websites with the '.es' and '.it' domains, which mostly contains reviews in the national language. From that domains we downloaded the reviews for the 10 most visited cities in Spain and Italy, respectively. We downloaded 10 reviews for every hotel of each city, obtaining a total of 17,020 reviews for Spanish and 33,325 for Italian. For each dataset, 500 reviews were selected by randomly sampling 50 reviews for each city. We thus obtained 139 unique reviews for each annotator, plus 83 reviews which all three annotators independently annotated.

We decided to annotate the aspects that were ratable on TripAdvisor at the time of our crawl (April 2015: Rooms, Cleanliness, Value, Service, Location, and Sleep Quality). Differently from the aspect schema in EN, we included the new aspect Sleep Quality, and we did not consider the missing aspects Check-in and Businnes, which are, in any case, the least frequent aspects in the Trip-MA dataset (see Table 2). We kept the additional aspects Food, Building, Other, and NotRelated, as they still appear frequently in the reviews. We adopted the same 3-values sentiment label schema of EN, i.e., Positive, Negative, or Neutral/Mixed.

Following the same procedure adopted by Marcheggiani et al. (2014), the Spanish and Italian annotator teams performed a preliminary annotation session on reviews not included in the final dataset. This preliminary activity was aimed at aligning the annotators' understanding about the labeling process for the different aspects, by sharing and solving any doubt that might arise during the annotation of some examples.

2.3 Statistics

Table 1 shows that English reviews have, on average, about double the number of sentences of Spanish and Italian reviews. This can be in part motivated by observing that the sentences in EN are, on average, 25% shorter than in ES and IT. Also, after a manual inspection of the data, we found that the EN part contains some reviews related to long vacations in resorts, thus describing in longer details the experience, while IT and ES reviews are mainly related to relatively short visits to classic hotels. However, the portion of opinionated sentences is similar across the three parts, indicating homogeneity in content, which is confirmed by the detailed aspect-level statistics reported in Table 2.

Both aspect and sentiment labels show imbalanced distributions that follow similar distributions across the three parts. The most frequent aspect in all collections is Other, followed by Rooms, Service, and Location. Building and Value are among the least frequent ones. The average value of the Pearson correlation between the lists of the shared aspects ranked by their relative frequency, measured pairwise among the three parts, is 0.795, which indicates a good uniformity of content among the parts. In all the three parts, Positive is the most frequent sentiment label, followed by Negative. Location is always the aspect with the highest frequency of positive labels.

3 Inter-annotator Agreement

We measured the inter-annotator agreement in two steps. The F_1 score measures the agreement on aspect identification, regardless of the sentiment label assigned. Then symmetric Macro-averaged Mean Absolute Error (sMAE^M) (Baccianella et al., 2009) measures the agreement on sentiment labels on the annotations for which the annotators agreed at the aspect level. Aspect NotRelated is not included in agreement evaluation, nor in the experiments of Section 4. sMAE^M is computed between each of the three possible pairs of annotators and then averaged to determine the agreement values reported in Table 3.

Agreement on aspect detection is higher for ES and IT than for EN. This difference is in part motivated by the fact that the two aspects that are missing in ES and IT have low agreement on EN, and the novel Sleep Quality aspect has instead a high agreement. However, also on the other aspects

		Other	Service	Rooms	Clean.	Food	Loc.	Check-in	Sleep-q.	Value	Build.	Busin.	NotRelated	*Total*

Table 3: Inter-annotator agreement. F_1 on sentence-level aspect identification (higher is better). sMAE^M on sentence-level sentiment agreement (only on matching aspects, lower is better).

there is, in general, a higher or equal agreement in ES and IT with respect to EN, indicating that the formers two were annotated in a more consistent way. The agreement on assignment of sentiment label is rather similar across the whole dataset.

4 Experiments

The experiments we present here are aimed at defining a shared baseline for future experiments. For this reason we chose a relatively simple setup that uses a simple learning model and minimal linguistic resources. We used a sentence-level Linear Chain (LC) Conditional Random Field (Lafferty et al., 2001) as described by Marcheggiani et al. (2014). With respect to the features extracted from text, we used three simple features types: word unigrams, bigrams, and SentiWordNet-based features, which consist of a Positive and a Negative feature extracted every time the review contains a word that is marked as such in SentiWordNet (Baccianella et al., 2010). To use SentiWordNet on ES and IT, we used Multilingual Central Repository (Gonzalez-Agirre et al., 2012) and MultiWordNet (Pianta et al., 2002) to map sentiment labels to Spanish and to Italian, respectively.

Experiments were run separately on the EN, ES, and IT parts, leaving cross-lingual experiments to future work. On each part we built five 70%/30% train/test splits, randomly generated by sampling the reviews annotated by single reviewers (we left out reviews annotated by all the reviewers, as we consider that part of the dataset more useful as a validation set for the optimization of methods tested in future experiments). We then run the five experiments and averaged their results.

4.1 Evaluation Measures

As for the agreement evaluation (Section 3), we split the evaluation of experiments into two parts, aspect detection and sentiment labeling. For the sentiment labeling part we used simple Macro-averaged Mean Absolute Error (MAE^M, not the symmetric version) as the true dataset labels are the reference ones in this case, while in the annotator agreement case the two sets of labels have equal importance.

4.2 Results

Experiments on ES and IT obtain better F_1 values than on EN, indicating that the observed higher human agreement can be also explained by a lower hardness of the task when working with Spanish

		Other	Service	Rooms	Clean.	Food	Loc.	Check-in	Sleep-q.	Value	Build.	Busin.	*Avg*

and Italian.

MAE^M values are all similar across languages, again confirming what has been observed on agreement. However, MAE^M values on experiments are sensibly worse than those measured on agreement, possibly due to the fact that we used very basic features, with limited use of sentiment-related information.

5 Conclusion

We have presented Trip-MAML a multi-lingual extension of Trip-MA, originally presented in (Marcheggiani et al., 2014). The extension process involved crawling and selecting the reviews for the two new languages, Spanish and Italian, and their annotation by a total of six native language speakers. We measured dataset statistics and inter-annotator agreement, which show that the new ES and IT parts we produced are consistent with the original EN part. We also presented experiments on the dataset, based on a linear chain CRFs model for the automatic detection of aspects and their sentiment labels, establishing a baseline for future research. Trip-MAML enables the exploration of cross-lingual approaches to the problem of multi-aspect sentiment classification.

Abstract

We present a novel way of extracting features from short texts, based on the activation values of an inner layer of a deep convolutional neural network. We use the extracted features in multimodal sentiment analysis of short video clips representing one sentence each. We use the combined feature vectors of textual, visual, and audio modalities to train a classifier based on multiple kernel learning, which is known to be good at heterogeneous data. We obtain 14% performance improvement over the state of the art and present a parallelizable decision-level data fusion method, which is much faster, though slightly less accurate.

1 Introduction

The advent of the Social Web has enabled anyone with a smartphone or computer to easily create and share their ideas, opinions and content with millions of other people around the world. Much of the content being posted and consumed online is video. With billions of phones, tablets and PCs shipping today with built-in cameras and a host of new video-equipped wearables like Google Glass on the horizon, the amount of video on the Internet will only continue to increase.

It has become increasingly difficult for researchers to keep up with this deluge of video content, let alone organize or make sense of it. Mining useful knowledge from video is a critical need that will grow exponentially, in pace with the global growth of content. This is particularly important in sentiment analysis (Cambria et al., 2013a; 2013b; 2014), as both service and product reviews are gradually shifting from unimodal to multimodal. We present a method for detecting sentiment polarity in short video clips of a person uttering a sentence.

We do it using all three modalities: visual, such as facial expression, audio, such as pitch, and textual, the contents of the uttered sentence. While the visual and the audio modalities provide additional evidence that improves classification accuracy, we found the textual modality to have the greater impact on the result (Cambria and Hussain, 2015; Cambria et al., 2013c; Poria et al., 2015a; 2015b).

In this paper, we propose a novel way for feature extraction from text. Given a training corpus with hand-annotated sentiment polarity labels, following Kim (2014), we train a deep convolutional neural network (CNN) on it. However, instead of using it as a classifier, as Kim did, we use the values from its hidden layer as features for a much more advanced classifier, which gives superior accuracy. Similar ideas have been suggested in the context of computer vision for dealing with images, but have not been applied in the context of NLP to textual data, and, specifically, for sentiment polarity classification.

2 Overview of the Method

In this paper, we present two different methods for dealing with multimodal data: feature-level fusion and decision-level fusion, each one having its advantages and disadvantages.

We extracted features from the data for each modality independently. In the case of feature-level fusion, we then concatenated the obtained feature vectors and fed the resulting long vector into a supervised classifier. In the case of decision-level fusion, we fed the features of each modality into separate classifiers, and then combined their decisions. Our experimental results show that both of these methods outperform the state of the art by a large margin.

Lisbon, Portugal, 17-21 September 2015.

3 Textual Features

We used a CNN as a trainable feature extractor to extract features from the textual data. Utterances in the original dataset are in Spanish. While usually it is better to work directly with the source language (Wang et al., 2013), in this work we translated utterances into English using Google translator. Without the translation into English, 68.56% accuracy was obtained.

The choice of CNN for feature extraction is justified by the following considerations:

1. The convolution layers of CNN can be seen as a feature extractor, whose output is then fed into a rather simplistic classifier useful for training the network but not the best at actual classification. CNN forms local features for each word and combine them to produce a global feature vector for the whole text. However, the features that CNN builds internally can be extracted and used as input for another, more advanced classifier. This turns CNN, originally a supervised classifier, into a trainable feature extractor.
2. As a feature extractor, CNN is automatic and does not rely on handcrafted features. In particular, it adapts well to the peculiarities of the specific dataset, in a supervised manner.
3. The features it gives are based on a hierarchy of local features, reflecting well the context.

A drawback of CNN as a classifier is that it finds only a local optimum, since it uses the same backpropagation technique as MLP. However, inspired by ideas introduced in the context of computer vision (Bluche et al., 2013), we, for the first time in the context of NLP, extract the features that CNN builds internally and feed them into a much more advanced classifier. In our experiments, this was SVM, or roughly its multi-kernel version MKL, which is good at finding the global optimum. Thus, the properties of CNN and SVM complement each other in such a way that their advantages are combined.

To form the input for the CNN feature extractor, for each word in the text we built a 306-dimensional vector by concatenating two parts:

1. *Word embeddings*. We used a publicly available word2vec dictionary (Mikolov et al., 2013a; 2013b; 2013c), trained on a 100 million word corpus from Google News using the continuous bag of words architecture. This dictionary provides a 300-dimensional vector for each word. For words not found in this dictionary, we used random vectors.
2. *Part of speech*. We used 6 basic parts of speech (noun, verb, adjective, adverb, preposition, conjunction) encoded as a 6-dimensional binary vector. We used Stanford Tagger as a part of speech tagger.

For each input text, the input vectors for the CNN were a concatenation of three parts:

1. Left padding. Two dummy "words" with zero vectors were added at the beginning of each text, in order to provide space for convolution, since at the convolution layers we used the kernel size of at most 3.
2. Text. All 306-dimensional vectors corresponding to each word were concatenated, preserving the word order.
3. Right padding. Again, at least 2 dummy "words" with zero vectors were added after each sentence to provide space for convolution. To form vectors for all texts in the corpus of the same dimensionality, they were also padded at the right with the necessary amount of additional dummy "words."

In our experiments, all texts were very short, consisting of one sentence, the longest one being of 65 words. Thus all input vectors were of dimension $306 \times (2 + 65 + 2) = 21{,}114$.

The CNN we used consisted of 7 layers:

1. Input layer, of 21,114 neurons.
2. Convolution layer, with a kernel size of 3 and 50 feature maps. The output of this layer was computed with a non-linear function; we used the hyperbolic tangent.
3. Max-pool layer with max-pool size of 2.
4. Convolution layer: kernel size of 2, 100 feature maps, also using the hyperbolic tangent.
5. Max-pool layer with max-pool size of 2.
6. Fully connected layer of 500 neutrons, whose values were later used as the extracted features. For regularization, we employed dropout on the penultimate layer with a constraint on L2-norms of the weight vectors.
7. Output softmax layer of 2 neurons, by the number of training labels—the sentiment polarity values: positive or negative. This layer was used only for training the CNN.

The CNN was trained using a standard backpropagation procedure. The training data for the output layer were the known sentiment polarity labels present in the training corpus for each text.

As features of the given text, we used the values of the penultimate, fully connected, layer of the CNN. In this way, we used the last output

		Text	Visual	Audio	Pérez-Rosas et al. (2013)	Our method

Table 1. Accuracy of state-of-the-art method compared with our method with feature-level fusion. The number of features is for our experiments, not for [16]. Shaded cells are shared with Table 2.

layer of the CNN only for training, but for actual decision-making, we replaced it with much more sophisticated classifiers, namely, with SVM or MKL. Using only CNN as a classifier, 75.50% was obtained which is in fact lower than the result (79.77%) obtained when CNN was used to extract trainable features for the SVM classifier.

We also tried other word vectors having different dimensions, e.g., Glove word vectors and Collobart's word vectors. However, the best accuracy was obtained using Google word2vec.

4 Visual Features

We split each clip into frames (still images). From each frame, we extracted 68 facial characteristic points (FCPs), such as the position of the left corner of the left eye, etc., using the facial recognition library CLM-Z (Baltrušaitis et al., 2012). For each pair of FCPs, we calculated the distance. Thus, we characterized each facial expression by $68 \times 67 / 2 = 2{,}278$ distances. In addition, for each frame we extracted 6 face position coordinates (3D-dimensional displacement and angular displacement of face and head) using the GAVAM software. This gave $2{,}278 + 6 = 2{,}284$ values per frame.

For each of these values, we calculated its mean value and standard deviation over all frames of the clip; 4568 features in total.

5 Audio Features

We used the openSMILE software (Eyben et al., 2010) to extract audio features related to the pitch and voice intensity. This software extracts the so-called low-level descriptors, such as Mel frequency cepstral coefficients, spectral centroid, spectral flux, beat histogram, beat sum, strongest beat, pause duration, pitch, voice quality, perceptual linear predictive coefficients, etc., and their statistical functions, such as amplitude mean, arithmetic mean, root quadratic mean, standard deviation, flatness, skewness, kurtosis, quartiles, inter-quartile ranges, linear regression slope, etc. This gave us 6373 audio features in total.

6 Feature-Level Fusion

Feature-level fusion consisted in concatenation of the feature vectors obtained for each of the three modalities. The resulted vectors and along with the sentiment polarity labels from the training set, were used to train a classifier with a multiple kernel learning (MKL) algorithm; we used the SPF-GMKL implementation (Jain et al., 2012) designed to deal with heterogeneous data. Clearly, feature vectors resulted from concatenating so different data sources are heterogeneous.

The parameters of the classifier were found by cross validation. We chose a configuration with 8 kernels: 5 RBF with gamma from 0.01 to 0.05 and 3 polynomial with powers 2, 3, 4. We also tried Simple-MKL; it gave slightly lower results.

7 Feature Selection

We significantly reduced the number of features using feature selection. We used two different feature selectors: one based on the cyclic correlation-based feature subset selection (CFS) and another based on principal component analysis (PCA) with top K features, where K was experimentally selected and varied for different experiment. For example, in case of audio, visual and textual fusion, K was set to 300.

The union of the features selected by the two methods was used. For each unimodal, each bimodal, and the multimodal experiment, separate feature extraction was performed. The number of

selected features for each experiment is given in Table 1. In all cases except for the unimodal experiment with audio modality, feature selection slightly improved the results, in addition to the improvement in processing time. In the only case where feature selection slightly deteriorated the result, the difference was rather small.

8 Unimodal Classification and Decision-Level Fusion

For unimodal experiments and for decision-level fusion, we used one classifier per each modality; specifically, we used SVM. For each modality, in this way we obtained the probabilities of the labels. In unimodal experiments, we chose the label with the greater probability.

For decision-level fusion, we added these probabilities with weights, which were chosen experimentally, and, again, used the most probable label. The weights we used for decision-level fusion were chosen using detailed search with an intuition that best performing unimodal classifier has higher importance in the fusion. We do not claim that these weights are optimal. They are indeed sub-optimal and hence encourage the scope of future research.

Knowing a specific decision for the text modality allowed us to use evidence from a separate classifier; we used the one based on the Sentic Patterns (SP) (Poria et al., 2014a). It structures natural language clauses into a sentiment hierarchy used to infer the overall polarity label (positive vs. negative) for the input sentence. E.g., a sentence "The car is very old but it is rather not expensive", is positive, expressing a favorable sentiment of the speaker, who recommends purchasing the product. However, "The car is very old though it is rather not expensive" is negative, expressing reluctance of the speaker to purchase the car. Despite the latter contains exactly the same concepts as the former, the polarity is opposite because of the adversative dependency.

On benchmark datasets, SP perform better than state of the art sentiment classifiers, which outperforms the textual classifier described in Section 3. Since SP are a superior classifier, we used it as a bias to modify the weight of the textual modality. However, SP do not report a probability, but only a binary decision, so we only used them to tweak the weights in the probability mix: when the text-based unimodal classifier agreed with SP, we increased the weight of the text modality. Another benefit of the decision-level fusion is its speed, since fewer features are used for each classifier and since SVM, used as a unimodal classifier, is faster than MKL. In addition, separate classifiers can be run in parallel.

9 Experimental Results

We report results for tenfold cross-validation.

9.1 Dataset

We experimented on the dataset described by Morency et al. (2011). The dataset consists of 498 short video fragments where a person utters one sentence. The items are manually tagged for sentiment polarity, which can be positive, negative, or neutral. We discarded the neutral items from the dataset, which gave us a dataset of 447 clips tagged as positive or negative.

The video in the dataset is present in MP4 format with the resolution of 360 × 480, to which the developers converted all videos originally collected in different formats with different resolution. The duration of the clips is about 5 seconds on average. About 80% of the clips present female speakers. The developers provided transcription of the text of the sentences, which we used in our textual modality processing.

9.2 Results for Each Modality Separately

As a baseline, we used classifiers trained on features extracted from each modality separately. The results are shown in Table 1, unimodal section. The number of features after feature selection is indicate for the modality used.

The table shows that the best results were obtained for textual modality; the visual modality performed worse, and the audio was least useful. However, even the worst of our results is much better than the state-of-the-art (Pérez-Rosas et al., 2013). In each modality separately, our results outperform the state of the art by about 9%, which is about 30% reduction in error rate.

9.3 Results with Feature-level Fusion

As a yet another baseline, we tried feature-level fusion of only two modalities.

The results are shown in Table 1, bimodal section. Again, the number of features after feature selection is indicated for the two modalities used. As expected, missing the audio features was the least important, missing the video features was more significant, and missing the text features was most painful for the accuracy.

Even the worst result obtained with fusion of two modalities outperformed our best unimodal result, as well as the best result of the state of the

	Sentic Patterns	Weights			Fusion Accuracy	
		Text	Visual	Audio	Feature	Decision
Unimodal accuracy	81.73%	79.77%	76.38%	74.22%		
Unimodal 3-way		3-way majority voting				72.83%
	no	0.45	0.3	0.25		81.24%
	yes	0.5 / 0.25	0.3 / 0.4	0.2 / 0.35		82.06%
Bimodal with unimodal		+	+	0.3	85.46%	85.53%
		+	0.23	+	84.12%	84.86%
	no	0.4	+	+	83.69%	84.48%
	yes	0.45 / 0.3	+	+	same	**86.27%**

Table 2. Accuracy of our method with decision-level fusion and feature selection.

art. Finally, the best result, shown in the multimodal section of Table 1, was obtained when all three modalities were fused. This result outperforms the corresponding result of the state of the art by 14%, which gives 56% of error reduction.

9.4 Results with Decision-level Fusion

The results for decision-level fusion are shown in Table 2, last column. The shaded cells are shared with Table 1. In the second section, three classifiers were fused at the decision level. In the third section, two modalities indicated with the plus sign were fused at the feature level (giving the accuracy indicated in the penultimate column) and then this classifier was fused at the decision level with the third modality. The weights correspond to the share of each modality. In the last section, the weight for the unimodal classifier is shown, and the weight for the bimodal classifier was its complement to 1.

For the experiments that involved tweaking of the weights with the SP oracle, pairs of weights are shown: the weight used when the text modality results corresponded (left) with the SP prediction and the weight used when they did not (right). The accuracy with at least partial feature-level fusion was better than that for no feature-level fusion at all (3-way). As in the bimodal section of Table 1, excluding audio from feature-level fusion was least problematic and excluding text was most problematic.

In all cases, decision-level fusion did not significantly improve the accuracy of the best summand. However, separating text-based classifier permitted us to use the Sentic Patterns tweak, which cannot be used if the text-only results are not known. With this tweak, the best result was obtained. Even with this improvement, the accuracy of decision-level fusion was slightly lower than that of feature-level fusion; in exchange for much about twice better processing speed.

A baseline decision level evaluation strategy was taken which allowed us to take majority voting among the predicted class labels by unimodal classifiers. Based on this strategy the final class label was chosen by the maximum of the three unimodal models' votes. For the multimodal fusion using this baseline method only 72.83% accuracy was obtained. As expected the proposed feature and decision level fusion outperformed this baseline method by a large margin.

10 Conclusion

We have presented a novel method for determining sentiment polarity in video clips of people speaking. We combine evidence from the words they utter, the facial expression, and the speech sound. The main novelty of this paper consists in using deep CNN to extract features from text and in using MKL to classify the multimodal heterogeneous fused feature vectors.

We also presented a faster variant of our method, based on decision-level fusion. In case of the decision level fusion experiment, the coupling of Sentic Patterns to determine the weight of textual modality has enriched the performance of multimodal sentiment analysis framework considerably. However, the parameter selection for decision level fusion produced suboptimal results. A systematic mathematical approach for decision level fusion is an important future work.

Our future work will focus on extracting more relevant features from the visual modality. We will employ deep 3D convolutional neural networks on this modality for feature extraction. We will use a feature selection method to obtain key features; this will ensure the scalability as well as stability of the framework. We will continue our study of reasoning over text (Jimenez et al., 2015; Pakray et al., 2011; Sidorov et al., 2014; Sidorov, 2014) and in particular of concept-based sentiment analysis (Poria et al., 2014b).

SLSA: A Sentiment Lexicon for Standard Arabic

Ramy Eskander and Owen Rambow
Center for Computational Learning Systems
Columbia University
{rnd2110,ocr2101}@columbia.edu

Abstract

Sentiment analysis has been a major area of interest, for which the existence of high-quality resources is crucial. In Arabic, there is a reasonable number of sentiment lexicons but with major deficiencies. The paper presents a large-scale Standard Arabic Sentiment Lexicon (SLSA) that is publicly available for free and avoids the deficiencies in the current resources. SLSA has the highest up-to-date reported coverage. The construction of SLSA is based on linking the lexicon of AraMorph with SentiWordNet along with a few heuristics and powerful back-off. SLSA shows a relative improvement of 37.8% over a state-of-the-art lexicon when tested for accuracy. It also outperforms it by an absolute 3.5% of F1-score when tested for sentiment analysis.

1 Introduction

Sentiment analysis is the process of identifying and extracting subjective information using Natural Language Processing (NLP). It helps identifying opinions and extracting relevant information that lies behind the analyzed data. Sentiment analysis has received enormous interest in NLP, and in particular in the context of web content. This includes social media, blogs, discussions, reviews and advertisement.

While there has been extensive work on sentiment analysis in English and other languages of interest, less work has been done for Arabic. A major concern in Arabic NLP is the morphological complexity of the language along with the limited number of resources, corpora in particular.

The goal of this work is to build a publicly available large-scale Sentiment Lexicon for Standard Arabic (SLSA). For every lemma and part-of-speech (POS) combination that exists in a large Standard Arabic lexicon, SLSA assigns the scores of three sentiment labels: positive, negative and objective, in addition to the English gloss. The positive and negative scores range between zero and one, while the objective score is defined as *1 - (positive score + negative score)*.

The existence of SLSA is valuable to the field of Arabic sentiment analysis, which is expected to receive considerable focus during the current decade. SLSA is the first sentiment lexicon for Arabic to combine the following four strengths.

High coverage SLSA lists the sentiment of about 35,000 lemma and POS combinations, which is the highest coverage reported for Standard Arabic sentiment lexicons.

High quality Unlike many of the current lexicons whose construction is based on semi-supervised learning and heuristic-based approaches, SLSA is not constructed via machine learning models, while the use of heuristics is minimal.

Richness As opposed to sparse surface-based lexicons, SLSA is a lemma-based resource that attaches POS and English gloss information to each lemma, where the information of a lemma is applicable to its inflected forms. This makes the lexicon more useful when used by other research.

Public Availability SLSA is based on free resources and is publicly available for free.[1]

2 Related Work

Work on building Arabic sentiment lexicons mainly falls into two categories: 1) linking an Arabic sentiment lexicon with an English one, and 2) applying semi-supervised or supervised learning techniques on Arabic resources. We summarize these two types in turn.

We start with a survey of work based on translation, which our work falls into as well. The most similar work to the one presented in this paper is ArSenL (Badaro et al., 2014). ArSenL is considered the first publicly available large-scale Standard Arabic sentiment lexicon. It was constructed using a combination of SentiWordNet (Baccianella et al., 2010), Arabic WordNet (Black et al., 2006) and SAMA (Graff et al., 2009). Ar-

[1]The lexicon is available at http://volta.ldeo.columbia.edu/~rambow/slsa.html

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2545–2550,
Lisbon, Portugal, 17-21 September 2015.

SenL outperforms the state-of-the-art Arabic sentiment lexicons. However, we show that SLSA has better coverage and quality. Moreover, ArSenL uses SAMA which is not publicly available for free, as opposed to SLSA which is based on free resources.

Another similar work to ArSenL is the resource developed by Alhazmi et al. (2013). They linked the Arabic WordNet to SentiWordNet via the provided synset offset information. However, the constructed lexicon has a limited coverage of nearly 10K lemmas, which makes it not very useful for further applications.

Abdul-Mageed and Diab (2014) presented SANA, a subjectivity and sentiment lexicon for Arabic. The lexicon combines pre-existing lexicons and involves automatic machine translation, manual annotations and gloss matching across several resources such as THARWA (Diab et al., 2014) and SAMA. SANA includes about 225K entries, where many of them are duplicates, inflected or not diacritized, which makes the resource noisy and less useable. Additionally, the automatic translation does not utilize the POS information, which affects the quality of the resource.

Other work that follows the translation approach includes the one presented by El-Halees (2011) where SentiStrength (Thelwall et al., 2010) was translated using a dictionary along with manual correction. Another instance is SIFAAT (Abdul-Mageed and Diab, 2012), an earlier version of SANA but with more reliance on translation. Another lexicon was built by Elarnaoty et al. (2012) who manually translated the MPQA lexicon (Wilson et al., 2005). The common aspect among those resources is the lack of adequate coverage and quality.

Mobarz et al. (2011) created a sentiment Arabic lexical Semantic Database (SentiRDI) by using a dictionary-based approach. The database has many inflected forms, i.e., it is not lemma-based. Moreover, the authors reported insufficient quality and plan to try other alternatives.

We now turn to work based entirely on Arabic resources. Mahyoub et al. (2014) created an Arabic sentiment lexicon that assigns sentiment scores to the words in Arabic WordNet using a lexicon-based approach. The lexicon was initially based on a few words and then expanded by exploiting synset relations in a semi-supervised learning manner. However, the lexicon is limited to about 23k lemmas and is not publicly available.

Another Arabic sentiment lexicon was created by Elhawary and Elfeky (2010). The lexicon was built using a similarity graph where the edges have similarity scores. A major drawback is the low coverage of the lexicon. Moreover, expanding the graph requires a huge corpus with polarity and semantic annotations and adds more sparsity.

3 Approach

Following the example of ArSenL (Badaro et al., 2014), SLSA is constructed by linking the lexicon of an Arabic morphological analyzer with SentiWordNet (Baccianella et al., 2010). Unlike ArSenL, SLSA uses AraMorph (Buckwalter, 2004), a morphological analyzer for Standard Arabic. An AraMorph entry represents a morpheme and contains the surface, lemma, part of speech (POS), and gloss information. The gloss information consists of a list of gloss terms, each of which contains one or more words (such as "*time limit / end*"). On the other side, SentiWordNet is a large-scale sentiment lexicon for English that assigns sentiment scores (positive, negative and objective) to the synsets in English WordNet (Miller et al., 1990) along with the POS and gloss information. Upon linking the two resources, the sentiment scores in SentiWordNet are applied to the entries of AraMorph to construct SLSA. The question this paper addresses is how to link these two resources, and we present a new linking algorithm compared to that used by ArSenL, with improved performance.

3.1 Preparing the Resources

It might seem intuitive to join the entries of AraMorph and SentiWordNet based on their glosses, but this does not work as expected. AraMorph and SentiWordNet were developed for different reasons and have different gloss structures (synonyms in AraMorph versus detailed descriptions in SentiWordNet). Mapping the glosses is one of the major bottlenecks in ArSenL, which is not able to find a match for 24% of the entries in SAMA. Instead, we link the two resources by relating the glosses of AraMorph to the synset terms in SentiWordNet. Additionally, we take POS into consideration as the glosses and synset terms might not be enough to disambiguate an entry. Next, we discuss the preparation steps that allow for the linking of the resources.

Cleaning-up AraMorph Some POS and lemma decisions in AraMorph are erroneous or not optimal. For example, some entries are assigned wrong POS tags, such as the NO_FUNC cases, or have inconsistent spellings of the lemmas. Also, some adverbs are redundant as they have the same lemma as an adjective. Accordingly, we cleaned up AraMorph in a way that allows for a better linking with SentiWordNet. The

cleaned-up AraMorph is closer to SAMA (used in ArSenL), which is itself a modified version of AraMorph. Practically, SAMA can replace AraMorph. However, the integration of AraMorph allows the lexicon to be publicly available for free, which SAMA prohibits.

Gloss Normalization Since the entries in AraMorph are bound to stems, the English glosses are inflected for number. As a result, we lemmatize the English glosses in AraMorph in order to be able to match to the synset terms in SentiWordNet. The lemmatization is done using Stanford CoreNLP Natural Language Processing Toolkit (Manning et al., 2014). Additionally, we remove from the glosses any descriptive text between parentheses, as well as the stop words *be*, *a*, *an* and *the* (unless *be* is the actual lemma of the AraMorph gloss). Moreover, if any of the lemmatized words in an AraMorph gloss does not match any of the synset terms in SentiWordNet and has a regular morphological derivation, the effect of the derivation is removed if the removal results in an existing synset term, e.g., *voluntariness* is converted to *voluntary* and *orientalization* becomes *orientalize*. We created the list of the derivational patterns manually by examining AraMorph glosses.

POS Mapping AraMorph has a rich POS tagset, while SentiWordNet has only four tags corresponding to nouns, adjectives, adverbs and verbs. Accordingly, AraMorph POS tags are mapped to the four tags in SentiWordNet. Some AraMorph POS types, such as particles, pronouns and prepositions, do not map to any SentiWordNet tags, and we exclude them as they have zero polarity scores, by definition.

AraMorph Rearrangement We collapse all the entries in AraMorph that have the same (lemma, POS) pair, and the English glosses become the union of the normalized glosses before the collapse. For example, a lemma might appear in two entries with two POS tags; *VERB_PERFECT* and *VERB_IMPERFECT* . After the preparation, the POS tags in both entries become the same (*VERB*), and the two entries collapse into one entry whose gloss is the union of the lemmatized past-tense and present-tense glosses. Figure 1 shows a sample of AraMorph before and after the preparation process (the Arabic transliteration is in the Buckwalter scheme (Buckwalter, 2004)).

SentiWordNet Rearrangement We extract all the unique combinations of synset terms and POS tags in SentiWordNet, while the indices of the synset terms are stripped off. However, since a synset term might appear in different synsets under the same POS with different indices and sentiment scores, the sentiment scores of an extracted entry is calculated as the average of all the sentiment scores that appear with the corresponding synset term and POS. Figure 2 shows a sample of SentiWordNet before and after the preparation process.

Stem	English Gloss	POS	Lemma
baliy~	tribulation/affliction	NOUN	baliy~ap_1

affliction	NOUN	0	0.625
afflict	VERB	0.0625	0.75

Processed SentiWordNet

Figure 2: A sample of the original SentiWordNet (the upper table) and the processed version (the lower table). The unique combinations of the synset terms and POS tags are extracted, where the sentiment scores of the extracted entries are the average of the scores in the contributing ones.

3.2 Linking the Resources

We start out by creating a link between an AraMorph entry and a SentiWordNet entry if any of the AraMorph one-word gloss terms and the POS match the SentiWordNet. Upon linking, we assign the AraMorph entry the sentiment scores of the matching one in SentiWordNet. The linking condition above applies successfully to 83.6% of the entries in AraMorph. If the condition does not apply, we relax it to allow for a more lenient POS agreement where *NOUN* and *ADJ* POS tags are used interchangeably, while the *VERB* entries in AraMorph become matchable with the *ADJ* ones in SentiWordNet. The reasons behind the decisions above are that AraMorph has hundreds of cases where the same lemma appears as *NOUN* and *ADJ*, while it is frequent that AraMorph assigns an adjectival gloss (preceded

by *be*) to *VERB* entries. The relaxed condition enables linking an additional 6.7% of AraMorph entries. If the relaxed condition is still not applicable for an AraMorph entry, the linking condition becomes more lenient by completely ignoring the POS agreement. The sentiment scores in that case become the average of the sentiment scores of the corresponding synset term across all the POS types. The latter condition allows matching additional 0.6% of AraMorph entries.

It might happen that none of the one-word gloss terms matches a synset term, or the gloss does not have any one-word gloss terms. In such a case, we consider multi-word gloss terms. We first remove the stop words, and then we test the relaxed condition on each word separately, starting with the shortest terms first. The process succeeds if a match could be established for all the words in a gloss term, and the sentiment scores become the average sentiment scores of the matching synset terms. The relaxed condition on multi-word terms solves additional 7.9% of the cases. Finally, if no match could be established across all the different gloss terms (1.2% of the entries), default neutral sentiment scores are assigned. The analysis of such cases is discussed in section 4.

Sometimes, a multi-word gloss term consists of words that denote excess (e.g., *most* and *more*), scarcity (e.g., *less* and *few*) or negation (e.g., *not*). We do not match such words to synset terms. Instead, they affect the polarity scores; we double the score, halve the score and swap the sign, respectively. We created the list of such words manually by examining AraMorph glosses.

Figure 3 illustrates the linking process between a sample of the processed AraMorph with a sample of the processed SentiWordNet, resulting in the construction of SLSA. The final SLSA lexicon consists of 34,821 entries. The counts of the different POS tags in SLSA along with the percentages of the different sentiment classes are reported in Table 1, while examples from the final lexicon are listed in Table 2.

POS	Count	Neutral %	+ve %	-ve %	Mixed %
NOUN	20,263	58.1	12.7	15.4	13.8
VERB	9,117	42.5	19.3	21.9	16.4
ADJ	5,395	36.5	18.7	17.0	27.8
ADV	46	73.9	10.9	2.2	13.0
ALL	34,821	50.7	15.3	17.3	16.7

kamod_1	NOUN	swarthiness;sadness	0	0.8	0.2

Table 2: Examples of SLSA entries; Obj. = Objective. All scores are rounded for readability.

4 Evaluation

4.1 Intrinsic Evaluation

As mentioned in section 3, no match could be established for 1.2% of AraMorph entries. We manually investigate these cases more closely. About 75% of the entries that are not covered in SLSA have lemmas that express Arabic or Islamic subjects that do not have English counterparts such as *hamozap* (an Arabic name) and *kunAfap* (an Arabic food). Another 5% of the cases are countries or nationalities that are not listed in SentiWordNet such as *EAjiy* (Ivorian). Additional 2% of the cases are due to misspelled or non-English glosses in AraMorph such as *bon appetit*. The remaining cases (around 18%) have glosses that do not match any of the synset terms in SentiWordNet.

We then conduct an intrinsic evaluation of SLSA where the performance is compared to that of ArSenL, which is the most similar state-of-the-art lexicon (see Section 2). First, we randomly select 400 (lemma, POS) pairs for the evaluation. Only four pairs (1%) are not covered in SLSA. On the other side, 103 pairs (26%) are absent in ArSenL, which is consistent with the claim of the authors of ArSenL that only 76% of SAMA entries are matched in SentiWordNet. We then evaluate the random entries that exist in both SLSA and ArSenL (297 entries). We ask human anno-

tators to judge the correctness of the values in the two lexicons. ArSenL may have several sentiment values for the same entry, each with its own confidence score, so we used the sentiment values with the highest confidence score (averaged in the case of multiple answers). Since judging the values as real numbers is hard for humans, we map the sentiment scores into three classes of intensity (zero, up to 0.55 and above 0.55). An entry is correct only if the values of the positive and negative polarity classes are both correct. Each entry was judged by two annotators (without knowing its origin). They had to discuss and come to an agreement in the cases of disagreement (about 15% of the cases). SLSA and ArSenL have the exact same scores in 58.2% of the cases, which increases to 83.5% when mapping to the intensity classes.

Table 3 lists the accuracy of a majority baseline (neutral), SLSA and ArSenL for the different POS types[2]. SLSA gives error reductions of 58.7% and 37.8% over the baseline and ArSenL, respectively.

About 93% of SLSA errors are cases where the sentiment scores are doubtful in SentiWordNet, while the other errors are due to incorrect glosses in AraMorph. It might happen that an AraMorph entry is incorrectly linked to a SentiWordNet entry causing an error, but we do not see this in any of the manually analyzed data.

POS	Count	Baseline %	ArSenL %	SLSA %
NOUN	183	57.4	71.6	81.4
ADJ	50	42.0	66.0	74.0
VERB	62	43.5	58.1	80.6
ADV	2	50.0	100.0	100.0
All	293	51.9	68.0	80.1

Table 3: Accuracy results of a majority baseline (neutral), SLSA and ArSenL, evaluated on a test set that is covered in both SLSA and ArSenL

4.2 Extrinsic Evaluation

We conduct an extrinsic evaluation of SLSA on the task of sentiment analysis where a subjective sentence is classified to be either positive or negative. The performance is compared to that of ArSenL. We use an evaluation setup similar to the one described in (Badaro et al., 2014) using the corpus developed by Abdul-Mageed et al. (2011). The corpus involves 400 documents from the Penn Arabic Treebank (part 1 version 3) (Maamouri et al., 2004) where the sentences are tagged as objective, subjective-positive, subjective-negative and subjective-neutral. The evaluation only involves the sentences tagged as subjective-positive and subjective-negative. Random 80% of the sentences are used for training, while the rest are left for testing.

We train a Support Vector Machines classifier, through LIBSVM (Chang and Lin, 2011), using sentence vectors of three features representing the averages of the positive scores, negative scores and objective scores of the non-stop words in the sentence divided by the count of the underlying words. The scores are obtained by querying the lexicon using the lemma and POS information.

We optimize the classification to obtain the best F1-score based on five-fold cross validation on the training set using different SVM kernels and parameters. Polynomial kernels give the best weighted-average F1-score[3] of 68.6% (using SLSA), which is an absolute 0.2% improvement over linear kernels. Table 3 lists the precision, recall and F1-score of a majority baseline (subjective-negative), SLSA and ArSenL. SLSA provides absolute weighted-average F1-score improvements of 22.9% and 3.5% over the baseline and ArSenL, respectively.

		Baseline %	ArSenL %	SLSA %
Positive	F1	0.0	54.5	58.5
	Precision	0.0	56.5	61.8
	Recall	0.0	52.5	55.6
Negative	F1	75.4	72.0	75.2
	Precision	60.6	70.4	72.8
	Recall	100.0	73.7	77.6
Weighted-Ave. F1		45.7	65.1	68.6

Table 4: Sentiment analysis results of a majority baseline (subjective-negative), SLSA and ArSenL

5 Conclusion and Future Work

We have presented a publicly available large-scale Standard Arabic Sentiment Lexicon (SLSA) that avoids the deficiencies in the current lexicons. The construction of SLSA is based on linking the lexicon of AraMorph with SentiWordNet along with a few heuristics and powerful back-off. SLSA has the highest up-to-date reported coverage. SLSA shows a relative improvement of 37.8% over a state-of-the-art lexicon when tested for accuracy. It also outperforms it by an absolute 3.5% of F1-score when tested for sentiment analysis.

The future plans include manually correcting SLSA to reach a nearly 100% accuracy. Additionally, the work will be extended to the Arabic dialects for which AraMorph-like morphological analyzers are available. We also plan to study the cases where English and Arabic translations have different sentiments due to cultural differences.

[2]There are only few adverbs in the test set because they are rare in Arabic, where only 0.1% of the lexicon entries are adverbs.

[3]The weighted-average F1-score is the sum of the F-1 score of the positive class and the F1-score of the negative class, each multiplied by its percentage.

Abstract

For sentiment classification, it is often recognized that embedding based on distributional hypothesis is weak in capturing sentiment contrast–contrasting words may have similar local context. Based on broader context, we propose to incorporate Theta Pure Dependence (TPD) into the Paragraph Vector method to reinforce topical and sentimental information. TPD has a theoretical guarantee that the word dependency is pure, i.e., the dependence pattern has the integral meaning whose underlying distribution can not be conditionally factorized. Our method outperforms the state-of-the-art performance on text classification tasks.

1 Introduction

Word embeddings can be learned by training a neural probabilistic language model or a unified neural network architecture for various NLP tasks (Bengio et al., 2003; Collobert and Weston, 2008; Collobert et al., 2011). In global context-aware neural language model (Huang et al., 2012), the global context vector is a weighted average of all word embeddings of a single document/paragraph. After trained with all word embeddings belonging to the current paragraph, a resulting Paragraph Vector can be obtained. Actually, Le and Mikolov's Paragraph Vector (Le and Mikolov, 2014) is trained based on the log-linear neural language model (Mikolov et al., 2013a).

For text classification, using a straightforward extension of language model (e.g. Le and Mikolov's Paragraph Vector) is considered not to be sensible. Embeddings learned for text classification should be very different from that learned for language modeling. For example, language models often calculate the probability of a sentence, therefore *this is a good movie* and *this is a bad movie* may not be discriminated from each other. In sentiment analysis task, the semantic representation of words needs to tell word *good* from *bad*, even if the two words have the same local context. For this reason, the local dependency is insufficient to model topical or sentiment information. Fortunately, if we have the global context of *good* like *interesting* or *amazing*, the sentiment meaning of the embedding will be explicit. However, the training of log-linear neural language model is based on local word dependencies (e.g., the co-occurrence of the words in a local window). Thus, Paragraph Vector can not explicitly model the word dependencies for those words that do not frequently appear in a local window but are actually closely dependent on each other.

In this paper, our aim is to extend the Paragraph Vector with global context which can capture topical or sentiment information effectively. However, if one explicitly considers the dependency patterns that are beyond the local window level, there is a possibility that the noisy dependency patterns can be involved and modeled in the distributed representation methods. Moreover, there should be an unique and explicit topical meaning in the patterns to guarantee no ambiguity in the global context. Therefore, we need a dependency mining method that not only models the long range dependency patterns, but also provides a theoretical guarantee that the dependency patterns are pure. Here, the "pure" dependency pattern is an integral semantic meaning/concept that cannot be factorized into sub dependency patterns.

In the language of statistics, Conditional Pure Dependence (CPD) means that the underlying distribution of the dependency patterns cannot be factorized under certain conditions (e.g., priors, observed words, etc.). It has been proved that CPD is the high-level pure dependence in (Hou et al.,

*Corresponding authors: Yuexian Hou and Peng Zhang.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2551–2556,
Lisbon, Portugal, 17-21 September 2015.

2013). However, judging CPD is NP-hard (Chickering et al., 2004). Fortunately, Theta Pure Dependence (TPD) is the sufficient criteria of CPD and can be identified in O(N) time, where N is the number of words (Hou et al., 2013). This finding motivates us to adopt TPD as the global context. Moreover, compared with other conventional co-occurrence-based methods, such as the Apriori algorithm (Agrawal et al., 1993), TPD based on the Information Geometry (IG) framework has a solid theoretical interpretations in statistics to guarantee the dependence is pure.

2 Modeling Topic with TPD

Compared with local context, global context can usually capture the text topic more precisely. It is easy to get local context by a sliding window. We define the centered word as the *current word* and the other words in the window as *local context words*. Global context words are extracted from all the documents in the corpus and can be divided into two parts: a) the words in the current document but outside of the local context window; b) the words never appeared in the document but in the corpus. The following example shows the words mentioned above, and the topic (the scene of filming) is easily captured by TPD:

- TPD: **scene** camera acting movie
  Text: there [*is great atmosphere in the* **scene** *from the location , the*] lighting , the fog and such , but the camera should be slowly following the killer...

The bracket stands for the local context window, and the size of window is 5, i.e. there are five local context words (in italics) in both sides of the current word (in bold). Global context words are underlined in the example.

In order to model the topic explicitly, the dependence pattern should report one and only one topical meaning. TPD has a theoretical guarantee that the dependency has an integral meaning whose underlying distribution can not be conditionally factorized. Formally, given a set of binary random variables $\mathbb{X} = \{X_1, \ldots, X_n\}$, where X_i denotes the occurrence $(X_i = 1)$ or absence $(X_i = 0)$ of the i-th word. Then the n-order TPD over $\mathbb{X}$ can be defined as follows.

DEFINITION 1. (TPD): $\mathbb{X} = \{X_1, \ldots, X_n\}$ is of n-order Theta Pure Dependence (TPD), iff the n-order θ coordinate $\theta_{12\ldots n}$ is significantly different from zero. (Hou et al., 2013)

TPD can be effectively identified by an explicit statistical test procedure: Log Likelihood Ratio Test (LLRT) (Nakahara and Amari, 2002) for θ-coordinate of IG. (Hou et al., 2013)

Here, we introduce two negative examples to further emphasize the importance of utilizing TPD. Example 1: *can, with, of*. The joint distribution of this words combination can be unconditionally factorized directly, since the occurrence of any word does not necessarily imply the occurrence of others. Example 2: *London, Chelsea, Sherlock Holmes*. As we all know, both *Chelsea* and *Sherlock Holmes* are closely related to *London*. *Chelsea* and *Sherlock Holmes* are two relatively independent topics, i.e. they are conditional independent given *London*. Although the three phrases are unconditionally dependent, their joint distribution can be conditionally factorized. Thus the dependency in both two examples can not be pure.

To explain TPD and the characteristic "pure" intuitively, let us look at a typical example of TPD: *climate, conference, Copenhagen*. The co-occurrence of the three words implies an unseparable high-level semantic entity compared with the two negative examples, introduced above. In negative examples, the high frequency of words co-occurrence can be explained as some kind of "coincidence", because each of them or their pairwise combinations has a high frequency, independently. However, the co-occurrence of TPD words cannot be fully explained as the random coincidence of, e.g., the co-occurrence of *Copenhagen* and *conference* (which can be any other conferences in Copenhagen) and the occurrence of *climate*.

The word "pure" in Hou et al. (2013) means that the joint probability distribution of these words is significantly different from the product of lower-order joint distributions or marginal distributions, w.r.t all possible decompositions. More formally, it requires that the joint distribution cannot be factorized unconditionally (UPD) or conditionally (CPD) in the language of graphical model. Let $x_i \in \{0, 1\}$ denote the value of X_i. Let $p(x)$, $x = [x_1, x_2, \ldots, x_n]^T$, be the joint probability distribution over $\mathbb{X}$. Then the definitions of UPD and CPD are as follows:

DEFINITION 2. (UPD): $\mathbb{X} = \{X_1, \ldots, X_n\}$ is of n-order Unconditional Pure Dependence (UPD), iff it can NOT be unconditionally factorized, i.e., there does NOT exist a k-partition $\{\mathbb{C}_1, \mathbb{C}_2, \ldots, \mathbb{C}_k\}$ of $\mathbb{X}$, $k > 1$, such at $p(x) =$

$p(c_1) * p(c_2)...p(c_k)$, where $p(c_i)$, $i = 1, \ldots, k$, is the joint distribution over $\mathbb{C}_i$. (Hou et al., 2013)

DEFINITION 3. (CPD): $\mathbb{X} = \{X_1, \ldots, X_n\}$ is of n-order Conditional Pure Dependence (CPD), iff it can NOT be conditionally factorized, i.e., there does NOT exist $\mathbb{C}_0 \subset \mathbb{X}$ and a k-partition $\{\mathbb{C}_1, \mathbb{C}_2, \ldots, \mathbb{C}_k\}$ of $\mathbb{V} = \mathbb{X} - \mathbb{C}_0$, $k > 1$, such at $p(v|c_0) = p(c_1|c_0) * p(c_2|c_0)...p(c_k|c_0)$, where $p(v|c_0)$ is the conditional joint distribution over $\mathbb{V}$ given $\mathbb{C}_0$, and $p(c_i|c_0)$, $i = 1, 2, \ldots, k$, is the conditional joint distribution over $\mathbb{C}_i$ given $\mathbb{C}_0$. In case that $\mathbb{C}_0$ is an empty set, we define $p(c_0) = 1$. (Hou et al., 2013)

Actually, CPD is stricter than UPD, and the dependence which just satisfies UPD is not pure enough to model the global context. Therefore, "pure" in our paper refers to the characteristic of CPD. However judging CPD is NP-hard. It is proved that a significant nonzero n-order θ parameter (TPD) entails the n-order CPD/UPD in Hou et al. (2013). The highest-order coordinate parameter in IG is a proper metric for the purity (i.e., the unique semantics) of high-order dependence. A pattern is TPD, iff the n-order θ coordinate $\theta_{12...n}$ is significantly different from zero. Moreover, The Log Likelihood Ratio Test implemented in the mixed coordinates can test whether $\theta_{12...n}$ is significantly different from zero.

Contrasting to TPD, the semantic coupling among the associations in the two negative examples is much weaker. In conclusion, *can, with, of* cannot give an explicit topic and *London, Chelsea, Sherlock Holmes* includes at least two topics. the co-occurrence of words in TPD (e.g. *climate, conference, Copenhagen*) implies an un-separable (pure) high-level semantic entity. A sufficient and unbroken meaning of dependence can not only supply the context but also avoid the ambiguity (or noise) in global context. Therefore, the meaning of pure is important in such a global context modeling method.

3 Global PV-DBOW and Dependence Vectors

A version of Paragraph Vector in Le and Mikolov (2014) PV-DBOW is extended with TPD to a new model: Global PV-DBOW (Glo-PV-DBOW). TPD has been extracted from the corpus before training. Given a sequence of training words w_1, w_2, w_3, ..., w_T and the global context glo_t of w_t, the objective of Glo-PV-DBOW is to maximize the average log probability:

$$L = \frac{1}{T}\sum_{t=1}^{T}\Big[\sum_{-c\le j\le c, j\neq 0} \log p(w_t|w_{t+j}) + \log p(w_t|glo_t) + \log p(w_t|doc_t)\Big] \quad (1)$$

where c is the local context window size. The indicator of the document that the current word w_t belongs to is denoted by doc_t. Further, we define $p(w_t|glo_t)$ in equation (2):

$$p(w_t|glo_t) = \prod_{a}^{A}\Big[p(w_t|dep_t^a)p(w_t|w_1^a, w_2^a, \ldots, w_N^a)\Big] \quad (2)$$

The indicator of the a-th w_t's TPD pattern is denoted as dep_t^a and can be trained to be a distributed representation of TPD: dependence vector $v_{dep_t^a}$. This (N+1)-order TPD consists of N+1 words: w_1^a, $w_2^a...w_N^a$ and w_t. The energy function of w_t and $w_i = (w_{t+j}, doc_t, dep_t^a)$ is uniform as follows:

$$E(w_t, w_i) = -{v_{w_t}}^T v_{w_i} \quad (3)$$

We define the energy function of TPD words:

$$E(w_t, w_1^a, w_2^a, \ldots w_N^a) = -\frac{1}{N}\sum_{n=1}^{N}{v_{w_t}}^T v_{w_n^a} \quad (4)$$

The resulting predictive distributions are given by

$$p(w_t|w_i) = \frac{exp({v_{w_t}}^T v_{w_i})}{\sum_{m=1}^{W} exp({v_{w_m}}^T v_{w_i})} \quad (5)$$

$$p(w_t|w_1^a, w_2^a, \ldots, w_N^a) = \frac{exp(\frac{1}{N}\sum_{n=1}^{N}{v_{w_t}}^T v_{w_n^a})}{\sum_{m=1}^{W} exp(\frac{1}{N}\sum_{n=1}^{N}{v_{w_m}}^T v_{w_n^a})} \quad (6)$$

Hierarchical softmax (Morin and Bengio, 2005) is adopted to reduce the cost of computation. The binary tree is specified with a Huffman tree, and the Huffman code of pseudo words m_i in w_t's Huffman path is denoted as x_{m_i}. For more about hierarchical softmax we used, please refer to (Mikolov et al., 2013b). Using stochastic gradient descent (SGD), distributed representations of the word, dependence and document have been trained. The update procedure of $v_{w_i} = (v_{w_{t+j}}, v_{doc_t}, v_{dep_t^a})$ is as same as the procedure described in (Mikolov et al., 2013b). Thus, the pseudo code for training TPD words is listed individually:

SGD FOR TRAINING THE TPD WORDS

$v_{w_t} \leftarrow current\_word$
$v_{w^a_{ave}} \leftarrow \frac{1}{N}\sum_{n=1}^{N} v_{w^a_n}$
$err \leftarrow 0$
for $\forall m_i$
    do $g \leftarrow (1 - x_{m_i} - \sigma({v_{m_i}}^T v_{w^a_{ave}})) * \alpha$
        $err+ = g * \frac{1}{N} * v_{m_i}$
        $m_i+ = g * v_{w^a_{ave}}$
for $n \leftarrow 1$ **to** N
    do $v_{w^a_n}+ = err$

4 Experiments

Apriori (not a pure dependency method) is contrastively adopted to implement Glo-PV-DBOW. Glo-PV-DBOW-TPD and Glo-PV-DBOW-Apri are all evaluated in two text classification tasks: sentiment analysis and topic discovery. The suffix (e.g., -2, -5) of our global method name denotes the order of dependency (the number of words in a dependence pattern). The order of dependency is changed because we want to show the superiority of the high-order TPD. The high-order TPD provides the more rich and explicit global context than the lower-order one since the high-order TPD cannot be reduced to the random coincidence of lower-order dependencies.

We cross-validate the hyperparameters and set the local context window size as 10, the dimension of embeddings as 100. In sentiment analysis task, Apriori's minimum support and TPD's theta_0 is respectively set as 0.004 and 1.4. While in topic discovery task, Apriori's minimum support and TPD's theta_0 is around 0.020 and 2.0 respectively. Since the classification accuracy of the approaches compared is a single result, we do not include any results for test of significance in our method and only report the average accuracy.

4.1 Sentiment Analysis on Movie Reviews

The binary sentiment classification on the IMDB dataset proposed by (Maas et al., 2011) is conducted. Results in Fig.1 show that global methods' performance is more stable than PV-DBOW's. Moreover, TPD works much better than Apriori, especially in the high-order dependence. Note that TPD-5 works better than TPD-2, while Apri-5 works worse than Apri-2. It can be explained that the Apriori algorithm is short of an explicit statistical test procedure to guarantee the pure dependence. Therefore, the Apriori algorithm is not suitable for generating the high-order dependence.

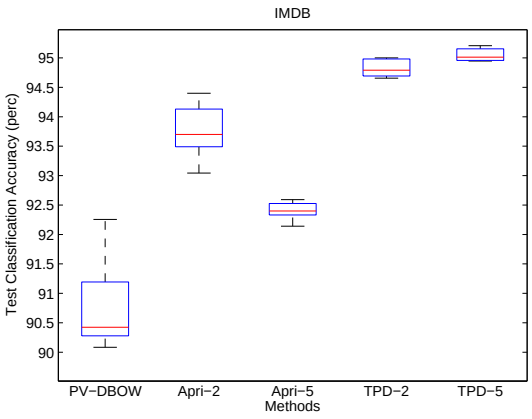

Figure 1: Box plot of classification accuracy over a local method (PV-DBOW) and 4 global methods (Apri-2/5, TPD-2/5).

Instead, the high-order TPD can provide the rich and explicit global context for the model. Meanwhile, it is verified that our method is good at capturing sentiment contrast.

Table 1 shows that Glo-PV-DBOW with 5-order TPD achieves the state-of-the-art performance. A promising result is an improvement of more than 2% over result published in Le and Mikolov (2014). Note that the algorithm process of Paragraph Vector (Le and Mikolov, 2014) is much more complex than PV-DBOW's. Paragraph Vector includes an extra inference stage. In addition, Paragraph Vector's document vector is a combination of two vectors: one learned by PV-DBOW and the other learned by Distributed Memory Model of Paragraph Vectors (PV-DM) (Le and Mikolov, 2014). The combined document vector has 800 dimensions, while all vectors in our experiments only have 100 dimensions.

4.2 Topic Discovery on News

The 20 Newsgroups dataset is a collection of approximately 20,000 newsgroup documents, partitioned across 20 different newsgroups. We follow (Crammer et al., 2012) to create binary problems from the dataset by creating binary decision problems of choosing between two similar groups. Therefore, the dataset is split into two sub-datasets as follows: *comp: comp.sys.ibm.pc.hardware vs. comp.sys.mac.hardware* and *sci: sci.electronics vs. sci.med*. Similarly, 1800 examples balanced between the two labels were selected for each problem.

The classification accuracy on each sub-dataset

Table 1: The performance of our method compared with other approaches on the IMDB dataset.

Model	Accuracy rate
BoW (bnc) (Maas et al., 2011)	87.80%
Full+Unlabeled+BoW (Maas et al., 2011)	88.89%
WRRBM (Dahl et al., 2012)	87.42%
WRRBM + BoW (bnc) (Dahl et al., 2012)	89.23%
SVM-bi (Wang and Manning, 2012)	89.16%
NBSVM-bi (Wang and Manning, 2012)	91.22%
PV-DBOW (Le and Mikolov, 2014)	90.79%
Paragraph Vector (Le and Mikolov, 2014)	92.58%
Sentence Vector + RNN-LM + NB-LM (Mesnil et al., 2014)	92.57%
mvCNN**o&w** (Johnson and Zhang, 2015)	93.34%
Glo-PV-DBOW-Apri-2	93.76%
Glo-PV-DBOW-Apri-5	92.41%
Glo-PV-DBOW-TPD-2	94.83%
Glo-PV-DBOW-TPD-5	**95.05%**

Table 2: The performance of our method compared to other approaches on 20 Newsgroup.

Model	Comp	Sci
Confidence-weighted (Crammer et al., 2012)	94.39%	97.56%
PV-DBOW (Le and Mikolov, 2014)	92.60%	98.02%
Glo-PV-DBOW-Apri-2	94.56%	98.42%
Glo-PV-DBOW-Apri-5	94.43%	98.13%
Glo-PV-DBOW-TPD-2	94.59%	**99.20%**
Glo-PV-DBOW-TPD-5	**95.47%**	98.74%

is recorded in Table 2. Compared with Confidence-weighted (Crammer et al., 2012) and PV-DBOW (Le and Mikolov, 2014), our extended models achieve the highest accuracy on each subdataset. Moreover, TPD as a pure dependence works better than Apriori when they provide the global context for our model. The topical information is effectively reinforced in embeddings by incorporating TPD.

4.3 Analysis on Word Embeddings

The cosine similarity of each word pair in 20 Newsgroups is computed. We list four center words and their nearest neighbors in PV-DBOW and Glo-PV-DBOW groups respectively. The rankings are labeled in front of neighbor words, and some notable neighbor words are in bold.

From Table 3, we can see that the statistical information of corpus like words co-occurrence can be mined by TPD. Therefore, the Glo-PV-DBOW's embeddings are context-aware and it can help a lot for classification tasks. The top 40 nearest neighbors of *ibm* are investigated, and we find *macintosh* and *mac* appeared in the PV-DBOW group but not in the Glo-PV-DBOW group. In

Table 3: Nearest neighbors of words ranking list based on cosine similarity.

Center word	PV-DBOW	Glo-PV-DBOW
ibm	1:aix	1:aix
	2:pc	2:pc
	...	3:pc's
	23:**macintosh**	4:**austin**
	34:**mac**	5:**workstations**
mac	1:macintosh	1:macintosh
	2:quicktime	2:**apple's**
	3:portable	3:quicktime
	4:utilities	4:**apple**
	5:**macs**	5:**macs**
486	1:386	1:386
	2:486dx	2:**cpu**
	3:33mhz	3:486dx
	4:486dx2	4:486dx2
	5:**cpu**	5:33mhz
Kingston	1:aix	1:aix
	2:mike	2:**ibm**
	3:sharks	3:jones
	4:jones	4:sharks
	5:**ibm**	5:mike

the corpus, the topic of documents is either *ibm* or *mac*. If we perform a classification task on "*ibm* versus *mac*", it will be hard to classify in the PV-DBOW group. That is because PV-DBOW tends to regard *ibm* and *mac* both as computers. However, the two different computer brands are distinguished in Glo-PV-DBOW. Further, *ibm* and *mac* co-occur rarely in one document, and the statistical information is noted by TPD.

5 Conclusion

This paper proposes to incorporate Theta Pure Dependence into Paragraph Vector to capture more topical and sentimental information in the context. The extended model is applied to a sentiment classification task and a topical detection task. Our accuracy outperforms the state-of-the-art result on the movie and news datasets. The approach can be improved further to fully leverage the un-factorized sense of high-order Theta Pure Dependence. In future, we will explore the applications of dependence distributed representation.

Abstract

We propose a novel data augmentation approach to enhance computational behavioral analysis using social media text. In particular, we collect a Twitter corpus of the descriptions of annoying behaviors using the *#petpeeve* hashtags. In the qualitative analysis, we study the language use in these tweets, with a special focus on the fine-grained categories and the geographic variation of the language. In quantitative analysis, we show that lexical and syntactic features are useful for automatic categorization of annoying behaviors, and frame-semantic features further boost the performance; that leveraging large lexical embeddings to create additional training instances significantly improves the lexical model; and incorporating frame-semantic embedding achieves the best overall performance.

1 Introduction

In the ever-expanding era of social media, many scientific disciplines, such as health and healthcare, biology, and learning sciences, have adopted computational approaches to exploit patterns and behaviors in large datasets (Wang et al., 2015; Chen and Lonardi, 2009; Baker and Yacef, 2009). In contrast, the primary methods for behavioral sciences still rely on lab experiments with limited amount of subjects, which are time consuming and financially expensive. In addition to this, it is also difficult to obtain a set of samples with geographical variations in traditional lab-based behavioral experiments.

I really hate being interrupted while I'm talking to someone #petpeeve #canyounot 🤦

Figure 1: An anonymized example of *#petpeeve* tweets.

While the social media data are abundantly available, computational approaches to behavioral sciences using Twitter are not well-studied. Even when statistical techniques are applied to these tasks, their concentration has been on simple statistical significance tests and descriptive statistics (De Charms, 2013; Zhang et al., 2013). Therefore, we believe that statistical natural language processing techniques are needed for insightful analysis and interpretation in behavioral studies.

In this paper, we use Twitter as a corpus for computational behavioral science. More specifically, we focus on a case study of analyzing annoying behaviors. To do this, we exploit a corpus of 9 million tweets (Cheng et al., 2010), and extract the tweets that describe these behaviors using the *#petpeeve* hashtags. *#petpeeve* is a popular Twitter hashtag, which describes behaviors that might be annoying to others. An example of *#petpeeve* tweets is shown in Figure 1. To facilitate the analysis, we manually annotate 3,375 tweets with 60 fine-grained categories, which will be described in Section 3. We use a sparse mixed-effects topic model to analyze the salient words in each category, as well as the geographic variations. We show that lexical, syntactic, and semantic features enhance the automatic categorization of annoying behaviors; and that the performance is further improved with a novel lexical and frame-semantic embedding based data augmentation ap-

*We understand that many people find long titles annoying, so we intentionally use a very long one to help people understand what "pet peeve" means.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2557–2563,
Lisbon, Portugal, 17-21 September 2015.

proach. Our main contributions are three-fold:

- We provide a Twitter corpus with fine-grained annotations for computational behavior studies;
- We qualitatively analyze the Twitter language concerning annoying behaviors, with a focus on the topics and geographical variations;
- We propose various linguistic features and a novel data augmentation approach for automatic categorization of annoying behaviors.

We outline related work in the next section. The dataset is described in Section 3. We introduce the approach for analyzing *#petpeeve* Tweets in Section 4. Experimental results are shown in Section 5. We discuss possible applications in Section 6, and conclude in Section 7.

2 Related Work

Psychologists, behavioral scientists, and computer scientists have studied a wide-range of methods for behavior extraction (Mast et al., 2015). For example, in lab experiments, arm and body postures (Marcos-Ramiro et al., 2013) are often used to extract self-touch and gestures, while eye gaze (Funes Mora and Odobez, 2012), head pose (Ba and Odobez, 2011), face location and motion (Nguyen et al., 2012), and full-body pose (Shotton et al., 2013) can also be used as cues to extract gazing, nodding, and arm-related behaviors. There are also significant amount of studies of extracting facial and speech features to understand smiling (Bartlett et al., 2008), eye contact (Marin-Jimenez et al., 2014), and verbal behaviors (Basu, 2002).

With the surge of interest in computational social science (Lazer et al., 2009), Twitter has become a popular resource to study data-driven methods in social science (Miller, 2011). For example, O'Connor et al. (2010a) align the Twitter messages with public opinion time series to study computational political science. Ritter et al. (2010) study Twitter dialogues using a clustering approach. Bollen et al. (2011) use a sentiment analysis approach to predict the American stock market via Twitter. Li et al. (2014b) have investigated the alignment of Twitter mood with weather for sentiment analysis. In recent years, language technology researchers have focused on developing genre-specific Twitter part-of-speech tagging (Gimpel et al., 2011), named entity recognition (Ritter et al., 2011), summarization (O'Connor et al., 2010b), sentiment analysis (Agarwal et al., 2011), event extraction (Ritter et al., 2012; Li et al., 2014a), paraphrasing (Xu et al., 2014), machine translation (Ling et al., 2013), and dependency parsing (Kong et al., 2014) methods. To the best of our knowledge, even though there have been studies on using Twitter hashtags to study language-related behaviors (González-Ibánez et al., 2011; Bamman and Smith, 2015), Twitter NLP approaches to non-linguistic behaviors are not well studied in general.

Table 1: The categories and percentages of annoying behaviors in *#petpeeve* tweets in our dataset. Note that 17% of the *#petpeeve* tweets are identified as *other* unrelated behaviors (not shown).

3 The Dataset

We use the Twitter corpus with 9 million sampled messages collected in prior work (Cheng et al., 2010), which includes a total of 121K users. The dataset includes latitude and longitude information.

We extract 3,375 tweets[1] with *#petpeeve* hashtags. We follow past work to annotate the tweets (Ritter et al., 2012; Li et al., 2014a): we apply the *LDA clustering + human-identification* approach to label the categories of the described annoying behaviors in these tweets. The human annotation process includes two stages: first, the annotators identify the 50 categories from the clustering process, and use these topics as a candi-

[1] http://www.cs.cmu.edu/~yww/data/petpeeves.zip

date label set to annotate the data; in the second stage, the categories are refined (to 60 classes) from the first pass, and the data is re-annotated with the refined human-specified category labels. Due to the complexity of this fine-grained annotation task, the inter-annotator agreement rate between two annotators is moderate (0.445).

The annotated categories and label distribution[2] of the dataset are shown in Table 1. In our random samples, the states that post the most *#petpeeve* tweets are NY, MD, CA, NJ, FL, GA, VA, TX, NC, PA, and DC. In our predictive experiments, we randomly select 60% of tweets for training, and 40% for testing.

4 Our Approach

In this section, we describe our methods for the qualitative and quantitative analyses. In particular, we briefly review a supervised approach of using sparse mixed-effects topic model to visualize the topical words to analyze this behavior data. For the quantitative task of automatic categorization of tweets, we propose a novel approach to create additional training data, using continuous lexical and semantic representations.

4.1 Supervised Topic Modeling

To analyze the salient words for each category of annoying behaviors, we utilize SAGE (Eisenstein et al., 2011), a state-of-the-art mixed-effect topic model, which has been used in several NLP applications (Sim et al., 2012; Wang et al., 2012). SAGE is ideal for our text analytic purposes, because it is supervised, and it builds relatively clean topic models by considering the additive effects and the background distribution of words. Therefore, we can use SAGE to visualize the salient words for each category of annoying behaviors using the 3,375 *#petpeeve* tweets. Each tweet is treated as a document, and we use Markov Chain Monte Carlo for inference. To facilitate the geographical analysis, we use Google's reverse geocoding service to extract the state information from coordinates, and apply SAGE for visualization.

[2]The categories that are not shown in the table are *backstabbing, boring, copycat, drinking, drug, empty promise, impoliteness, inconsiderate, indirect, insecurity, interference, irresponsible, jealous, judge, loneliness, misunderstanding, negativity, noisy, parents, politics, repetition, showoff, snobbish, stability, swearing, time-wasting, ungratefulness, and others*.

4.2 Embedding-Based Data Augmentation for Automatic Categorization of Tweets

In addition to the visualization task, we also ask the question: can we use linguistic cues to predict tweets that describe different annoying behaviors? We formulate the problem as a multiclass classification task, and consider the following feature sets:

- **Lexical Features**: we extract unigrams as surface-level lexical features.
- **Part-of-Speech Features**: to model shallow syntactic cues, we extract lexicalized part-of-speech features using the Stanford part-of-speech tagger (Toutanova et al., 2003).
- **Dependency Triples**: to better understand the deeper syntactic dependencies of keywords in tweets, we have also extracted typed dependency triples (e.g., *nsubj(hate,I)*) using the MaltParser (Nivre et al., 2007).
- **Frame-Semantics Features**: SEMAFOR (Das et al., 2010) is a state-of-the-art frame-semantics parser that produces FrameNet-style semantic annotation. We use SEMAFOR to extract frame-level semantic features.

Embeddings for Data Augmentation Since the Twitter messages are often short and noisy, and the training data is relatively scarce for each class, we consider the feasibility of leveraging external resources, in particular, continuous word embeddings (Mikolov et al., 2013a) to enhance the multiclass text categorization model.

Two major challenges for leveraging word embeddings for tweet classification are: 1) because word embeddings are continuous, it is difficult to fuse them with other discrete syntactic and semantic features; 2) it is not straightforward how one should transform the word-level representation to the tweet-level representation. In our preliminary experiments, we have evaluated the continuous word representation method (Turian et al., 2010), as well as incorporating neighboring words in the embeddings as additional features, but both methods fail to outperform the lexical baseline that uses only bag-of-word unigrams.

To solve this problem, we propose the use of neighboring words in continuous representations to create new instances to augment the training

Table 3: The geographical variation of the annoying behaviors.

dataset. More specifically, in the embedding vocabulary $\mathcal{W}$, we search for the k-nearest-neighbor (knn) word w for a query term using cosine similarity between query $\vec{Q}$ and target word vectors $\vec{W}$:

$$\arg\max_{w \in \mathcal{W}} cosine(\vec{Q}, \vec{W}) \quad (1)$$

For each word in a tweet, we query the external embeddings, and replace them with their knn words to create a new training instance. For example, consider the tweet *"Being late is terrible"* with the *punctuality* label, after searching for knn words for each token, we create a new training instance: *"Be behind are bad"* with the same label.

Frame-Semantic Embeddings Although lexical (Mikolov et al., 2013a) and dependency based embeddings (Levy and Goldberg, 2014) have been studied, semantic-based embedding is still less understood. We consider the continuous embedding of semantic frames (Baker et al., 1998). To do this, we semantically parsed 3.8 million tweets using SEMAFOR (Das et al., 2010), and built a continuous bag-of-frame model to represent each semantic frame using Word2Vec[3]. We then use the same data augmentation approach to create additional instances with these semantic frame embeddings.

Table 4: Comparing linguistic features for categorizing annoying behaviors. The best results are highlighted in **bold**.* indicates that the result is significantly better than the lexical baseline ($p < .0001$).

5 Experiments

5.1 Qualitative Analysis

We show the results of the visualization of salient words for each category of tweets in Table 2. SAGE clearly does a good job identifying annoying specific behaviors in each category. For example, in the *traffic* category, we see that the keywords *"cop"* and *"pulled"* that associate with traffic stop are identified. Also, *"slow"* and *"speed"* are also recognized as annoying behaviors during traffic. In the *selfishness* category, the word *"ONLY"* and *"Selfish"* are corrected identified. In the *silence* category, we see that the word *"R"* is promising, because it indicates the behavior when someone reads a blackberry message without reply. We see that many slang expressions are associated with various labels.

In Table 3, we show the geographical variation of tweets. The word *"dmv"* (DC-Maryland-Virginia) is correctly associated with MD and DC, and when we search the database, these *#petpeeve* tweets mainly refer to the 2010 snowstorm in the Winter affecting these areas. The *"daddy"* is prominent in the state of Florida, while the word *"rims"* is also identified, showing the unique car culture of this southern state.

5.2 Quantitative Evaluation

Experimental Setup We use the logistic regression model from LibShortText (Yu et al., 2013)

Methods	Prec.	Rec.	F1	Imp.
Lexical Baseline (No Data Augmentation)	.341	.342	.341	—
+ UrbanDictionary Embeddings	.343	.344	.344	0.9%
+ Twitter Embeddings*	.357	.358	.358	4.7%
+ GoogleNews Embeddings*	**.364**	**.366**	**.365**	**6.1%**
All Features Baseline (No Data Augmentation)	.365	.367	.366	—
+ Lexical (GoogleNews) and Frame-Semantic Embeddings*	.376	.377	.376	2.7%
+ Lexical (Twitter) and Frame-Semantic Embeddings*	**.379**	.380	.379	3.6%
+ Lexical (UD) and Frame-Semantic Embeddings*	**.379**	**.381**	**.380**	**3.8%**

Table 5: The effectiveness of leveraging continuous embeddings to create additional training instances. Imp.: relative improvement to the baseline without data augmentation. The best results for each section are highlighted in **bold**.* indicates that the result is significantly better than the baseline without data augmentation ($p < .0001$).

as the classifier in our 60-way multi-class classification experiments. Grid search is used to select the best hyper-parameter using the training data only. A final classifier is then trained using the best hyper-parameters and test set results are reported. We set $k = 5$ for knn in our data augmentation experiments: the training data is expanded to 5 times of the original size. We use a paired two-tailed student's t test to assess the statistical significance.

Word2Vec is used to train various lexical and semantic embedding models. We consider three lexical embeddings and one frame-semantic embeddings for data augmentation: 1) GoogleNews Lexical Embeddings trained with 100 billion words (Mikolov et al., 2013b); 2) Twitter Lexical Embeddings trained with 51 million of words; 3) Urban Dictionary lexical embeddings trained with 53 million of words from slang definitions and examples; 4) Twitter Semantic Frame Embeddings trained with 27 million frames.

Varying Feature Sets We compare various features in Table 4. We see that adding shallow part-of-speech features does not have a strong effect on the performance, but adding the dependency triples significantly outperforms the lexical baseline. We see that the semantic frames are particular useful, showing a 7% relative improvement over the baseline.

The Effectiveness of Data Augmentation Table 5 shows the results of data augmentation. We see that using the Google News lexical embeddings to augment the training data brings a 6.1% relative F1 improvement over the lexical baseline. When considering the additional frame-semantic embeddings from Twitter, our system obtains the best F1 of 0.380, bringing a 3.8% improvement over the no data augmentation baseline with all linguistic features.

6 Discussion

We provide a case study of automatically categorizing annoying behaviors using *#petpeeve* Tweets. We hope that this study can further solicit relevant research on fine-grained analysis of annoying behaviors in different dimensions, and use computational approaches to improve social good. For example, by using coordinates and other APIs, one might analyze the annoying behaviors in the public working environments (e.g., office, meeting rooms, etc.). By understanding what annoys their employees, companies can renovate their working setups, refine their policies, and improve the satisfaction and productivity of their employees.

In addition to *#petpeeve* Tweets, there are many other interesting hashtags that align well with traditional topics in behavior sciences. For example, hashtags like *#occupywallstreet* can be used to study crowd behaviors in terms of a political unrest. The *#ALS* hashtag can be used to study public behaviors in reaction to philanthropic campaigns. Overall, Tweets from carefully selected hashtags can be inexpensive to obtain, and facilitate significant amount of behavioral studies.

7 Conclusion

In this paper, we have presented a case study of the annoying behaviors using Twitter as a corpus. Our fine-grained visualization approach shows insights of different categories of these behaviors, with the geographical effects. We also show that linguistic cues are useful to categorize these behaviors automatically, and that using lexical and semantic embeddings as a data augmentation method significantly improves the performance.

Detection of Steganographic Techniques on Twitter

Abstract

We propose a method to detect hidden data in English text. We target a system previously thought secure, which hides messages in tweets. The method brings ideas from image steganalysis into the linguistic domain, including the training of a feature-rich model for detection. To identify Twitter users guilty of steganography, we aggregate evidence; a first, in any domain. We test our system on a set of 1M steganographic tweets, and show it to be effective.

1 Introduction

Consider this: two isolated prisoners, communicating by letters scrutinised by the prison warden. They cannot write openly about escape plots, and the warden destroys any written in code. They must *hide* the true message within the letter, using *steganography*: the art of hiding information.

In *cover modification*[1] steganography, a *cover* object is tweaked so that it carries a hidden message: this is called *embedding*, the tweaked version is the *stego* object, and the message is the *payload* (Fridrich, 2009). The message should not be detectable to any observer (the standard terminology for this is the *warden*, taken from the prisoner metaphor) who knows the system is deployed, but does not know the original cover.

We are concerned here with *linguistic steganography*, in which the cover is a piece of text, and the message is embedded using textual transformations intended to preserve the meaning of the original: synonym substitutions, syntactical transformations, etc. Note that we are not concerned with the subset of linguistic steganography that hides in file formatting (e.g. white space, as in Por et al. (2008)), which has no security against an informed warden (in the case of hiding information by adding extraneous white space, the warden simply has to look for consistent irregular use of spaces to spot an active steganographer).

The field suffers from a number of issues: compared to images, text covers have low capacity (Chang and Clark, 2010); certain methods are weak against human attackers (Grosvald and Orgun, 2011) (most paraphrase systems cannot guarantee perfectly fluent stego objects); finally, authors are generally concerned with the performance of the transformation (whether they produce grammatically/semantically correct transformations), rather than whether the generated stego objects are detectable or not (e.g. Chang and Clark (2010)).

However, there is a new challenger in the field. We proposed a new linguistic stegosystem (Wilson et al., 2014) and verified its security against human judges, who were unable to distinguish genuine covers from manipulated stego objects.

This paper aims to attack CoverTweet statistically. We are in the shoes of the warden, attempting to classify stego objects from innocent[2] cover objects. We propose techniques new to linguistic steganalysis, including a large set of features that detect unusual and inconsistent use of language and the aggregation of evidence from multiple sentences. This last development, known in the steganographic literature as *pooled steganalysis* (Ker, 2007), represents a first in both linguistic and image steganalysis.

[1] There are other steganographic paradigms, not in scope. *Translation* based methods hide information in the automatic translation of the cover (e.g. Meng et al. (2011)). Cover *generation* methods automatically produce text containing the payload (e.g. Chapman et al. (2001)).

[2] It is usual to call steganographers and their output 'guilty' (with non-steganographers and unchanged cover objects being 'innocent'). This has the possibility of seeming politically charged, so we will use the term 'active' instead: be aware that this is not the usual terminology.

Lisbon, Portugal, 17-21 September 2015.

2 Linguistic Stegosystems

T-Lex (Winstein, 1998) is the oldest available cover-modification based linguistic stegosystem. It uses a dictionary containing a small number of disjoint synonym sets extracted from WordNet (Miller, 1995). Each set is unambiguously ordered (e.g. alphabetically), then values are embedded by changing cover words for their synonyms. Due to the the small dictionary, the *capacity* of covers is only ~ 0.1 bits per sentence.

CoverTweet is a modern evolution of T-Lex. It hides information in tweets by applying paraphrase rules taken from the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013), a set of 169M rules. The system applies suitable rules to a given cover, generating a set of possible stego objects. These are ranked by a distortion measure (derived from the probabilities of applied rules and from sentence probabilities given by a language model), and assigned a keyed hash. A human operator filters the options for fluency, and chooses the best stego object with the desired hash.

CoverTweet uses a subset of the PPDB, restricted to lexical and phrasal substitutions. Even with the reduced set of rules, 4 bits can be embedded per tweet, and it was proven secure against human judges (Wilson et al., 2014).

Twitter is a realistic setting for steganography. There is precedent for information hiding and mass monitoring on micro-blogging sites, such as the use of code words and government censorship on the Chinese website Sina Weibo (Chen et al., 2013). For this reason, we are attacking this setting.

There are many other linguistic stegosystems, using an array of different hiding methods (e.g. adjective deletion, word order, anaphora resolution: (Chang and Clark, 2012a), (Chang and Clark, 2012b), (Vybornova and Macq, 2007)). Approximately 1 bit of payload per cover sentence is usual, making CoverTweet the exception. Unfortunately for steganalysis literature, the vast majority of these require data that is unavailable (and too expensive to reproduce); beyond CoverTweet, the only system that can be evaluated is T-Lex.

3 Related Work

To our knowledge, there have been only five prior attempts at linguistic steganalysis on cover modification based systems; of these, four attack T-Lex, the other attacks an equivalent proprietary system. Taskiran et al. (2006) was the first, using n-gram language models to extract features from stego text, before training a support vector machine (SVM) on the features. We will adopt some of these features for our attack.

Subsequent work (Xin-guang et al. (2006); Yu et al. (2009); Chen et al. (2011); Xiang et al. (2014)) has used smaller models: they have all designed a *single* feature to exploit a weakness, and used this (or the mean and variance of it) to train a classifier for attack. Analysis of results, especially the effect of embedding rate on detection, has been lacking or non-existent. This focus on individual features echoes the early work on image steganalysis, which has since shifted towards feature-rich models. We will be utilising the latter here, in addition to the pooled steganalysis paradigm.

4 Proposed features

Below we describe four classes of proposed features for individual tweets. Each class will be evaluated individually, and in combination.

Basic features Including: word count (including tokenised punctuation); the mean and variance of the number of characters in each word; the total stop word count[3]; and the counts for each individual stop word. (131 features)

n-gram features Using a 5-gram model, for n from 1 to 5, the mean, variance and total log likelihood of the n-grams in the tweet. (15 features)

Word length Equivalent to the n-gram features, using a 10-gram model of word length. We expect the PPDB to replace common words with uncommon longer words, or multiple shorter words. (30 features)

PPDB features *Kerckhoffs' principle* (Fridrich, 2009), which states that a stegosystem must be secure even when the attacker (*us*) knows how the system works, introduces an interesting opportunity for linguistic steganalysis. As all linguistic stegosystems rely on automatic paraphrasing, and generally require a source of data, it is conservative to assume that the attacker has access to this data source. As the attacker, we can derive features from this data.

Applying this, we extracted features using the same subset of the PPDB that CoverTweet uses. To our knowledge, this is the first work to explicitly apply Kerckhoffs' principle to linguistic

[3]We use the Natural Language Toolkit (Bird, 2006) for the list of 127 stop words.

steganalysis. This set includes: a repeat of the n-gram features, but only taking into account n-grams that contain at least one word in[4] the PPDB; the mean and variance of character count for words in the PPDB; for phrase lengths j from 1 to 5, the proportion of j-grams in the tweet that are in the PPDB; likelihood of the most probable paraphrased sentence, extracted by generating sentences in the same way as CoverTweet. Finally, a substitution score: each word or phrase in the PPDB is replaced by its most likely substitute, according to the language model. The max, min, mean and variance of the log likelihoods for the resulting sentences are used. (27 features)

4.1 Pooling the features

Individual linguistic stego objects carry a tiny payload, making detection an incredibly difficult task. In some cases, the stego tweet will be identical to the cover, making the task impossible. Although we do not hope to reliably identify stego tweets individually, the warden can still try to catch the active steganographers: through *pooled steganalysis* (Ker, 2007). Here, the warden considers all the evidence for each user, and aims to identify those actively using steganography. We combine features from batches of tweets, by the same user: taking the max, min, mean and variance of each feature. If performing steganography causes small consistent changes to a feature, this will be apparent in the mean. If it causes inconsistent changes, it may be apparent in the variance. If it occasionally produces an extreme result, the max and min will capture this. (812 features)

5 Method and Results

Here we take the role of an automatic censor, attempting to identify users on Twitter who are sending secret messages. We imagine a scenario where CoverTweet is openly available, and so can assume this is the system utilised by the active users.

5.1 Data and Embedding

From the Harvard TweetMap (Mostak, 2013), we gathered 72M English language tweets, from 1.2M users. Each tweet was canonicalised as follows: tokenised; made lowercase; usernames replaced by a uniform token; URLs replaced by a uniform token. We randomly selected 1000 users with 1000-2000 tweets to train and test a classifier. On the remaining tweets, we trained a 10-gram word length model, and a 5-gram language model, using SRILM (Stolcke, 2002) with Kneyser-Ney smoothing. For vocabulary, the language model was given every word in the PPDB, and every word in the set of tweets, including the removed tweets. We do not expect this to provide an unrealistic advantage to the censor: any word not in the PPDB cannot hide information.

We randomly took 10 users from the set of 1000, and produced 100 stego tweets for each, for three payload sizes: 1, 2 and 4 bits. The stego tweets were generated using CoverTweet, with a human operator selecting the most fluent option containing a desired (randomly generated) payload. If there were no fluent options, the tweet was skipped. If the tweet already contained the desired payload (if the hash value of the tweet already matched the message), it was left unchanged. We refer to this data as Manual CoverTweet (M-CT).

Due to the expensive nature of generating data with a human judge, and to assess the value of the human in-the-loop, we also automatically generated 1M stego tweets, by embedding data in 1000 tweets for each of the 1000 users. The same three payload sizes were used. Here, the tweet with the highest probability (provided by the language model and the PPDB) was selected. Again, the tweet was left unchanged if the tweet already contained the desired payload. Tweets were only skipped if there were no options with the correct payload. We refer to this as Automatic CoverTweet (A-CT). Finally, we embedded 1 bit in the same tweets using T-Lex, rejecting any that contained no words in the T-Lex dictionary; the result was approximately 100 tweets on average per user.

We split the users in half, training a linear ensemble classifier (Kodovskỳ et al., 2012) (designed to work with large feature sets for steganalysis) on feature instances from one half, testing it on the other. We only classified tweets by users for whom the classifier had no prior knowledge. All error rates are averaged over 10 different random user splits. For the M-CT data, where we have a much smaller set of data, we performed 10-fold cross validation, leaving one user out for testing each fold.

In each experiment we matched training and testing data: the training data was produced by the

[4]Where we say a word or phrase is 'in' the PPDB, we mean it features in one or more paraphrase rules that could have been applied to the original tweet.

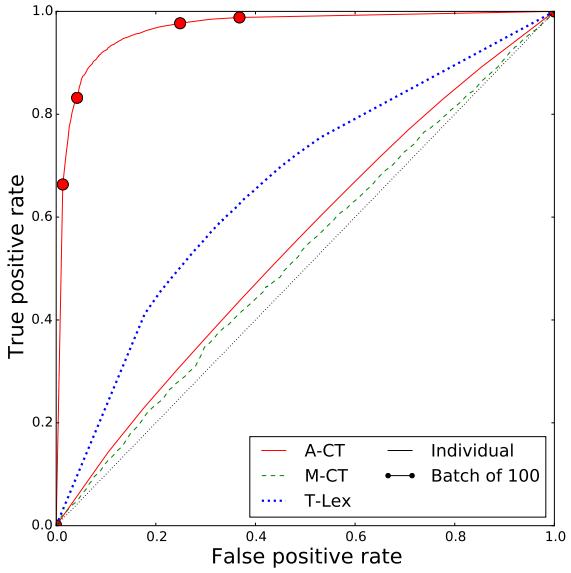

Figure 1: ROCs for each embedding method, for individual tweets or batches containing 1 bit.

	Batch size	AUC
A-CT	1	0.551
M-CT	1	0.509
T-Lex	1	0.667
A-CT	100	0.9631

Table 1: AUC values for the ROCs shown in Figure 1

same method as the testing data. For M-CT we tried an alternative scheme, by training on A-CT data, but testing on M-CT; this did not work reliably, and the accuracy of the resulting model went down as pooled batch size increased. The exploration of this phenomenon is left for later work.

5.2 A note on unchangeable covers

Some tweets cannot hide the payload, either when there are no paraphrase options for that hash, or when the human (for M-CT) vetoes all the options. This is the *non-shared selection channel* problem in steganography. Methods such as *syndrome trellis codes* (Filler et al., 2011) allow the unchangeable cover elements to be sent without compromising the message. These have not been applied to linguistic steganography, but we simulate their use: we remove the unchangeable tweets from the cover and stego sets, essentially giving the steganographer and detector the ability to ignore such tweets.

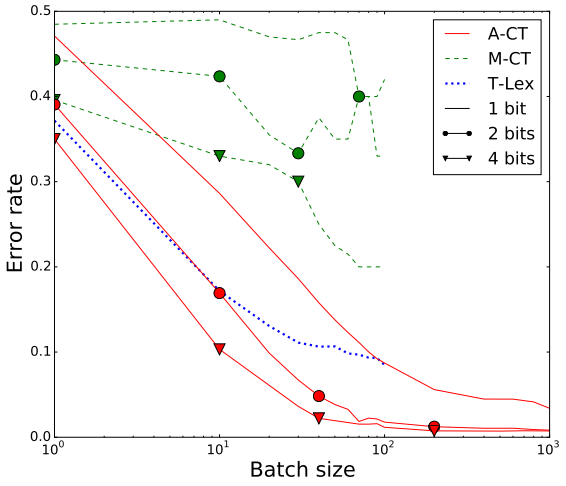

Figure 2: The effect of batch size on error rate. Batches of 100 are the maximum for M-CT and T-Lex, but we go up to 1000 with A-CT.

5.3 Results

As expected, the performance of the classifiers trained on individual tweets is poor (see Figure 1). In particular, the models trained on A-CT and M-CT data have very low accuracy on data with 1 bit payload, performing only slightly better than random guessing. T-Lex tweets prove slightly easier to detect. This does not mean that the systems are secure however. Though we cannot identify individual stego tweets, when we pool evidence we find we are able to train a model that can identify active users with high accuracy, for all data sets.

Figure 2 shows the change in error rate as the batch size (the number of tweets we pool) is increased. We can clearly see that increasing batch size improves accuracy. We also see that increasing payload size makes active users easier to spot. This is unsurprising: CoverTweet is forced to choose from fewer options when payload increases.

The experiment showed us that M-CT is the most secure stegosystem, though not immune to the effects of pooling. When combining features from 100 tweets, the classifier had an error rate of 0.21 on 4 bit M-CT data; data generated in the same way, with the same payload, was previously shown to be secure against human judges. With large batches, detection of A-CT is almost perfect.

To establish which class of features had the biggest effect on detection, we trained models on each combination of features described in Section 4. A subset of these combinations are shown

	b	n	p	w	b+n	n+p	p+w	b+n+p	p+n+c	all
A-CT (2 bits)	0.345	0.311	0.217	0.376	0.266	0.204	0.203	0.180	0.191	0.169
T-Lex (1 bit)	0.448	0.226	0.273	0.317	0.226	0.202	0.218	0.198	0.168	0.168

Table 2: Error rates for models trained on different combinations of feature class, for a batch of 10. The feature sets are as follows: basic (b), n-gram (n), PPDB (p) and word length (w).

in Table 2, for A-CT and T-Lex.We can see that for A-CT, the PPDB features easily outperform others, with an error rate of 0.217 when used alone; the warden's knowledge of the system is powerful. The second best is the n-gram set, though it performs better on T-Lex than on A-CT. This is most likely due to CoverTweet's use of the language model in the embedding stage: the system is attempting to minimise the distortion that these features are looking for. T-Lex has no such distortion measure, leaving it open to this sort of attack.

Basic and PPDB feature sets fare worse on T-Lex. The basic features are aimed at changes in word count and stop word usage: neither of these are affected by T-Lex substitutions. The PPDB features are at a disadvantage with T-Lex, as they are designed for CoverTweet. If T-Lex's data source were used instead of CoverTweet's, the performance would likely improve significantly.

The combination of PPDB and n-gram features on T-Lex gives us some interesting insight: despite the mismatch of substitution source, we still see an improvement over the n-gram features used on their own. This suggests that the warden does not need the exact data source as the steganographer for these features to be useful.

6 Conclusion

It was believed that linguistic steganography was weak against humans, but CoverTweet disproved it. We have shown that individual stego objects are seemingly also strong against statistical attacks. However, by pooling multiple pieces of evidence against a user, the warden can drastically improve detection rate. With each steganographic tweet sent, the user creeps closer to being caught. This is the first steganalytic classifier, in any domain, that successfully exploits pooled evidence. The design of steganographic systems must now take this type of attacker into account. It would interesting to determine whether human judges are capable of pooling large amounts of scant evidence: we conjecture not.

Results suggest that detection is improved by utilising rich-feature models; we only scratched the surface with regards to this. There are many avenues to explore, such as using multiple language models from which to extract features (this is the analogue of filter banks used in contemporary image steganalysis (Fridrich and Kodovskỳ, 2012)).

The security of a system should first be measured against a powerful (informed) attacker. We played this role by using features extracted using exact knowledge of the CoverTweet system (the PPDB features); this class of features was particularly effective against CoverTweet. The system should now be evaluated against a weaker attacker. We have seen that detection is still reliable when the warden knows the wrong system (T-Lex), but further experiments are required to determine exactly how detection rate is affected by mismatches in paraphrase sources, or language model.

Abstract

We consider the task of automatically identifying participants' motivations in the public health campaign Movember and investigate the *impact* of the different motivations on the amount of campaign donations raised. Our classification scheme is based on the *Social Identity Model of Collective Action* (van Zomeren et al., 2008). We find that automatic classification based on Movember profiles is fairly accurate, while automatic classification based on tweets is challenging. Using our classifier, we find a strong relation between types of motivations and donations. Our study is a first step towards scaling-up collective action research methods.

1 Introduction

Social media is a valuable source for studying health-related behaviors (De Choudhury, 2014). For example, Twitter was used for disease surveillance (Lamb et al., 2013; Aramaki et al., 2011), and was studied for its role in disseminating medical information (Desai et al., 2012) and organizing public health campaigns (Emery et al., 2014; Wehner et al., 2014). Social media data provides many opportunities to study social phenomena such as health campaigns, but statistics based on aggregating *across* social media users only provide a big picture of the phenomenon. A deeper analysis of such phenomena requires fine-grained information about the involved users. Since such information is often not readily available, numerous studies have appeared on automatically inferring user characteristics (Bamman et al., 2014; Eisenstein et al., 2010; Nguyen et al., 2013).

In the context of health campaigns, social scientists have been interested in the *motivations* of the participants (Cugelman et al., 2011). Knowledge about individual motivations helps to explain the emergence and effectiveness of collective action, such as volunteering (Bekkers and Wiepking, 2011) or mobilizing other people (van den Broek et al., 2015). The Social Identity Model of Collective Action (SIMCA) (van Zomeren et al., 2008) identifies three key motivations of participants: 1) *social identification* with the campaign organization and community, 2) a perception of *injustice* about the cause, and 3) *collective efficacy*, the collective belief that the campaign can make a difference. Taken together, these three motivations predict the chance that an individual will participate in collective action, such as participation in an online health campaign. Aggregating motivations to group-level may explain the effectiveness of online health campaigns. Social scientists, however, have not used computational methods to measure these motivations (Johnston et al., 2009), so that their analyses are often confined to small datasets.

Our study is a first step towards scaling-up collective action research methods. To do so, we explore automatic classification of the motivation types according to the SIMCA model. We analyze the global health campaign Movember (movember.com), which aims to raise funds and awareness of men-related health issues by engaging online conversations. Movember's fundraisers ask their friends to sponsor their moustache and their efforts in the month of November. The funds are donated to research concerned with men-related health issues, such as prostate cancer.

Movember participants provide their motivations in their Movember profile. For example, a participant writing '*In honor of my Grandfather*' could be considered having an injustice motivation, while '*To lead the brave men of Team [...] (and our exceptionally understanding significant others) in epic moustachery.*' indicates a social identification motivation. Because such explicit motivation statements are not available for many online health campaigns, we also explore motiva-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2570–2576,
Lisbon, Portugal, 17-21 September 2015.

tion classification based on the tweets of participants during the campaign instead.

Our paper makes the following contributions:

- We automatically classify the motivations of Movember participants and explore the use of *free-text* motivations provided in Movember profiles and *tweets* posted by the participants during the campaign (Section 3).
- We apply our classifier to all *US* and *UK* Movember profiles and find that participants with an injustice motivation raise significantly more funds (Section 4).

2 Dataset

In this section we discuss the collection and the annotation of the data.

2.1 Collection

We collect data from two different sources.

Movember Profiles We focus on participants from the two countries with the highest number of English speaking Movember participants: the United States and the United Kingdom. From Movember we obtained the identifiers of all participants of these two countries and we crawled all US and UK Movember profiles in May 2015. We extracted information such as the name, motivation (free-text), amount raised and whether the participant was part of a team. We collected 166,422 US and 138,546 UK profiles.

Twitter Data We link Movember participants to Twitter accounts based on tweets with a link to a Movember profile in 2013 and 2014 (e.g., '*please support my moustache [LINK]*'). If the Levenshtein distance between the name of the author of the tweet and the name in the Movember profile was 1 or less, we considered it a match (in total: 5,519 users). Manual inspection of 100 matches showed that this method was highly precise (100% precision). However, some matches were missed due to the low Levenshtein distance threshold. For each Twitter user in our dataset, we collected the last 3,600 tweets.

We kept all tweets written between October 18 and December 14 (2 weeks before and after the campaign). For each user, we used tweets from either 2013 or 2014, depending on whether the user posted a tweet with a Movember link at least once during the period, given preference to the year 2014.

2.2 Annotation

We annotated the campaign participants based on their provided motivations in their 'My motivation' section of their Movember profiles. The motivation categories in our codebook are based on the Social Identity Model of Collective Action (van Zomeren et al., 2008):

- *Injustice:* A shared emotion that includes both affective (e.g, anger) and cognitive perceptions (ideology) of an unfair situation (van Zomeren et al., 2008). It covers the ideological motivation to join a campaign, when potential participants compare the cause and the situation of patients with their personal values (Klandermans, 2004). For example, '*my dad*', '*I had testicular cancer*' or '*because men's health is important to me*'.
- *Social identity:* A sense of belonging together that emerges out of common attributes, experiences and external labels (van Zomeren et al., 2008). Participants may have social motivations to identify with the online health campaign, while not being interested in the cause (Kristofferson et al., 2014). This category includes psychological benefits, such as reputation or fun, that the social interactions of a campaign provide. For example, '*my friends asked me again to join them*', or '*a great excuse to grow a stache*'.
- *Collective efficacy:* The shared belief that ones group is capable of resolving its grievances through a campaign (Bandura, 2000; Klandermans, 2004; van Zomeren et al., 2008), for example by stating '*this campaign can make a difference!*'.

Multiple motivations may be assigned to a single campaign participant. Exactly recurring motivation texts that occurred frequently (more than 50 times, based on data analysis), were most likely prefilled texts. They were not annotated, because it was unclear whether participants used these 'default' motivations on purpose. For example, the most frequent motivation '*my motivation is to use the power of the moustache to have an everlasting impact on the face of mens health*' appeared in 104k profiles. The interrater reliability calculated using Cohen's Kappa was found to be satisfactory to good based on 200 double annotations: injustice (0.71), social identity (0.67) and collective efficacy (0.47) (Landis and Koch, 1977).

Features	Injustice				Social Identity				Collective Efficacy

Table 1: Results free-text motivations: precision (P), recall (R), F_1 score and AUC.

From the set of Movember participants with matched Twitter accounts, we annotated a randomly selected subset of 2,108 participants. 21.8% of the participants had more than one motivation type assigned. We randomly split our dataset into a training and test set (Table 2). We have made our annotations available to other researchers[1].

	Train	Test
# Participants	1,494	614
% US / UK	54.8/45.2	53.3/46.7
% Injustice	37.6	40.2
% Social identity	48.7	46.9
% Collective efficacy	36.1	35.0

Table 2: Dataset statistics

3 Classification Experiments

In this section we present results on automatically identifying the motivations of Movember participants. Because participants may have multiple motivation types, we train binary classification models for each motivation type separately. We use logistic regression with L2 regularization, implemented using the Scikit-learn toolkit (Pedregosa et al., 2011). We report results on the test set using precision, recall, F_1 score and the Area Under Curve (AUC) metric. Note that a majority class classifier achieves an AUC of 0.5. Feature development and parameter tuning was done based on cross-validation on the training set. Based on the same set of Movember participants, we explore the use of two different types of data: the provided free-text motivations in Movember profiles (Section 3.1) and tweets of the participants (Section 3.2).

[1] `http://www.dongnguyen.nl/data.html`: The identifiers of the Movember and corresponding Twitter accounts, the country, text provided in the Movember profiles, and the annotations.

3.1 Free-text Movember Motivations

All text is lowercased and tokenized. We explore the following features: 1) Token unigrams and bigrams (frequency values), 2) LDA with 20 topics (Blei et al., 2003) trained on text from all US and UK Movember profiles (with the topic proportions as feature values), 3) Text length, and 4) Country (US=1, UK=0) to control for prior motivation distributions in the two countries.

The token features already lead to a high performance, and no notable increase in performance is observed by adding the other features (Table 1). The features with the highest weight are shown in Table 4. The performance numbers are in line with the obtained inter-annotator agreement. For example, the performance is highest on the injustice category, which also had the highest inter-annotator agreement (and vice versa for collective efficacy).

The lengths of texts alone have predictive power. The texts are short (on average 158.4 characters), but there are markable differences between motivation types. Participants with an injustice motivation write longer motivations: the average length of their texts is 213.74 chars in the training set, compared to 148.24 chars (social identity) and 130.93 chars (collective efficacy).

Injustice	Social Identity	Collective Efficacy
LDA topic[a]	fun	LDA topic[b]
cancer	team	beat
friend	moustache	and family
lost	mo	change
father	grow	yourself
had	mustache	all of

Table 3: Results on tweets: precision (P), recall (R), F_1 score and AUC.

3.2 Tweets

In this section, we present experiments on identifying the motivations based on Twitter data.

Preprocessing Many of the tweets posted during the time of the campaign are not about the campaign itself. Based on manually selected character sequences[2], we separate relevant from non-relevant tweets. The tweets are tokenized using the CMU POS tagger (Owoputi et al., 2013). The average number of tweets per user during the studied period is 109.1 (median: 46.0) and the average number of relevant tweets is 8.0 (median: 4.0).

Features We explore the same features as with the free-text motivations and several new features:

- *Unigram and bigram tokens*: URLs and user mentions are replaced by generic tokens. We only keep tokens used by at least 10 Twitter users and we use their normalized frequency.
- *URLs*: We extract tokens from URLs by taking the hostname, and paths up to depth 2 (e.g., *us.movember.com/team/12345* results in *us.movember.com*, *us.movember.com/team* and *us.movember.com/team/12345*).
- *User mentions*: The Twitter accounts that are mentioned.
- *Effort*: Length (#characters), #tweets about Movember, #tweets about Movember/#total number of tweets.
- *LDA* with 20 topics (Blei et al., 2003). The model is trained on 1.5M tweets from 2013 and 2014 about the Movember campaign.
- *Country*: US=1, UK=0.
- *Behavior*: Fraction of retweets, tweets that contain a user mention, hashtag, URL, or are a reply. Number of days with a tweet about Movember. Fraction of tweets in each week.

Results The results are reported in Table 3. The URLs and behavior features were excluded from the run with the combined feature set, because their individual results suggest no predictive power (possibly due to the small training set). The results are fairly low and just above the 0.5 AUC value of a random classifier. To test whether the best performing classifiers for each motivation type (based on their AUC scores) are significantly better than a random classifier, we use permutation tests. We permute the labels to break the link with the features and calculate the AUC scores of the classifiers by training and testing on 1000 of such permutations. The best classifiers for the injustice and social identity motivation types are significantly better than random (p <0.01), but the performance of the collective efficacy classifier is only slightly significant (p <0.05).

To understand the low performance numbers, we took a closer look at the task and the data. First, we aimed to get a sense of the difficulty of the task. In a small experiment based on 100 Twitter users from the test set, one of the authors read the tweets and tried to identify the motivations. The results were also low (injustice: 0.488, social identity: 0.548, and collective efficacy: 0.590), suggesting that the task in itself is also difficult for humans.

The task is challenging because many users only post a few tweets about the campaign. In our data, 382 users have only one relevant tweet and 1,271 users have 5 relevant tweets or less. Furthermore, many of the tweets posted during the campaign focus on the Movember community (Bravo and Hoffman-Goetz, 2015; Dwi Prasetyo et al., 2015), making it hard to distinguish between the different motivations. For example, *instagram.com* is among the top three of hostnames for all motivation types. Sometimes participants

[2] '*movember*', '*mobro*', '*mosista*', '*cancer*', '*shave*', '*donat*', '*tache*', '*prostate*', '*mo*', '*testicular*', '*mental*' '*men's health*'

do explicitely mention their motivation (e.g., '*In honour of my dad, [..], I'm growing a horrible moustache for an incredible cause, #Movember. Donate here: [LINK]*'), but such instances are rare and in general the motivations of participants are much less visible through their tweets.

Social media plays a large role in mediating social relationships and users adapt their behavior to the online communities they are participating in (Danescu-Niculescu-Mizil et al., 2013; Nguyen and Rosé, 2011). This may explain why most participants, regardless of their motivation, emphasize the Movember community and its practices (such as the growing of moustaches) in their tweets. Various studies within the emerging field of Computational Social Science (Lazer et al., 2009) have found that Twitter tends to be a good reflection of society (Lamb et al., 2013; O'Connor et al., 2010). However, our results emphasize that the nature of the used platform influences how humans behave, and that this should be taken into account when interpreting the data. In the case of Movember, Twitter data alone could give a misleading view of the motivations of the campaign's participants.

4 Motivations and Campaign Behavior

In this section we present a linear regression analysis (n=90,484) of how motivations affect campaign donations by applying our classifier to all US and UK Movember profile texts. Participants of the Movember campaign can be part of a team. We therefore included actual team membership as a control variable, as we expect that team members increase fundraisers' effort due to peer pressure. In our analysis, we exclude all participants that have predefined motivations (214,484 out of the 304,968 profiles), because these may not reflect the actual motivation.

The social identity motivation is the most frequent in both countries, but the countries differ in their distributions regarding the injustice and collective efficacy motivations (Table 5).

	% Injustice	% Identity	% Efficacy
UK	31.0	49.7	46.1
US	37.6	50.3	32.1

Table 5: Motivation distribution based on automatic annotation (n=90,484). Note that participants may have multiple motivations.

On average, US participants donate more than UK participants (Table 6). US campaign participants with an injustice motivation raise significantly (coef = 91.525, $p < 0.001$) more money than participants with a social identity (coef = -5.479, $p =$ not significant) or collective efficacy motivation (coef = -5.765, $p < 0.1$). Participants that are part of a team raise significantly (coef = 75.849, $p < 0.001$) more money than participants without a team. Similar results were obtained for the UK. Furthermore, participants with a social identity motivation are more often part of a team (UK: 58% vs. 51% of the participants without a social identity motivation, US: 80% vs. 76%). The regression analysis reveals that being part of a team has a stronger and more positive effect on the amounts raised than the expression of identity as a motivation in the Movember profiles. Our findings are in line with recent Slacktivism research which proposes that people that express social motivations are reluctant to give more than token support due to a lack of interest in the campaigns cause (van den Broek et al., 2015; Kristofferson et al., 2014). Actual team membership, however, contributes to the effectiveness of online fundraising.

	Injustice	Identity	Efficacy
UK ($)	203.74	128.36	123.39
US ($)	234.47	156.07	169.03

Table 6: Average amount raised (n=90,484). British pounds were converted in dollars following the exchange rate in November 2013.

5 Conclusion

We explored the task of automatically identifying the motivations of Movember campaign's participants. A classifier based on Movember profile texts performed better than a classifier based on Twitter data, possibly due to the role of Twitter in building social relationships. Based on US and UK Movember data, we found a strong link between motivations and donations, and motivations and team membership. Classification of motivations might help campaign organizers to improve their communication strategies. Our study is limited to the Movember campaign. Future research might diverge to other types of online collective action, such as online petitions and open source communities. We also plan to explore larger datasets and features based on network structures.

Acknowledgements Thanks to Ariana Need and Anna Priante for helpful discussions and feedback on the article, Movember for support on collecting the Movember accounts and feedback on the article, and Twitter for providing part of the tweets used in this study through the Twitter Data Grant. Thanks also to the anonymous reviewers for their helpful comments. This research was funded in part by the 3TU Federation and the Dutch national project COMMIT. The first author was also supported by the Netherlands Organization for Scientific Research (NWO) grant 640.005.002 (FACT).

Abstract

Domestic abuse affects people of every race, class, age, and nation. There is significant research on the prevalence and effects of domestic abuse; however, such research typically involves population-based surveys that have high financial costs. This work provides a qualitative analysis of domestic abuse using data collected from the social and news-aggregation website reddit.com. We develop classifiers to detect submissions discussing domestic abuse, achieving accuracies of up to 92%, a substantial error reduction over its baseline. Analysis of the top features used in detecting abuse discourse provides insight into the dynamics of abusive relationships.

1 Introduction

Globally, 30% of women fifteen and older have experienced physical and/or sexual intimate partner violence at some point in their life (Devries et al., 2013). While domestic abuse tends to have greater prevalence in low-income and non-western countries, it is still endemic in regions like North America and Western Europe. In the United States, by an intimate partner, 9.4% of women have been raped, 16.9% of women and 8% of men have experienced sexual violence other than rape, and 24.3% of women and 13.8% of men have experienced severe physical violence (Black et al., 2011). This translates to an estimated economic cost of $5.8 billion for direct medical and mental health care services, along with lost productivity and reduced lifetime earnings (Craft, 2003). Economic costs are calculable and provide concrete metrics for policy makers, but the physical and psychological effects felt by victims of domestic abuse are the true costs. Domestic abuse is the 12^{th} leading cause of years of life lost (Murray et al., 2013), and it contributes to health issues including frequent headaches, chronic pain, difficulty sleeping, anxiety, and depression (Black et al., 2011).

The data used to calculate such statistics are often derived from costly and time-consuming population-based surveys that primarily seek to obtain insight into the prevalence and consequences of domestic abuse. Due to safety concerns for victims and researchers, these surveys follow strict guidelines set by the World Health Organization (Garcia-Moreno et al., 2001). Great care must be taken by the researchers to ensure the safety of the participants, and therefore the number of participants is often quite small (Burge et al., 2014). One way to avoid the cost of wide scale surveys while still maintaining appropriate research conditions is to leverage the abundance of data publicly available on the web. Of particular interest are moderated forums that allow discourse between users.

Reddit[1] is one such website, and the chosen source of data for this paper. This site has a wide range of forums dedicated to various topics, called *subreddits*, each of which are moderated by community volunteers. For subreddits dedicated to sensitive topics such as depression, domestic abuse, and suicide, the moderators tend to ensure that the anonymous submitter has access to local help hotlines if a life-threatening situation is described. They also enforce respectful behavior and ensure that the submissions are on topic by deleting disrespectful or off-topic posts. Finally, they ensure that site rules are followed, including the strict disallowal of *doxing*, the practice of using submission details to reveal user identities.

Reddit allows lengthy submissions, unlike Twitter, and therefore the use of standard English is more common. This allows natural language processing tools like semantic role labelers trained on standard English to function better. Finally, Red-

[1] See `www.reddit.com`.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2577–2583,
Lisbon, Portugal, 17-21 September 2015.

dit allows users to comment on submissions, providing them with the ability to ask questions, give advice, and provide support. This makes its data ideal for sensitive subjects not typically discussed in social media.

This work makes two contributions: classifiers for identifying texts discussing domestic abuse and an analysis of discussions of domestic abuse in several subreddits.

2 Related Work

Social media sites are an emerging source of data for public health studies, such as mental health, bullying, and disease tracking. These sites provide less intimidating and more accessible channels for reporting, collectively processing, and making sense of traumatic and stigmatizing experiences (Homan et al., 2014; Walther, 1996). Many researchers have focused on Twitter data, due to its prominent presence, accessibility, and the characteristics of tweets. For instance, De Choudhury et al. (2013) predicted the onset of depression from user tweets, while other studies have modeled distress (Homan et al., 2014; Lehrman et al., 2012). Most relevantly, Schrading et al. (2015) used the #WhyIStayed trend to predict whether a tweet was about staying in an abusive relationship or leaving, analyzing the lexical structures victims of abuse give for staying or leaving.

Reddit has been studied less in this area, with work mainly focusing on mental health. In Pavalanathan and De Choudhury (2015), a large number of subreddits on the topic of mental health were identified and used to determine the differences in discourse between throwaway[2] and regular accounts. They observed almost 6 times more throwaway submissions in mental health subreddits over control subreddits, and found that throwaway accounts exhibit considerable disinhibition in discussing sensitive aspects of the self. This motivates our work in analyzing Reddit submissions on domestic abuse, which can be assumed to have similar levels of throwaway accounts and discussion. Additionally, Balani and De Choudhury (2015) used standard ngram features, along with submission and author attributes to classify a submission as high or low self-disclosure.

[2]Anonymous, one-time accounts to submit a single (often personal or sensitive) submission or comment.

3 Dataset[3] and Data Analysis

Following the procedure in Balani and De Choudhury (2015) for subreddit discovery, we identified several subreddits that focus on domestic abuse. Additionally, we determined subreddits unrelated to domestic abuse, to be used as a control set. Table 1 shows the subreddits, the total number of unique posts (called *submissions*[4]), and total number of replies to those submissions (called *comments*) collected.

Domestic Abuse	**# Submissions**	**# Comments**
abuseinterrupted	1653	1069
domesticviolence	749	2145
survivorsofabuse	512	2172
Control	**# Submissions**	**# Comments**
casualconversation	7286	285575
advice	5913	31323
anxiety	4183	23300
anger	837	3693

Table 1: The domestic abuse subreddits and control subreddits with the total number of submissions and comments collected.

The *anger* and *anxiety* subreddits were chosen as control subreddits in order to help the classifier discriminate between the dynamics of abusive relationships and the potential effects of abuse on victims. For example, anxiety and anger may be affect caused by domestic abuse, but they are also caused by a wide variety of other factors. By including these subreddits in the control set, a classifier should utilize the situations, causes, and stakeholders in abusive relationships as features, not the affect particularly associated with abusive relationships. Similarly, the *advice* subreddit was chosen as a way to help the classifier understand that advice-seeking behavior is not indicative of abuse. The *casualconversation* subreddit allows discussion of anything, providing an excellent sample of general written discourse. The domestic abuse subreddits have far fewer active users, submissions, and comments in total.

3.1 Preprocessing

All experiments used the same preprocessing steps. From the collected subreddits, only submissions with at least one comment were chosen to be included for study. We then ran the submission text through the Illinois Curator (Clarke et

[3]Released on nicschrading.com/data/.

[4]Submission text is its title and selftext (an optional text body) concatenated together.

al., 2012) to provide semantic role labeling (SRL) (Punyakanok et al., 2008). A total of 552 domestic abuse submissions were parsed, and we randomly chose an even distribution of the control subreddits (138 each), yielding a total sample size of 1104. All submissions were normalized by lowercasing, lemmatizing, and stoplisting. External links and URLs were replaced with *url* and references to subreddits, e.g. */r/domesticviolence*, were replaced with *subreddit_link*.

3.2 Descriptive Statistics

We present basic descriptive statistics on the set of 552 abuse submissions and 552 non-abuse submissions in Table 2.

	Abuse	**Non-Abuse**
Avg comments/post	5.4 ± 6.1	13.2 ± 25.3
Avg score/post	6.1 ± 5.1	7.5 ± 16.4
Avg tokens/post	278 ± 170	208 ± 164
# unique submitters	482	535
Avg comment depth	0.96 ± 1.5	1.5 ± 1.9
Avg comment score	2.2 ± 2.7	2.1 ± 2.9
Avg tokens/comment	107 ± 128	53.4 ± 79.9
# comments	2989	6964
# unique commenters	1022	2519

Table 2: Basic descriptive statistics. The score is provided by users voting on submissions/comments they feel are informative. The depth of a comment indicates where in a reply chain it falls. A depth of 0 means it is in reply to the submission, a depth of 1 means it is in reply to a depth 0 comment, etc. The $\pm$ values are standard deviation metrics.

In general, the non-abuse subreddits have more discourse between commenters, as indicated by a larger comment depth, however, the abuse subreddits tend to have longer submissions and replies. The abuse subreddits perhaps also have a smaller more tight-knit, community as indicated by fewer numbers of unique submitters and commenters.

3.3 Ngram Attributes

To get a sense of the language used between the two sets of subreddits, the most frequent 1-, 2-, and 3-grams were examined. While there are many common and overlapping ngrams in the two sets, each set does have distinct ngrams. In the abuse set, distinct ngrams include the obvious *abuse* (1595 occurences), *domestic violence* (202), and *abusive relationship* (166). Additionally, unique 3-grams related to the agents and situations in abusive relationships like *local dv agency* (12) and *make feel bad* (11) appear. Also included are unique empathetic and helping discourse from comments, including *let know* (121), and *feel free pm*[5] (27). This indicates that comment data could improve classification results, as support and empathy may be more prevalent in the *abuse* set than in the control set.

3.4 Semantic Role Attributes

From the SRL tool, our dataset was tagged with various arguments of predicates. This data is particularly useful in our study, as we are interested in examining the semantic actions and stakeholders within an abusive relationship. By performing a lookup in Proposition Bank (Martha et al., 2005) with a given argument number, predicate, and sense, we retrieved unique role labels for each argument.

We determined the top 100 most frequent roles and predicates in the two sets, and took only the unique roles and predicates within each set to see what frequently occurring but unique roles and predicates exist within the abuse and control group.

Role Label	**Predicate**
caller, 175	abuse, 433
thing hit, 174	share, 167
agent, hitter - animate only!, 164	believe, 164
abuser, agent, 162	call, 151
entity abused, 139	remember, 149
utterance, 115	cry, 147
patient, entity experiencing hurt/damage, 113	!tell, 142
utterance, sound, 104	send, 127
belief, 104	thank, 127
benefactive, 103	realize, 124

Table 3: Top 10 unique roles and predicates with their frequency for the abuse data. An exclamation point on a predicate indicates negation.

Table 3 contains roles and predicates that are powerful indicators of an abusive relationship, including a *caller*, *hitter*, *thing hit*, *abuser*, and *entity experiencing hurt/damage*. Importantly, several predicates that appear in this data also appear in a study on discussions of domestic abuse in Twitter data, including *believe* and *realize*, which indicate cognitive manipulation in the victims of domestic abuse (Schrading et al., 2015).

[5]The initials *pm* stand for private message.

Classifer	N	P	R	N+P	N+R	P+R	N+P+R
Linear SVM	$\mathbf{90 \pm 3}$	72 ± 5	73 ± 4	88 ± 3	88 ± 3	73 ± 4	87 ± 3

Table 4: Classification accuracies of Linear SVM. N=Ngrams, P=Predicates, R=Roles.

4 Classification Experiments

In order to discover the semantic and lexical features salient to abusive relationships, we designed several classifiers. The subreddit category to which a submission was posted was used as the gold standard label of *abuse* or *non-abuse*. The labels were validated by examining the top ngrams, roles, and predicates in Section 3, and taking into account that these subreddits are moderated for on-topic content. We ran several experiments to study classifiers, the impact of features, and the effect of comments on prediction performance.

4.1 Combinations of Features

We used the 1-, 2-, and 3-grams in the submission text, the predicates, and the semantic role labels as features, using TF-IDF vectorization[6]. Perceptron, naïve Bayes, logistic regression, random forest, radial basis function SVM, and linear SVM classifiers were parameter optimized using 10-fold cross validation. Table 4 contains the results for the best classifier. The best features are the ngrams, achieving the highest accuracies alone. Predicates and semantic roles perform admirably, but bring the classifier accuracies down slightly when added to ngrams. To determine the top features for prediction, we examined the weights of the top performing classifier, Scikit-learn's (Pedregosa et al., 2011) Linear SVM with C=0.1, as in Guyon et al. (2002). These, along with their weights, are shown in Table 5.

4.2 Comment Data Only

We experimented with only comment data to predict if they were posted in an *abuse* or *non-abuse* subreddit. Because ngram features performed best in the previous experiment, a larger set of submissions (1336 per class) was used. A final held out testset was created from 10% of these submissions, giving 1202 submissions per class for the devset and 134 per class for the testset. Taking the comments from these submissions yielded 4712 abuse and 19349 non-abuse comments for the devset and 642 abuse and 2264 non-abuse comments for the testset. 10-fold cross-validation was used on the devset to tune the classifier. Using a Linear SVM with C=1 achieved an F1 score of $0.70 \pm .02$ on the devset. On the held out testset, it achieved a precision of 0.68, recall of 0.62, and F1 score of 0.65. Examining its weights gives features similar to those in Table 5, with additional empathetic discourse like *thank*, *hug*, and *safe* in the abuse class.

[6]Binary features and only unigrams were tried but these did not improve results.

Abuse	Non Abuse
abusive, 1.3	anxiety, 1.1
child, 0.93	anger, 1.1
abuser, 0.86	job, 0.52
relationship, 0.84	school, 0.46
therapy, 0.83	hour, 0.45
survivor, 0.83	week, 0.45
domestic, 0.73	fuck, 0.44
happen, 0.72	class, 0.42
violence, 0.68	college, 0.41
father, 0.67	fun, 0.40

Table 5: Top 10 features based on Linear SVM weights using only ngrams from submissions. The classifier may be relying heavily on the anxiety and anger subreddits to discriminate between abuse and non-abuse, as indicated by the sharp drop in SVM weight from *anger* to *job*. Abuse word weights are more evenly distributed.

4.3 Comment and Submission Text Combined

Concatenating the comments to their respective submissions may improve results, but because comments can be completely off-topic or in reply to other comments, we experimented with only the top-scoring comments and those most similar to the submission text. To compute similarity we used a sum of the word vector representations from Levy and Goldberg (2014) as included in spaCy (Honnibal, 2015) and used cosine similarity. Taking only the top 90^{th} percentile in user voting score and text similarity, we had 2688 abuse comments and 7852 non-abuse comments concatenated to the 1336 submissions of their class. This method achieves extremely high accuracy of $94\% \pm 2\%$ on the devset and 92% on the testset using a Linear SVM with C=1. A classifier trained only on the submission text data from the same devset/testset split obtains the lower accuracies of

$90\% \pm 2\%$ on the devset and 86% on the testset, indicating that comments can add predictive power. The top features are similar to those in Table 5.

4.4 Uneven Set of Submissions

Using the method in Section 4.3 to train the classifier, a larger, uneven set of data was examined (still using only ngrams). This set contained 1336 *abuse* and 17020 *non-abuse* instances. From this set, 15% were held out for final examination as a testset and the rest was used as a devset with 5-fold cross-validation. On the devset, an F1 score of 0.81 ± 0.01 was achieved while on the testset it had a precision of 0.84, recall of 0.74, and F1 score of 0.79. The best classifier was a Linear SVM with C=100. The confusion matrix of the testset is in Table 4.4.

		Predicted Class	
		Abuse	**Non-Abuse**
Actual Class	**Abuse**	152	53
	Non-Abuse	29	2520

Table 6: Confusion matrix on the testset of the Abuse/Non-Abuse classifier.

This classifier has good precision for the *abuse* class, and decent recall, meaning that there can be confidence that submissions flagged as *abuse* are indeed about *abuse*. By applying this classifier to a large held out set of data, these results suggest that many potentially relevant submissions would be flagged for examination, and they would mostly be about *abuse*.

4.5 Testing on Completely Held Out Subreddits

To get a sense of efficacy in the wild in detecting submissions about abuse, the best classifier from Section 4.4 was taken (trained on the devset data) and run on a large set of submissions from the *relationships* and *relationship_advice* subreddits. These subreddits are general forums for discussion and advice on any relationship (not necessarily intimate). Their submissions tend to be long, descriptive, and extremely personal.

After running the abuse classifier on the submissions from these subreddits with at least 1 comment (13623 in total, with their 90^{th} percentile comments concatenated), 423 submissions were flagged as being about abuse. 101 of these 423 were annotated by 3 annotators (co-authors), using the labels *A* (the submission discusses an abusive relationship), *M* (off-hand mention of abuse), *N* (not about abuse), and *O* (off-topic submission or other).

From the three annotators' annotations, on average 59% are *A*, 16% are *M*, 23% are *N*, and 2% are *O*. The percentage of overall agreement was 72% and Randolph's free-marginal multirater kappa (Warrens, 2010) score was 0.63. Annotators occasionally had a hard time distinguishing between *A* and *M*, as context may have been missing. Combining the two by considering all *M* as *A*, the average percent of *A* increases to 75%, the percentage of overall agreement improves to 86% and the kappa score improves to 0.79. Taking the statistic that on average 75% of the flagged submissions in the annotated subset are about abuse or have a mention of abuse indicates that this classifier should hopefully have a precision of around 0.75 on unseen Reddit data at large. Understandably, the precision drops by about .1 compared to its use on the subreddits it was trained and tested on. A precision of 0.75 on this set of data would mean that any statistics from this set may include some noise, but overall, the trends should reveal important results about abuse.

5 Conclusion

This work provides an analysis of domestic abuse using the online social site Reddit. Language analysis reveals interesting patterns used in discussing abuse, as well as initial data about the semantic actions and stakeholders involved in abusive relationships. Multiple classifiers were implemented to determine the top semantic and linguistic features in detecting abusive relationships. Simpler features such as ngrams performed above the more complex predicate and role labels extracted from a semantic role labeler, though the more complex structures contribute to interesting insights in data analysis. Future work could use a larger training set from multiple online sites to analyze the patterns of online abuse discourse across varied forums.

Abstract

First Story Detection is hard because the most accurate systems become progressively slower with each document processed. We present a novel approach to FSD, which operates in constant time/space and scales to very high volume streams. We show that when computing novelty over a large dataset of tweets, our method performs 192 times faster than a state-of-the-art baseline without sacrificing accuracy. Our method is capable of performing FSD on the full Twitter stream on a single core of modest hardware.

1 Introduction

First Story Detection (FSD), also called New Event Detection, is the task of identifying the very first document in a stream to mention a new event[1]. FSD was introduced as port of the TDT[2] initiative and has direct applications in finance, news and government security. The most accurate approaches to FSD involve a runtime of $O(n^2)$ and cannot scale to unbounded high volume streams such as Twitter. We present a novel approach to FSD that operates in $O(1)$ per tweet. Our method is able to process the load of the average Twitter Firehose[3] stream on a single core of modest hardware while retaining effectiveness on par with one of the most accurate FSD systems. During the TDT program, FSD was applied to news wire documents and solely focused on effectiveness, neglecting efficiency and scalability. The traditional approach to FSD (Petrovic et al., 2010) computes the distance of each incoming document to all previously seen documents and the minimum distance determines the novelty score. Documents, whose minimum distance falls above a certain threshold are considered to talk about a new event and declared as first stories. Consequently, the computational effort increases with each document processed.

1.1 Related Work

Researchers have proposed a range of approaches to scale FSD to large data streams. Sankaranarayanan et al. (2009) were one of the first to apply FSD to Twitter. They reduced the volume by classifying documents into news/non-news and only compared to tweets within a 3-day window. They did not perform a quantitative evaluation of their approach. Sakaki et al. (2010) and Li et al. (2012) applied keyword filtering in conjunction with classification algorithms, which allowed them to efficiently detect certain events with high precision. These two approaches, although efficient and effective, require a user to explicitly define a set of keywords or to provide a set of examples that he wants to track. The approach cannot detect previously unknown events.

Phuvipadawat and Murata (2010), Ozdikis et al. (2012) and Cordeiro (2012), scale their systems by only considering tweets containing hashtags. Although efficient, this method don't consider 90% of the tweets (Petrovic, 2013), which limits their scope.

Cataldi et al. (2010), Weng et al.(2011) and Cordeiro (2012) use the degree of burstiness of terms during a time interval to detect new events. This approach is not suitable for FSD as events are detected with a time lag, once they grow in popularity.

Petrovic et al. (2010) were the first to demonstrate FSD on Twitter in constant time and space, while maintaining effectiveness comparable to those of pair-wise comparison systems. The key was to

Lisbon, Portugal, 17-21 September 2015.

reduce the search space using Locality Sensitive Hashing (LSH). Each tweet was hashed, placing it into buckets that contain other similar tweets, which are subsequently compared. Operation in constant space was ensured by keeping the number of tweets per bucket constant. Because LSH alone performed ineffectively, Petrovic et al. (2010) additionally compared each incoming tweet with the k most recent tweets.

Allan et al. (2003) analysed scoring functions for novelty detection while focusing on their effectiveness. They presented a language-model (LM) based novelty measure using the KL divergence between the LM of a document and a single LM built on all previously scored documents, which they referred to as an aggregate measure language model. The idea of maintaining a single representation covering all previously seen documents, instead of performing pairwise comparisons with every document is closely related to the approach presented in this paper.

2 Approach

First Story Detection is a challenging task (Allan et al., 2000). The highest FSD accuracy is achieved by nearest-neighbour methods, where each incoming document (tweet) is compared to all documents that came before it, and the novelty score is determined by the most-similar documents in the past. This approach requires us to make $n-1$ comparisons[4] to determine the novelty of document d_n. The approach becomes progressively slower with each processed document, and cannot scale up to unbounded streams like Twitter. Prior attempts to speed up FSD involve organising previously seen documents $d_1 \ldots d_{n-1}$ into clusters (Allan et al., 1989) or LSH buckets (Petrovic et al., 2010). The document d_n is then compared only to past documents in the nearest cluster or LSH bucket, resulting in substantially fewer than n comparisons. While this approach is reasonably effective, it does lead to decreased accuracy, as potentially relevant past documents may exist in other clusters/buckets and would not be compared against.

2.1 First Story Detection in constant time

Our method computes the novelty of document d_n in a time that is constant with respect to n. The main difference from previous approaches is that we do not compare d_n to individual documents that came before it. Instead, we store the content of past documents $d_1 \ldots d_{n-1}$ in a single lookup table H_{n-1}. When d_n arrives, we count what fraction of its content is novel by looking it up in H_{n-1}. The number of lookups is polynomial in $|d_n|$ (the length of the document), and is independent of n.

Formally, let d_n denote the set of distinct words occurring in the n'th document in the stream. Let a k-term $t{=}\{w_1, w_2, \ldots\}$ denote a non-empty set of up to k distinct words. We define the content c_n to be the set of all k-terms that can be formed from the words in the document $d_n : c_n = \{\, t : t \subset d_n,\ |t| \leq k\}$. We estimate the novelty of document d_n as the proportion of novel k-terms, i.e. k-terms that do not appear in the history H_{n-1}:

$$\mathrm{N}(d_n) = \sum_{t \in c_n} \alpha_{|t|} \binom{|d_n|}{|t|}^{-1} \begin{Bmatrix} 1 : t \notin H_{n-1} \\ 0 : t \in H_{n-1} \end{Bmatrix} \quad (1)$$

Here $\alpha_{|t|}$ is the weight assigned to k-terms of size $|t|$, and $\binom{|d_n|}{|t|}$ is the total number of such k-terms formed from d_n. After the novelty is computed, we update the history H to include all k-terms formed from d_n:

$$H_n \leftarrow H_{n-1} \cup c_n \quad (2)$$

The computational cost of equations (1) and (2) is determined by the number of k-terms formed from the document d_n, and can be bounded at $O(|d_n|^k)$ operations. The complexity is manageable, as tweets are short and we keep k small.

2.2 Operating in constant time and space

We use a Bloom filter (Bloom, 1970) to maintain the history H_{n-1} of previously seen k-terms. For each k-term t we compute a 32-bit Murmur[5] hashcode, and use it as an index into a fixed-length bit-array. This ensures that both membership testing ($t{\in}H$) and history update can be performed in constant time. Constraining H to be a fixed-length array also means that our method operates in constant space, irrespective of the size of the stream and its vocabulary growth. In contrast to our method, previous approaches to FSD required more and more memory to maintain the history of the stream (see Figure 3).

[4] Each comparison requires $|d_n|$ scalar multiplications; $|d|$ denotes the number of distinct words in document d.

[5] https://en.wikipedia.org/wiki/MurmurHash

A potential downside of using a Bloom filter is that it introduces a small probability of false matches: a novel k-term t_i may collide with a previously observed k-term t_j and would be reported as non-novel. The probability of collision is directly proportional to the load factor of the Bloom filter, i.e. the fraction of non-zero bits in the array. By Heaps law (Egghe, 2007) the number of distinct words (and k-terms) will continue to grow and will eventually saturate the bit-array. To mitigate this problem, we introduce a deletion strategy: whenever the load factor exceeds a pre-determined threshold ρ, we zero out a random bit in H. This allows us to keep low the probability of false matches, at the cost of forgetting some previously-seen k-terms.

2.3 Parameter settings

We make the following parameter choices based on initial experiments on our training dataset. We set the maximum size of k-terms to be $k = 3$ and keep the Bloom filter load factor under $\rho = 0.6$. We tokenize the tweets on punctuation, treat all hashtags and mentions as words, stem them using the stemmer by Krovetz (1993), but do not remove stopwords. We optimise the weights $\alpha_1 \ldots \alpha_k$ using grid search on the same training data set.

3 Experiments

In a streaming setting, documents arrive one at a time on a continual basis. FSD requires computing a novelty score for each document in a single-pass over the data. High novelty scores indicate new topics. We use the standard TDT evaluation procedure (Allan, 2002) and the official TDT3 evaluation scripts with standard settings for evaluating FSD accuracy. The Detection Error Trade-off (DET) curve shows the trade-off between miss and false alarm probability for the full range of novelty scores. The normalized Topic Weighted Minimum Cost (C_{min}) is a linear combination of miss and false alarm probabilities, which allows comparing different methods based on a single value metric. Efficiency is measured by the throughput of tweets per second and the memory footprint. To ensure a fair comparison, all reported numbers are averaged over 5 runs on an idle machine using a single core (Intel-Xeon CPU with 2.27GHz).

3.1 Data set

We use the data set developed by Petrovic (2013), Petrovic et al. (2013b) as a test set, which consists of 27 topics and 116,000 tweets from the period of April till September 2011. Parameters were tuned using a sample of the data set annotated by Wurzer et al. (2015) as a training set.

3.2 Baselines

We compare our system (**k-term**) against 3 baselines.

UMass is a state-of-the-art FSD system, developed by Allan et al. (2000). It is known for its high effectiveness in the TDT2 and TDT3 competitions (Fiscus, 2001) and widely used as a benchmark for FSD systems (Petrovic et al., 2010; Kasiviswanathan et al., 2011; Petrovic 2013;). UMass makes use of an inverted index and k-nearest-neighbour clustering, which optimize the system for speed by ensuring a minimal number of comparisons. To maximise efficiency, we set-up UMass to operate in-memory by turning off its default memory mapping to disk. This ensures fair comparisons, as all algorithms operate in memory.

LSH-FSD is a highly-scalable system by Petrovic et al. (2010). It is based on Locality Sensitive Hashing (LSH) and claims to operate in constant time and space while performing on a comparable level of accuracy as UMass. We configure their system using the default parameters (Petrovic et al., 2010).

KL-FSD We also compare our approach with the aggregate measure language model (Allan et al., 2003) because it builds upon a similar principle.

3.3 Effectiveness and Efficiency

In Table 1, the UMass system shows state-of-the-art accuracy ($C_{min} = 0.79$, lower is better), but can only process 30 tweets per second. LSH-FSD operates 17 times faster, at the cost of a 13% decrease in accuracy ($C_{min} = 0.90$). Our system (k-term) operates on par with UMass in terms of accuracy, while being 197 times faster. KL-FSD, which is based on uni-grams, reveals the highest throughput at a considerable cost of efficiency ($C_{min} = 0.96$).

To further investigate accuracy we also compare the systems over the full range of the novelty thresholds illustrated by the DET plot in Figure 1.

Algorithm	Cmin	%-diff	tweets/sec	speed-up
UMass	0.7981	-	30	-
LSH-FSD	0.9061	-13.5%	500	17x
KL-FSD	0.9648	-21%	**6,600**	220x
k-term	**0.7966**	+0.2%	5,900	197x

Table 1: Comparing the effectiveness and efficiency of our system (k-term) with the 3 baselines

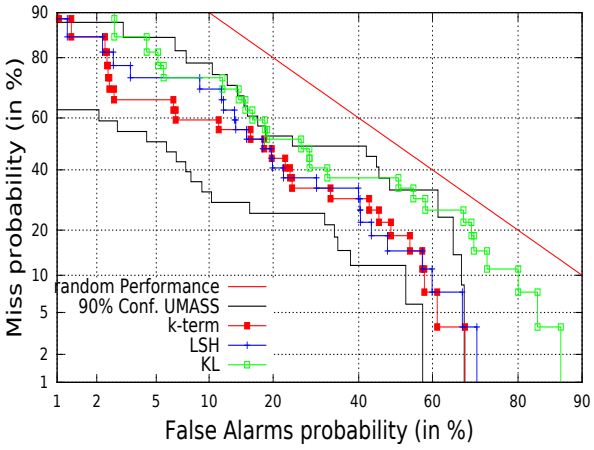

Figure 1: DET plot of UMass, Kl-FSD, LSH-FSD and k-term showing that LSH and k-term are statistically indistinguishable from UMass in terms of effectiveness;

Additionally we show the 90% confidence interval of UMass in two solid lines. We observer that both, FSD-LSH and our system (k-term) are statistically indistinguishable form UMass at any Miss-False Alarm trade-off point: their DET curves fall entirely within the 90% confidence interval of UMass. Note that DET curve of UMass is formed by the middle of it's 90% confidence interval curves. KL-FSD in contrast results in significantly worse accuracy than UMass in the mid-range and in particular the high recall area of the DET plot. We conclude that uni-grams are insufficient for determining the novelty of tweets.

3.4 FSD in constant time and space

High-volume streams require operation in constant time and space. Figure 2 compares the change in throughput of LSH-FSD, UMass and k-term as we process more and more tweets in the stream. Additionally, the plot also shows the average rate of tweets in the Twitter Firehose[6] at 5,787 tweets per second. Note that our system processes the equivalent of the full Twitter stream on a single core of modest hardware. This surpasses the throughput of LSH-FSD, a system known for high

[6]https://about.twitter.com/company (last updated: March 31, 2015)

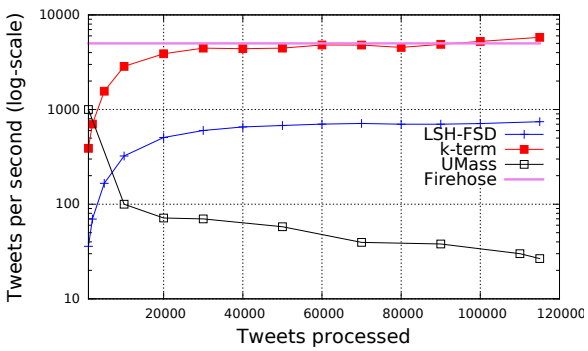

Figure 2: Throughput of UMass, LSH-FSD and k-term in comparison to the full Twitter stream (Firehose)

efficiency, by more than an order of magnitude. The throughput of LSH-FSD and k-term increases up until 20k documents because both approaches require initialisation of their data structures, which makes them slow when the number of documents is low. UMass has no initialization and performs the fastest when the number of documents is kept low. The pair-wise comparison of UMass causes it's throughput to decrease drastically with every new document. In Figure 2 we compare the memory requirements of k-term and LSH-FSD at different points in the stream. Although Petrovic et al. (2010) designed their system (LSH-FSD) to operate in constant space, we found that the memory requirement gradually increases with the number of documents processed, as seen in Figure 3. We hypothesise that this increase results from new terms added to the vocabulary. Our system has a strictly constant memory footprint.

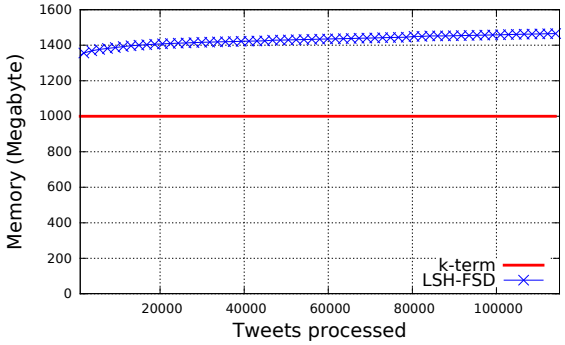

Figure 3: Space requirement for LSH-FSD and k-term; showing constant space for k-term

4 Conclusion

We presented an approach to FSD in a high volume streaming setting in constant time and space. Our approach computes novelty based on a single

lookup table that represents past documents. Shifting from direct comparisons with previous documents to comparisons with a single model that combines them, accounts for a great increase in efficiency. For the first time, we showed that it is possible to perform FSD on the full Twitter stream on a single core of modest hardware. This greatly outperforms state-of-the-art systems by an order of magnitude without sacrificing accuracy.

Abstract

Social media is a rich source of rumours and corresponding community reactions. Rumours reflect different characteristics, some shared and some individual. We formulate the problem of classifying tweet level judgements of rumours as a supervised learning task. Both supervised and unsupervised domain adaptation are considered, in which tweets from a rumour are classified on the basis of other annotated rumours. We demonstrate how multi-task learning helps achieve good results on rumours from the 2011 England riots.

1 Introduction

There is an increasing need to interpret and act upon rumours spreading quickly through social media, especially in circumstances where their veracity is hard to establish. For instance, during an earthquake in Chile rumours spread through Twitter that a volcano had become active and that there was a tsunami warning in Valparaiso (Mendoza et al., 2010). Other examples, from the riots in England in 2011, were that rioters were going to attack Birmingham's children hospital and that animals had escaped from the zoo (Procter et al., 2013).

Social scientists (Procter et al., 2013) analysed manually a sample of tweets expressing different judgements towards rumours and categorised them manually in supporting, denying or questioning. The goal here is to carry out tweet-level judgement classification automatically, in order to assist in (near) real-time rumour monitoring by journalists and authorities (Procter et al., 2013). In addition, information about tweet-level judgements has been used as a first step for early rumour detection by (Zhao et al., 2015).

The focus here is on tweet-level judgement classification on unseen rumours, based on a training set of other already annotated rumours. Previous work on this problem either considered unrealistic settings ignoring temporal ordering and rumour identities (Qazvinian et al., 2011) or proposed regular expressions as a solution (Zhao et al., 2015). We expect posts expressing similar opinions to exhibit many similar characteristics across different rumours. Based on the assumption of a common underlying linguistic signal, we build a transfer learning system that labels newly emerging rumours for which we have little or no annotated data. Results demonstrate that Gaussian Process-based multi task learning allows for significantly improved performance.

Birmingham children's hospital guarded by police? Really? Who would target a childrens hospital #disgusting #Birminghamriots	question

Table 1: Tweets on a rumour about hospital being attacked during 2011 England Riots.

The novel contributions of this paper are: 1. Formulating the problem of classifying judgements of rumours in both supervised and unsupervised domain adaptation settings. 2. Showing how a multi-task learning approach outperforms single-task methods.

2 Related work

In the context of rumour spread in social media, researchers have studied differences in informa-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2590–2595,
Lisbon, Portugal, 17-21 September 2015.

tion flows between content of varying credibility. For instance, Procter et al. (2013) grouped source tweets and re-tweets into information flows (Lotan et al., 2011), then ranked these by flow size, as a proxy of significance. Information flows were then categorised manually. Along similar vein, Mendoza et al. (2010) found that users deal with true and false rumours differently: the former are affirmed more than 90% of the time, whereas the latter are challenged (questioned or denied) 50% of the time. Friggeri et al. (2014) analyzed a set rumours from the *Snopes.com* website that have been matched to Facebook public conversations. They concluded that false rumours are more likely to receive a comment with link to *Snopes.com* website. However, none of the above attempted to automatically classify rumours.

With respect to automatic methods for detecting misinformation and disinformation in social media, Ratkiewicz et al. (2011) detect political abuse (a kind of disinformation) spread through Twitter. The task is defined in purely information diffusion settings and is not necessarily related with the truthfulness of the piece of information. Castillo et al. (2013) proposed methods for identifying newsworthy information cascades on Twitter and then classifying these cascades as credible and not credible. The main difference from our task is that credibility classification is carried out over the entire information cascade, classified objects are not necessarily rumours and no explicit judgement classification was performed in their approach.

Early rumour identification is the focus of Zhao et al. (2015), where regular expressions are used for finding questioning and denying tweets as a key pre-requisite step for rumour detection. Unfortunately, when we applied these regular expressions on our dataset, they yielded only 16% recall for questioning and 14% recall for denying tweets. Consequently, this motivated us to seek a better approach to tweet-level classification.

The work most relevant to ours is due to Qazvinian et al. (2011). Their method first carries out rumour retrieval, whereby tweets are classified into rumour related and non-rumour related. Next, rumour-related tweets are classified into supporting and not-supporting. The classifier is trained by ignoring rumour identities, i.e., pooling together tweets from all rumours, and ignoring the temporal dependencies between tweets. In contrast, we formulate the rumour classification problem as transfer learning, where unseen rumours (or rumours with few initial tweets observed) are classified using already known rumours – a much harder and more practical setting. Moreover, unlike Qazvinian et al. (2011), we consider the multi-class classification problem and do not collaps questioning and denying tweets into a single class, since they differ significantly.

Rumour	Supporting	Denying	Questioning
army bank	62	42	73
hospital	796	487	132
London Eye	177	295	160
McDonald's	177	0	13
Miss Selfridge's	3150	0	7
police beat girl	783	4	95
zoo	616	129	99

Table 2: Counts of tweets with supporting, denying or questioning labels in each rumour collection.

3 Data

We evaluate our work on several rumours circulating on Twitter during the England riots in 2011 (see Table 2). The dataset was analysed and annotated manually as supporting, questioning, or denying a rumour, by a team of social scientists studying the role of social media during the riots (Procter et al., 2013). The original dataset also included commenting tweets, but these have been removed from our experiments due to their small number (they constituted only 5% of the corpus).

As can be seen from the dataset overview in Table 2, different rumours exhibit varying proportions of supporting, denying and questioning tweets, which was also observed in other studies of rumours (Mendoza et al., 2010; Qazvinian et al., 2011). These variations in majority classes across rumours underscores the modeling challenge in tweet-level classification of rumour attitudes.

With respect to veracity, one rumour has been confirmed as true (Miss Selfridge's being on fire), one is unsubstantiated (police beat girl), and the remaining five are known to be false. Note, however, that the focus here is not on classifying truthfulness, but instead on identifying the attitude expressed in each tweet towards the rumour.

4 Problem formulation

Let R be a set of rumours, each of which consists of tweets discussing it, $\forall_{r \in R}\, T_r = \{t^r_1, \cdots, t^r_{r_n}\}$. $T = \cup_{r \in R} T_r$ is the complete set of tweets from all rumours. Each tweet is classified as supporting, denying or questioning with respect to its rumour: $y(t) \in \{0, 1, 2\}$, where 0 denotes supporting, 1 means denying and 2 denotes questioning.

First, we consider the Leave One Out (LOO) setting, which means that for each rumour $r \in R$, we construct the test set equal to T_r and the training set equal to $T \setminus T_r$. Therefore this is a very challenging and realistic scenario, where the test set contains an entirely unseen rumour, from those in the training set.

The second setting is Leave Part Out (LPO). In this formulation, a very small number of initial tweets from the target rumour is added to the training set $\{t^r_1, \cdots, t^r_{r_k}\}$. This scenario becomes applicable typically soon after a rumour breaks out and journalists have started monitoring and analysing the related tweet stream. The experiments section investigates how the number of initial training tweets influences classification performance on a fixed test set, namely: $\{t^r_{r_l}, \cdots, t^r_{r_n}\}$, $l > k$.

The tweet-level classification problem here assumes that tweets from the training set are already labelled with the rumour discussed and the attitude expressed towards that. This information can be acquired either via manual annotation as part of expert analysis, as is the case with our dataset, or automatically, e.g. using pattern-based rumour detection (Zhao et al., 2015). Afterwards, our method can be used to classify the attitudes expressed in each new tweet from outside the training set.

5 Gaussian Processes for Classification

Gaussian Processes are a Bayesian non-parametric machine learning framework that has been shown to work well for a range of NLP problems, often beating other state-of-the-art methods (Cohn and Specia, 2013; Lampos et al., 2014; Beck et al., 2014; Preotiuc-Pietro et al., 2015). We use Gaussian Processes as this probabilistic kernelised framework avoids the need for expensive cross-validation for hyperparameter selection.[1]

[1]There exist frequentist kernel methods, like SVMs, which additionally require extensive heldout parameter tuning.

The central concept of Gaussian Process Classification (GPC; (Rasmussen and Williams, 2005)) is a latent function f over inputs $\mathbf{x}$: $f(\mathbf{x}) \sim \mathcal{GP}(m(\mathbf{x}), k(\mathbf{x}, \mathbf{x}'))$, where m is the mean function, assumed to be 0 and k is the kernel function, specifying the degree to which the outputs covary as a function of the inputs. We use a linear kernel, $k(\mathbf{x}, \mathbf{x}') = \sigma^2 \mathbf{x}^\top \mathbf{x}'$. The latent function is then mapped by the probit function $\Phi(f)$ into the range $[0, 1]$, such that the resulting value can be interpreted as $p(y = 1|\mathbf{x})$.

The GPC posterior is calculated as

$$p(f^*|X, \mathbf{y}, \mathbf{x}_*) = \int p(f^*|X, \mathbf{x}_*, \mathbf{f}) \frac{p(\mathbf{y}|\mathbf{f})p(\mathbf{f})}{p(\mathbf{y}|X)} d\mathbf{f},$$

where $p(\mathbf{y}|\mathbf{f}) = \prod_{j=1}^{n} \Phi(f_j)^{y_j}(1 - \Phi(f_j))^{1-y_j}$ is the Bernoulli likelihood of class y. After calculating the above posterior from the training data, this is used in prediction, i.e.,

$$p(y_* = 1|X, \mathbf{y}, \mathbf{x}_*) = \int \Phi(f_*)\, p(f_*|X, \mathbf{y}, \mathbf{x}_*)\, df_*\,.$$

The above integrals are intractable and approximation techniques are required to solve them. There exist various methods to deal with calculating the posterior; here we use Expectation Propagation (EP; (Minka and Lafferty, 2002)). In EP, the posterior is approximated by a fully factorised distribution, where each component is assumed to be an unnormalised Gaussian.

In order to conduct multi-class classification, we perform a one-vs-all classification for each label and then assign the one with the highest likelihood, amongst the three (supporting, denying, questioning). We choose this method due to interpretability of results, similar to recent work on occupational class classification (Preotiuc-Pietro et al., 2015).

Intrinsic Coregionalization Model In the LPO setting initial labelled tweets from the target rumour are observed as well. In this case, we propose to weight the importance of tweets from the reference rumours depending on how similar their characteristics are to the tweets from the target rumour available for training. To handle this with GPC, we use a multiple output model based on the Intrinsic Coregionalisation Model (ICM; (Álvarez et al., 2012)). It has already been applied successfully to NLP regression problems (Beck et al., 2014) and it can also be applied to classification

ones. ICM parametrizes the kernel by a matrix which represents the extent of covariance between pairs of tasks. The complete kernel takes form of

$$k((\mathbf{x}, d), (\mathbf{x}', d')) = k_{data}(\mathbf{x}, \mathbf{x}')B_{d,d'} ,$$

where B is a square coregionalization matrix, d and d' denote the tasks of the two inputs and k_{data} is a kernel for comparing inputs $\mathbf{x}$ and $\mathbf{x}'$ (here, linear). We parametrize the coregionalization matrix $B = \boldsymbol{\kappa} I + \boldsymbol{v}\boldsymbol{v}^T$, where $\boldsymbol{v}$ specifies the correlation between tasks and the vector κ controls extent of task independence.

Hyperparameter selection We tune hyperparameters $\mathbf{v}$, $\boldsymbol{\kappa}$ and σ^2 by maximizing evidence of the model $p(\mathbf{y}|X)$, thus having no need for a validation set.

Methods We consider GPs in three different settings, varying in what data the model is trained on and what kernel it uses. The first setting (denoted GP) considers only target rumour data for training. The second (GPPooled) additionally considers tweets from reference rumours (i.e. other than the target rumour). The third setting is GPICM, where an ICM kernel is used to weight influence from tweets from reference rumours.

6 Features

We conducted a series of preprocessing steps in order to address data sparsity. All words were lowercased; stopwords removed; all emoticons were replaced with words[2]; and stemming was performed. In addition, multiple occurrences of a character were replaced with a double occurrence (Agarwal et al., 2011), to correct for misspellings and lengthenings, e.g., *looool*. All punctuation was also removed, except for ., *!* and *?*, which we hypothesize to be important for expressing emotion. Lastly, usernames were removed as they tend to be rumour-specific, i.e., very few users comment on more than one rumour.

After preprocessing the text data, we use either the resulting bag of words (BOW) feature representation or replace all words with their Brown cluster ids (Brown), using 1000 clusters acquired from a large scale Twitter corpus (Owoputi et al., 2013). In all cases, simple re-tweets are removed from the training set to prevent bias (Llewellyn et al., 2014).

[2]We used the dictionary from: `http://bit.ly/1rX1Hdk` and extended it with: :o, : |, =/, :s, :S, :p.

method	acc
Majority	0.68
GPPooled Brown	0.72
GPPooled BOW	0.69

Table 3: Accuracy taken across all rumours in the LOO setting.

7 Experiments and Discussion

Table 3 shows the mean accuracy in the LOO scenario following the GPPooled method, which pools all reference rumours together ignoring their task identities. ICM can not use correlations to target rumour in this case and so can not be used. The majority baseline simply assigns the most frequent class from the training set.

We can observe that methods perform on a level similar to majority vote, outperforming it only slightly. This indicates how difficult the LOO task is, when no annotated target rumour tweets are available.

Figure 1 shows accuracy for a range of methods as the number of tweets about the target rumour used for training increases. Most notably, performance increases from 70% to around 80%, after only 10 annotated tweets from the target rumour become available, as compared to the results on unseen rumours from Table 3. However, as the amount of target rumour increases, performance does not increase further, which suggests that even only 10 human-annotated tweets are enough to achieve significant performance benefits. Note also how the use of reference rumours is very important, as methods using only the target rumour obtain accuracy similar to the Majority vote classifier (GP Brown and GP BOW).

The top performing methods are GPCIM and GPPooled, where use of Brown clusters consistently improves results for both methods over BOW, irrespective of the number of tweets about the target rumour annotated for training. Moreover, GPICM is better than GPPooled both with Brown and BOW features and GPCIM with Brown is ultimately the best performing of all.

In order to analyse the importance of Brown clusters, Automatic Relevance Determination (ARD) is used (Rasmussen and Williams, 2005) for the best performing GPICM Brown in the LPO scenario. Only the case where the first 10 tweets are used for training is considered, since it already

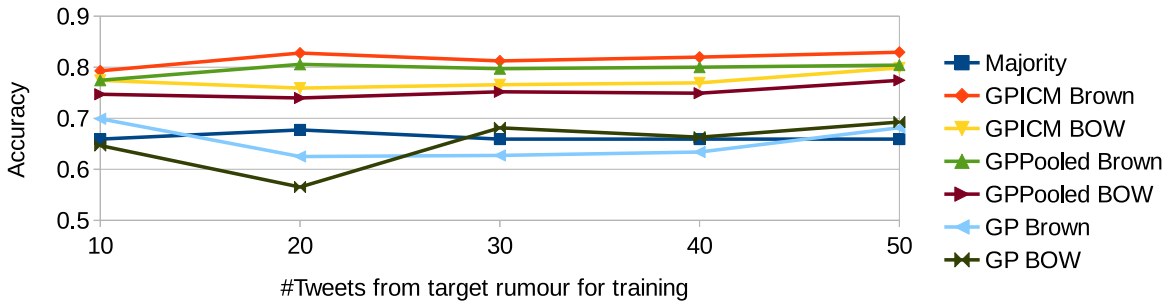

Figure 1: Accuracy measures for different methods versus the size of the target rumour used for training in the LPO setting. The test set is fixed to all but the first 50 tweets of the target rumour.

supporting	denying	questioning
?	fake	?

001000	10001101	01000111110
fake	!	true
11111000001	10001100	111110010110
true	bullshit	searching
111110010110	11110101011111	01111000010

Table 4: Top 5 Brown clusters, each shown with a representative word. For further details please see the cluster definitions at `http://www.ark.cs.cmu.edu/TweetNLP/cluster_viewer.html`.

performs very well. Using ARD, we learn a separate length-scale for each feature, thus establishing their importance. The weights learnt for different clusters are averaged over the 7 rumours and the top 5 Brown clusters for each label are shown in Table 4. We can see that clusters around the words *fake* and *bullshit* turn out to be important for the denying class, and *true* for both supporting and questioning classes. This reinforces our hypothesis that common linguistic cues can be found across multiple rumours. Note how punctuation proves important as well, since clusters *?* and *!* are also very prominent.

8 Conclusions

This paper investigated the problem of classifying judgements expressed in tweets about rumours. First, we considered a setting where no training data from target rumour is available (LOO). Without access to annotated examples of the target rumour the learning problem becomes very difficult. We showed that in the supervised domain adaptation setting (LPO) even annotating a small number of tweets helps to achieve better results. Moreover, we demonstrated the benefits of a multi task learning approach, as well as that Brown cluster features are more useful for the task than simple bag of words.

Judgement estimation is undoubtedly of great value e.g. for marketing, politics and journalism, helping to target widely believed topics. Although the focus here is on classifying community reactions, Castillo et al. (2013) showed that community reaction is correlated with actual rumour veracity. Consequently our classification methods may prove useful in the broader and more challenging task of annotating veracity.

An interesting direction for future work would be adding non-textual features. For example, the rumour diffusion pattern (Lukasik et al., 2015) may be a useful cue for judgement classification.

Identification and Verification of Simple Claims about Statistical Properties

Andreas Vlachos and **Sebastian Riedel**
Department of Computer Science
University College London
{a.vlachos,s.riedel}@cs.ucl.ac.uk

Abstract

In this paper we study the identification and verification of simple claims about statistical properties, e.g. claims about the *population* or the *inflation rate* of a country. We show that this problem is similar to extracting numerical information from text and following recent work, instead of annotating data for each property of interest in order to learn supervised models, we develop a distantly supervised baseline approach using a knowledge base and raw text. In experiments on 16 statistical properties about countries from Freebase we show that our approach identifies simple statistical claims about properties with 60% precision, while it is able to verify these claims without requiring any explicit supervision for either tasks. Furthermore, we evaluate our approach as a statistical property extractor and we show it achieves 0.11 mean absolute percentage error.

1 Introduction

Statistical properties are commonly used to describe entities, e.g. *population* for countries, *net_value* for companies, *points_scored* for athletes, etc. Claims about such properties are very common in news articles and social media, however they can be erroneous, either due to author error or negligence at the time of writing or because they eventually become out of date. While manual verification (also referred to as fact-checking) is conducted by journalists in news organizations and dedicated websites such as `www.emergent.info`, the volume of the claims calls for automated approaches, which is one of the main objectives of computational journalism (Cohen et al., 2011; Flew et al., 2012).

In this paper we develop a baseline approach to identify and verify simple claims about statistical properties against a database. The task is illustrated in Figure 1. Given a sentence, we first identify whether it contains a claim about a property we are interested in (`population` in the example), which entity it is about and the value claimed (Lesotho and 2,000,000 respectively). We then proceed to verify the value claimed in text for the property of this entity against the value known in a knowledge base such as Freebase and return a score reflecting the accuracy of the claim (absolute percentage error in the example).

Text: Lesotho, a landlocked enclave of South Africa, has a population of nearly 2 million and covers an area slightly smaller than the U.S. state of Maryland.
Entity: Lesotho **Property:** `population` **Value claimed in text:** 2,000,000
Value in knowledge base: 2,193,843 **Absolute percentage error:** 0.09

Figure 1: Claim identification and verification.

Claim identification is essentially an instance of information extraction. While it would be possible to develop supervised models, this would require expensive manual data annotation for each property of interest. Instead, we follow the distant supervision paradigm (Craven and Kumlien, 1999; Mintz et al., 2009) using supervision obtained by combining triples from a knowledge base and raw text. However, statistical properties are more challenging in applying the distant supervision assumption than relations between named entities due to the fact that the numerical values are often approximated in text, as in the example of Figure 1. Consequently, linking the values mentioned in text with those in the knowledge base is not trivial and thus it is not straightforward to generate training instances for the property of interest.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 2596–2601,
Lisbon, Portugal, 17-21 September 2015.

To address this issue, we propose a distantly supervised claim identification approach that relies on approximate instead of exact matching between values in text and the knowledge base. In experiments on 16 statistical properties about countries from Freebase we show that our approach identifies simple statistical claims with 60% precision, while it is able to verify these claims without requiring any explicit supervision for this task. In developing our approach, we also evaluate it as a statistical property extractor achieving 0.11 mean absolute percentage error. The code and the datasets developed are publicly available from `https://github.com/uclmr/simpleNumericalFactChecker`.

2 Claim identification algorithm

Our approach to claim identification relies on discovering textual patterns between an entity and a numerical value used to express the property of interest. For example, the first, second and fourth patterns in Table 1 express the *population* property, and we would like our approach to select them to identify claims about this property.

During training, we assume as input a set of entity-value pairs from the knowledge base for the property of interest (top-right part of Table 1) and a set of textual patterns (bottom-left part), each associated with entity-value pairs (bottom-right part). The patterns and the entity-value pairs associated with them are obtained by processing raw text, which we discuss in Section 3.

The key difficulty compared to other applications of distant supervision is that numerical values are often approximated in text. Thus, instead of looking for patterns that report the exact values for each entity, we develop an approach for finding the patterns that predict the values well. Intuitively, the algorithm ranks all text patterns according to how well they predict the values for the property at question and then greedily selects them till the accuracy of the aggregate predictions by the selected paterns stop improving. To compare the predicted entity-value pairs $\hat{EV}$ against the property entity-value pairs EV_{prop} we use the mean absolute percentage error (MAPE):

$$MAPE(EV_{prop}, \hat{EV}) = \frac{1}{|E|} \sum_{e \in E'} \frac{|v_e - \hat{v_e}|}{|v_e|} \quad (1)$$

Note that only the values predicted for entities in both EV_{prop} and $\hat{EV}$ (denoted by E') are taken into account in this equation, thus in calculating MAPE for the pattern "X has _ inhabitants" from Table 1 against the entity-values for *population* only the two values present are considered. MAPE is commonly used in measuring forecasting accuracy of algorithms in finance (Hyndman and Koehler, 2006). Unlike mean absolute error or mean squared error it adjusts the errors according to the magnitude of the correct value.

Initially (line 1) the algorithm decides on a default value (v_{def}) to return for the property at question among three options: the mean of the training values, their median or zero. The criterion for the choice is which one results in a better MAPE score on the training data. We refer to this prediction as the `InformedGuess`. This default value is used when predicting (lines 16-29) in case there are no values for an entity in the patterns selected, e.g. if only the pattern "X has _ inhabitants" is selected and the prediction for Iceland is requested.

Following this, the patterns are ranked according to the MAPE score of their entity values with respect to the entity values of the property at question (lines 2-4). We then iterate over the patterns in the order they were ranked. For every pattern, we add it to the set of patterns used in predicting (lines 8-9), and evaluate the resulting predictions using MAPE with respect to the training values (line 10). If MAPE is increased (predictions become worse), then we remove the newly added pattern from the set and stop. Otherwise, we continue with the next pattern in the queue.

In experiments with this algorithm we found that while it often identified useful patterns, sometimes it was misled by patterns that had very few entities in common with the property and the values of those entities happen to be similar to those of the property. For example, the pattern "_ tourists visited X" in Figure 1 has only one entity-value pair ("France:68,000,000") and the value is very close to the *population* value for "France". To ameliorate this issue, we adjusted the MAPE scores used in the ranking step (line 4) according to the number of values used in the calculation using the following formula:

$$\text{adjusted}MAPE = \frac{c}{c+N} MAPE \quad (2)$$

where N is the number of values used in calculating MAPE in Equation 1 and c is a parameter that regulates the adjustment. Lower c puts more importance on the number of values used,

population	France:66,028,467, Russia:143,700,000, Iceland:325,600
the population of X is _	France:66,000,000, Russia:140,000,000, Iceland:325,000
X's population is estimated at _	France:66,030,000, Russia:145,000,000
X's inflation rate is _	France:0.9, Iceland:4.0
X has _ inhabitants	Russia:140,000,000, Iceland:300,000
_ tourists visited X	France:68,000,000

Table 1: Property and text patterns associated with entity-value pairs.

Algorithm 1: Claim identification algorithm

Input: Entity-values for property $EV_{prop} = \{(e_1, v_1), (e_2, v_2), \ldots\}$, patterns $P = \{p1, p2, \ldots\}$, entity-values for pattern p: EV_p

Output: Selected patterns P_{sel}

v_{def} = `InformedGuess` (EV_{prop})
priorityQueue $Q = \emptyset$
foreach *pattern* $p \in P$ **do**
    `push` (Q, (p, `MAPE` (EV_{prop}, EV_p)))
$P_{sel} = \emptyset$
mp = `MAPE` (EV_{prop}, `predict` (E, P_{sel}))
while $Q \neq \emptyset$ **do**
    pattern p = `pop` (Q)
    P'_{sel} = $P_{sel} \cup \{p\}$
    mp' = `MAPE` (EV_{prop}, `predict` (E, P'_{sel}))
    if $mp' > mp$ **then**
        break
    else
        $mp = mp'$
        $P_{sel} = P'_{sel}$
function `predict`**(entities** E**, patterns** P_{sel}**)**
    $\hat{EV} = \emptyset$
    foreach $e \in E$ **do**
        $sum = 0$
        $count = 0$
        foreach $p \in P_{sel}$ **do**
            if $(e, v) \in EV_p$ **then**
                $sum+ = p\{e\}$
                $count+ = 1$
        if $count > 0$ **then**
            $\hat{EV} = \hat{EV} \cup (e, sum/count)$
        else
            $\hat{EV} = \hat{EV} \cup (e, v_{def})$
    return $\hat{EV}$

thus leading the algorithm to choosing patterns assessed with more values, and thus more reliably.

3 Data collection

To evaluate the claim identification approach developed we compiled a dataset of statistical properties from Freebase. We downloaded a snapshot[1] of all instances of the *statistical_region* entity type with all their properties with their most recent values, keeping only those were from 2010 onwards. From those we selected the 16 properties listed in Table 2, each property having values for 150-175 regions (mostly countries).

To collect texts from which the text patterns between entities and numerical values will be extracted we downloaded documents from the web. In particular, for each region combined with each property we formed a query consisting of the two and submitted it to Bing via its Search API. Following this we obtained the top 50 results for each query, downloaded the HTML pages corresponding to each result and extracted their textual content with BoilerPipe (Kohlschütter et al., 2010). We then processed the texts using the Stanford CoreNLP toolkit (Manning et al., 2014) and from each sentence we extracted textual patterns between all the named entities recognized as locations and all the numerical values. Two kinds of patterns were extracted for each location and numerical value: surface patterns (as the ones shown in Table 1) and lexicalized dependency paths.

This pattern extraction process resulted in a large set of triples consisting of a region, a pattern and a value. Different sentences might result in triples containing the same region and textual pattern but different value. Such variation can arise due to either the approximations of values in text or due to the pattern being highly ambiguous, e.g. "X is _". We distinguish between the two by requiring each region-pattern combination to have appeared at least twice and its values to have stan-

[1] Data was collected in May 2014.

dard deviation less than 0.1. In this case, then the region-pattern value is set to the mean of the values it is encountered with, otherwise is removed.

4 Information extraction experiments

We first evaluate our approach as a statistical property extractor for two reasons. First, while our main goal is to develop a claim identification approach, there is no data for this task to evaluate, thus making development difficult. On the other hand, we can evaluate statistical property extraction in a straightforward way, thus facilitating development and parameter tuning. Second, the algorithm described learns such an extractor, thus it is of interest to know its performance.

We split the values collected from Freebase into 2/3 for training and 1/3 for testing, ensuring that all regions are present in both datasets. The accuracy is evaluated using MAPE. When using adjusted MAPE we set the parameter c for each property using 4-fold cross-validation.

The performance of Algorithm 1 using the unadjusted MAPE was 0.72 averaged over all properties. Using the adjusted version this was greatly improved to 0.49. We also evaluated the `InformedGuess` prediction which returns the same value for all regions (it chooses the value that performs best among the mean, the median and 0), and its overall MAPE was 0.79. Recalling that Algorithm 1 returns the `InformedGuess` in case no pattern is found for an entity, we also evaluate the performance without returning a value for such entities, thus ignoring them in the evaluation. In that case the performance with unadjusted MAPE improves to 0.17 but 10% coverage, while with adjusted MAPE it improves to 0.11 with 43% coverage. Best performances were achieved for relations such as *population* which have a wide range of values that is well separated from the rest, while percentage rates were usually harder for the opposite reason. Thus we conclude that the algorithm with adjusted MAPE selects better patterns for each property that are encountered more frequently, which is important for the main goal of this paper, claim identification.

5 Claim identification and verification

We now evaluate our approach on claim identification. For each property, we run Algorithm 1 using adjusted MAPE and the parameter c as chosen in the experiments of the previous section to select patterns expressing it. We then process all texts and if a sentence contains one of the selected patterns between an entity and a value, it is returned for manual inspection as shown in Figure 1.

Freebase property	claims	precision
consumer_price_index	116	0.93
cpi_inflation_rate	464	0.92
diesel_price_liter	212	1.00
fertility_rate	307	0.99
gdp_growth_rate	39	0.31
gdp_nominal	308	0.98
gdp_nominal_per_capita	415	0.20
gni	413	0.62
gni_per_capita	795	0.49
health_expenditure	197	0.99
internet_users_%	93	0.00
life_expectancy	581	0.45
population	1583	0.9
population_growth_rate	1377	0.11
renewable_freshwater	105	1.00
undernourishment	87	0.13
OVERALL	7092	0.60

Table 2: Claim identification results.

The claims returned were labeled by the authors of the paper as correctly or incorrectly identified according to the following guidelines. A claim is extracted correctly only if both the entity and the value are extracted correctly and the sentence expresses the property at question. E.g. a claim identified in a sentence containing a country and its correct GDP growth rate without stating it as such (the same percentage rate can be true for multiple statistical properties) is considered incorrect. Furthermore, we considered claims referring to past measurements (e.g. results of a past census) to be correctly identified.

Results for each property are shown in Table. 2. Overall precision was 60% over 7,092 statements, and it varied substantially across properties. Perfect precision was found for claims of *renewable_freshwater* for which one textual pattern was responsible for all the claims identified and it was correct. On the other hand, the zero precision for claims of *internet_user_%* was due to identifying correctly sentences listing countries and their respective values for this property but not identifying the country-value pairs correctly. More representative of properties with precise claim identifi-

cation was *population*, for which the relatively few errors were due to the patterns learned not being able to distinguish between different types of population e.g. general vs working population. On the other hand, the claims for *gni_per_capita* had low accuracy because they were confused with those of *gdp_nominal_per_capita*, as their values tend to be relatively close. The claims identified and annotated manually are attached to our submission. Finally, some errors are due to the algorithm being constrained to extract a claim considering only the text pattern between the entity and the value, thus ignoring parts of the sentence that might be relevant. For example, the pattern "the population of X is _" is generally reliable, but in the sentence "The population of Tajikistan is 90 % Muslim" it extracts a claim incorrectly.

The verification stage of the simple claims we extract is rather simple; we just score the claims according to the absolute percentage error of the value claimed in text with respect to the value in known in Freebase. In the process of labeling the claims identified we did a qualitative analysis of the claims with high error. We found cases where our algorithm flagged cases of out of date estimates of populations used, e.g. the webpage `http://www.economywatch.com/world_economy/bolivia`[2] states that the population of Bolivia is 9 million, while it is estimated to be above 10 million.

6 Discussion - Related work

As explained, we tackle claim identification as an instance of information extraction, and propose a baseline able to perform both tasks. However, it is important to distinguish between them. In claim identification we are interested in all claims about a property, even inaccurate ones; in information extraction on the other hand, and especially its formulation as knowledge base population, we are interested in the accurate claims only, since extracting inaccurate ones will lead to erroneous information added to the knowledge base. The difference between the two tasks is captured by the verification task. In this paper our main goals are identification and verification, but we train our approach on information extraction, relying on the assumption that most claims made in the texts retrieved via the web search engine are accurate.

In related work, Nakashole and Mitchell (2014) developed an approach to verify subject-verb-object triples against a knowledge base, taking into account the objectivity of the language used in the sources stating the triple. Our approach is agnostic to the syntactic form of the claims, thus it can identify claims expressed in greater linguistic variety. Ciampaglia et al. (2015) fact-checked subject-predicate-object triples against a knowledge graph constructed from DBpedia, but they considered only the paths between the subject and the predicate in their algorithm thus ignoring the predicate itself. Dong et al. (2015) established the trustworthiness of a web source by comparing the subject-predicate-object triples extracted from it to the Knowledge Vault built by Google, but did not focus on claim identification and verification. Adar et al. (2009) developed an approach to detect inconsistencies between versions of Wikipedia in different languages, but they focused on manually extracted infoboxes. Finally, Vlachos and Riedel (2014) compiled a dataset of claims fact-checked by journalists, but the claims are much more complex than the ones we considered in this paper.

Other work that discussed the extraction of statistical properties includes the approaches of Hoffmann et al. (2010) and Intxaurrondo et al. (2015), both employing approximate matching to deal with the approximation of numerical values in text. In order to learn their model, Hoffmann et al. (2010) take advantage of the structure of the articles in Wikipedia developing a classifier that identifies the schema followed by each article, which is not straightforward to extend to texts beyond this source. Intxaurrondo et al. (2015) on the other hand focus on tweets and make the assumption that the entity discussed in each tweet is determined in advance, thus the extractor needs only to associate a numerical value with the property of interest, i.e. the task is reduced from triple extraction to labeling values.

7 Conclusions - Future work

In this paper we developed a distantly supervised approach for identification and verification of simple statistical claims. We evaluated both as statistical property extractor and as a claim identifier on 16 relations from Freebase. In future work we aim to improve our approach by taking into account continuous representations of the words in the patterns and to extend it to more complex claims, e.g. claims about change in financial indicators.
