We introduce neural network models (Conv-GRNN and LSTM-GRNN) for document level sentiment classification. The approach encodes semantics of sentences and their relations in document representation, and is effectively trained end-to-end with supervised sentiment classification objectives. We conduct extensive experiments on four review datasets with two evaluation metrics. Empirical results show that our approaches achieve state-of-the-art performances on all these datasets. We also find that (1) traditional recurrent neural network is extremely weak in modeling document composition, while adding neural gates dramatically boosts the performance, (2) LSTM performs better than a multi-filtered CNN in modeling sentence representation.

We briefly discuss some future plans. How to effectively compose sentence meanings to document meaning is a central problem in natural language processing. In this work, we develop neural models in a sequential way, and encode sentence semantics and their relations automatically without using external discourse analysis results. From one perspective, one could carefully define a set of sentiment-sensitive discourse relations (Zhou et al., 2011), such as "contrast", "condition", "cause", etc. Afterwards, relation-specific gated RNN can be developed to explicitly model semantic composition rules for each relation (Socher et al., 2013a). However, defining such a relation scheme is linguistic driven and time consuming, which we leave as future work. From another perspective, one could compose document

representation over discourse tree structures rather than in a sequential way. Accordingly, Recursive Neural Network (Socher et al., 2013b) and Structured LSTM (Tai et al., 2015; Zhu et al., 2015) can be used as composition algorithms. However, existing discourse structure learning algorithms are difficult to scale to massive review texts on the web. How to simultaneously learn document structure and composition function is an interesting future work.

Acknowledgments

The authors give great thanks to Yaming Sun and Jiwei Li for the fruitful discussions. We also would like to thank three anonymous reviewers for their valuable comments and suggestions. Abstract

The tasks in fine-grained opinion mining can be regarded as either a token-level sequence labeling problem or as a semantic compositional task. We propose a general class of discriminative models based on recurrent neural networks (RNNs) and word embeddings that can be successfully applied to such tasks without any task-specific feature engineering effort. Our experimental results on the task of opinion target identification show that RNNs, without using any hand-crafted features, outperform feature-rich CRF-based models. Our framework is flexible, allows us to incorporate other linguistic features, and achieves results that rival the top performing systems in SemEval-2014.

1 Introduction

Fine-grained opinion mining involves identifying the opinion holder who expresses the opinion, detecting opinion expressions, measuring their intensity and sentiment, and identifying the target or aspect of the opinion (Wiebe et al., 2005). For example, in the sentence "John says, the hard disk is very noisy", John, the opinion holder, expresses a very negative (i.e., sentiment with intensity) opinion towards the target "hard disk" using the opinionated expression "very noisy". A number of NLP applications can benefit from fine-grained opinion mining including opinion summarization and opinion-oriented question answering.

The tasks in fine-grained opinion mining can be regarded as either a token-level sequence labeling problem or as a semantic compositional task at the sequence (e.g., phrase) level. For example, identifying opinion holders, opinion expressions and opinion targets can be formulated as a token-level sequence tagging problem, where the task is to label each word in a sentence using the conventional BIO tagging scheme. For example, Table 1 shows a sentence tagged with BIO scheme for opinion target (middle row) and for opinion expression (bottom row) identification tasks. On the other hand, characterizing intensity and sentiment of an opinionated expression can be regarded as a semantic compositional problem, where the task is to aggregate vector representations of tokens in a meaningful way and later use them for sentiment classification (Socher et al., 2013).

The	**hard**	**disk**	is	*very*	*noisy*

O	O	O	O	B-EXPR	I-EXPR

Table 1: An example sentence annotated with BIO labels for opinion target (`TARG` tags) and for opinion expression (`EXPR` tags) extraction.

Conditional random fields (CRFs) (Lafferty et al., 2001) have been quite successful for different fine-grained opinion mining tasks, e.g., opinion expression extraction (Yang and Cardie, 2012). The state-of-the-art model for opinion target extraction is also based on a CRF (Pontiki et al., 2014). However, the success of CRFs depends heavily on the use of an appropriate feature set and feature function expansion, which often requires a lot of engineering effort for each task in hand.

An alternative approach of deep learning automatically learns latent features as distributed vectors and have recently been shown to outperform CRFs on similar tasks. For example, Irsoy and Cardie (2014) apply deep recurrent neural networks (RNNs) to extract opinion expressions from sentences and show that RNNs outperform CRFs. Socher et al. (2013) propose recursive neural networks for a semantic compositional task to identify the sentiments of phrases and sentences hierarchically using the syntactic parse trees.

Meanwhile, recent advances in word embed-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1433–1443,
Lisbon, Portugal, 17-21 September 2015.

ding induction methods (Collobert and Weston, 2008; Mikolov et al., 2013b) have benefited researchers in two ways: (*i*) they have contributed to significant gains when used as extra word features in existing NLP systems (Turian et al., 2010; Lebret and Lebret, 2013), and (*ii*) they have enabled more effective training of RNNs by providing compact input representations of the words (Mesnil et al., 2013; Irsoy and Cardie, 2014).

Motivated by the recent success of deep learning, in this paper we propose a general class of models based on RNN architecture and word embeddings, that can be successfully applied to fine-grained opinion mining tasks without any task-specific feature engineering effort. We experiment with several important RNN architectures including Elman-RNN, Jordan-RNN, long short term memory (LSTM) and their variations. We acquire pre-trained word embeddings from several external sources to give better initialization to our RNN models. The RNN models then fine-tune the word vectors during training to learn task-specific embeddings. We also present an architecture to incorporate other linguistic features into RNNs.

Our results on the task of opinion target extraction show that word embeddings improve the performance of state-of-the-art CRF models, when included as additional features. They also improve RNNs when used as pre-trained word vectors and fine-tuning them on the task gives the best results. A comparison between models demonstrates that RNNs outperform CRFs, even when they use word embeddings as the only features. Incorporating simple linguistic features into RNNs improves the performance even further. Our best results with LSTM RNN outperform the top performing system on the Laptop dataset and achieve the second best on the Restaurant dataset in SemEval-2014. We make our source code available.[1]

In the remainder of this paper, after discussing related work in Section 2, we present our RNN models in Section 3. In Section 4, we briefly describe the pre-trained word embeddings. The experiments and analysis of results are presented in Section 5. Finally, we summarize our contributions with future directions in Section 6.

2 Related Work

A line of previous research in fine-grained opinion mining focused on detecting opinion (subjective) expressions, e.g., (Wilson et al., 2005; Breck et al., 2007). The common approach was to formulate the problem as a sequence tagging task and use a CRF model. Later approaches extended this to jointly identify opinion holders (Choi et al., 2005), and intensity and polarity (Choi and Cardie, 2010).

Extracting aspect terms or opinion targets have been actively investigated in the past. Typical approaches include association mining to find frequent item sets (i.e., co-occurring words) as candidate aspects (Hu and Liu, 2004), classification-based methods such as hidden Markov model (Jin et al., 2009) and CRF (Shariaty and Moghaddam, 2011; Yang and Cardie, 2012; Yang and Cardie, 2013), as well as topic modeling techniques using Latent Dirichlet Allocation (LDA) model and its variants (Titov and McDonald, 2008; Lin and He, 2009; Moghaddam and Ester, 2012).

Conventional RNNs (e.g., Elman type) and LSTM have been successfully applied to various sequence prediction tasks, such as language modeling (Mikolov et al., 2010; Sundermeyer et al., 2012), speech recognition (Graves and Jaitly, 2014; Sak et al., 2014) and spoken language understanding (Mesnil et al., 2013). For sentiment analysis, Socher et al. (2013) propose to use recursive neural networks to hierarchically compose semantic word vectors based on syntactic parse trees, and use the vectors to identify the sentiments of the phrases and sentences. Le and Zuidema (2015) extended recursive neural networks with LSTM to compute a parent vector in parse trees by combining information of both output and LSTM memory cells from its two children.

Most relevant to our work is the recent work of Irsoy and Cardie (2014), where they apply deep Elman-type RNN to extract opinion expressions and show that deep RNN outperforms CRF, semi-CRF and shallow RNN. They used word embeddings from Google without fine-tuning them.

Although inspired, our work differs from the work of Irsoy and Cardie (2014) in many ways. (*i*) We experiment with not only Elman-type, but also with a Jordan-type and with a more advanced LSTM RNN, and demonstrate the performance of various RNN models. (*ii*) We use not only Google embeddings as pre-trained word vectors, but also other embeddings including SENNA and Amazon, and show their performances. (*iii*) We also fine-tune the embeddings for our task, which is shown to be very crucial. (*iv*) We present an RNN ar-

[1] https://github.com/ppfliu/opinion-target

chitecture to include other linguistic features and show its effectiveness. (*v*) Finally, we present a comprehensive experiment exploring different embedding dimensions and hidden layer sizes for all the variations of the RNNs (i.e., including features and bi-directionality).

3 Recurrent Neural Models

The recurrent neural models in this section compute compositional vector representations for word sequences of arbitrary length. These high-level (i.e., hidden-layer) distributed representations are then used as features to classify each token in the sentence. We first describe the common properties shared among the RNNs below, followed by the descriptions of the specific RNNs.

Each word in the vocabulary V is represented by a D dimensional vector in the shared look-up table $L \in \mathbb{R}^{|V| \times D}$. Note that L is considered as a model parameter to be learned. We can initialize L randomly or by pre-trained word embedding vectors (see Section 4). Given an input sentence $\mathbf{s} = (s_1, \cdots, s_T)$, we first transform it into a feature sequence by mapping each word token $s_t \in \mathbf{s}$ to an index in L. The look-up layer then creates a context vector $\mathbf{x_t} \in \mathbb{R}^{mD}$ covering $m-1$ neighboring tokens for each s_t by concatenating their respective vectors in L. For example, given the context size $m = 3$, the context vector $\mathbf{x_t}$ for the word *disk* in Figure 1 is formed by concatenating the embeddings of *hard*, *disk* and *is*. This window-based approach is intended to capture short-term dependencies between neighboring words in a sentence (Collobert et al., 2011).

The concatenated vector is then passed through non-linear recurrent hidden layers to learn high-level compositional representations, which are in turn fed to the output layer for classification using `softmax`. Formally, the probability of k-th label in the output for classification into K classes:

$$P(y_t = k|\mathbf{s}, \theta) = \frac{exp\ (\mathbf{w}_k^T \mathbf{h_t})}{\sum_{k=1}^{K} exp\ (\mathbf{w}_k^T \mathbf{h_t})} \quad (1)$$

where, $\mathbf{h}_t = \phi(\mathbf{x}_t)$ defines the transformations of $\mathbf{x}_t$ through the hidden layers, and $\mathbf{w}_k$ are the weights from the last hidden layer to the output layer. We fit the models by minimizing the negative log likelihood (NLL) of the training data. The NLL for the sentence $\mathbf{s}$ can be written as:

$$J(\theta) = \sum_{t=1}^{T} \sum_{k=1}^{K} y_{tk}\ log\ P(y_t = k|\mathbf{s}, \theta) \quad (2)$$

where, $y_{tk} = I(y_t = k)$ is an indicator variable to encode the gold labels, i.e., $y_{tk} = 1$ if the gold label $y_t = k$, otherwise 0.[2] The loss function minimizes the cross-entropy between the predicted distribution and the target distribution (i.e., gold labels). The main difference between the models described below is how they compute $\mathbf{h}_t = \phi(\mathbf{x}_t)$.

3.1 Elman-type RNN (Elman, 1990)

In an Elman-type RNN (Fig. 1a), the output of the hidden layer $\mathbf{h}_t$ at time t is computed from a non-linear transformation of the current input $\mathbf{x}_t$ and the previous hidden layer output $\mathbf{h}_{t-1}$. Formally,

$$\mathbf{h}_t = f(U\mathbf{h}_{t-1} + V\mathbf{x}_t + \mathbf{b}) \quad (3)$$

where f is a nonlinear function (e.g., `sigmoid`) applied to the hidden units. U and V are weight matrices between two consecutive hidden layers, and between the input and the hidden layers, respectively, and $\mathbf{b}$ is the bias vector.

This RNN thus creates internal states by remembering previous hidden layer, which allows it to exhibit dynamic temporal behavior. We can interpret $\mathbf{h}_t$ as an intermediate representation summarizing the past, which is in turn used to make a final decision on the current input.

3.2 Jordan-type RNN (Jordan, 1997)

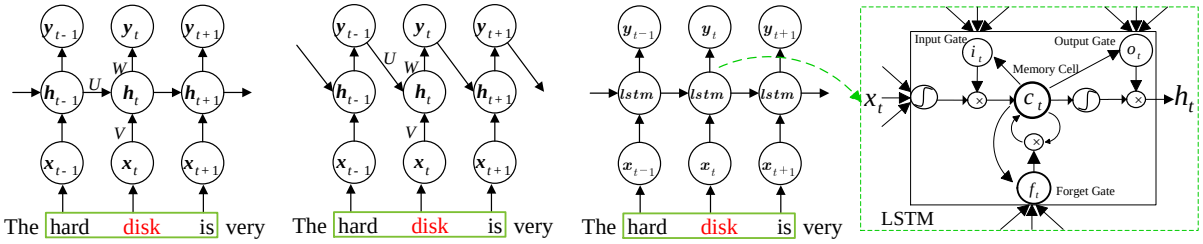
Jordan-type RNNs (Fig. 1b) are similar to Elman-type RNNs except that the hidden layer $\mathbf{h}_t$ at time t is fed from the previous output layer $\mathbf{y}_{t-1}$ instead of the previous hidden layer $\mathbf{h}_{t-1}$. Formally,

$$\mathbf{h}_t = f(U\mathbf{y}_{t-1} + V\mathbf{x}_t + \mathbf{b}) \quad (4)$$

where U, V, $\mathbf{b}$, and f are similarly defined as before. Both Elman-type and Jordan-type RNNs are known as simple RNNs. These types of RNNs are generally trained using stochastic gradient descent (SGD) with backpropagation through time (BPTT), where errors (i.e., gradients) are propagated back through the edges over time.

One common issue with BPTT is that as the errors get propagated, they may soon become very small or very large that can lead to undesired values in weight matrices, causing the training to fail.

[2] This is also known as one-hot vector representation.



(a) Elman-type RNN (b) Jordan-type RNN (c) Long Short-Term Memory (LSTM) RNN

Figure 1: Elman-type, Jordan-type and LSTM RNNs with a lookup-table layer, a hidden layer and an output layer. The concatenated context vector for the word "disk" at time t is $x_t = [x_{hard}, x_{disk}, x_{is}]$ with a context window of size 3. One memory block in the LSTM hidden layer has been enlarged.

This is known as the *vanishing* and the *exploding* gradients problem (Bengio et al., 1994). One simple way to overcome this issue is to use a truncated BPTT (Mikolov, 2012) for restricting the back-propagation to only few steps like 4 or 5. However, this solution limits the RNN to capture long-range dependencies. In the following, we describe an elegant RNN architecture to address this problem.

3.3 Long Short-Term Memory RNN

Long Short-Term Memory or LSTM (Hochreiter and Schmidhuber, 1997) is specifically designed to model long term dependencies in RNNs. The recurrent layer in a standard LSTM is constituted with special (hidden) units called *memory blocks* (Fig. 1c). A memory block is composed of four elements: (*i*) a memory cell c (i.e., a neuron) with a self-connection, (*ii*) an input gate i to control the flow of input signal into the neuron, (*iii*) an output gate o to control the effect of the neuron activation on other neurons, and (*iv*) a forget gate f to allow the neuron to adaptively reset its current state through the self-connection. The following sequence of equations describe how a layer of memory blocks is updated at every time step t:

$$\mathbf{i}_t = \sigma(U_i\mathbf{h}_{t-1} + V_i\mathbf{x}_t + C_i\mathbf{c}_{t-1} + \mathbf{b}_i) \quad (5)$$
$$\mathbf{f}_t = \sigma(U_f\mathbf{h}_{t-1} + V_f\mathbf{x}_t + C_f\mathbf{c}_{t-1} + \mathbf{b}_f) \quad (6)$$
$$\mathbf{c}_t = \mathbf{i}_t \odot g(U_c\mathbf{h}_{t-1} + V_c\mathbf{x}_t + \mathbf{b}_c) + \mathbf{f}_t \odot \mathbf{c}_{t-1} \quad (7)$$
$$\mathbf{o}_t = \sigma(U_o\mathbf{h}_{t-1} + V_o\mathbf{x}_t + C_o\mathbf{c}_t + \mathbf{b}_o) \quad (8)$$
$$\mathbf{h}_t = \mathbf{o}_t \odot h(\mathbf{c}_t) \quad (9)$$

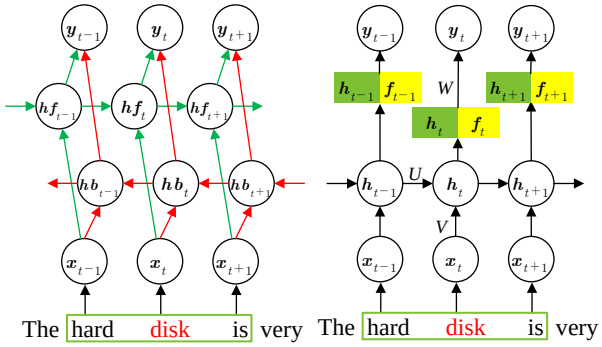
where U_k, V_k and C_k are the weight matrices between two consecutive hidden layers, between the input and the hidden layers, and between two consecutive cell activations, respectively, which are associated with gate k (i.e., input, output, forget and cell), and $\mathbf{b}_k$ is the associated bias vector. The symbol $\odot$ denotes a element-wise product of the two vectors. The gate function σ is the `sigmoid` activation, and g and h are the cell input and cell output activations, typically a `tanh`. LSTMs are generally trained using truncated or full BPTT.

3.4 Bidirectionality

Notice that the RNNs defined above only get information from the past. However, information from the future could also be crucial. In our example sentence (Table 1), to correctly tag the word *hard* as a **B-TARG**, it is beneficial for the RNN to know that the next word is *disk*. Our window-based approach, by considering the neighboring words, already captures short-term dependencies like this from the future. However, it requires tuning to find the right window size, and it disregards long-range dependencies that go beyond the context window, which is typically of size 1 (i.e., no context) to 5 (see Section 5.2). For instance, consider the two sentences: (*i*) *Do you know about the crunchy tuna here, it is to die for.* and (*ii*) *Do you know about the crunchy tuna here, it is imported from Norway.* The phrase *crunchy tuna* is an aspect term in the first (subjective) sentence, but not in the second (objective) one. The RNN models described above will assign the same labels to *crunchy* and *tuna* in both sentences, since the preceding sequences and the context window (of size 1 to 5) are the same.

To capture long-range dependencies from the future as well as from the past, we propose to use bidirectional RNNs (Schuster and Paliwal, 1997), which allow bidirectional links in the network. In an Elman-type bidirectional RNN (Fig. 2a), the forward hidden layer $\overrightarrow{\mathbf{h}_t}$ and the backward hidden layer $\overleftarrow{\mathbf{h}_t}$ at time t are computed as follows:

$$\overrightarrow{\mathbf{h}_t} = f(\overrightarrow{U}\mathbf{h}_{t-1} + \overrightarrow{V}\mathbf{x}_t + \overrightarrow{\mathbf{b}}) \quad (10)$$
$$\overleftarrow{\mathbf{h}_t} = f(\overleftarrow{U}\mathbf{h}_{t-1} + \overleftarrow{V}\mathbf{x}_t + \overleftarrow{\mathbf{b}}) \quad (11)$$



(a) (b)

Figure 2: (a) Bidirectional Elman-type RNN and (b) Linguistic features concatenated with the hidden layer output in Elman-type RNN.

where $\overrightarrow{U}$, $\overrightarrow{V}$ and $\overrightarrow{\mathbf{b}}$ are the forward weight matrices as before; and $\overleftarrow{U}$, $\overleftarrow{V}$ and $\overleftarrow{\mathbf{b}}$ are their backward counterparts. The concatenated vector $\mathbf{h}_t = [\overrightarrow{\mathbf{h}_t}, \overleftarrow{\mathbf{h}_t}]$ is passed to the output layer. We can thus interpret $\mathbf{h}_t$ as an intermediate representation summarizing the past and the future, which is then used to make a final decision on the current input.

Similarly, the unidirectional LSTM RNN can be extended to bidirectional LSTM by allowing bidirectional connections in the hidden layer. This amounts to having a backward counterpart for each of the equations from 5 to 9.

Notice that the forward and the backward computations of bidirectional RNNs are independently done until they are combined in the output layer. This means, during training, after backpropagating the errors from the output layer to the forward and to the backward hidden layers, two independent BPTT can be applied – one to each direction.

3.5 Fine-tuning of Embeddings

In our RNN framework, we intend to avoid manual feature engineering efforts by using word embeddings as the only features. As mentioned before, we can initialize the embeddings randomly and learn them as part of model parameters by backpropagating the errors to the look-up layer. One issue with random initialization is that it may lead the SGD to get stuck in local minima (Murphy, 2012). On the other hand, one can plug the readily available embeddings from external sources (Section 4) in the RNN model and use them as features without tuning them further for the task, as is done in any other machine learning model. However, this approach does not exploit the automatic feature learning capability of NN models, which is one of the main motivations of using them.

In our work, we use the pre-trained word embeddings to better initialize our models, and we fine-tune them for our task in training, which turns out to be quite beneficial (see Section 5.2).

3.6 Incorporating other Linguistic Features

Although NNs learn word features (i.e., embeddings) automatically, we may still be interested in incorporating other linguistic features like part-of-speech (POS) tags and chunk information to guide the training and to learn a better model. However, unlike word embeddings, we want these features to be fixed during training. As shown in Figure 2b, this can be done in our RNNs by feeding these additional features directly to the output layer, and learn their associated weights in training.

4 Word Embeddings

Word embeddings are distributed representations of words, represented as real-valued, dense, and low-dimensional vectors. Each dimension potentially describes syntactic or semantic properties of the word. Here we briefly describe the three types of pre-trained embeddings that we use in our work.

4.1 SENNA Embeddings

Collobert et al. (2011) present a unified NN architecture for various NLP tasks (e.g., POS tagging, chunking, semantic role labeling, named entity recognition) with a window-based approach and a sentence-based approach (i.e., the input layer is a sentence). Each word in the input layer is represented by M features, each of which has an embedding vector associated with it in a *lookup table*. To give their network a better initialization, they learn word embeddings using a non-probabilistic language model, which was trained on English Wikipedia for about 2 months. They released their 50-dimensional word embeddings (vocabulary size $130K$) under the name SENNA.[3]

4.2 Google Embeddings

Mikolov et al. (2013a) propose two log-linear models for computing word embeddings from large corpora efficiently: (*i*) a *bag-of-words* model CBOW that predicts the current word based on the context words, and (*ii*) a *skip-gram* model that predicts surrounding words given the current word.

[3] http://ronan.collobert.com/senna/

They released their pre-trained 300-dimensional word embeddings (vocabulary size $3M$) trained by the skip-gram model on part of Google news dataset containing about 100 billion words.[4]

4.3 Amazon Embeddings

Since we work on customer reviews, which are less formal than Wikipedia and news, we have also trained *domain-specific* embeddings (vocabulary size $1M$) using the CBOW model of *word2vec* tool (Mikolov et al., 2013b) from a large corpus of Amazon reviews.[5] The corpus contains $34,686,770$ reviews (4.7 billion words) on Amazon products from June 1995 to March 2013 (McAuley and Leskovec, 2013). For comparison with SENNA and Google, we learn word embeddings of 50- and 300-dimensions.

5 Experiments

In this section, we present our experimental settings and results for the task of opinion target extraction from customer reviews.

5.1 Experimental Settings

Datasets: In our experiments, we use the two review datasets provided by the *SemEval-2014 task 4: aspect-based sentiment analysis* evaluation campaign (Pontiki et al., 2014), namely the *Laptop* and the *Restaurant* datasets. Table 2 shows some basic statistics about the datasets. The majority of aspect terms have only one word, while about one third of them have multiple words. In both datasets, some sentences have no aspect terms and some have more than one aspect terms. We use the standard train:test split to compare our results with the SemEval best systems. In addition, we show a more general performance of our models on the two datasets based on 10–fold cross validation.

	Laptop		Restaurant	
	Train	Test	Train	Test
Sentences	3045	800	3041	800
Sentence length	15	13	14	14
One-word targets	1494	364	2786	818
Multi-word targets	864	290	907	316
Total targets	2358	654	3693	1134

Table 2: Corpora statistics.

[4]https://code.google.com/p/word2vec/

[5]https://snap.stanford.edu/data/web-Amazon.html

Evaluation Metric: The evaluation metric measures the standard precision, recall and F_1 score based on *exact* matches. This means that a candidate aspect term is considered to be correct only if it exactly matches with the aspect term annotated by the human. In all our experiments when comparing two models, we use paired t-test on the F_1 scores to measure statistical significance and report the corresponding p-value.

CRF Baseline: We use a linear-chain CRF (Lafferty et al., 2001) of order 2 as our baseline, which is the state-of-the-art model for opinion target extraction (Pontiki et al., 2014). Specifically, the CRF generates (binary) feature functions of order 1 and 2; see (Cuong et al., 2014) for higher order CRFs. The features used in the baseline model include the current word, its POS tag, its prefixes and suffixes between one to four characters, its position, its stylistics (e.g., case, digit, symbol, alphanumeric), and its context (i.e., the same features for the two preceding and the two following words). In addition to the hand-crafted features, we also include the three different types of word embeddings described in Section 4.

RNN Settings: We pre-processed each dataset by lowercasing all words and spelling out each digit number as `DIGIT`. We then built the vocabulary from the training set by marking rare words with only one occurrence as `UNKNOWN`, and adding a `PADDDING` word to make context windows for boundary words.

To implement *early stopping* in SGD, we prepared a *validation set* by separating out randomly 10% of the available training data. The remaining 90% is used for training. The weights in the network were initialized by sampling from a small random uniform distribution $\mathcal{U}(-0.2, 0.2)$. The time step in the truncated BPTT was fixed to 6 based on the performance on the validation set; smaller values hurt the performance, while larger values showed no significant gains but increased the training time.

We use a fixed learning rate of 0.01, but we change the batch size depending on the sentence length following Mesnil et al. (2013). The net effect is a variable step size in the SGD. We run SGD for 30 epochs, calculate the F_1 score on the validation set after each epoch, and stop if the accuracy starts to decrease. The size of the context window and the hidden layer are empirically set based on the performance on the validation set. We experimented

with the window size $\in \{1, 3, 5\}$, and found 3 to be the optimal on the validation set. The hidden layer sizes we experimented with are 50, 100, 150, and 200; we report the optimal values in Table 3 (see $|h_l|$ and $|h_r|$ columns).

Linguistic Features in RNNs: In addition to the neural features, we also explore the contribution of simple linguistic features in our RNN models using the architecture described in Section 3.6. Specifically, we encode four POS tag classes (*noun, adjective, verb, adverb*) and BIO-tagged chunk information (*NP, VP, PP, ADJP, ADVP*) as binary features. We feed these extra features directly to the output layer of the RNNs and learn their relative weights. Part-of-speech and phrasal information are arguably the most informative features for identifying aspect terms (i.e., aspect terms are generally noun phrases). BIO tags could be useful to find the right text spans (i.e., aspect terms are unlikely to violate phrasal boundaries).

5.2 Results and Discussion

Table 3 presents our results of aspect term extraction on the *standard testset* in F_1 scores. In Table 4, we show the results on the *whole datasets* based on 10-fold cross validation. RNNs in Table 4 are trained using SENNA embeddings. We perform significance tests on the 10-fold results. In the following, we highlight our main findings.

Contributions of Word Embeddings in CRF: From the first group of results in Table 3, we can observe that even though CRF uses a handful of hand-designed features, including word embeddings still leads to sizable improvements on both datasets. The domain-specific Amazon embeddings (300 dim.) yield more general performance across the datasets, delivering the best gain of absolute 3.54% on the Laptop and the second best on the Restaurant dataset. Google embeddings give the best gain on the Restaurant dataset (absolute 3.08%). The contribution of embeddings in CRF is also validated by the 10-fold results in Table 4 (see first two rows), where SENNA embeddings yield significant improvements – absolute 1.47% on Laptop ($p < 0.03$) and absolute 1.24% on Restaurant ($p < 0.01$). This demonstrates that word embeddings offer generalizations that complement other strong features, and thus should be considered.

CRF vs. RNNs: When we compare the results of

Table 5: Effects of fine-tuning in Elman-RNN and Jordan-RNN.

RNNs with those of CRF in Table 3, we see that most of our RNN models outperform CRF models with the maximum absolute gains of 2.80% by **LSTM-RNN+Feat.** on Laptop and 1.70% by **Bi-Elman-RNN+Feat.** on Restaurant. What is remarkable is that RNNs without any hand-crafted features outperform feature-rich CRF models by a good margin – absolute maximum gains of 2.23% by Elman-RNN and 1.83% by **Bi-LSTM-RNN** on Laptop. When we compare their general performance on the 10-folds in Table 4, we observe similar gains, maximum 5.88% on Laptop and 1.97% on Restaurant, which are significant with $p < 6 \times 10^{-6}$ on Laptop and $p < 2 \times 10^{-4}$ on Restaurant. These results demonstrate that RNNs as sequence labelers are more effective than CRFs for fine-grained opinion mining tasks. This can be attributed to RNN's ability to learn better features automatically and to capture long-range sequential dependencies between the output labels.

Comparison among RNN Models: A comparison among the RNN models in Table 3 tells that Elman RNN generally outperforms Jordan RNN. However, bi-directionality and LSTM do not provide clear gains over the simple Elman RNN. In fact, bi-directionality hurts the performance in most cases. This finding contrasts the finding of Irsoy and Cardie (2014) in opinion expression detection task, where bi-directional Elman RNNs outperform their uni-directional counterparts. However, when we analyzed the data, we found it to be unsurprising because aspect terms are generally shorter than opinion expressions. For example, the average length of an aspect term in our Restaurant dataset is 1.4, where the average length of an expressive subjective expression in their MPQA corpus is 3.3. Therefore, the information required to correctly identify aspect terms (e.g., *hard disk*) is already captured by the simple (as opposed to LSTM) unidirectional link and the context window covering the neighboring words. LSTM and Bi-directionality increase the number of parameters in the RNNs, which might contribute to overfitting on this specific task.[6]

[6]Bi-directional links double the number of parameters in RNNs.

As a partial solution to this problem, we experimented with a bi-directional Elman-RNN, where both directions share the same parameters. Therefore, the number of parameters remains the same as the uni-directional one. This modification improves the performance over the non-shared one slightly but not significantly. This demands for better modeling of the two sources of information rather than simple concatenation or sharing.

Contributions of Linguistic Features in RNNs: Although our linguistic features are quite simple (i.e., POS tags and chunk), they give gains on both datasets when incorporated into Elman and LSTM RNNs. The maximum gains on the standard testset (Table 3) are 0.64% on Laptop and 1.96% on Restaurant for Bi-Elman, and 1.48% on Laptop and 1.58% on Restaurant for LSTM. Similar gains are also observed on the 10-folds in Table 4, where the maximum gains are 1.25% on Laptop and 1.44% on Restaurant. These gains are significant with $p < 0.004$ on Laptop and $p < 6 \times 10^{-5}$ on Restaurant. Linguistic features thus complement word embeddings in RNNs.

Importance of Fine-tuning in RNNs: Finally, in order to show the importance of fine-tuning the word embeddings in RNNs on our task, we present in Table 5 the performance of Elman and Jordan RNNs, when the embeddings are used as they are (*'-tune'*), and when they are fine-tuned (*'+tune'*) on the task. The table also shows the contributions of pre-trained embeddings as compared to random initialization. Surprisingly, Amazon embeddings without fine-tuning deliver the worst performance, even lower than the Random initialization. We found that with Amazon embeddings the network gets stuck in a local minimum from the very first epoch.

Other pre-trained (untuned) embeddings improve over the Amazon and Random by providing better initialization. In most cases fine-tuning makes a big difference. For example, the absolute gains for fine-tuning SENNA embeddings in Elman RNN are 13.01% in Laptop and 4.11% in Restaurant. Remarkably, fine-tuning brings both Random and Amazon embeddings close to the best ones.

Comparison with SemEval-2014 Systems: When our RNN results are compared with the top performing systems in the SemEval-2014 (last two rows in Table 3), we see that RNNs without using any linguistic features achieve the second best results on both Laptop and Restaurant datasets. Note that these RNNs only use word embeddings, while IHS_RD and DLIREC use complex features like dependency relations, named entity, sentiment orientation of words, word cluster and many more in their CRF models, most of which are expensive to compute; see (Toh and Wang, 2014; Chernyshevich, 2014). The performance of our RNNs improves when they are given access to very simple features like POS tags and chunks, and **LSTM-RNN+Feat.** achieves the best results on the Laptop dataset.

6 Conclusion and Future Direction

We presented a general class of discriminative models based on recurrent neural network (RNN) architecture and word embeddings, that can be successfully applied to fine-grained opinion mining tasks without any task-specific manual feature engineering effort. We used pre-trained word embeddings from three external sources in different RNN architectures including Elman-type, Jordan-type, LSTM and their several variations.

Our results on the opinion target extraction task demonstrate that word embeddings improve the performance of both CRF and RNN models, however, fine-tuning them in RNNs on the task gives the best results. RNNs outperform CRFs, even when they use word embeddings as the only features. Incorporating simple linguistic features into RNNs improves the performance further. Our best results with LSTM RNN outperform the top performing system on the Laptop dataset and achieve the second best on the Restaurant dataset in SemEval-2014 evaluation campaign. We made our code publicly available for research purposes.

In the future, we would like apply our models to other fine-grained opinion mining tasks including opinion expression detection and characterizing the intensity and sentiment of the opinion expressions. We would also like to explore to what extent these tasks can be jointly modeled in an RNN-based multi-task learning framework.

Abstract

Joint models of syntactic and semantic parsing have the potential to improve performance on both tasks—but to date, the best results have been achieved with pipelines. We introduce a joint model using CCG, which is motivated by the close link between CCG syntax and semantics. Semantic roles are recovered by labelling the deep dependency structures produced by the grammar. Furthermore, because CCG is lexicalized, we show it is possible to factor the parsing model over words and introduce a new A* parsing algorithm—which we demonstrate is faster and more accurate than adaptive supertagging. Our joint model is the first to substantially improve both syntactic and semantic accuracy over a comparable pipeline, and also achieves state-of-the-art results for a non-ensemble semantic role labelling model.

1 Introduction

Joint models of syntactic and semantic parsing are attractive; they can potentially avoid the error propagation that is inherent in pipelines by using semantic models to inform syntactic attachments. However, in practice, the performance of joint systems for semantic role labelling (SRL) has been substantially beneath that of pipelines (Sutton and McCallum, 2005; Lluís et al., 2009; Johansson, 2009; Titov et al., 2009; Naradowsky et al., 2012; Lluís et al., 2013; Henderson et al., 2013). In this paper, we present the first approach to break this trend, by building on the close relationship of syntax and semantics in CCG grammars to enable both (1) a simple but highly effective joint model and (2) an efficient A* parsing algorithm.

Semantic dependencies can span an unbounded number of syntactic dependencies, causing significant inference and sparsity challenges for joint models. For example, in the Figure 1, the semantic dependency between *He* and *deny* spans three syntactic edges. This fact makes it difficult to jointly parse syntactic and semantic dependencies with dynamic programs, and means that dependency path features can be sparse. Syntactic dependencies also often have ambiguous semantic interpretations—for example in *He opened the door* and *The door opened*, the syntactic subject corresponds to different semantic roles.

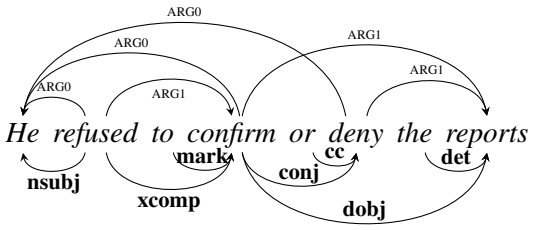

Figure 1: Mismatch between syntactic and semantic dependencies.

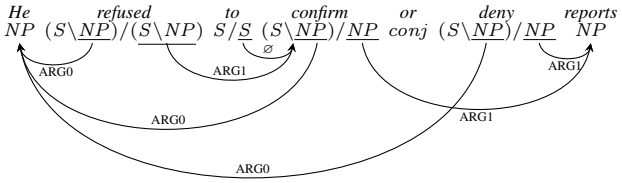

Figure 2: Dependencies produced by a CCG parse. SRL dependencies can be recovered by labelling the edges with a semantic role or ∅. Figure 3 shows a CCG derivation for these dependencies.

We address these challenges with a new joint model of CCG syntactic parsing and semantic role labelling. The CCG formalism is particularly well suited; it models both short- and long-range syntactic dependencies which correspond directly to the semantic roles we aim to recover. The joint model simply involves labelling a subset of these dependencies with the appropriate roles, as seen in Figure 2. This labelling decision can be easily integrated into existing parsing algorithms. CCG also helps resolve cases where interpretation depends on the valency of the pred-

Lisbon, Portugal, 17-21 September 2015.

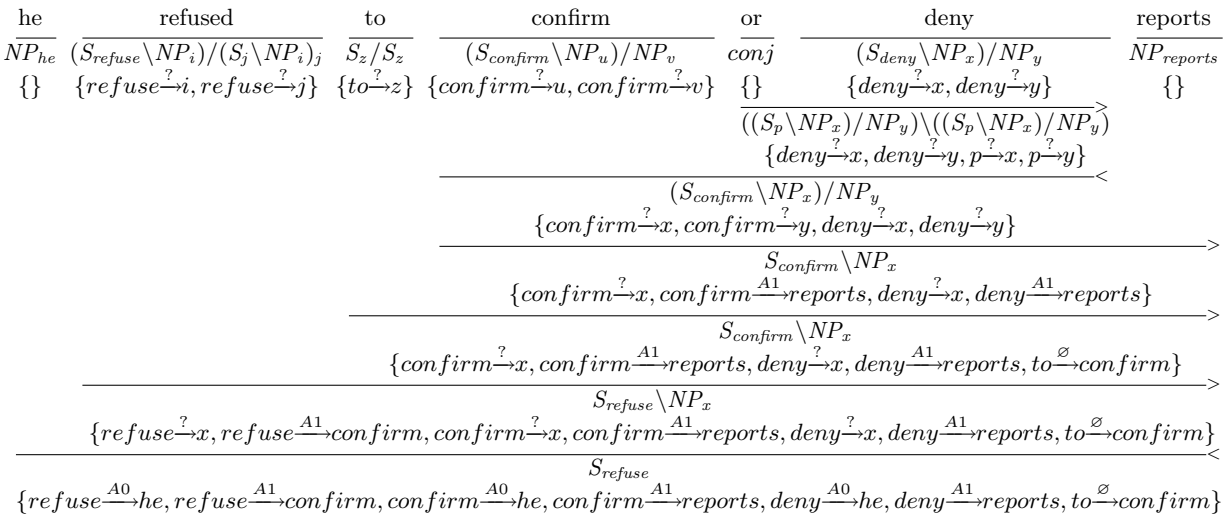

Figure 3: Jointly building a CCG parse and semantic dependencies representation. Subscripts beneath categories denote heads, which are unified when spans combine. One dependency is created for each argument of each lexical category. In our approach, dependency labels are initially underspecified (represented $f \xrightarrow{?} a$) until an attachment is determined by the derivation and a label is chosen by the model.

icate, such as ergative verbs, by learning lexical entries that pair syntactic arguments with semantic roles, such as $open : S\backslash NP_{ARG1}$ and $open : (S\backslash NP_{ARG0})/NP_{ARG1}$. Figure 3 shows a detailed trace of how the example from Figure 2 is parsed with our model.

We also present a new A* algorithm for the joint model. Because CCG is strongly lexicalized, we are able to introduce a new type of *extended lexical entries* that allows us to factor the model over words and develop effective new upper bounds on the Viterbi outside parse score. A* parsing algorithms have previously been developed for models with tree-structured syntactic dependencies (Klein and Manning, 2003; Auli and Lopez, 2011b), and models with no bi-lexical dependencies, including supertag-factored CCGs (Lewis and Steedman, 2014a). We generalize these techniques to SRL-style graph-structured dependencies.

Experiments demonstrate that our model not only outperforms pipeline semantic role labelling models, but improves the quality of the syntactic parser. PropBank SRL performance is 1.6 points higher than comparable existing work, and semantic features improve syntactic accuracy by 1.6 points. Our A* algorithm is 5 times faster than CKY parsing, with no loss in accuracy. The combination of CCG-based joint modelling and A* decoding gives an efficient, accurate, and linguistically principled parser.[1]

[1]The parser is available from: `https://github.com/mikelewis0/EasySRL`

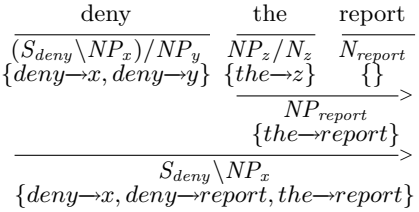
2 Background

2.1 CCG Dependencies

CCG parses define an implicit dependency graph, by associating each argument of each category with a dependency. In contrast to Stanford dependency trees, CCG dependency graphs can be non-projective, and words can have multiple parents. For example, in Figure 2, *He* is an argument of *refuse*, *confirm* and *deny*.

To create dependencies, categories are marked with headedness information—which we denote with subscripts. For example, in the category $(S_{deny}\backslash NP_x)/NP_y$, the final head for the sentence S will be *deny*, and that two dependencies will be introduced from *deny* to unspecified arguments x and y. During parsing, variables are unified with heads, creating fully specified dependencies.

Re-using variables allows dependencies to propagate. For example, the determiner category NP_i/N_i marks that the head of the resulting NP is equal to the head of its N argument (e.g. the head of *the report* is *report*), as in the following parse:



The same mechanism allows long-range arguments to be propagated. Figure 3 shows several long-range arguments, such as how co-indexation

propagates the subject of *deny* to *he*. For more details, see Hockenmaier (2003).

2.2 A* CCG parsing

A* parsing searches for an optimal parse, without building a complete chart (in contrast to CKY parsing). This is particularly attractive for CCG, because the formalism's lexical and derivational ambiguity causes the parse charts to be very dense, in practice. Lewis and Steedman (2014a) showed that A* CCG parsing can be highly efficient, but used a restricted model without bi-lexical features.

In A* parsing, entries y are added to the chart in order of their cost $f(y) = g(y) + h(y)$, where $g(y)$ is the inside score for the entry, and $h(y)$ is an upper bound on the Viterbi outside score. Because partial parses are built in order of increasing $f(y)$, the first complete parse added to the chart is guaranteed to be optimal. The key to making A* parsing efficient is computing tight upper bounds on the outside score. In Lewis and Steedman's supertag-factored model, the bound can be computed as the sum of the highest-scoring supertags in the outside parse.

The agenda is initialized with items representing every category for every word. Then, after each item is added to the chart, the agenda is updated with all binary and unary rules that can be applied to the new item. For more details, see Lewis and Steedman (2014a).

3 Model

Our joint model of CCG and SRL parsing simply involves labelling CCG syntactic dependencies (which are implicit in CCG parses), with SRL roles (or null). This formulation allows us to easily adapt the log-linear CCG parsing model of Clark and Curran (2007) to the joint setting by working with extended dependencies that including syntactic and semantic information.

More formally, we can define a notion of consistency to specify the labelling of syntactic dependencies. A set of semantic dependencies π is consistent with a CCG derivation d if each semantic dependency corresponds to a single syntactic dependency—for example, see the dependencies in Figure 3. The CCG derivation in Figure 3 would also be consistent with the SRL dependency $refuse \xrightarrow{ARG2} he$, but not $refuse \xrightarrow{ARG1} reports$ (because the derivation does not produce the required syntactic dependency).

Now, we can define a log-linear model over pairs of consistent CCG derivations d and SRL dependencies π:

$$p(d, \pi|x) = \frac{e^{\theta \cdot \phi(x,d,\pi)}}{\sum_{(d',\pi') \in GEN(x)} e^{\theta \cdot \phi(x,d',\pi')}}$$

where $GEN(x)$ is the space of consistent pairs for sentence x.

3.1 Dependencies

Because we enforce consistency, we can work with joint dependencies that are a combination of CCG and SRL dependencies. We denote a dependency as a 6-tuple of functor f, lexical category c, argument number n, preposition p, argument a and semantic role r: $\langle f, c, n, p, a, r \rangle$. The first three of these (f,c,n) are lexically specified, but a and r are lexically underspecified until the attachment is determined by the derivation, and a label is chosen by the model. For example, in Figure 3, the lexical entry for *deny* has two underspecified dependencies: $\langle deny, (S\backslash\mathbf{NP})/NP, 1, \varnothing, ?, ? \rangle$ and $\langle deny, (S\backslash NP)/\mathbf{NP}, 2, \varnothing, ?, ? \rangle$.[2] At the end of the derivation, the dependencies are specified as: $\langle deny, (S\backslash\mathbf{NP})/NP, 1, \varnothing, he, ARG0 \rangle$ and $\langle deny, (S\backslash NP)/\mathbf{NP}, 2, \varnothing, reports, ARG1 \rangle$.

The preposition p is lexically underspecified for PP arguments, but otherwise $\varnothing$. Prepositions are marked lexically on $PP/*$ categories, and then propagated, for example:

$$\dfrac{\dfrac{\dfrac{\begin{array}{c}\text{fly}\\ (S_{fly}\backslash NP_x)/PP_y^p\\ \{fly \xrightarrow{?} x, fly \xrightarrow{?} y\}\end{array} \quad \dfrac{\begin{array}{c}\text{to}\\ PP_z^{to}/NP_z\\ \{to \xrightarrow{?} z\}\end{array} \quad \begin{array}{c}\text{Lisbon}\\ NP_{Lisbon}\\ \{\}\end{array}}{PP^{to}_{Lisbon}\ \{to \xrightarrow{\varnothing} Lisbon\}}<}{S_{fly}\backslash NP_x\ \{fly \xrightarrow{?} x, fly \xrightarrow{ARG1} Lisbon, to \xrightarrow{\varnothing} Lisbon\}}<$$

In the above example, the dependency from *fly* to *Lisbon* corresponds to the tuple: $\langle fly, (S\backslash NP)/\mathbf{PP}, 2, to, Lisbon, ARG1 \rangle$. Propagating both the noun and preposition from prepositional phrases allows the model to use both for features, and improved results.

3.2 Features

We use the following feature classes, which decompose over categories, dependencies, and local rule instantiations.

[2] Bold-face is used to highlight the argument of a category corresponding to a dependency. For example $(S\backslash\mathbf{NP})/NP$ denotes the first (subject) dependency of a transitive verb.

3.2.1 Supertagging Features

Supertagging features ϕ^{CAT} score categories for words. A single feature is used, which is the (unnormalized) score from Lewis and Steedman (2014b)'s supertagging model. The supertagger outputs a distribution over categories for each word independently. The model is trained on supertags extracted from an adaptation of CCGrebank (Honnibal et al., 2010). The adaptation makes minor changes to better match PropBank.

3.2.2 Preposition Features

Preposition features ϕ^{PP} score whether the nth argument of the word at index f with category c should take a PP argument headed by preposition p. We use features $x_f{+}p$, $l_f{+}c$ and $l_f{+}c{+}n{+}p$, where x_f is the fth word, and l_f is its lemma.

3.2.3 Labelling Features

Labelling features ϕ^{ROLE} determine whether the nth argument of a word with lemma l, and category c should take a role r. We use $n{+}r$, $c{+}n{+}r$, $c{+}n{+}p{+}r$, $l{+}c{+}n{+}p{+}r$, $n{+}r$, r, $l{+}p{+}r$, $c{+}n{+}r$, $l{+}r$, $h{+}r$, where h is an indicator of whether l is hyphenated, and p is the preposition of PP arguments.

3.2.4 Dependency Features

Dependency features ϕ^{DEP} score dependencies, based on the functor index f, argument index a and role r. We use $l_f{+}r{+}l_a$, $l_f{+}r{+}c_a$, $d{+}r$, $c_{f+o}{+}r$, $c_{a+o}{+}r$, where o is an offset from $-3 \ldots +3$, d is the distance between f and a, c_i is a cluster or POS tag for word i, and l_i is the lemma of word i. Clusters were created from pre-trained word embeddings (Levy and Goldberg (2014)) using k-means, with $k = 20, 50, 200, 1000, 2500$. These features only apply when the role $r \neq \varnothing$.

3.2.5 Derivation Features

Derivation features ϕ^{DERIV} score properties of the syntactic derivation. To simplify computation of the upper bounds for the A* parsing algorithm given in Section 5, the weights of these features are constrained to be ≤ 0. For simplicity, we only use features for unary rules—for example, a feature records when the unary rule $N \rightarrow NP$ converts a determiner-less N to a NP.

4 Lexical Factorization

In this section, we show how to factor the model into *extended lexical entries*. This factorization allows us to efficiently compute upper bounds on the scores of partial parses, which is crucial to the A* algorithm described in Section 5.

The key observation is that our supertagging, labelling and dependency features can each be associated with exactly one word (using the functor for the dependency features). Therefore, we can equivalently view the complete parse as a series of *extended lexical entries*: $y = y_0 ... y_N$. Extended lexical entries are composed of a lexical category, and a role and attachment for each argument of the category. The set of extended lexical entries specifies the yield of the parse. For example, the parse from Figure 2 can be represented as the following extended lexical entries:

he	$\vdash NP$
refused	$\vdash (S\backslash NP_{ARG0=he})/(S\backslash NP)_{ARG1=confirm}$
to	$\vdash S/S_{\varnothing=confirm}$
confirm	$\vdash (S\backslash NP_{ARG0=he})/NP_{ARG1=reports}$
or	$\vdash conj$
deny	$\vdash (S\backslash NP_{ARG0=he})/NP_{ARG1=reports}$
reports	$\vdash NP$

The score for a sentence x and joint SRL-CCG parse y, $\theta \cdot \phi(x, y)$, can be decomposed into scores of its extended lexical entries y_i, plus a score for the derivation features:

$$\theta \cdot \phi(x, y) = \sum_{y_i \in y} \theta \cdot \phi(x, y_i) + \theta \cdot \phi^{DERIV}(x, y)$$

The space of possible extended lexical entries for word x_i is defined by $GENLEX(x_i)$, which is expressed with a CFG, as shown in Figure 4a.

The features defined in Section 3.2 decompose over the rules of $GENLEX$—so it can be weighted with the globally trained feature weights.

Expressing $GENLEX(x_i)$ as a CFG allows us to efficiently compute upper bounds on the score of y_i when it is only partially specified, using the Viterbi algorithm—which we will make use of in Section 5. Making the attachment choice independent of the syntactic category greatly improves the efficiency of these calculations.

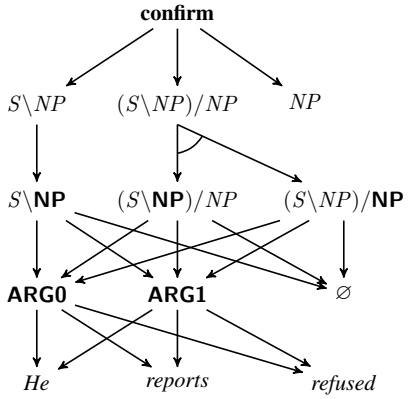
5 A* Parsing

To efficiently decode our model, we introduce a new A* parsing algorithm. As discussed in Section 2.2, the key to efficient A* parsing is computing tight upper bounds on the Viterbi outside score of partial parses, with the function h.

The intuition behind our algorithm is that we can use the lexical factorization of Section 4 to compute upper bounds for words individually,

Lexical Category Choice	
x_i	$\rightarrow NP \mid S\backslash NP \mid (S\backslash NP)/PP \mid \ldots$
One dependency is created for every argument of the category	
$S\backslash NP$	$\rightarrow S\backslash \mathbf{NP}$
$(S\backslash NP)/PP$	$\rightarrow (S\backslash \mathbf{NP})/PP,\ \ (S\backslash NP)/\mathbf{PP}$
$\ldots$	
Preposition choice for PP arguments	
$(S\backslash NP)/\mathbf{PP}$	$\rightarrow (S\backslash NP)/\mathbf{PP^{in}} \mid (S\backslash NP)/\mathbf{PP^{for}} \mid \ldots$
$\ldots$	
Semantic role label choice for the argument	
$S\backslash \mathbf{NP}$	$\rightarrow S\backslash \mathbf{NP_{ARG0}} \mid S\backslash \mathbf{NP_{ARG1}} \mid \ldots$
$(S\backslash \mathbf{NP})/PP$	$\rightarrow (S\backslash \mathbf{NP_{ARG0}})/PP \mid (S\backslash \mathbf{NP_{ARG1}})/PP \ldots$
$(S\backslash NP)/\mathbf{PP^X}$	$\rightarrow (S\backslash NP)/\mathbf{PP^X_{ARG0}} \mid (S\backslash NP)/\mathbf{PP^X_{ARG1}} \cdots$
$\ldots$	
Attachment choice	
$ARG0$	$\rightarrow x_0 \mid \ldots \mid x_{i-1} \mid x_{i+1} \mid \ldots \mid x_N$
$ARG1$	$\rightarrow x_0 \mid \ldots \mid x_{i-1} \mid x_{i+1} \mid \ldots \mid x_N$
$\ldots$	

(a) The grammar $GENLEX(x_i)$



(b) Visualization of a fragment of $GENLEX(confirm)$

Figure 4: (a) The grammar $GENLEX(x_i)$, which defines the space of extended lexical entries, and (b) a visualization of a fragment of $GENLEX(confirm)$. Extended lexical entries, including **confirm** $\vdash (S\backslash NP_{ARG0=he})/NP_{ARG1=reports}$ and **confirm** $\vdash NP$, are specified by choosing one category (top level in both a and b), enumerating all arguments (second level), selecting the preposition for PP arguments (when present), selecting a semantic role label for each, and finally choosing the argument head word. The features are local to the grammar rules, enabling efficient dynamic programs for upper bound computations on partially specified entries, such as **confirm** $\vdash (S\backslash NP_{r=a})/NP_{ARG1=reports}$.

then create an upper bound for the parse as a sum of upper bounds for words. The bound is not exact, because the grammar may not allow the combination of the best lexical entry for each word.

Section 5.1 gives a declarative definition of h for any partial parse, and 5.2 explains how to efficiently compute h during parsing.

5.1 Upper Bounds for Partial Parses

This section defines the upper bound on the Viterbi outside score $h(y_{i,j})$ for any partial parse $y_{i,j}$ of span $i \ldots j$. For example, in the parse in Figure 3, $y_{3,5}$ is the partial parse of *confirm or deny* with category $(S\backslash NP)/NP$.

As explained in Section 4, a parse can be decomposed into a series of extended lexical entries. Similarly, a partial parse can be viewed as a series of *partially specified* extended lexical entries $y_0 \ldots y_N$. For example, in Figure 3, the partial parse of the span *confirm or deny reports*, the extended lexical entries for the words outside the span (*He*, *refused* and *to*) are completely unspecified. The extended lexical entries for words inside the span have specified categories, but can contain underspecified dependencies:

confirm	$\vdash (S\backslash NP_{r=a})/NP_{ARG1=reports}$
or	$\vdash conj$
deny	$\vdash (S\backslash NP_{r'=a'})/NP_{ARG1=reports}$
reports	$\vdash NP$

Therefore, we can compute an upper bound for the outside score of a partial parse as a sum of the upper bounds of the unspecified components of each extended lexical entry. Note that because the derivation features are constrained to be ≤ 0, they do not affect the calculation of the upper bound.

We can then find an upper bound for completely unspecified spans using by summing the upper bounds for the words. We can pre-compute an upper bound for the span $h_{i,j}$ for every span i, j as:

$$h_{i,j} = \sum_{k=i}^{j} \max_{y_k \in GENLEX(x_k)} \theta \cdot \phi(x, y_k)$$

The max can be efficiently computed using the Viterbi algorithm on $GENLEX(x_k)$ (as described in Section 4).

The upper bound on the outside score of a partial parse is then the sum of the upper bounds of the words outside the parse, and the sum of the scores of the best possible specifications for each underspecified dependency:

$$h(y_{i,j}) = \sum_{\langle f,c,n,?,?,? \rangle \in \mathbf{deps}(y_{i,j})} \max_{a',p',r'} \theta \cdot \phi(\langle f, c, n, p', a', r' \rangle) + h_{0,i-1} + h_{j+1,N}$$

where $\mathbf{deps}(y)$ returns the underspecified dependencies from partial parse.

For example, in Figure 3, the upper bound for the outside score of the partial parse of *confirm or deny reports* is the sum of the upper bounds

for the other words independently ($h_{0,3}$) added to the score of the best attachments and roles for the subjects of *confirm* and *deny* independently.

5.2 Additive Updates

During parsing, the upper bound h can be efficiently computed recursively with additive updates. Initially h is the sum of the upper bounds for each word independently $h_{0,N}$. Then, when specifying categories or labelling dependencies, the score is updated.

- When specifying a category for a word x_i, the Viterbi score of $GENLEX(x_i)$ is subtracted from h, and the sum of Viterbi scores for each of the category's (underspecified) dependencies is added to h.
- When specifying a semantic role for a dependency with functor f, causing the dependency to be fully specified, the Viterbi score for the node representing that dependency in $GENLEX(x_f)$ is subtracted from h.
- When a binary rule combines two partial parses $y_{i,j}$ and $y_{j+1,k}$, the bound on the outside score is updated by summing the bounds of the outside scores of the child parses, and subtracting the overall upper bound for the sentence (to avoid double-counting):
  $h(y_{i,k}) = h(y_{i,j}) + h(y_{j+1,k}) - h_{0,N}$
  This update can be derived from the definition of h.

These are the only cases where h is updated.

6 Training

During training, we optimize parameters θ for the marginal likelihood of the semantic dependencies π_i given a sentence x_i, treating syntactic derivations d as a latent variable and using L_2 regularization.

$$L(\theta) = \log \prod_i p_\theta(\pi_i|x_i) - \frac{\sum_j \theta_j^2}{2\sigma^2}$$
$$= \sum_i \log \frac{\sum_{d \in \Delta(x_i,\pi_i)} e^{\theta \cdot \phi(x_i,d,\pi_i)}}{\sum_{(d',\pi') \in GEN(x_i)} e^{\theta \cdot \phi(x_i,d',\pi')}} - \frac{\sum_j \theta_j^2}{2\sigma^2}$$

where $GEN(x_i)$ is the set of consistent CCG and SRL parses for a sentence x_i (see Section 3), and $\Delta(x_i, \pi_i)$ is the set of CCG derivations that are maximally consistent with gold SRL parses π_i. More formally, if $\textbf{labelled}(y)$ returns the set of labelled dependencies from parse y, then:

$$\Delta(x, \pi) = \arg\max_{y \in GEN(x)} |\pi \cap \textbf{labelled}(y)|$$

The arguments of PropBank dependencies can span multiple words, so CCG dependencies are marked as equivalent if their argument is anywhere within the PropBank span.

The approach is closely related to the hybrid dependency model (Clark and Curran, 2007). However the CCGbank dependencies used by Clark and Curran's model constrain all lexical and attachment decisions (only allowing 'spurious' derivational ambiguity) whereas our use of semantic dependencies models most of the syntactic parse as latent.

6.1 Hyperparameters

Calculating the gradient of the loss function requires computing the marginal probability of the correct parses. Computing marginal probabilities exactly involves summing over all possible CCG parses, which is intractable. Instead, following Clark and Curran, we limit the size of training charts using a variable-width supertagger beam β, initially 10^{-3}. If the chart size exceeds 100000 nodes, we double β and re-parse. For computing Δ, we use a more restrictive beam of $\beta = 0.01$ to improve the quality of the positive training examples. We optimize using L-BFGS (Liu and Nocedal, 1989), with $\sigma^2 = 0.06$.

6.2 Pruning

To improve efficiency, we compute a number of thresholds, by aligning gold CCGbank dependencies with PropBank. If an argument of a category occurs with a particular semantic role less than 3 times in the aligned data, it is pruned from the training and decoding charts. We also filter infrequent features before training. We count the number of times each feature occurs in the aligned data, and filter features occurring less than 3 times. During decoding, we prune lexical categories whose probability under the supertagging model is less than a factor of 10^{-2} of that of the best category for that word. If the chart size exceeds 20000 nodes, we back off to a pipeline model (roughly 3% of sentences). Finally, we build and use a tag dictionary in the same way as Lewis and Steedman (2014a).

7 Experiments

7.1 Experimental Setup

We used PropBank Section 00 for development, Sections 02-21 for training, and Section 23 for testing. The **Pipeline** baseline first parses with a supertag-factored A* model, and chooses a semantic role for each CCG dependency with a log-linear classifier. The classifier uses the role and attachment features used by the parser.

7.2 Semantic Role Labelling

We evaluate our parser as a dependency-based SRL model on PropBank, comparing with CoNLL-2008 systems (Surdeanu et al., 2008).

Comparison systems Following Täckström et al. (2015), we compare with the best 'single parser' SRL models, which use only a single syntactic parse.[3]

Much recent work has evaluated using gold predicate identification (Hajič et al., 2009; FitzGerald et al., 2015). This setting is particularly unrealistic for our joint model, where gold predicate identification would be a highly useful feature for the supertagger; we only compare with models that use automatic predicate identification. To the best of our knowledge, the best SRL results with automatic predicate identification were achieved at CoNLL-2008.

A number of other models have been evaluated on CoNLL-2008 data. While we cannot compare directly on our metric, the best reported joint model (Johansson, 2009) scored 1.4 points lower than the Che et al. (2008) system we compare to on the CoNLL metric on PropBank. Other joint models, such as those of Titov et al. (2009) and Lluís et al. (2013), achieve similar performance.

Evaluation Metric Comparing fairly with existing work is complicated by the mismatch between heads found by our model and those used in other evaluations. Headedness decisions are often arbitrary—for example, whether a prepositional phrase is headed by the noun or preposition—and different choices were made in the design of CCGbank and the CoNLL-2008 headedness rules.

To solve this problem, we introduce a new *within-constituent* metric, which awards dependencies as correct if they attach anywhere within the original PropBank-annotated argument spans. For example, if the PropBank annotates that the *ARG*0 of *owned* is *by Google*, a dependency to either *by* or *Google* is judged correct. We compute new scores for the CoNLL-2008 submissions on our metric, filtering reference and continuation arguments (which are artifacts of the CoNLL conversion of PropBank, but not required by our metric), and nominal predicates based on POS tag. The ranking of the top 5 CoNLL-2008 open-track models is identical under our metric and the original one (up to statistical significance), suggesting that our metric is equally discriminative. However, perhaps interestingly, the ranking of Vickrey and Koller (2008) does improve—likely due to the use of a syntactic formalism with different headedness rules. For simplicity, we do not include predicate senses in the evaluation.

[3]The best models use reranking with powerful global features (Toutanova et al., 2008; Johansson and Nugues, 2008) or ensemble methods (Surdeanu et al., 2007; Punyakanok et al., 2008). These techniques have the potential to improve any SRL system, including ours, at some expense in speed.

	PropBank			Brown		
Model	P	R	F1	P	R	F1
Vickrey	**87.3**	77.3	82.0	**74.0**	64.5	68.9
Che	85.3	78.6	81.8	71.1	65.7	68.0
Zhao	82.4	79.8	81.1	66.6	64.9	65.7
Riedel	83.6	74.7	78.9	69.3	62.7	65.8
Pipeline	79.2	73.9	76.4	69.3	64.0	66.1
Joint	84.8	**82.2**	**83.5**	71.2	**69.2**	**70.2**

Table 1: Comparison with the best single-parser SRL models on PropBank from CoNLL-2008. The comparison models are Vickrey and Koller (2008), Che et al. (2008), Zhao and Kit (2008) and Riedel and Meza-Ruiz (2008).

Results are given in Table 1 and show that our joint model greatly outperforms the pipeline version, demonstrating the value of joint reasoning. It also scores 1.5 points higher than the best comparable models in-domain, and 1.3 points higher out-of-domain. To the best of our knowledge, this is the first joint syntax/SRL model to outperform strong pipeline models.

7.3 Efficiency Experiments

We explore whether our A* decoding is more efficient than alternatives, including both algorithmic and feature computation. While the A* search builds very small charts, the features must be precomputed for the heuristic. In CKY parsing, features can be computed lazily.

Model	Sentences per second	PropBank F1
Pipeline A*	**38.3**	76.4
Joint CKY	6.0	**83.5**
Joint AST	20.3	83.0
Joint A*	31.3	**83.5**

Table 2: Parser speed on PropBank Section 23

We compare with a CKY parsing over the same space. If no parse is found, or the chart size exceeds 400000 nodes, we back off to the pipeline (tuned so that the backoff is used roughly as often as for the A* parser). We also compare with adaptive supertagging (AST, Clark and Curran (2007)), which is the same except for first attempting to parse with a restrictive supertagger beam $\beta = 0.1$.

Table 2 shows the results. The A* pipeline is fast, but inaccurate. CKY is 5 times slower than A* in the same space, whereas adaptive supertagging trades accuracy for speed. The best previously reported speed improvement using A* parsing is a factor of 1.2 times faster (Auli and Lopez, 2011b). Our new A* algorithm dominates existing alternatives in both speed and accuracy.

7.4 Syntactic Parsing

We also evaluate our model for CCG parsing accuracy, using CCGrebank (Honnibal et al., 2010), and comparing with a C&C parser model adapted to this dataset. Results are shown in Table 3. Of course, given our latent syntax, and the fact we have no model of CCGbank dependencies, we do not expect state-of-the-art accuracy. However, the 1.6 point improvement over the pipeline shows that SRL dependencies are useful for disambiguating syntactic attachment decisions. Many errors were caused by disagreements between CCGbank and PropBank—PropBank is likely to be more accurate as it was hand-annotated, rather than automatically converted from the Penn Treebank. In effect, our latent model of syntax is successfully learning a grammar that better produces the correct semantics.

Table 4 shows the syntactic dependencies which are improved most by modelling semantics. Unsurprisingly, verb arguments and adjuncts relations show large improvements. However, we also see more accurate attachment of relative clauses. While we do not model relative clauses explicitly, correctly attaching them is essential for propagating certain verb arguments (e.g. the subject of *broke* in *the glass on the table that broke*).

Model	P	R	F1
C&C	81.8	81.2	81.5
Pipeline	76.6	77.7	77.2
Joint	78.3	79.4	78.8

Table 3: Labelled F1 for CCGbank dependencies on CCGrebank Section 23

Dependency	Type	Δ F1
$((S_{dcl}\backslash NP)/\mathbf{PP})/NP$		+12.6
$((S_{dcl}\backslash NP)/PP)/\mathbf{NP}$		+11.0
$((S_b\backslash NP)/\mathbf{PP})/NP$	Verb	+10.7
$(S_{dcl}\backslash NP)/\mathbf{PP}$	arguments	+8.1
$(S_{ng}\backslash \mathbf{NP})/NP$		+7.6
$(S_{pt}\backslash \mathbf{NP})/NP$		+6.8
$((S\backslash NP)\backslash(\mathbf{S}\backslash\mathbf{NP}))/NP$	Verb	+16.9
$((S\backslash NP)\backslash(\mathbf{S}\backslash\mathbf{NP}))/S_{dcl}$	adjuncts	+11.9
$(N\backslash\mathbf{N})/(S_{dcl}\backslash NP)$	Relative	+12.5
$(NP\backslash\mathbf{NP})/(S_{dcl}\backslash NP)$	clauses	+8.5

Table 4: CCG syntactic dependencies with the largest change in F1 between the Pipeline and Joint models (of those occurring at least 100 times in the development set).

7.5 Error Analysis

Table 5 gives an analysis of recall errors from the first 100 sentences of PropBank Section 00. One third of errors were syntactic attachment errors. A further 14% were triggered by cases where the parser found the correct attachment, but gave an adjunct a core argument CCG category (or vice versa). Many of these decisions are not obvious—for example in *rose sharply*, PropBank considers *sharply* to be an argument and not an adverb. 21% of errors were caused by choosing the wrong SRL

Error	Percentage
Attachment error	33%
Correct attachment, wrong label	21%
Correct attachment, unlabelled	20%
Argument/adjunct distinction	14%
Problematic constructions	9%
Dubious annotation	4%

Table 5: Error analysis of recall errors from 100 development set sentences.

label. Another 20% were caused by predicates assigning arguments the null semantic role ∅. The major cause of these errors is predicates that act syntactically like adjectives (e.g. *publishing* in *Dutch publishing group*) where syntactic cues are weak. Finally, 9% involved long-range arguments that our current grammar is unable to project. One common case is constructions like *X has a plan to buy Y*, where the grammar does not propagate the subject of *buy* to *X*. Further improvements to CCGbank may help to resolve these cases.

8 Related Work

Joint syntactic and SRL models There have been many proposals for jointly parsing syntactic and semantic dependencies. Lluís et al. (2013) introduce a joint arc-factored model for parsing syntactic and semantic dependencies, using dual-decomposition to maximize agreement between the models. SRL performance is slightly worse than a pipeline version. Naradowsky et al. (2012) introduce a SRL model with latent syntax representations, by modelling a latent dependency tree during training, which is marginalized out at test time. However, performance at English SRL is roughly 7 points beneath state of the art. Other notable models include those of Johansson (2009) and Titov et al. (2009).

CCG parsing Our log-linear model is closely related to that of Clark and Curran (2007), but we model SRL dependencies instead of CCG dependencies. The best CCG parsing results were achieved by Auli and Lopez (2011a), who, like us, score CCG parses based jointly on supertagging and dependency model scores. Decoding their model requires dual-decomposition, to maximize agreement between the separate models. We avoid the need for this technique by using a unigram supertagging model, rather than a sequence model.

CCG semantics Work on semantic parsing has mapped sentences onto semantic representations with latent CCGs (Zettlemoyer and Collins, 2009; Kwiatkowski et al., 2010; Kwiatkowski et al., 2013) for restricted domains. Recent work has scaled these techniques to wide-coverage datasets (Artzi et al., 2015). Krishnamurthy and Mitchell (2014) also explore joint CCG syntactic and semantic parsing. They use a smaller semantic lexicon, containing 130 predicates, rather than the 3257 PropBank verbs. In contrast to our results, jointly modelling the semantics lowers their model's syntactic accuracy.

Other CCG-based SRL models haved used CCG dependencies as features for predicting semantic roles (Gildea and Hockenmaier, 2003; Boxwell et al., 2009), but performance is limited by relying on 1-best parses—a problem we resolved with a joint model.

A* parsing A* parsing has previously been explored for less general models than ours. Klein and Manning (2003) and Auli and Lopez (2011b) use A* parsing for models with tree-structured dependencies. The best reported speed improvement is parsing 1.2 times faster, whereas we improve by a factor of 5. Our model also allows the more complex graph-structured dependencies required for semantic role labelling. Lewis and Steedman (2014a) demonstrate an efficient A* algorithm for CCG, but cannot model dependencies.

9 Conclusions and Future Work

We have shown that using CCG can allow joint models of syntax and semantics to outperform pipelines, and achieve state-of-the-art results on PropBank SRL. Our new A* parsing algorithm is 5 times faster than CKY parsing, without loss of accuracy. Using latent syntax allows us to train the model purely from semantic dependencies, enabling future work to train against other annotations such as FrameNet (Baker et al., 1998), Ontonotes (Hovy et al., 2006) or QA-SRL (He et al., 2015). The semantic labels provided by PropBank can also be integrated into wide-coverage CCG semantic parsers (Bos, 2008; Lewis and Steedman, 2013) to improve performance on downstream applications.

Abstract

Semantic parsing maps a sentence in natural language into a structured meaning representation. Previous studies show that semantic parsing with synchronous context-free grammars (SCFGs) achieves favorable performance over most other alternatives. Motivated by the observation that the performance of semantic parsing with SCFGs is closely tied to the translation rules, this paper explores extending translation rules with high quality and increased coverage in three ways. First, we introduce structure informed non-terminals, better guiding the parsing in favor of well formed structure, instead of using a uninformed non-terminal in SCFGs. Second, we examine the difference between word alignments for semantic parsing and statistical machine translation (SMT) to better adapt word alignment in SMT to semantic parsing. Finally, we address the unknown word translation issue via synthetic translation rules. Evaluation on the standard GeoQuery benchmark dataset shows that our approach achieves the state-of-the-art across various languages, including English, German and Greek.

1 Introduction

Semantic parsing, the task of mapping natural language (NL) sentences into a formal meaning representation language (MRL), has recently received a significant amount of attention with various models proposed over the past few years. Consider the NL sentence paired with its corresponding MRL in Figure 1(a). Semantic parsing can be naturally viewed as a statistical machine translation (SMT) task, which translates a sentence in NL (i.e., the source language in SMT) into its meaning representation in MRL (i.e., the target language in SMT). Indeed, many attempts have been made to directly apply statistical machine translation (SMT) systems (or methodologies) to semantic parsing (Papineni et al., 1997; Macherey et al., 2001; Wong and Mooney, 2006; Andreas et al., 2013). However, although recent studies (Wong and Mooney, 2006; Andreas et al., 2013) show that semantic parsing with SCFGs, which form the basis of most existing statistical syntax-based translation models (Yamada and Knight, 2001; Chiang, 2007), achieves favorable results, this approach is still behind the most recent state-of-the-art. For details, please see performance comparison in Andreas et al. (2013) and Lu (2014).

NL: What is the area of Seattle
MRL: answer(area_1(cityid('seattle', _)))
(a) before pre-processing

NL': what be the area of seattle
MRL': answer@1 area_1@1 cityid@2 seattle@s _@0
(b) after pre-processing

Figure 1: Example of a sentence pair in NL and MRL.

The key issues behind the limited success of applying SMT systems directly to semantic parsing lie in the difference between semantic parsing and SMT: *MRL is not a real natural language with different properties from natural language*. First, MRL is machine-interpretable and thus strictly structured with the meaning representation in a nested structure of functions and arguments. Second, the two languages are intrinsically asymmetric since each token in MRL carries specific mean-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1455–1465,
Lisbon, Portugal, 17-21 September 2015.

ing[1] while this does not hold in NL since auxiliary words and some function words usually have no counterparts in MRL. Third and finally, the expressions in NL are more flexible with respect to lexicon selection and token ordering. For example, since sentences in NL *'could you tell me the states that utah borders'*, *'what states does utah border'*, and *'utah borders what states'* convey the same meaning, they should have the same expression in MRL.

Motivated by the above observations, we believe that semantic parsing with *standard* SMT components is not an ideal approach. Alternatively, this paper proposes an effective, yet simple way to enrich SCFG in hierarchical phrase-based SMT for better semantic parsing. Specifically, since the translation rules play a critical role in SMT, we explore to improve translation rule quality and increase its coverage in three ways. First, we enrich non-terminal symbols as to capture contextual and structured information. The enrichment of non-terminal symbols not only guides the translation in favor of well formed structures, but also is beneficial to translation. Second, we examine the difference between word alignments for semantic parsing and SMT to better adapt word alignment in SMT to semantic parsing. Third, unlike most existing SMT systems that keep unknown words untranslated and intact in translation, we exploit the translation of unknown words via synthetic translation rules. Evaluation on GeoQuery benchmark dataset shows that our approach obtains consistent improvement and achieves the state-of-the-art across various languages, including English, German and Greek.

2 Background: Semantic Parsing as Statistical Machine Translation

In this section, we present the framework of semantic parsing as SMT, which was proposed in Andreas et al. (2013).

Pre-Processing Various semantic formalisms have been considered for semantic parsing. Examples include the variable-free semantic representations (that is, the meaning representation for each utterance is tree-shaped), the lambda calculus expressions, and dependency-based compositional semantic representations. In this work, we specifically focus on the variable-free semantic representations, as shown in Figure 1. On the target side, we convert these meaning representations to series of strings similar to NL. To do so, we simply take a preorder traversal of every functional form, and label every function with the number of arguments it takes. Figure 1(b) shows an example of converted meaning representation, where each token is in the format of $A@B$ where *A* is the symbol while *B* is either *s* indicating that the symbol is a string or a number indicating the symbol's arity (constants, including strings, are treated as zero-argument functions).

On the source side, we perform stemming (for English and German) and lowercasing to overcome data sparseness.

Hereafter, we refer to the pre-processed NL and MRL as NL$'$ and MRL$'$ respectively.

Translation Given a corpus of NL$'$ sentences paired with MRL$'$, we learn a semantic parser by adopting a string-to-string translation system. Typical components in such a translation system include word alignments between the source and the target languages, translation rule extraction, language model learning, parameter tuning and decoding. For more details about each component, please refer to (Chiang, 2007). In the rest of this paper, we refer to the source language (side) as NL$'$, and the target language (side) as MRL$'$.

Post-Processing We convert MRL$'$ back into MRL by recovering parentheses and commas to reconstruct the corresponding tree structure in MRL. This can be easily done by examining each symbol's arity. It eliminates any possible ambiguity from the tree reconstruction: given any sequence of tokens in MRL$'$, we can always reconstruct the tree structure (if one exists). For those translations that can not be successfully converted, we call them *ill-formed* translations.

3 Semantic Parsing with Enriched SCFG

In this section, we present the details of our enriched SCFG for semantic parsing.

3.1 Enriched SCFG

In hierarchical phrase-based (HPB) translation models, synchronous rules take the form $X \rightarrow \langle \gamma, \alpha, \sim \rangle$, where X is the non-terminal symbol, γ and α are strings of lexical items and non-terminals in the source and target side respectively, and $\sim$ indicates the one-to-one cor-

[1] As seen in Section 2, delimiters, including parentheses and commas which do not carry any meaning will be removed in pre-processing and be recovered in post-processing

respondence between non-terminals in γ and α. From an aligned phrase pair *<state that border, state@1 next_to_2@1>* in Figure 2(a), for example, we can get a synchronous rule $X \rightarrow \langle \text{state } X_{[1]}, \text{state@1 } X_{[1]} \rangle$, where we use boxed indices to indicate which nonterminal occurrences are linked by $\sim$. The fact that SCFGs in HPB models contain only one type of non-terminal symbol[2] is responsible for ill-formed translation (e.g., *answer@1 state@1*). To this end, we enrich the non-terminals to capture the tree structure information, guiding the translation in favor of well-formed translations. The enrichment of non-terminals is two-fold: first, it can handle MRL with a nested structure to guarantee the well-formed translations; second, related studies in SMT have shown that introducing multiple non-terminal symbols in SCFGs benefits translation (Zollmann and Venugopal, 2006; Li et al., 2012).

Given a word sequence e_j^i from position i to position j in MRL′, we enrich the non-terminal symbol X to reflect the internal structure of the word sequence of e_j^i . A correct translation rule selection therefore not only maps source terminals into target terminals, but is both constrained and guided by structure information in the non-terminals. As mentioned earlier, we regard the nested structure in MRL′ as function-argument structure, where each function takes one or more arguments as input while its return serves as an argument to the outside function. As in Figure 1, function *cityid* holds two arguments and returns as an argument to function *area_1*. For a word sequence e_j^i, we examine its completeness, which is defined as:

Definition 1. *For word sequence e_j^i, it is regarded as complete if it satisfies 1) every function (if exists) meets its argument requirement; and 2) it can serve as **one** argument to another function.*

We use symbol *C* to label word sequences which are complete. For an incomplete word sequence, we examine 1) the number of arguments it requires on the right to be complete; and 2) the arity of a function it requires on the left to be complete. Then the sequence is labeled as $(\text{C}\backslash\text{F}m)/An$, indicating it requires n arguments on the right and a function with m arities on the left. [3]

[2]In practice, non-terminal symbol S is used in glue rules. However, this is not relevant in the present discussion.

[3]This is similar to the naming convention in combinatory categorial grammar (CCG) (Steedman, 2000)

texas, stateid@1 texas@s *C*→ ⟨texas, stateid@1 texas@s⟩
seattle, seattle@s _@0 *C*\F2→ ⟨seattle, seattle@s _@0⟩
that border, next_to_2@1 *C/A1*→ ⟨that border, next_to_2@1⟩
state that border, state@1 next_to_2@1 *C/A1*→ ⟨state *C/A1*$_{[1]}$, state@1 *C/A1*$_{[1]}$⟩

(a) Examples of phrase pairs in enriched SCFG.

state that border , state@1 next_to_2@1 *C/A1*→ ⟨*C/A1*$_{[1]}$ *C/A1*$_{[2]}$, *C/A1*$_{[1]}$ *C/A1*$_{[2]}$⟩
state that border texas have the highest population, l..one@1 p..1@1 state@1 n..@1 s..@1 t..@s *C*→ ⟨*C*$_{[1]}$ *C/A1*$_{[2]}$, *C/A1*$_{[2]}$ *C*$_{[1]}$⟩

(b) Examples of glue rules in enriched SCFG.

Table 1: Example of translation rules in enriched SCFG, where underline and underwave indicate the first and the second phrases respectively.

Specifically, we omit $\backslash\text{F}m$ and $/An$ if $m = 0$ and $n = 0$ respectively.[4]

Table 1(a) demonstrates examples of phrase pairs in our enriched SCFG. For instance, word sequence *stateid@1 texas@s* is complete, and thus labeled as *C*. Similarly, to be complete, word sequence *next_to_2@1* requires one argument on the right side, labeled as $C/A1$ accordingly.

When extracting translation rules from aligned datasets, we follow Chiang (2007) except that we use enriched non-terminal symbols rather than X. Each translation rule is associated with a set of translation model features $\{\phi_i\}$, including phrase translation probability $p(\alpha \mid \gamma)$ and its inverse $p(\gamma \mid \alpha)$, the lexical translation probability $p_{lex}(\alpha \mid \gamma)$ and its inverse $p_{lex}(\gamma \mid \alpha)$, and a rule penalty that learns the preference for longer or shorter derivations.

Inverted Glue Rules In SMT decoding (Chiang, 2007), if no rule (e.g., a rule whose left-hand side is *X*) can be applied or the length of the potential source span is larger than a pre-defined length (e.g., 10 as in Chiang (2007)), a glue rule (either $S \rightarrow \langle X_{[1]}, X_{[1]} \rangle$ or $S \rightarrow \langle S_{[1]} X_{[2]}, S_{[1]} X_{[2]} \rangle$) will be used to simply stitch two consequent translated phrases together in a *monotone* way. Although this will reduce computational and modeling challenges, it obviously prevents some reasonable translation derivations because in certain cases, the order of phrases may be inverted on the target

[4]If $m = 0$, it indicates that no function is needed.

side. In this work, we additionally use an inverted glue rule which combines two non-terminals in a *swapped* way. Each glue rule, either *straight* or *inverted*, contains only two non-terminal symbols and is associated with two features, including phrase translation probability $p(\alpha \mid \gamma)$, and a glue rule penalty. Table 1(b) shows examples of a straight and an inverted glue rules. Moreover, these glue rules can be applied to any two neighboring translation nodes if the non-terminal symbols are matched.

3.2 Word Alignment for Semantic Parsing

Word alignment is an essential step for rule extraction in SMT, where recognizing that *wo shi* in Chinese is a good translation for *I am* in English requires establishing a correspondence between *wo* and *I*, and between *shi* and *am*. In the SMT community, researchers have developed standard, proven alignment tools such as GIZA++ (Och and Ney, 2003), which can be used to train IBM Models 1-5. However, there is one fundamental problem with the IBM models (Brown et al., 1993): each word on one side can be traced back to exactly one particular on the other word (or the *null* token which indicates the word aligns to no word on the other side). Figure 2(a) shows an example of GIZA++ alignment output from source side to target side, from which we can see that each source word aligns to exactly one target word. While alignment of multiple target words to one source word is common in SMT, a trick is then to run IBM model training in both directions. Then two resulting word alignments can be symmetrized, for instance, taking the intersection or the union of alignment points of each alignment. For example, Figure 2(b) shows GIZA++ alignment output from target side to source side while Figure 2(c) shows the symmetrization result with widely used grow-diag-final-and strategy.

Although symmetrization of word alignments works for SMT, can it be applied to semantic parsing? There are reasons to be doubtful. Word alignment for semantic parsing differs from alignment for SMT in several important aspects, at least including:

1. It is intrinsically asymmetric: within the semantic formalism used in this paper, NL′ is often longer than MRL′, and commonly contains words which have no counterpart in MRL′.
2. Little training data is available. SMT alignment models are typically trained in unsupervised fashion, inducing lexical correspondences from massive quantities of sentence-aligned bitexts.

Consequently, the symmetrization of word alignments may not work perfectly for semantic parsing. According to word alignment in Figure 2(c), a phrase extractor will generate a phrase pair ⟨*have the highest, largest_one@1*⟩, which is non-intuitive. By contrast, a more useful and general phrase pair ⟨*highest, largest_one@1*⟩ is typically excluded because *largest_one@1* aligns to all of *have*, *the*, and *highest*. Similarly, another useful phrase pair ⟨*texas, texas@s*⟩ is prohibited since *texas* aligns to both *stateid@1* and *texas@s*.

Ideally a new semantic parsing aligner should be able to capture the semantic equivalence. Unfortunately we are not aware of any research on alignment for semantic parsing, possibly due to lack of a paucity of high quality, publicly available data from which to learn. Instead of developing new alignment algorithm for semantic parsing, we make use of all the alignments as shown in Figure 2. That is to say, we triple the training data with each sentence pair having three alignments, i.e., two alignments in both directions, and the symmetrization alignment.[5] The advantages include: first, considering more possible alignments would increase the phrase coverage, especially when the training data is little; second, including the alignment from both directions would alleviate the error propagation caused by mis-aligned stop words (e.g., *be*, *the* in NL′ and *stateid@1* in MRL′). As a result, the phrase extractor will include phrase pairs of both ⟨*highest, largest_one@1*⟩ and ⟨*texas, texas@s*⟩. Our experiment shows that using the combination of all the three alignments achieve better performance than using any one, or any combination of two. Moreover, we found that we could achieve comparable performance even with manual alignment.

[5] Combining multiple alignments from different alignment models usually improves translation performance in SMT (Tu et al., 2012). However, our preliminary experiments showed that this did not yield higher improvement in semantic parsing, which in turn also demonstrates the difference in alignments for semantic parsing and SMT.

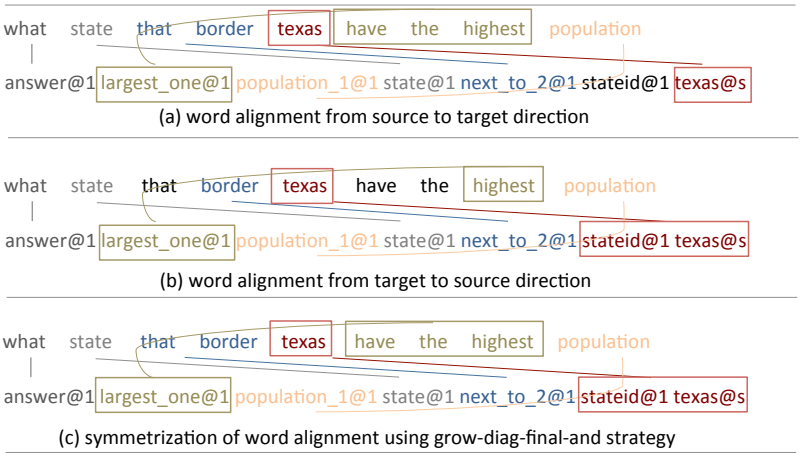

Figure 2: Example of a sentence pair with different alignments.

3.3 Synthetic Translation Rules for Unknown Word Translation

Most NLP tasks face the problem of unknown words, especially if only little training data is available. For example, it is estimated that 5.7% sentences in the (English) test data in our experiments have unknown words. Unknown words usually remain intact in the translation in most machine translation systems (Koehn et al., 2007; Dyer et al., 2010), resulting in the fact that certain translations can not be converted back to tree structures. This indicates that in semantic parsing the translation of a word can be from two categories: 1) a token in MRL; or 2) *null* (i.e., not translated at all), we generate synthetic translation rules for unknown word translation.

As a baseline, we simply skip unknown words as Kwiatkowski et al. (2010) by adding translation rules that translate them to *null* in MRL′. Each such rule is accompanied with one feature indicating that it is a translation rule for unknown word.

Alternatively, taking advantage of publicly available resources, we generate synthetic translation rules for unknown words pivoted by their semantically close words. Algorithm 1 illustrates the process to generate synthetic translation rules for unknown word translation. Given an unknown word w_u, it generates its synthetic rules in two steps: 1) finding top n (e.g., 5 as in our experiments) close words via Word2Vec;[6] and 2) generating synthetic translation rules based on the close words. Note that it may generate a synthetic rule with *null* at the target side since the lexical translation table derived from aligned training data contains translation to *null*. Each synthetic translation rule for unknown words is associated with three features returned from function $generate\_rule$.

Algorithm 1: Generating synthetic translation rules for unknown words

Input: Unknown word w_u in the source language
Source side training data vocabulary: W
Lexical translation tables T1 and T2 (two directions)
Output: Synthetic translation rule set R for w_u
1. **foreach** word w_i in W
2. $s_i = sim(w_u, w_i)$
3. get the top n words $WB = \{wb_1 ... wb_n\}$ with the highest $\{s_i\}$
4. $R = \phi$
5. **foreach** wb_i in WB
6. **foreach** t_j such $\langle wb_i, t_j \rangle$ in T1 and T2
7. $R \cup = generate\_rule(w_u, wb_i, t_j, T_1, T_2)$
8. **return** R

sim: returns the similarity between w_u and w_i.

$generate\_rule$: returns rule $\langle w_u, t_j \rangle$ with a feature indicating the similarity between w_u and wb_i, and two features indicating the lexical translation probabilities from wb_i to t_j and the way around.

4 Experimentation

In this section, we test our approach on the GeoQuery dataset, which is publicly available.

4.1 Experimental Settings

Data GeoQuery dataset consists of 880 questions paired with their corresponding tree structured semantic representations. Following the experimental setup in Jones et al. (2012), we use the 600 question pairs to train and tune our SMT de-

[6] It is available at http://code.google.com/p/word2vec/. We use Word2Vec rather than other linguistic resources like WordNet because the approach can be easily adopted to other languages only if there exists large monolingual data to train Word2Vec models.

coder, and evaluated on the remaining 280. Note that there is another version of GeoQuery dataset where the semantic representation is annotated with lambda calculus expressions and which is extensively studied (Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Liang et al., 2011; Kwiatkowski et al., 2013). Performance on the version of lambda calculus is higher than that on the tree structured version, however, the results obtained over the two versions are not directly comparable.

SMT Setting We use cdec (Dyer et al., 2010) as our HPB decoder. As mentioned above, 600 instances are used to train and tune our decoder. To get fair results, we split the 600 instances into 10 folds, each having 60 instances. Then for each fold, we use it as the tuning data while the other 540 instances and the NP list are used as training data.[7] We use IRSTLM toolkit (Federico et al., 2008) to train a 5-gram LM on the MRL′ side of the training data, using modified Kneser-Ney smoothing. We use Mira (Chiang et al., 2008) to tune the parameters of the system to maximize BLEU (Papineni et al., 2002). When extracting translation rules from aligned training data, we include both *tight* and *untight* phrases.

Evaluation We use the standard evaluation criteria for evaluation by executing both the predicted MRL and the gold standard against the database and obtaining their respective answer. Specifically, we convert a translation from MRL′ into MRL (if exists). The translation then is considered correct if and only if its MRL retrieves the same answers as the gold standard MRL (Jones et al., 2012), allowing for a fair comparison between our systems and previous works. As in Jones et al. (2012), we report accuracy, i.e. the percentage of translations with correct answers, and F1, i.e. the harmonic mean of precision (the proportion of correct answers out of translations with an answer) and recall (the proportion of correct answers out of all translations). In this section, we report our performance scores and analysis numbers averaged on our 10 SMT models.

[7]The NP list is from GeoQUery dataset in Jones et al. (2012), which contains MRs for every noun phrase that appears in the NL utterances of each language. As in Andreas et al. (2013), the NP list is included by appending all entries as extra training sentences with 50 times the weight of regular training examples, to ensure that they are learned as translation rules.

SCFG	alignment	Acc.	F1
non-enriched	src2tgt	75.0	82.5
	tgt2src	78.5	82.5
	gdfa	77.5	83.5
	src2tgt + tgt2src	81.4	85.0
	src2tgt + gdfa	77.1	83.1
	tgt2src + gdfa	80.6	83.9
	all	81.5	85.2

	src2tgt + gdfa	78.8	83.7
	tgt2src + gdfa	83.1	86.1
	all	82.9	86.1
	gold	84.1	87.1

Table 2: Performance of our (non-) enriched SCFG systems with different alignment settings.

4.2 Experimental Results

Table 2 shows the results of (non-) enriched SCFG systems over different alignment settings. In Table 2, *src2tgt* and *tgt2src* indicate alignment of source to target direction and alignment of target to source direction, respectively; *gdfa* indicates symmetrization of alignment with grow-diag-final-and strategy; *src2tgt+tgt2src* indicates doubling the training data with each sentence pair having both *src2tgt* and *tgt2src* alignments, similar for *src2tgt+gdfa* and *tgt2src+gdfa*; *all* indicates tripling the training data with each sentence pair having three alignments. Finally, *gold* indicates using gold alignment. [8]

Effect of Enriched SCFG From Table 2, we observe that enriched SCFG systems outperform non-enriched SCFG systems over all alignment settings, indicating the effect of enriching nonterminals. In particular for *tgt2src* alignment, it obtains improvements of 3.5% in accuracy and 2.7% in F1.

As mentioned earlier, the non-enriched SCFG system may result in ill-formed translations, which can not be converted back to tree structure. One natural way to overcome this issue, as in Andreas et al. (2013), would be to simply filter n-best translation till a well-formed one is found. However, we see very limited performance changes in accuracy and F1, suggesting that the effect of using n-best translation is very limited. For example, after using n-best translation, the non-enriched SCFG system with *all* alignment obtains 82.0 in accuracy (increased from 81.5) and 84.5 in

[8]We manually aligned sentence pairs in NL′ and MRL′.

alignment	Rec.	Pre.	F1
src2tgt	96.3	68.8	80.3
tgt2src	90.0	77.0	83.0
gdfa	95.1	62.7	75.6

Table 3: Alignment performance.

F1 (reduced from 85.2).

Effect of Word Alignment With respect to the performance over different alignment settings, we have the following observations from Table 2:

- Semantic parsing is substantially sensitive to alignment. Surprisingly, *gdfa* alignment, which is widely adopted in SMT, is inferior to *tgt2src* alignment. As expected, *src2tgt* alignment achieves the worst performance.

- Thanks to the increased coverage, doubling the training data (e.g., rows of *src2tgt+tgt2src*, *src2tgt+gdfa*, and *tgt2src+gdfa*) usually outperforms its corresponding single alignment. Moreover, tripling the training data (e.g., rows of *all*) achieves slightly better performance than any way of doubling the training data. This is expected since the *gdfa* alignment actually comes from the alignments of *src2tgt* and *tgt2src*, thus doubling the training with *src2tgt* and *tgt2src* have already included most aligns in *gdfa* alignment.

- Our approach of tripling the training data achieves comparable performance to the one with gold alignment, suggesting that instead of developing a brand new algorithm for semantic parsing alignment, we can simply make use of GIZA++ alignment output.

In terms of the *src2tgt*, *tgt2src* and *gdfa* alignments, the trend of the results is consistent over both non-enriched and enriched SCFG systems: the systems with *tgt2src* alignment work best while the systems with *src2tgt* alignment work worst. Next we look at the non-enriched SCFG systems to explore the behavior differences among the three alignments.

We examine the alignment accuracy against the gold alignment on training data (except the NP list part). As shown in Table 3, *src2tgt* has the highest recall while *tgt2src* has the highest precision. This is partly due to: 1) In *src2tgt* alignment, each source word aligns to exactly one particular target word (or the *null* token), resulting in frequent

		enriched + gdfa	
		correct	wrong
non-enriched + gdfa	correct	211	6
	wrong	10	53
enriched + all	correct	215	17
	wrong	6	42

Table 4: Confusion matrices of three SMT systems on English test sentences.

alignment errors for source side words that have no counterpart in target side. For example, both words of *the* and *be* on source side, which play functional roles in NL, rather than semantic roles, align to 15 different target words. 2) Except for a few words on target side, including *stateid@1*, *all@0* which have strong occurrence patterns (e.g., *stateid@1* is always followed by a state name), each word has counterpart on source side.

As to have a clearer understanding on the individual contribution of using enriched non-terminals and multiple word alignments, Table 4 presents two confusion matrices which show numbers of sentences that are correctly/wrongly parsed by three SMT systems on English test sentences. It shows that, for example, 211 sentences are correctly parsed by both non-enriched and enriched SCFG systems with *gdfa* alignment. Moving from performance of the non-enriched SMT system with *gdfa* alignment to that of the enriched SMT system with *all* alignment, we observe that on average more than half of the improvement comes from using multiple word alignments, the rest from using enriched non-terminals.

Effect of Unknown Word Translation Since each of our SMT model is actually trained on 540 instances (plus the NP list), the rate of unknown words in the test data tends to be higher than that in a system trained with the whole 600 instances. Based on the system of enriched SCFG with *all* alignment, Table 5 shows the results of applying unknown word translation. It shows that translating all unknown words into *null* obtains 2.4 points in accuracy over the system without it (e.g., 85.3 *vs.* 82.9). However, the slight improvement in F1 (e.g., 86.3 *vs.* 86.1) suggests that there are many scenarios that translating unknown words into *null* is incorrect. Fortunately, our semantic approach is partially able to generate correct translation rules for those unknown words which have translation in MRL′. Actually, the effect of our approach is highly dependent on the quality of the close words found via Word2Vec. With a manual examination

System	Acc.	F1
No unknown word translation	82.9	86.1
null: baseline	85.3	86.3
semantic: ours	86.3	87.1

Table 5: Performance with unknown word translation.

on the test data, we found that 11 out of all 17 unknown words should be translated into a corresponding token in MRL. For 8 of them, the synthetic translation rule set returned by Algorithm 1 contains correct translation rules.

Effect across Different Languages We have also tested our approach on the same dataset with other three languages. Specifically, while we are not aware of public resources to looking for semantically close words in German, Greek and Thai, we translate unknown words into *null* for the three languages. Table 6 shows the performance over four different languages. It shows that our approach, including enriched SCFG, tripling training data with three alignments, and unknown word translation, obtains consistent improvement over the four languages.

Decoding Time Analysis We analyze the effect on the decoding time of our approach, which is closely related to the size of phrase tables. Firstly, splitting non-terminal X into enriched ones increases the size of phrase tables. [9] This is not surprising since a phrase with non-terminal X (e.g., *the X* on the source side) may be further specified as multiple phrases with various non-terminals (e.g., *the C*, *the C/A1*, etc.). As a result, the average number of phrases per sentence (in English test data, hereafter) increases from 453 to 893 while the decoding time of the SMT decoder increases from 0.11 seconds to 0.19 seconds per sentence on average. Secondly, using multiple alignments also leads to larger phrase tables. This is illustrated by the increase of average number of phrases per sentence from 893 to 2055 while the decoding time moves from 0.19 seconds to 0.38 seconds per sentence on average. Finally, finding similar words via Word2Vec, however, is quite fast since this is bounded by the vocabulary size of our training set. Thanks to the small size of unknown words, adding unknown word translation rules has a very limited impact on the size of phrase table, consequently negligible changes on decoding time.

[9] In cdec, we generate a phrase table for each sentence.

5 Related Work

While there has been substantial work on semantic parsing, we focus our discussions on several approaches (e.g., SCFG approach, hybrid tree approach, and others approaches) that focus on the variable-free semantic representations.

WASP (Wong and Mooney, 2006) was strongly influenced by SMT techniques. Although WASP was also using multiple non-terminal symbols in SCFG to guarantee well-formed translations, our work differs from theirs in at least three ways. First, we use a different inventory of non-terminal symbols from theirs which was derived from MRL parses in the GeoQuery dataset. Second, to avoid the issues caused by word alignment between NL and MRL, we triple training data with each sentence pair having multiple alignments. However, WASP used a sequence of productions to represent MRL before running GIZA++. Third, we use typical features in HPB SMT (e.g., phrase translation probabilities, lexical translation probabilities, language model feature, etc.) while WASP used rule identity features. SMT-SemParse (Andreas et al., 2013) adapted standard SMT components for semantic parsing. The present work is based on theirs with all the extensions detailed in Section 3.

HYBRIDTREE+ (Lu et al., 2008) learned a synchronous generative model which simultaneously generated a NL sentence and an MRL tree. tsVB (Jones et al., 2012) used tree transducers, which were similar to the hybrid tree structures, to learn a generative process under a Bayesian framework. RHT (Lu, 2014) defined distributions over *relaxed hybrid tree* structures that jointly represented both sentences and semantics. Most recently, f-RHT (Lu, 2015) introduced constrained semantic forests to improve RHT model.

SCISSOR (Ge and Mooney, 2005) augmented syntactic parse tree with semantic information and then performed integrated semantic and syntactic parsing to NL sentences. KRISP (Mooney, 2006) used string classifiers to label substrings of an NL with entities from the meaning representation. UBL (Kwiatkowski et al., 2010) performed semantic parsing with an automatically-induced CCG lexicon.

Table 7 shows the evaluation results of our system as well as those of several other comparable related works which share the same experiment setup as ours. We can observe from Table 7 that semantic parsing with SMT components gives

competitive performance when all the extensions (described in Section 3) are used. Specifically, it significantly outperforms the semantic parser with standard SMT components (Andreas et al., 2013). Our approach reports the best accuracy and F1 scores on English, German, and Greek. While we are able to obtain improvement on Thai, the performance is still lower than those of RHT and TREETRANS. This is probably because of the low quality of word alignment output between this Asian language and MRL.

6 Conclusion and Future Work

In this paper, we have presented an enriched SCFG approach for semantic parsing which realizes the potential of the SMT approach. The performance improvement is contributed from the extension of translation rules with informative symbols and increased coverage. Such an extension share a similar spirit as generalization of a CCG lexicon for CCG-based semantic parser (Kwiatkowski et al., 2011; Wang et al., 2014). Experiments on benchmark data have shown that our model is competitive to previous work and achieves state-of-the-art performance across a few different languages.

Recently the research of semantic parsing in open domain with weakly (or un-) supervised setups, under different settings where the goal was to optimize the performance of certain downstream NLP tasks such as answering questions, has received a significant amount of attention (Poon and Domingos, 2009; Clarke et al., 2010; Berant et al., 2013; Berant and Liang, 2014). One direction of our future work is to extend the current framework to support the generation of synthetic translation rules from weaker signals (e.g., from question-answer pairs), rather than from aligned parallel data.

We also noticed recent advance in tree-based SMT. Applying such string-to-tree or tree-to-tree translation models (Yamada and Knight, 2001; Shen et al., 2008) to semantic parsing will naturally resolve the inconsistent semantic structure issue, though they require additional information to generate tree labels on the target side. However, due to the constraint that each target phrase needs to map to a syntactic constituent, phrase tables in tree-based translation models usually suffer from the low coverage issue, especially if the training data size is small. Therefore, another direction of our future work is to explore specific problems that will emerge when employing tree-based SMT systems to semantic parsing, and provide solutions to them.

Acknowledgments

The authors would like to thank Zhaopeng Tu, S. Matthew English and three anonymous reviewers for providing helpful suggestions, and also acknowledge Jacob Andreas for help in running SMT-SemParse. Abstract

This paper introduces GEOS, the first automated system to solve unaltered SAT geometry questions by combining text understanding and diagram interpretation. We model the problem of understanding geometry questions as submodular optimization, and identify a formal problem description likely to be compatible with both the question text and diagram. GEOS then feeds the description to a geometric solver that attempts to determine the correct answer. In our experiments, GEOS achieves a 49% score on official SAT questions, and a score of 61% on practice questions.[1] Finally, we show that by integrating textual and visual information, GEOS boosts the accuracy of dependency and semantic parsing of the question text.

1 Introduction

This paper introduces the first fully-automated system for solving unaletered SAT-level geometric word problems, each of which consists of text and the corresponding diagram (Figure 1). The geometry domain has a long history in AI, but previous work has focused on geometric theorem proving (Feigenbaum and Feldman, 1963) or geometric analogies (Evans, 1964). Arithmetic and algebraic word problems have attracted several NLP researchers (Kushman et al., 2014; Hosseini et al., 2014; Roy et al., 2015), but *geometric* word problems were first explored only last year by Seo et al. (2014). Still, this system merely aligned diagram elements with their textual mentions (e.g., "Circle O")—it did not attempt to fully represent geometry problems or solve them. Answering geometry questions requires a method that interpert question text and diagrams in concert.

[1]The source code, the dataset and the annotations are publicly available at geometry.allenai.org.

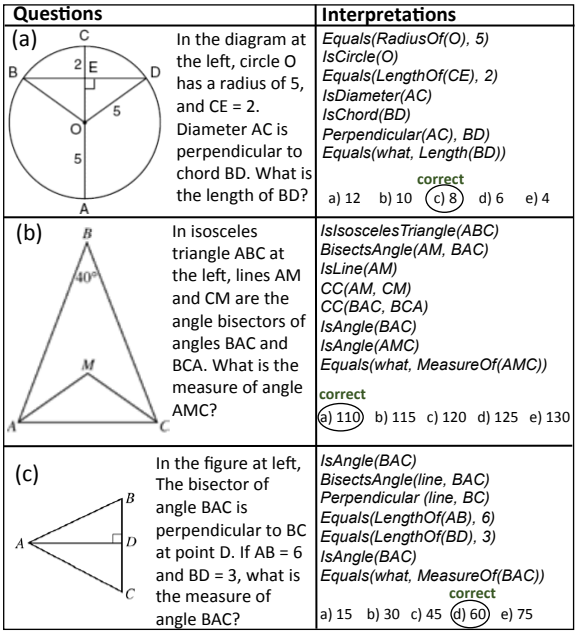

Figure 1: Questions (left column) and interpretations (right column) derived by GEOS.

The geometry genre has several distinctive characteristics. First, diagrams provide essential information absent from question text. In Figure 1 problem (a), for example, the unstated fact that lines BD and AC intersect at E is necessary to solve the problem. Second, the text often includes difficult references to diagram elements. For example, in the sentence "In the diagram, the longer line is tangent to the circle", resolving the referent of the phrase "longer line" is challenging. Third, the text often contains implicit relations. For example, in the sentence "AB is 5", the relations `IsLine(AB)` and `length(AB)=5` are implicit. Fourth, geometric terms can be ambiguous as well. For instance, radius can be a type identifier in "the length of radius AO is 5", or a predicate in "AO is the radius of circle O". Fifth, identifying the correct arguments for each relation is challenging. For example, in sentence "Lines AB and CD are perpendicular to EF", the parser has to determine *what* is perpendicular to EF—line AB? line

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1466–1476,
Lisbon, Portugal, 17-21 September 2015.

CD? Or both AB and CD? Finally, it is hard to obtain large number of SAT-level geometry questions; Learning from a few examples makes this a particularly challenging NLP problem.

This paper introduces GEOS, a system that maps geometry word problems into a logical representation that is compatible with both the problem text and the accompanying diagram (Figure 1). We cast the mapping problem as the problem of selecting the subset of relations that is most likely to correspond to each question.

We compute the mapping in three main steps (Figure 2). First, GEOS uses text- and diagram-parsing to overgenerate a set of relations that potentially correspond to the question text, and associates a score with each. Second, GEOS generates a set of relations (with scores) that corresponds to the diagram. Third, GEOS selects a subset of the relations that maximizes the joint text and diagram scores. We cast this maximization as a submodular optimization problem, which enables GEOS to use a close-to-optimal greedy algorithm. Finally, we feed the derived formal model of the problem to a geometric solver, which computes the answer to the question.

GEOS is able to solve *unseen* and *unaltered* multiple-choice geometry questions. We report on experiments where GEOS achieves a 49% score on official SAT questions, and a score of 61% on practice questions, providing the first results of this kind. Our contributions include: (1) designing and implementing the first end-to-end system that solves SAT plane geometry problems; (2) formalizing the problem of interpreting geometry questions as a submodular optimization problem; and (3) providing the first empirical results on the geometry genre, making the data and software available for future work.

2 Related Work

Semantic parsing is an important area of NLP research (Zettlemoyer and Collins, 2005; Ge and Mooney, 2006; Flanigan et al., 2014; Eisenstein et al., 2009; Kate and Mooney, 2007; Goldwasser and Roth, 2011; Poon and Domingos, 2009; Berant and Liang, 2014; Kwiatkowski et al., 2013; Reddy et al., 2014). However, semantic parsers do not tackle diagrams—a critical element of the geometry genre. In addition, the overall number of available geometry questions is quite small compared to the size of typical NLP corpora, making it challenging to learn semantic parsers directly from geometry questions. Relation extraction is another area of NLP that is related to our task (Cowie and Lehnert, 1996; Culotta and Sorensen, 2004). Again, both diagrams and small corpora are problematic for this body of work.

Our work is part of grounded language acquisition research (Branavan et al., 2012; Vogel and Jurafsky, 2010; Chen et al., 2010; Hajishirzi et al., 2011; Liang et al., 2009; Koncel-Kedziorski et al., 2014; Bordes et al., 2010; Kim and Mooney, 2013; Angeli and Manning, 2014; Hixon et al., 2015; Koncel-Kedziorski et al., 2014; Artzi and Zettlemoyer, 2013) that involves mapping text to a restricted formalism (instead of a full, domain independent representation). In the geometry domain, we recover the entities (e.g., circles) from diagrams, derive relations compatible with both text and diagram, and re-score relations derived from text parsing using diagram information. Casting the interpretation problem as selecting the most likely subset of literals can be generalized to grounded semantic parsing domains such as navigational instructions.

Coupling images and the corresponding text has attracted attention in both vision and NLP (Farhadi et al., 2010; Kulkarni et al., 2011; Gupta and Mooney, 2010; Gong et al., 2014; Fang et al., 2014). We build on this powerful paradigm, but instead of generating captions we show how processing multimodal information help improve textual or visual interpretations for solving geometry questions.

Diagram understanding has been explored since early days in AI (Lin et al., 1985; Hegarty and Just, 1989; Novak, 1995; O'Gorman and Kasturi, 1995; Bulko, 1988; Srihari, 1994; Lovett and Forbus, 2012). Most previous approaches differ from our method because they address the twin problems of diagram understanding and text understanding in isolation. Often, previous work relies on manual identification of visual primitives, or on rule-based system for text analysis. The closest work to ours is the recent work of Seo et al. (2014) that aligns geometric shapes with their textual mentions, but does not identify geometric relations or solve geometry problems.

3 Problem Formulation

A geometry question is a tuple (t, d, c) consisting of a text t in natural language, a diagram d

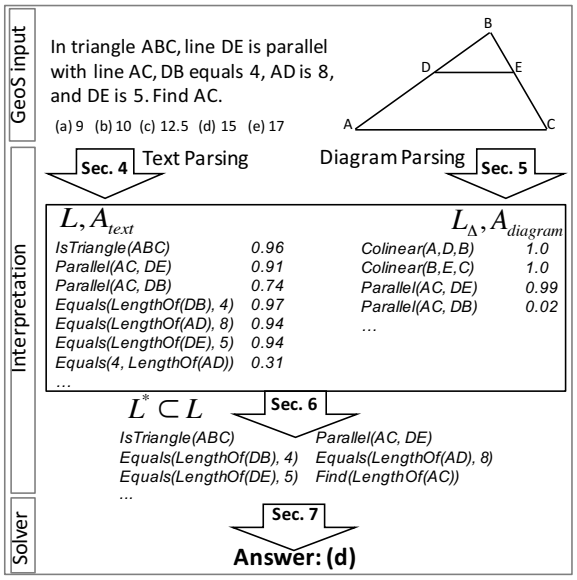

Figure 2: Overview of our method for solving geometry questions.

in raster graphics, and multiple choice answers $c = \{c_1, \ldots, c_M\}$ ($M = 5$ in SAT). Answering a geometry question is to find a correct choice c_i.

Our method, GEOS, consists of two steps (Figure 2): (1) *interpreting* a geometry question by deriving a logical expression that represents the meaning of the text and the diagram, and (2) *solving* the geometry question by checking the satisfiablity of the derived logical expression. In this paper we mainly focus on *interpreting* geometry questions and use a standard algebraic solver (see section 7 for a brief description of the solver).

Definitions: We formally represent logical expressions in the geometry domain with the language Ω, a subset of typed first-order logic that includes:

- *constants*, corresponding to known numbers (e.g., `5` and `2` in Figure 1) or entities with known geometric coordinates.
- *variables*, corresponding to unknown numbers or geometrical entities in the question (e.g., `O` and `CE` in Figure 1).
- *predicates*, corresponding to geometric or arithmetic relations (e.g., `Equals`, `IsDiameter`, `IsTangent`).
- *functions*, corresponding to properties of geometrical entities (e.g., `LengthOf`, `AreaOf`) or arithmetic operations (e.g., `SumOf`, `RatioOf`).

Each element in the geometry language has either boolean (e.g., `true`), numeric (e.g., `4`), or entity (e.g., `line`, `circle`) type. We refer to all symbols in the language Ω as *concepts*.

We use the term *literal* to refer to the application of a predicate to a sequence of arguments (e.g., `IsTriangle(ABC)`). Literals are possibly negated atomic formulas in the language Ω. Logical formulas contain constants, variables, functions, existential quantifiers and conjunctions over literals (e.g., $\exists$`x, IsTriangle(x)`$\wedge$`IsIsosceles(x)`).

Interpretation is the task of mapping a new geometry question with each choice, (t, d, c_m), into a logical formula γ in Ω. More formally, the goal is to find $\gamma^* = \arg\max_{\gamma \in \Gamma} score(\gamma; t, d, c_m)$ where Γ is the set of all logical formulas in Ω and $score$ measures the interpretation score of the formula according to both text and diagram. The problem of deriving the best formula γ^* can be modeled as a combinatorial search in the space of literals L (note that each logical formula γ is represented as a conjunction over literals l_i).

GEOS efficiently searches this combinatorial space taking advantage of a submodular set function that scores a subset of literals using both text and diagram. The best subset of literals is the one that has a high *affinity* with both text and diagram and is *coherent* i.e., does not suffer from redundancy (see Section 6). More formally,[2]

$$L^* = \arg\max_{L' \subset L} \lambda \underbrace{\mathcal{A}(L', t, d)}_{\text{Affinity}} + \underbrace{\mathcal{H}(L', t, d)}_{\text{Coherence}}, \quad (1)$$

where $\mathcal{A}(L', t, d)$ measures the affinity of the literals in L' with both the text and the diagram, $\mathcal{H}(L', t, d)$ measures the coverage of the literals in L' compared to the text and discourages redundancies, and λ is a trade-off parameter between $\mathcal{A}$ and $\mathcal{H}$.

The affinity $\mathcal{A}$ is decomposed into text-based affinity, $\mathcal{A}_{text}$, and diagram-based affinity, $\mathcal{A}_{diagram}$. The text-based affinity closely mirrors the linguistic structure of the sentences as well as type matches in the geometry language Ω. For modeling the text score for each literal, we learn a log-linear model. The diagram-based affinity $\mathcal{A}_{diagram}$ grounds literals into the diagram, and scores literals according to the diagram parse. We describe the details on how to compute $\mathcal{A}_{text}$ in section 4 and $\mathcal{A}_{diagram}$ in section 5.

4 Text Parser

The text-based scoring function $\mathcal{A}_{text}(L, t)$ computes the affinity score between the set of liter-

[2]We omit the argument c_m for the ease of notation.

1. $\{l_j\}, \mathcal{A}_{text} \leftarrow$ TEXT PARSING(language Ω, text-choice pair (t, c_i)) (Section 4)
   (i) **concept identification:** initialize a hypergraph G with concept nodes.
   (ii) **relation identification:** add a hyperedge (relation) r_j between two or three related concept nodes and assign a weight $\mathcal{A}_{text}(r_j, t; \theta)$ based on the learned classifier.
   (iii) **literals parsing:** obtain all subtrees of G, which are equivalent to all possible literals, $\{l'_j\}$. Let $\mathcal{A}_{text}(l_j, t) = \sum_j \mathcal{A}_{text}(r_j, t; \theta)$ for all r_j in the literal l_i.
   (iv) **relation completion:** obtain a complete literal l_j for each (under-specified) l'_j, dealing with implication and coordinating conjunctions.
2. $L_\Delta, \mathcal{A}_{diagram} \leftarrow$ DIAGRAM PARSING(diagram image d, literals $\{l_j\}$) (Section 5)
3. $L^* \leftarrow$ GREEDY MAXIMIZATION(literals $L = \{l_j\}$, score functions $\mathcal{A}_{text}$ and $\mathcal{A}_{diagram}$) (Section 6)
   (i) **initialization**: $L' \leftarrow \{\}$
   (ii) **greedy addition**: $add(L', l_j)$ s.t. $l_j = \text{argmax}_{l_j \in L \setminus L'} \mathcal{F}(L' \cup \{l_j\}) - \mathcal{F}(L')$, where $\mathcal{F} = \lambda\mathcal{A} + \mathcal{H}$
   (iii) **iteration**: repeat step (ii) while the gain is positive.
4. Answer $c^* \leftarrow$ one of choices s.t. $L^* \cup L_\Delta$ are simultaneously satisfiable according to SOLVER (Section 7)

Figure 3: Solving geometry questions with GEOS.

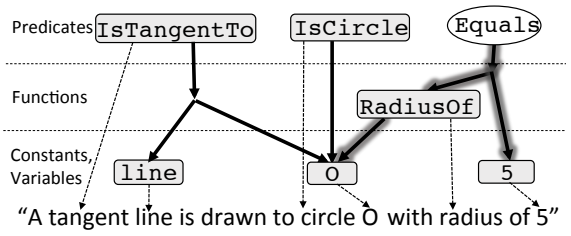

Figure 4: Hypergraph representation of the sentence "A tangent line is drawn to circle O with radius of 5".

als L and the question text t. This score is the sum of the affinity scores of individual literals $l_j \in L$ i.e., $\mathcal{A}_{text}(L, t) = \sum_j \mathcal{A}_{text}(l_j, t)$ where $\mathcal{A}_{text}(l_j, t) \mapsto [-\infty, 0]$.[3] GEOS learns a discriminative model $\mathcal{A}_{text}(l_j, t; \theta)$ that scores the affinity of every literal $l_j \in L$ and the question text t through supervised learning from training data.

We represent literals using a hypergraph (Figure 4) (Klein and Manning, 2005; Flanigan et al., 2014). Each node in the graph corresponds to a concept in the geometry language (i.e. constants, variables, functions, or predicates). The edges capture the *relations* between concepts; concept nodes are connected if one concept is the argument of the other in the geometry language. In order to interpret the question text (Figure 3 step 1), GEOS first identifies concepts evoked by the words or phrases in the input text. Then, it learns the affinity scores which are the weights of edges in the hypergraph. It finally completes relations so that type matches are satistfied in the formal language.

4.1 Concept Identification

Concepts are defined as symbols in the geometry language Ω. The concept identification stage maps words or phrases to their corresponding concepts in the geometry language. Note that a phrase can be mapped to several concepts. For instance, in the sentence "ABCD is a square with an area of 1", the word "square" is a noun referring to some object, so it maps to a variable `square`. In a similar sentence "square ABCD has an area 1", the word "square" describes the variable `ABCD`, so it maps to a predicate `IsSquare`.

GEOS builds a *lexicon* from training data that maps stemmed words and phrases to the concepts in the geometry language Ω. The lexicon is derived from all correspondences between geometry keywords and concepts in the geometry language as well as phrases and concepts from manual annotations in the training data. For instance, the lexicon contains ("square", {`square`, `IsSquare`}) including all possible concepts for the phrase "square". Note that GEOS does not make any hard decision on which identification is correct in this stage, and defers it to the relation identification stage (Section 4.2). To identify numbers and explicit variables (e.g. "5", "AB", "O"), GEOS uses regular expressions. For an input text t, GEOS assigns one node in the graph (Figure 4) for each concept identified by the lexicon.

4.2 Relation Identification

A relation is a directed hyperedge between concept nodes. A hyperedge connects two nodes (for unary relations such as the edge between `RadiusOf` and `O` in Figure 4) or three nodes (for binary relations such as the hyperedge between `Equals` and its two arguments `RadiusOf` and `5` in Figure 4).

We use a discriminative model (logistic regression) to predict the probability of a relation r_i being correct in text t: $P_\theta(y_i|r_i, t) = \frac{1}{1+\exp(f_{text}(r_i,t)\cdot\theta)}$, where $y_i \in \{0, 1\}$ is the label

[3] For the ease of notation, we use $\mathcal{A}_{text}$ as a function taking sets of literals or a literal.

Dependency tree distance	Shortest distance between the words of the concept nodes in the dependency tree. We use indicator features for distances of -3 to 3. Positive distance shows if the child word is at the right of the parent's in the sentence, and negative otherwise.
Word distance	Distance between the words of the concept nodes in the sentence.
Dependency tree edge label	Indicator functions for the outgoing edges of the parent and child for the shortest path between them.
Part of speech tag	Indicator functions for the POS tags of the parent and the child.
Relation type	Indicator functions for unary / binary parent and child nodes.
Return type	Indicator functions for the return types of the parent and the child nodes. For example, return type of `Equals` is `boolean`, and that of `LengthOf` is `numeric`.

Table 1: The features of the unary relations. The features of the binary relations is computed in a similar way.

(a)	sentence:	"What is the perimeter of ABCE?"
	intermediate:	`∃ what, ABCE: Bridged(what, PerimeterOf(ABCE))`
	final:	`∃ what, ABCE: Equals(what, PerimeterOf(ABCE))`
(b)	sentence:	"AM and CM bisect BAC and BCA."
	intermediate:	`∃ AM, CM, BAC, BCA: BisectsAngle(AM, BAC) ∧ CC(AM, CM) ∧ CC(BAC, BCA)`
	final:	`∃ AM, CM, BAC, BCA: BisectsAngle(AM, BAC) ∧ BisectsAngle(CM, BCA)`

Figure 5: Showing the two-stage learning with the intermediate representation that demonstrates implication.

for r_i being correct in t, $f_{text}(r_i, t)$ is a feature vector of t and r_i, and θ is a vector of parameters to be learned. We define the affinity score of r_i by $\mathcal{A}_{text}(r_i, t; \theta) = \log P_\theta(y_i | r_i, t)$. The weight of the corresponding hyperedge is the relation's affinity score. We learn θ using the maximum likelihood estimation of the training data (details in Section 8), with L2 regularization.

We train two separate models for learning unary and binary relations. The training data consists of sentence-relation-label tuples (t, r, y); for instance, ("A tangent line is drawn to circle O", `IsTangent(line, O)`, 1) is a positive training example. All incorrect relations in the sentences of the training data are negative examples (e.g. ("A tangent line is drawn to circle O", `IsCircle(line)`, 0)).

The features for the unary and binary models are shown in Table 1 for the text t and the relation r_i. We use two main feature categories. Structural features: these features capture the syntactic cues of the text in the form of text distance, dependency tree labels, and part of speech tags for the words associated with the concepts in the relation. Geometry language features: these features capture the cues available in the geometry language Ω in the form of the types and the truth values of the corresponding concepts in the relation.

At inference, GEOS uses the learned models to calculate the affinity scores of all the literals derived from the text t. The affinity score of each literal l_j is calculated from the edge (relation) weights in the corresponding subgraph, i.e. $\mathcal{A}_{text}(l_j, t) = \sum_i \mathcal{A}_{text}(r_i, t; \theta)$ for all r_i in the literal l_j.

4.3 Relation Completion

So far, we have explained how to score the affinities between explicit relations and the question text. Geometry questions usually include *implicit* concepts. For instance, "Circle O has a radius of 5" implies the `Equals` relationship between "Radius of circle O" and "5". In addition, geometry questions include *coordinating conjunctions* between entities. In "AM and CM bisect BAC and BCA", "bisect" is shared by two lines and two angles (Figure 5 (b)). Also, consider two sentences: "AB and CD are perpendicular" and "AB is perpendicular to CD". Both have the same semantic annotation but very different syntactic structures.

It is difficult to directly fit the syntactic structure of question sentences into the formal language Ω for *implications* and *coordinating conjunctions*, especially due to small training data. We, instead, adopt a two-stage learning inspired by recent work in semantic parsing (Kwiatkowski et al., 2013). Our solution assumes an intermediate representation that is syntactically sound but possibly *underspecified*. The intermediate representation closely mirrors the linguistic structure of the sentences. In addition, it can easily be transferred to the formal representation in the geometry language Ω.

Figure 5 shows how implications and coordinating conjunctions are modeled in the intermediate representation. `Bridged` in Figure 5 (a) indicates that there is a special relation (edge) between the two concepts (e.g., `what` and `PerimeterOf`), but the alignment to the geometry language $\mathcal{L}$ is not clear. `CC` in Figure 5 (b) indicates that there is a special relation between two concepts that are connected by "and" in the sentence. GEOS *completes*

the under-specified relations by mapping them to the corresponding well-defined relations in the formal language.

Implication: We train a log-linear classifier to identify if a `Bridged` relation (implied concept) exists between two concepts. Intuitively, the classification score indicates the likelihood that certain two concepts (e.g., `What` and `PerimeterOf`) are *bridged*. For training, positive examples are pairs of concepts whose underlying relation is underspecified, and negative examples are all other pairs of concepts that are not bridged. For instance, (`what`, `PerimeterOf`) is a positive training example for the `bridged` relation. We use the same features in Table 1 for the classifier.

We then use a deterministic rule to map *bridged* relations in the intermediate representation to the correct *completed* relations in the final representation. In particular, we map `bridged` to `Equals` if the two children concepts are of type `number`, and to `IsA` if the concepts are of type entity (e.g. `point`, `line`, `circle`).

Coordinating Conjunctions: `CC` relations model coordinating conjunctions in the intermediate representation. For example, Figure 5 (b) shows the conjunction between the two angles `BAC` and `BCA`. We train a log-linear classifier for the `CC` relations, where the setup of the model is identical to that of the binary relation model in Section 4.2.

After we obtain a list of `CC(x,y)` in the intermediate representation, we use deterministic rules to coordinate the entities x and y in each `CC` relation (Figure 5 (b)). First, GEOS forms a set $\{x, y\}$ for every two concepts x and y that appear in `CC(x,y)` and transforms every x and y in other literals to $\{x, y\}$. Second, GEOS transforms the relations with expansion and distribution rules (Figure 3 Step 1 (iv)). For instance, `Perpendicular({x,y})` will be transferred to `Perpendicular(x, y)` (expansion rule), and `LengthOf{x,y})` will be transferred to `LengthOf(x)` $\wedge$ `LengthOf(y)` (distribution rule).

5 Diagram Parser

We use the publicly available diagram parser (Seo et al., 2014) to obtain the set of all visual elements (points, lines, circles, etc.), their coordinates, their relationships in the diagram, and their alignment with entity references in the text (e.g. "line AB", "circle O"). The diagram parser serves two purposes: (a) computing the diagram score as a measure of the affinity of each literal with the diagram; (b) obtaining high-confidence visual literals which cannot be obtained from the text.

Diagram score: For each literal l_j from the text parsing, we obtain its diagram score $\mathcal{A}_{diagram}(l_j, d) \mapsto [-\infty, 0]$. GEOS grounds each literal derived from the text by replacing every variable (entity or numerical variable) in the relation to the corresponding variable from the diagram parse. The score function is the relaxed indicator function of whether a literal is true according to the diagram. For instance, in Figure 1 (a), consider the literal $l =$ `Perpendicular(AC, BD)`. In order to obtain its diagram score, we compute the angle between the lines AC and BD in the diagram and compare it with $\pi/2$. The closer the two values, the higher the score (closer to 0), and the farther they are, the lower the score. Note that the variables `AC` and `BD` are grounded into the diagram before we obtain the score; that is, they are matched with the actual corresponding lines AC and BD in the diagram.

The diagram parser is not able to evaluate the correctness of some literals, in which case their diagram scores are *undefined*. For instance, `Equals(LengthOf(AB), 5)` cannot be evaluated in the diagram because the scales in the diagram (pixel) and the text are different. For another example, `Equals(what, RadiusOf(circle))` cannot be evaluated because it contains an ungrounded (query) variable, `what`. When the diagram score of a literal l_j is undefined, GEOS lets $\mathcal{A}_{diagram}(l_j) = \mathcal{A}_{text}(l_j)$.

If the diagram score of a literal is very low, then it is highly likely that the literal is false. For example, in Figure 2, `Parallel(AC, DB)` has a very low diagram score, 0.02, and is apparently false in the diagram. Concretely, if for some literal l_j, $\mathcal{A}_{diagram}(l_i) < \epsilon$, then GEOS disregards the text score of l_i by replacing $\mathcal{A}_{text}(l_j)$ with $\mathcal{A}_{diagram}(l_j)$. On the other hand, even if the diagram score of a literal is very high, it is still possible that the literal is false, because many diagrams are not drawn to scale. Hence, GEOS adds both text and diagram scores in order to score literals (Section 6).

High-confidence visual literals: Diagrams often contain critical information that is not present in the text. For instance, to solve the question in Figure 1, one has to know that the points `A`, `E`, and `C` are colinear. In addition, diagrams include numer-

ical labels (e.g. one of the labels in Figure 1(b) indicates the measure of the angle ABC = 40 degrees). This kind of information is confidently parsed with the diagram parser by Seo et al. (2014). We denote the set of the high-confidence literals by L_Δ that are passed to the solver (Section 7).

6 Optimization

Here, we describe the details of the objective function (Equation 1) and how to efficiently maximize it. The integrated affinity score of a set of literals L' (the first term in Equation 1) is defined as:

$$\mathcal{A}(L', t, d) = \sum_{l'_j \in L'} \left[\mathcal{A}_{text}(l'_j, t) + \mathcal{A}_{diagram}(l'_j, d)\right]$$

where $\mathcal{A}_{text}$ and $\mathcal{A}_{diagram}$ are the text and diagram affinities of l'_j, respectively.

To encourage GEOS to pick a subset of literals that cover the concepts in the question text and, at the same time, avoid redundancies, we define the coherence function as:

$$\mathcal{H}(L', t, d) = N_{\text{covered}}(L') - R_{\text{redundant}}(L')$$

where N_{covered} is the number of the concept nodes used by the literals in L', and $N_{\text{redundant}}$ is the number of redundancies among the concept nodes of the literals. To account for the different scales between $\mathcal{A}$ and $\mathcal{H}$, we use the trade-off parameter λ in Equation 1 learned on the validation dataset.

Maximizing the objective function in Equation 1 is an NP-hard combinatorial optimization problem. However, we show that our objective function is submodular (see Appendix (Section 11) for the proof of submodularity). This means that there exists a greedy method that can provide a reliable approximation. GEOS greedily maximizes Equation 1 by starting from an empty set of literals and adding the next literal l_j that maximizes the gain of the objective function until the gain becomes negative (details of the algorithm and the gain function are explained in Figure 3 step 3).

7 Solver

We now have the best set of literals L^* from the optimization, and the high-confidence visual literals L_Δ from the diagram parser. In this step, GEOS determines if an assignment exists to the variables X in $L^* \cup L_\Delta$ that simultaneously satisfies all of the literals. This is known as the problem of automated geometry theorem proving in computational geometry (Alvin et al., 2014).

We use a numerical method to check the satisfiablity of literals. For each literal l_j in $L^* \cup L_\Delta$, we define a relaxed indicator function $g_j : S \mapsto z_j \in [-\infty, 0]$. The function $z_j = g_j(S)$ indicates the relaxed satisfiability of l_j given an assignment S to the variables X. The literal l_j is completely satisfied if $g_j(S) = 0$. We formulate the problem of satisfiability of literals as the task of finding the assignment S^* to X such that sum of all indicator functions $g_j(S^*)$ is maximized, i.e. $S^* = \arg\max_S \sum_j g_j(S)$. We use the basing-hopping algorithm (Wales and Doye, 1997) with sequential least squares programming (Kraft, 1988) to globally maximize the sum of the indicator functions. If there exists an assignment such that $\sum_j g_j(S) = 0$, then GEOS finds an assignment to X that satisfies all literals. If such assignment does not exist, then GEOS concludes that the literals are not satisfiable simultaneously. GEOS chooses to answer a geometry question if the literals of exactly one answer choice are simultaneously satisfiable.

8 Experimental Setup

Logical Language Ω: Ω consists of 13 types of entities and 94 function and predicates observed in our development set of geometry questions.

Implementation details: Sentences in geometry questions often contain in-line mathematical expressions, such as "If AB=x+5, what is x?". These mathematical expressions cause general purpose parsers to fail. GEOS uses an equation analyzer and pre-processes question text by replacing "=" with "equals", and replacing mathematical terms (e.g., "x+5") with a dummy noun so that the dependency parser does not fail.

GEOS uses Stanford dependency parser (Chen and Manning, 2014) to obtain syntactic information, which is used to compute features for relation identification (Table 1). For diagram parsing, similar to Seo et al. (2014), we assume that GEOS has access to ground truth optical character recognition for labels in the diagrams. For optimization, we tune the parameters λ to 0.5, based on the training examples.[4]

Dataset: We built a dataset of SAT plane geometry questions where every question has a tex-

[4] In our dataset, the number of all possible literals for each sentence is at most 1000.

	Total	Training	Practice	Official
Questions	186	67	64	55
Sentences	336	121	110	105
Words	4343	1435	1310	1598
Literals	577	176	189	212
Binary relations	337	110	108	119
Unary relations	437	141	150	146

Table 2: Data and annotation statistics

tual description in English accompanied by a diagram and multiple choices. Questions and answers are compiled from previous official SAT exams and practice exams offered by the College Board (Board, 2014). In addition, we use a portion of the publicly available high-school plane geometry questions (Seo et al., 2014) as our training set.

We annotate ground-truth logical forms for all questions in the dataset. Table 2 shows details of the data and annotation statistics. For evaluating dependency parsing, we annotate 50 questions with the ground truth dependency tree structures of all sentences in the questions. [5]

Baselines: *Rule-based text parsing* + GEOS *diagram* solves geometry questions using literals extracted from a manually defined set of rules over the textual dependency parser, and scored by diagram. For this baseline, we manually designed 12 high-precision rules based on the development set. Each rule compares the dependency tree of each sentence to pre-defined templates, and if a template pattern is matched, the rule outputs the relation or function structure corresponding to that template. For example, a rule assigns a relation *parent(child-1, child-2)* for a triplet of *(parent, child-1, child-2)* where *child-1* is the subject of *parent* and *child-2* is the object of the parent.

GEOS *without text parsing* solves geometry questions using a simple heuristic. With simple textual processing, this baseline extracts numerical relations from the question text and then computes the scale between the units in the question and the pixels in the diagram. This baseline rounds the number to the closest choice available in the multiple choices.

GEOS *without diagram parsing* solves geometry questions only relying on the literals interpreted from the text. It outputs all literals whose text scores are higher than a tuned threshold, 0.6 on the training set.

GEOS *without relation completion* solves geometry questions when text parsing does not use the intermediate representation and does not include the relation completion step.

9 Experiments

We evaluate our method on three tasks: solving geometry question, interpreting geometry questions, and dependency parsing.

Solving Geometry Questions: Table 3 compares the score of GEOS in solving geometry questions in practice and official SAT questions with that of baselines. SAT's grading scheme penalizes a wrong answer with a negative score of 0.25. We report the SAT score as the percentage of correctly answered questions penalized by the wrong answers. For official questions, GEOS answers 27 questions correctly, 1 questions incorrectly, and leaves 27 un-answered, which gives it a score of 26.75 out of 55, or 49%. Thus, GEOS's precision exceeds 96% on the 51% of questions that it chooses to answer. For practice SAT questions, GEOS scores 61%.[6]

In order to understand the effect of individual components of GEOS, we compare the full method with a few ablations. GEOS significantly outperforms the two baselines GEOS *without text parsing* and GEOS *without diagram parsing*, demonstrating that GEOS benefits from both text and diagram parsing. In order to understand the text parsing component, we compare GEOS with *Rule-based text parsing* + GEOS *Diagram* and GEOS *without relation completion*. The results show that our method of learning to interpret literals from the text is substantially better than the rule-based baseline. In addition, the relation completion step, which relies on the intermediate representation, helps to improve text interpretation.

Error Analysis: In order to understand the errors made by GEOS, we use *oracle text parsing* and *oracle diagram parsing* (Table 3). Roughly 38% of the errors are due to failures in text parsing, and about 46% of errors are due to failures in diagram parsing. Among them, about 15% of errors were due to failures in both diagram and text parsing. For an example of text parsing failure, the literals in Figure 6 (a) are not scored accurately due to missing coreference relations (Hajishirzi et al., 2013). The rest of errors are due to problems that require more complex reasoning (Figure 6 (b)).

[5] The source code, the dataset and the annotations are publicly available at `geometry.allenai.org`.

[6] Typically, 50th percentile (penalized) score in SAT math section is 27 out of 54 (50%).

	SAT score (%)	
Method	Practice	Official
GEOS w/o diagram parsing	7	5
GEOS w/o text parsing	10	10
Rule-based text parsing + GEOS diagram	31	24
GEOS w/o relation completion	42	33
GEOS	**61**	**49**
Oracle text parsing + GEOS diagram parsing	78	75
GEOS text parsing + oracle diagram parsing	81	79
Oracle text parsing + oracle diagram parsing	88	84

Table 3: SAT scores of solving geometry questions.

	P	R	F1
Rule-based text parsing	**0.99**	0.23	0.37
GEOS w/o diagram	0.57	**0.82**	0.67
GEOS	0.92	0.76	**0.83**

Table 4: Precision and recall of text interpretation.

Interpreting Question Texts: Table 4 details the precision and recall of GEOS in deriving literals for geometry question texts for official SAT questions. The rule-based text parsing baseline achieves a high precision, but at the cost of lower recall. On the other hand, the baseline GEOS *without diagram* achieves a high recall, but at the cost of lower precision. Nevertheless, GEOS attains substantially higher F1 score compared to both baselines, which is the key factor in solving the questions. Direct application of a generic semantic parser (Berant et al., 2013) with full supervision does not perform well in the geometry domain, mainly due to lack of enough training data. Our initial investigations show the performance of 33% F1 in the official set.

Improving Dependency Parsing: Table 5 shows the results of different methods in dependency parsing. GEOS returns a dependency parse tree by selecting the dependency tree that maximizes the text score in the objective function from the top 50 trees produced by a generic dependency parser, Stanford parser (Chen and Manning, 2014). Note that Stanford parser cannot handle mathematical symbols and equations. We report the results of a baseline that extends the Stanford dependency parser by adding a pre-processing step to separate the mathematical expressions from the plain sentences (Section 8).

We evaluate the performance of GEOS against the best tree returned by Stanford parser by reporting the fraction of the questions whose dependency parse structures match the ground truth annotations. Our results show an improvement of 16% over the Stanford dependency parser when equipped with the equation analyzer. For example, in "AB is perpendicular to CD at E", the Stanford dependency parser predicts that "E" depends on "CD", while GEOS predicts the correct parse in which "E" depends on "perpendicular".

	Accuracy
Stanford dep parse	0.05
Stanford dep parse + eq. analyzer	0.64
GEOS	**0.78**

Table 5: Accuracy of dependency parsing.

10 Conclusion

This paper introduced GEOS, an automated system that combines diagram and text interpretation to solve geometry problems. Solving geometry questions was inspired by two important trends in the current NLP literature. The first is in designing methods for grounded language acquisition to map text to a restricted formalism (instead of a full, domain independent representation). We demonstrate a new algorithm for learning to map text to a geometry language with a small amount of training data. The second is designing methods in coupling language and vision and show how processing multimodal information help improve textual or visual interpretations.

Our experiments on unseen SAT geometry problems achieve a score of 49% of official questions and a score of 61% on practice questions, providing a baseline for future work. Future work includes expanding the geometry language and the reasoning to address a broader set of geometry questions, reducing the amount of supervision, learning the relevant geometry knowledge, and scaling up the dataset.

11 Appendix: Proof of Submodularity of Equation 1

We prove that the objective function in equation (1), $\lambda\mathcal{A}(L') + \mathcal{H}(L')$ is submodular by showing that $\mathcal{A}(L')$ and $\mathcal{H}(L')$ are submodular functions.

Submodularity of $\mathcal{A}$. Consider $L' \subset L$, and a new literal to be added, $l_i \in L \setminus L'$. By the definition of $\mathcal{A}$, it is clear that $\mathcal{A}(L' \cup \{l_j\}) = \mathcal{A}(L') + \mathcal{A}(\{l_j\})$. Hence, for all $L'' \subset L' \subset L$,

$$\mathcal{A}(L'' \cup \{l_j\}) - \mathcal{A}(L'') = \mathcal{A}(L' \cup \{l_j\}) - \mathcal{A}(L')$$

. Thus $\mathcal{A}$ is submodular.

Submodularity of $\mathcal{H}$. We prove that the coverage function, $\mathcal{H}_{\text{cov}}$, and the negation of the redundancy function, $-\mathcal{H}_{\text{red}}$ are submodular independently, and thus derive that their sum is submodular. For both, consider we are given $L'' \subset L' \subset L$, and a new literal $l_j \in L \setminus L'$. Also, let K'' and K' denote the the sets of concepts covered by L'' and L', respectively, and let K_j denote the set of concepts covered by l_j.

Coverage: Since $K'' \subset K'$, $|K'' \cup K_j| - |K''| \geq |K' \cup K_j| - |K'|$, which is equivalent to

$$\begin{aligned}&\mathcal{H}_{\text{cov}}(L'' \cup \{l_j\}) - \mathcal{H}_{\text{cov}}(L'') \\ &\quad \geq \mathcal{H}_{\text{cov}}(L' \cup \{l_j\}) - \mathcal{H}_{\text{cov}}(L')\end{aligned}$$

Redundancy: Note that $\mathcal{H}_{\text{red}}(L'' \cup \{l_j\}) - \mathcal{H}_{\text{red}}(L'') = |K'' \cap K_j|$, and similarly, $\mathcal{H}_{\text{red}}(L' \cup \{l_j\}) - \mathcal{H}_{\text{red}}(L') = |K' \cap K_j|$. Since $K'' \subset K'$, thus $|K'' \cap K_j| \leq |K' \cap K_j|$. Hence,

$$\begin{aligned}&\mathcal{H}_{\text{red}}(L'' \cup \{l_j\}) - \mathcal{H}_{\text{red}}(L'') \\ &\quad \leq \mathcal{H}_{\text{red}}(L' \cup \{l_j\}) - \mathcal{H}_{\text{red}}(L'),\end{aligned}$$

By negating both sides, we derive that the negation of the redundancy function is submodular.

Abstract

Understanding language goes hand in hand with the ability to integrate complex contextual information obtained via perception. In this work, we present a novel task for grounded language understanding: disambiguating a sentence given a visual scene which depicts one of the possible interpretations of that sentence. To this end, we introduce a new multimodal corpus containing ambiguous sentences, representing a wide range of syntactic, semantic and discourse ambiguities, coupled with videos that visualize the different interpretations for each sentence. We address this task by extending a vision model which determines if a sentence is depicted by a video. We demonstrate how such a model can be adjusted to recognize different interpretations of the same underlying sentence, allowing to disambiguate sentences in a unified fashion across the different ambiguity types.

1 Introduction

Ambiguity is one of the defining characteristics of human languages, and language understanding crucially relies on the ability to obtain unambiguous representations of linguistic content. While some ambiguities can be resolved using intra-linguistic contextual cues, the disambiguation of many linguistic constructions requires integration of world knowledge and perceptual information obtained from other modalities.

In this work, we focus on the problem of grounding language in the visual modality, and introduce a novel task for language understanding which requires resolving linguistic ambiguities by utilizing the visual context in which the linguistic content is expressed. This type of inference is frequently called for in human communication that occurs in a visual environment, and is crucial for language acquisition, when much of the linguistic content refers to the visual surroundings of the child (Snow, 1972).

Our task is also fundamental to the problem of grounding vision in language, by focusing on phenomena of linguistic ambiguity, which are prevalent in language, but typically overlooked when using language as a medium for expressing understanding of visual content. Due to such ambiguities, a superficially appropriate description of a visual scene may in fact not be sufficient for demonstrating a correct understanding of the relevant visual content. Our task addresses this issue by introducing a deep validation protocol for visual understanding, requiring not only providing a surface description of a visual activity but also demonstrating structural understanding at the levels of syntax, semantics and discourse.

To enable the systematic study of visually grounded processing of ambiguous language, we create a new corpus, *LAVA* (Language and Vision Ambiguities). This corpus contains sentences with linguistic ambiguities that can only be resolved using external information. The sentences are paired with short videos that visualize different interpretations of each sentence. Our sentences encompass a wide range of syntactic, semantic and dis-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1477–1487,
Lisbon, Portugal, 17-21 September 2015.

course ambiguities, including ambiguous prepositional and verb phrase attachments, conjunctions, logical forms, anaphora and ellipsis. Overall, the corpus contains 237 sentences, with 2 to 3 interpretations per sentence, and an average of 3.37 videos that depict visual variations of each sentence interpretation, corresponding to a total of 1679 videos.

Using this corpus, we address the problem of selecting the interpretation of an ambiguous sentence that matches the content of a given video. Our approach for tackling this task extends the *sentence tracker* introduced in (Siddharth et al., 2014). The sentence tracker produces a score which determines if a sentence is depicted by a video. This earlier work had no concept of ambiguities; it assumed that every sentence had a single interpretation. We extend this approach to represent multiple interpretations of a sentence, enabling us to pick the interpretation that is most compatible with the video.

To summarize, the contributions of this paper are threefold. First, we introduce a new task for visually grounded language understanding, in which an ambiguous sentence has to be disambiguated using a visual depiction of the sentence's content. Second, we release a multimodal corpus of sentences coupled with videos which covers a wide range of linguistic ambiguities, and enables a systematic study of linguistic ambiguities in visual contexts. Finally, we present a computational model which disambiguates the sentences in our corpus with an accuracy of 75.36%.

2 Related Work

Previous language and vision studies focused on the development of multimodal word and sentence representations (Bruni et al., 2012; Socher et al., 2013; Silberer and Lapata, 2014; Gong et al., 2014; Lazaridou et al., 2015), as well as methods for describing images and videos in natural language (Farhadi et al., 2010; Kulkarni et al., 2011; Mitchell et al., 2012; Socher et al., 2014; Thomason et al., 2014; Karpathy and Fei-Fei, 2014; Siddharth et al., 2014; Venugopalan et al., 2015; Vinyals et al., 2015). While these studies handle important challenges in multimodal processing of language and vision, they do not provide explicit modeling of linguistic ambiguities.

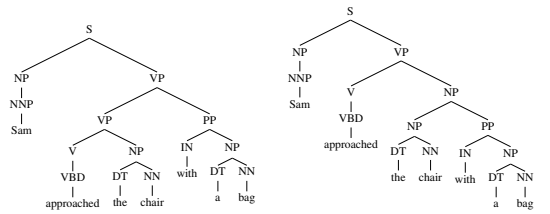
Previous work relating ambiguity in language to the visual modality addressed the problem of word sense disambiguation (Barnard et al., 2003). However, this work is limited to context independent interpretation of individual words, and does not consider structure-related ambiguities. Discourse ambiguities were previously studied in work on multimodal coreference resolution (Ramanathan et al., 2014; Kong et al., 2014). Our work expands this line of research, and addresses further discourse ambiguities in the interpretation of ellipsis. More importantly, to the best of our knowledge our study is the first to present a systematic treatment of syntactic and semantic sentence level ambiguities in the context of language and vision.

The interactions between linguistic and visual information in human sentence processing have been extensively studied in psycholinguistics and cognitive psychology (Tanenhaus et al., 1995). A considerable fraction of this work focused on the processing of ambiguous language (Spivey et al., 2002; Coco and Keller, 2015), providing evidence for the importance of visual information for linguistic ambiguity resolution by humans. Such information is also vital during language acquisition, when much of the linguistic content perceived by the child refers to their immediate visual environment (Snow, 1972). Over time, children develop mechanisms for grounded disambiguation of language, manifested among others by the usage of iconic gestures when communicating ambiguous linguistic content (Kidd and Holler, 2009). Our study leverages such insights to develop a complementary framework that enables addressing the challenge of visually grounded disambiguation of language in the realm of artificial intelligence.

3 Task

In this work we provide a concrete framework for the study of language understanding with visual context by introducing the task of grounded language disambiguation. This task requires to choose the correct linguistic representation of a sentence given a visual context depicted in a video. Specifically, provided with a sentence, n candidate interpretations of that sentence and a video that depicts the content of the sentence, one needs to choose the interpretation that corresponds to the content of the video.

To illustrate this task, consider the example in figure 1, where we are given the sentence "Sam approached the chair with a bag" along with two different linguistic interpretations. In the first in-

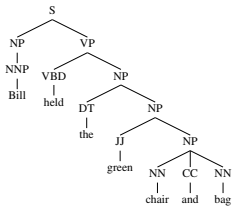


(a) First interpretation

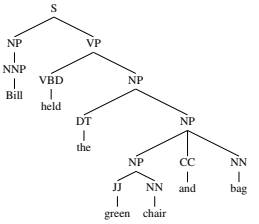
(b) Second interpretation

(c) Visual context

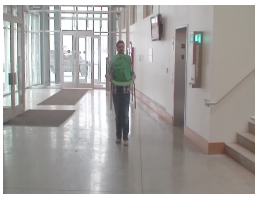
Figure 1: An example of the visually grounded language disambiguation task. Given the sentence "Sam approached the chair with a bag", two potential parses, (a) and (b), correspond to two different semantic interpretations. In the first interpretation Sam has the bag, while in the second reading the bag is on the chair. The task is to select the correct interpretation given the visual context (c).



(a) First interpretation



(b) Second interpretation



(c) First visual context

(d) Second visual context

Figure 2: Linguistic and visual interpretations of the sentence "Bill held the green chair and bag". In the first interpretation (a,c) both the chair and bag are green, while in the second interpretation (b,d) only the chair is green and the bag has a different color.

terpretation, which corresponds to parse 1(a), Sam has the bag. In the second interpretation associated with parse 1(b), the bag is on the chair rather than with Sam. Given the visual context from figure 1(c), the task is to choose which interpretation is most appropriate for the sentence.

4 Approach Overview

To address the grounded language disambiguation task, we use a compositional approach for determining if a specific interpretation of a sentence is depicted by a video. In this framework, described in detail in section 6, a sentence and an accompanying interpretation encoded in first order logic, give rise to a grounded model that matches a video against the provided sentence interpretation.

The model is comprised of Hidden Markov Models (HMMs) which encode the semantics of words, and trackers which locate objects in video frames. To represent an interpretation of a sentence, word models are combined with trackers through a cross-product which respects the semantic representation of the sentence to create a single model which recognizes that interpretation.

Given a sentence, we construct an HMM based representation for each interpretation of that sentence. We then detect candidate locations for objects in every frame of the video. Together the reforestation for the sentence and the candidate object locations are combined to form a model which can determine if a given interpretation is depicted by the video. We test each interpretation and report the interpretation with highest likelihood.

5 Corpus

To enable a systematic study of linguistic ambiguities that are grounded in vision, we compiled a corpus with ambiguous sentences describing visual actions. The sentences are formulated such that the correct linguistic interpretation of each sentence can only be determined using external, non-linguistic, information about the depicted activity. For example, in the sentence "Bill held the green chair and bag", the correct scope of "green" can only be determined by integrating additional information about the color of the bag. This information is provided in the accompanying videos, which visualize the possible interpretations of each sentence. Figure 2 presents the syntactic parses for this example along with frames from the respective videos. Although our videos contain visual uncertainty, they are not ambiguous with respect to the linguistic interpretation they are presenting, and hence a video always corresponds to a single candidate representation of a sentence.

The corpus covers a wide range of well

known syntactic, semantic and discourse ambiguity classes. While the ambiguities are associated with various types, different sentence interpretations always represent distinct sentence meanings, and are hence encoded semantically using first order logic. For syntactic and discourse ambiguities we also provide an additional, ambiguity type specific encoding as described below.

- **Syntax** Syntactic ambiguities include Prepositional Phrase (PP) attachments, Verb Phrase (VP) attachments, and ambiguities in the interpretation of conjunctions. In addition to logical forms, sentences with syntactic ambiguities are also accompanied with Context Free Grammar (CFG) parses of the candidate interpretations, generated from a deterministic CFG parser.

- **Semantics** The corpus addresses several classes of semantic quantification ambiguities, in which a syntactically unambiguous sentence may correspond to different logical forms. For each such sentence we provide the respective logical forms.

- **Discourse** The corpus contains two types of discourse ambiguities, Pronoun Anaphora and Ellipsis, offering examples comprising two sentences. In **anaphora** ambiguity cases, an ambiguous pronoun in the second sentence is given its candidate antecedents in the first sentence, as well as a corresponding logical form for the meaning of the second sentence. In **ellipsis** cases, a part of the second sentence, which can constitute either the subject and the verb, or the verb and the object, is omitted. We provide both interpretations of the omission in the form of a single unambiguous sentence, and its logical form, which combines the meanings of the first and the second sentences.

Table 2 lists examples of the different ambiguity classes, along with the candidate interpretations of each example.

The corpus is generated using Part of Speech (POS) tag sequence templates. For each template, the POS tags are replaced with lexical items from the corpus lexicon, described in table 3, using all the visually applicable assignments. This generation process yields an overall of 237 sentences,

	Ambiguity	Templates	#
Syntax	PP	NNP V DT [JJ] NN_1 IN DT [JJ] NN_2.	48

	Conjunction	NNP_1 [and NNP_2] V DT JJ NN_1 and NN_2. NNP V DT NN_1 or DT NN_2 and DT NN_3.	40
Semantics	Logical Form	NNP_1 and NNP_2 V a NN. Someone V the NNS.	35
Discourse	Anaphora	NNP V DT NN_1 and DT NN_2. It is JJ.	36
	Ellipsis	NNP_1 V NNP_2. Also NNP_3.	18

Table 1: POS templates for generating the sentences in our corpus. The rightmost column represents the number of sentences in each category. The sentences are produced by replacing the POS tags with all the visually applicable assignments of lexical items from the corpus lexicon shown in table 3.

of which 213 sentences have 2 candidate interpretations, and 24 sentences have 3 interpretations. Table 1 presents the corpus templates for each ambiguity class, along with the number of sentences generated from each template.

The corpus videos are filmed in an indoor environment containing background objects and pedestrians. To account for the manner of performing actions, videos are shot twice with different actors. Whenever applicable, we also filmed the actions from two different directions (e.g. approach from the left, and approach from the right). Finally, all videos were shot with two cameras from two different view points. Taking these variations into account, the resulting video corpus contains 7.1 videos per sentence and 3.37 videos per sentence interpretation, corresponding to a total of 1679 videos. The average video length is 3.02 seconds (90.78 frames), with in an overall of 1.4 hours of footage (152434 frames).

A custom corpus is required for this task because no existing corpus, containing either videos or images, systematically covers multimodal ambiguities. Datasets such as *UCF Sports* (Rodriguez et al., 2008), *YouTube* (Liu et al., 2009), and *HMDB* (Kuehne et al., 2011) which come out of the activity recognition community are accompanied by action labels, not sentences, and do not control for the content of the videos aside from the principal action being performed. Datasets for image and video captioning, such as *MSCOCO* (Lin et al., 2014) and *TACOS* (Regneri et al., 2013),

	Ambiguity	Example	Linguistic interpretations	Visual setups
Syntax	PP	Claire left the green chair with a yellow bag.	Claire [left the green chair] [with a yellow bag].	The bag is with Claire.
			Claire left [the green chair with a yellow bag].	Bag is on the chair.
	VP	Claire looked at Bill picking up a chair.	Claire looked at [Bill [picking up a chair]].	Bill picks up the chair.
			Claire [looked at Bill] [picking up a chair].	Claire picks up the chair.
	Conjunction	Claire held a green bag and chair.	Claire held a [green [bag and chair]].	The chair is green.
			Claire held a [[green bag] and [chair]].	The chair is not green.
		Claire held the chair or the bag and the telescope.	Claire held [[the chair] or [the bag and the telescope]].	Claire holds the chair.
			Claire held [[the chair or the bag] and [the telescope]].	Claire holds the chair and the telescope.
Semantics	Logical Form	Claire and Bill moved a chair.	**chair**(x), **move**(Claire, x), **move**(Bill, x)	Claire and Bill move the same chair.
			chair(x), **chair**(y), **move**(Claire, x), **move**(Bill, y), $x \neq y$	Claire and Bill move different chairs.
		Someone moved the two chairs.	**chair**(x), **chair**(y), $x \neq y$, **person**(u), **move**(u, x), **move**(u, y)	One person moves both chairs.
			chair(x), **chair**(y), $x \neq y$, **person**(u), **person**(v), $u \neq v$, **move**(u, x), **move**(v, y)	Each chair moved by a different person.
Discourse	Anaphora	Claire held the bag and the chair. It is yellow.	It = bag	The bag is yellow.
			It = chair	The chair is yellow.
	Ellipsis	Claire looked at Bill. Also Sam.	Claire looked at Bill and Sam.	Claire looks at Bill and Sam.
			Claire and Sam looked at Bill.	Claire and Sam look at Bill.

Table 2: An overview of the different ambiguity types, along with examples of ambiguous sentences with their linguistic and visual interpretations. Note that similarly to semantic ambiguities, syntactic and discourse ambiguities are also provided with first order logic formulas for the resulting sentence interpretations. Table 4 shows additional examples for each ambiguity type, with frames from sample videos corresponding to the different interpretations of each sentence.

Syntactic Category	Visual Category	Words
Nouns	Objects, People	chair, bag, telescope, someone, proper names
Verbs	Actions	pick up, put down, hold, move (transitive), look at, approach, leave
Prepositions	Spacial Relations	with, left of, right of, on
Adjectives	Visual Properties	yellow, green

Table 3: The lexicon used to instantiate the templates in figure 1 in order to generate the corpus.

aim to control for more aspects of the videos than just the main action being performed but they do not provide the range of ambiguities discussed here. The closest dataset is that of Siddharth et al. (2014) as it controls for object appearance, color, action, and direction of motion, making it more likely to be suitable for evaluating disambiguation tasks. Unfortunately, that dataset was designed to avoid ambiguities, and therefore is not suitable for evaluating the work described here.

6 Model

To perform the disambiguation task, we extend the sentence recognition model of Siddharth et al. (2014) which represents sentences as compositions of words. Given a sentence, its first order logic interpretation and a video, our model produces a score which determines if the sentence is depicted by the video. It simultaneously tracks the participants in the events described by the sentence while recognizing the events themselves. This allows it to be flexible in the presence of noise by integrating top-down information from the sentence with bottom-up information from object and property detectors. Each word in the query sentence is represented by an HMM (Baum et al., 1970), which recognizes tracks (i.e. paths of detections in a video for a specific object) that satisfy the semantics of the given word. In essence, this model can be described as having two layers, one in which object tracking occurs and one in which words observe tracks and filter tracks that do not satisfy the word constraints.

Given a sentence interpretation, we construct a sentence-specific model which recognizes if a video depicts the sentence as follows. Each predicate in the first order logic formula has a corresponding HMM, which can recognize if that predicate is true of a video given its arguments. Each variable has a corresponding tracker which attempts to physically locate the bounding box corresponding to that variable in each frame of a

PP Attachment	Sam looked at Bill with a telescope.
VP Attachment	Bill approached the person holding a green chair.
Conjunction	Sam and Bill picked up the yellow bag and chair.
Logical Form	Someone put down the bags.
Anaphora	Sam picked up the bag and the chair. It is yellow.
Ellipsis	Sam left Bill. Also Clark.

Table 4: Examples of the six ambiguity classes described in table 2. The example sentences have at least two interpretations, which are depicted by different videos. Three frames from each such video are shown on the left and on the right below each sentence.

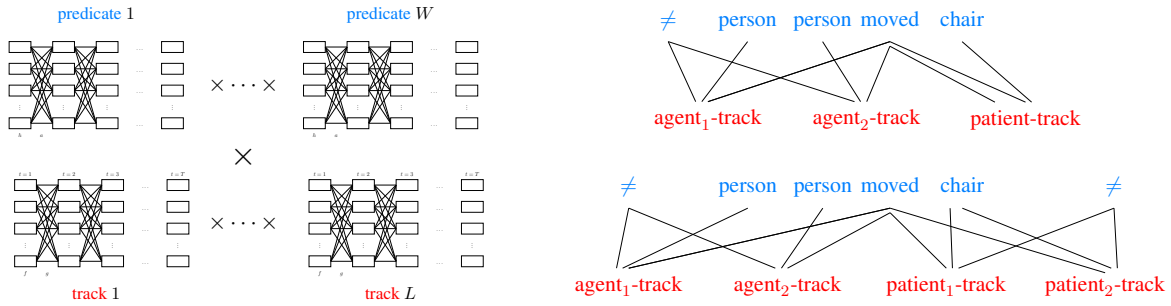

Figure 3: (left) Tracker lattices for every sentence participant are combined with predicate HMMs. The MAP estimate in the resulting cross-product lattice simultaneously finds the best tracks and the best state sequences for every predicate. (right) Two interpretations of the sentence "Claire and Bill moved a chair" having different first order logic formulas. The top interpretation corresponds to Bill and Claire moving the same chair, while the bottom one describes them moving different chairs. Predicates are highlighted in blue at the top and variables are highlighted in red at the bottom. Each predicate has a corresponding HMM which recognizes its presence in a video. Each variable has a corresponding tracker which locates it in a video. Lines connect predicates and the variables which fill their argument slots. Some predicates, such as *move* and $\neq$, take multiple arguments. Some predicates, such as *move*, are applied multiple times between different pairs of variables.

video. This creates a bipartite graph: HMMs that represent predicates are connected to trackers that represent variables. The trackers themselves are similar to the HMMs, in that they comprise a lattice of potential bounding boxes in every frame. To construct a joint model for a sentence interpretation, we take the cross product of HMMs and trackers, taking only those cross products dictated by the structure of the formula corresponding to the desired interpretation. Given a video, we employ an object detector to generate candidate detections in each frame, construct trackers which select one of these detections in each frame, and finally construct the overall model from HMMs and trackers.

Provided an interpretation and its corresponding formula composed of P predicates and V variables, along with a collection of object detections, $b^{\text{frame}}_{\text{detection index}}$, in each frame of a video of length T the model computes the score of the video-sentence pair by finding the optimal detection for each participant in every frame. This is in essence the Viterbi algorithm (Viterbi, 1971), the MAP algorithm for HMMs, applied to finding optimal object detections $j^{\text{frame}}_{\text{variable}}$ for each participant, and the optimal state $k^{\text{frame}}_{\text{predicate}}$ for each predicate HMM, in every frame. Each detection is scored by its confidence from the object detector, f and each object track is scored by a motion coherence metric g which determines if the motion of the track agrees with the underlying optical flow. Each predicate, p, is scored by the probability of observing a particular detection in a given state h_p, and by the probability of transitioning between states a_p. The structure of the formula and the fact that multiple predicates often refer to the same variables is recorded by θ, a mapping between predicates and their arguments. The model computes the MAP estimate as:

$$\max_{j_1^1,\ldots,j_1^T} \cdots \max_{j_V^1,\ldots,j_V^T} \max_{k_1^1,\ldots,k_1^T} \cdots \max_{k_P^1,\ldots,k_P^T} \sum_{v=1}^{V}\sum_{t=1}^{T} f(b^t_{j_v^t}) + \sum_{t=2}^{T} g(b^{t-1}_{j_v^{t-1}}, b^t_{j_v^t}) + \sum_{p=1}^{P}\sum_{t=1}^{T} h_p(k_p^t, b^t_{j^t_{\theta_p^1}}, b^t_{j^t_{\theta_p^2}}) + \sum_{t=2}^{T} a_p(k_p^{t-1}, k_p^t)$$

for sentences which have words that refer to at most two tracks (i.e. transitive verbs or binary predicates) but is trivially extended to arbitrary arities. Figure 3 provides a visual overview of the model as a cross-product of tracker models and word models.

Our model extends the approach of Siddharth et al. (2014) in several ways. First, we depart from the dependency based representation used in that work, and recast the model to encode first order logic formulas. Note that some complex first order logic formulas cannot be directly encoded in the model and require additional inference steps. This extension enables us to represent ambiguities in which a given sentence has multiple logical interpretations for the same syntactic parse.

Second, we introduce several model components which are not specific to disambiguation, but are required to encode linguistic constructions that are present in our corpus and could not be handled by the model of Siddharth et al. (2014). These new components are the predicate "not equal", disjunction, and conjunction. The key addition among these components is support for the new predicate "not equal", which enforces that two tracks, i.e. objects, are distinct from each other. For example, in the sentence "Claire and Bill moved a chair" one would want to ensure that the two movers are distinct entities. In earlier work, this was not required because the sentences tested in that work were designed to distinguish objects based on constraints rather than identity. In other words, there might have been two different people but they were distinguished in the sentence by their actions or appearance. To faithfully recognize that two actors are moving the chair in the earlier example, we must ensure that they are disjoint from each other. In order to do this we create a new HMM for this predicate, which assigns low probability to tracks that heavily overlap, forcing the model to fit two different actors in the previous example. By combining the new first order logic based semantic representation in lieu of a syntactic representation with a more expressive model, we can encode the sentence interpretations required to perform the disambiguation task.

Figure 3(left) shows an example of two different interpretations of the above discussed sentence "Claire and Bill moved a chair". Object trackers, which correspond to variables in the first order logic representation of the sentence interpretation, are shown in red. Predicates which constrain the possible bindings of the trackers, corresponding to predicates in the representation of the sentence, are shown in blue. Links represent the argument structure of the first order logic formula, and determine the cross products that are taken between the predicate HMMs and tracker lattices in order to form the joint model which recognizes the entire interpretation in a video.

The resulting model provides a single unified formalism for representing all the ambiguities in table 2. Moreover, this approach can be tuned to different levels of specificity. We can create models that are specific to one interpretation of a sentence or that are generic, and accept multiple interpretations by eliding constraints that are not common between the different interpretations. This allows the model, like humans, to defer deciding on a particular interpretation or to infer that multiple interpretation of the sentence are plausible.

7 Experimental Results

We tested the performance of the model described in the previous section on the *LAVA* dataset presented in section 5. Each video in the dataset was pre-processed with object detectors for humans, bags, chairs, and telescopes. We employed a mixture of CNN (Krizhevsky et al., 2012) and DPM (Felzenszwalb et al., 2010) detectors, trained on held out sections of our corpus. For each object class we generated proposals from both the CNN and the DPM detectors, and trained a scoring function to map both results into the same space. The scoring function consisted of a sigmoid over the confidence of the detectors trained on the same held out portion of the training set. As none of the disambiguation examples discussed here rely on the specific identity of the actors, we did not detect their identity. Instead, any sentence which contains names was automatically converted to one which contains arbitrary "person" labels.

The sentences in our corpus have either two or three interpretations. Each interpretation has one or more associated videos where the scene was shot from a different angle, carried out either by different actors, with different objects, or in different directions of motion. For each sentence-video pair, we performed a 1-out-of-2 or 1-out-of-3 classification task to determine which of the interpretations of the corresponding sentence best fits that video. Overall chance performance on our dataset is 49.04%, slightly lower than 50% due to the 1-out-of-3 classification examples.

The model presented here achieved an accuracy of 75.36% over the entire corpus averaged across all error categories. This demonstrates that the model is largely capable of capturing the underlying task and that similar compositional cross-modal models may do the same. For each of the 3 major ambiguity classes we had an accuracy of 84.26% for syntactic ambiguities, 72.28% for semantic ambiguities, and 64.44% for discourse ambiguities.

The most significant source of model failures are poor object detections. Objects are often rotated and presented at angles that are difficult to recognize. Certain object classes like the telescope

are much more difficult to recognize due to their small size and the fact that hands tend to largely occlude them. This accounts for the degraded performance of the semantic ambiguities relative to the syntactic ambiguities, as many more semantic ambiguities involved the telescope. Object detector performance is similarly responsible for the lower performance of the discourse ambiguities which relied much more on the accuracy of the person detector as many sentences involve only people interacting with each other without any additional objects. This degrades performance by removing a helpful constraint for inference, according to which people tend to be close to the objects they are manipulating. In addition, these sentences introduced more visual uncertainty as they often involved three actors.

The remaining errors are due to the event models. HMMs can fixate on short sequences of events which seem as if they are part of an action, but in fact are just noise or the prefix of another action. Ideally, one would want an event model which has a global view of the action, if an object went up from the beginning to the end of the video while a person was holding it, it's likely that the object was being picked up. The event models used here cannot enforce this constraint, they merely assert that the object was moving up for some number of frames; an event which can happen due to noise in the object detectors. Enforcing such local constraints instead of the global constraint of the motion of the object over the video makes joint tracking and event recognition tractable in the framework presented here but can lead to errors. Finding models which strike a better balance between local information and global constraints while maintaining tractable inference remains an area of future work.

8 Conclusion

We present a novel framework for studying ambiguous utterances expressed in a visual context. In particular, we formulate a new task for resolving structural ambiguities using visual signal. This is a fundamental task for humans, involving complex cognitive processing, and is a key challenge for language acquisition during childhood. We release a multimodal corpus that enables to address this task, as well as support further investigation of ambiguity related phenomena in visually grounded language processing. Finally, we present a unified approach for resolving ambiguous descriptions of videos, achieving good performance on our corpus.

While our current investigation focuses on structural *inference*, we intend to extend this line of work to *learning* scenarios, in which the agent has to deduce the meaning of words and sentences from structurally ambiguous input. Furthermore, our framework can be beneficial for image and video retrieval applications in which the query is expressed in natural language. Given an ambiguous query, our approach will enable matching and clustering the retrieved results according to the different query interpretations.

Efficient and Expressive Knowledge Base Completion Using Subgraph Feature Extraction

Matt Gardner and Tom Mitchell
Carnegie Mellon University
mg1@cs.cmu.edu, tom.mitchell@cmu.edu

Abstract

We explore some of the practicalities of using random walk inference methods, such as the Path Ranking Algorithm (PRA), for the task of knowledge base completion. We show that the random walk probabilities computed (at great expense) by PRA provide no discernible benefit to performance on this task, so they can safely be dropped. This allows us to define a simpler algorithm for generating feature matrices from graphs, which we call subgraph feature extraction (SFE). In addition to being conceptually simpler than PRA, SFE is much more efficient, reducing computation by an order of magnitude, and more expressive, allowing for much richer features than paths between two nodes in a graph. We show experimentally that this technique gives substantially better performance than PRA and its variants, improving mean average precision from .432 to .528 on a knowledge base completion task using the NELL KB.

1 Introduction

Knowledge bases (KBs), such as Freebase (Bollacker et al., 2008), NELL (Mitchell et al., 2015), and DBPedia (Mendes et al., 2012) contain large collections of facts about things, people, and places in the world. These knowledge bases are useful for various tasks, including training relation extractors and semantic parsers (Hoffmann et al., 2011; Krishnamurthy and Mitchell, 2012), and question answering (Berant et al., 2013). While these knowledge bases may be very large, they are still quite incomplete, missing large percentages of facts about common or popular entities (West et al., 2014; Choi et al., 2015). The task of knowledge base completion—filling in missing facts by examining the facts already in the KB, or by looking in a corpus—is one attempt to mitigate the problems of this knowledge sparsity.

In this work we examine one method for performing knowledge base completion that is currently in use: the Path Ranking Algorithm (PRA) (Lao et al., 2011; Dong et al., 2014). PRA is a method for performing link prediction in a graph with labeled edges by computing feature matrices over node pairs in the graph. The method has a strong connection to logical inference (Gardner et al., 2015), as the feature space considered by PRA consists of a restricted class of horn clauses found in the graph. While PRA can be applied to any link prediction task in a graph, its primary use has been in KB completion (Lao et al., 2012; Gardner et al., 2013; Gardner et al., 2014).

PRA is a two-step process, where the first step finds potential path types between node pairs to use as features in a statistical model, and the second step computes random walk probabilities associated with each path type and node pair (these are the values in a feature matrix). This second step is very computationally intensive, requiring time proportional to the average out-degree of the graph to the power of the path length for *each cell* in the computed feature matrix. In this paper we consider whether this computational effort is well-spent, or whether we might more profitably spend computation in other ways. We propose a new way of generating feature matrices over node pairs in a graph that aims to improve both the efficiency and the expressivity of the model relative to PRA.

Our technique, which we call *subgraph feature extraction* (SFE), is similar to only doing the first step of PRA. Given a set of node pairs in a graph, we first do a local search to characterize the graph around each node. We then run a set of feature extractors over these local subgraphs to obtain feature vectors for each node pair. In the simplest case, where the feature extractors only

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1488–1498,
Lisbon, Portugal, 17-21 September 2015.

look for paths connecting the two nodes, the feature space is equivalent to PRA's, and this is the same as running PRA and binarizing the resultant feature vectors. However, because we do not have to compute random walk probabilities associated with each path type in the feature matrix, we can extract much more expressive features, including features which are not representable as paths in the graph at all. In addition, we can do a more exhaustive search to characterize the local graph, using a breadth-first search instead of random walks. SFE is a much simpler method than PRA for obtaining feature matrices over node pairs in a graph. Despite its simplicity, however, we show experimentally that it substantially outperforms PRA, both in terms of running time and prediction performance. SFE decreases running time over PRA by an order of magnitude, it improves mean average precision from .432 to .528 on the NELL KB, and it improves mean reciprocal rank from .850 to .933.

In the remainder of this paper, we first describe PRA in more detail. We then situate our methods in the context of related work, and provide additional experimental motivation for the improvements described in this paper. We then formally define SFE and the feature extractors we used, and finally we present an experimental comparison between PRA and SFE on the NELL KB. The code and data used in this paper is available at http://rtw.ml.cmu.edu/emnlp2015_sfe/.

2 The Path Ranking Algorithm

The path ranking algorithm was introduced by Lao and Cohen (2010). It is a two-step process for generating a feature matrix over node pairs in a graph. The first step finds a set of potentially useful path types that connect the node pairs, which become the columns of the feature matrix. The second step then computes the values in the feature matrix by finding random walk probabilities as described below. Once the feature matrix has been computed, it can be used with whatever classification model is desired (or even incorporated as one of many factors in a structured prediction model), though almost all prior work with PRA simply uses logistic regression.

More formally, consider a graph $\mathcal{G}$ with nodes $\mathcal{N}$, edges $\mathcal{E}$, and edge labels $\mathcal{R}$, and a set of node pairs $(s_j, t_j) \in \mathcal{D}$ that are instances of some relationship of interest. PRA will generate a feature vector for each (s_j, t_j) pair, where each feature is some sequence of edge labels -e_1-e_2-. . .-e_l-. If the edge sequence, or *path type*, corresponding to the feature exists between the source and target nodes in the graph, the value of that feature in the feature vector will be non-zero.

Because the feature space considered by PRA is so large,[1] and because computing the feature values is so computationally intensive, the first step PRA must perform is *feature selection*, which is done using random walks over the graph. In this step of PRA, we find path types π that are likely to be useful in predicting new instances of the relation represented by the input node pairs. These path types are found by performing random walks on the graph $\mathcal{G}$ starting at the source and target nodes in $\mathcal{D}$ and recording which paths connect some source node with its target.[2] Note that these are *two-sided*, *unconstrained* random walks: the walks from sources and targets can be joined on intermediate nodes to get a larger set of paths that connect the source and target nodes. Once connectivity statistics have been computed in this way, k path types are selected as features. Lao et al. (2011) use measures of the precision and recall of each feature in this selection, while Gardner et al. (2014) simply pick those most frequently seen.

Once a set of path features has been selected, the second step of PRA is to compute values for each cell in the feature matrix. Recall that rows in this matrix correspond to node pairs, and the columns correspond to the path types found in the first step. The cell value assigned by PRA is the probability of arriving at the target node of a node pair, given that a random walk began at the source node and was constrained to follow the path type: $\mathrm{p}(t|s, \pi)$. There are several ways of computing this probability. The most straightforward method is to use a path-constrained breadth-first search to exhaustively enumerate all possible targets given a source node and a path type, count how frequently each target is seen, and normalize the distribution. This calculates the desired probability exactly, but at the cost of doing a breadth-first search (with

[1] The feature space consists of the set of all possible edge label sequences, with cardinality $\sum_{i=1}^{l} |\mathcal{R}|^i$, assuming a bound l on the maximum path length.

[2] A deterministic algorithm, such as a breadth-first search, could obviously be used here instead of random walks, and indeed Lao's original work did use a more exhaustive search. However, when moving to the larger graphs corresponding to the NELL and Freebase KBs, Lao (2011) (and all future work) switched to using random walks, because the graph was too large.

complexity proportional to the average per-edge-label out-degree to the power of the path length) per source node per path type.

There are three methods that can potentially reduce the computational complexity of this probability calculation. The first is to use random walks to approximate the probability via rejection sampling: for each path type and source node, a number of random walks are performed, attempting to follow the edge sequence corresponding to the path type. If a node is reached where it is no longer possible to follow the path type, the random walk is restarted. This does not reduce the time necessary to get an arbitrarily good approximation, but it does allow us to decrease computation time, even getting a fixed complexity, at the cost of accepting some error in our probability estimates. Second, Lao (2012) showed that when the target node of a query is known, the exponent can be cut in half by using a two-sided BFS. In this method, some careful bookkeeping is done with dynamic programming such that the probability can be computed correctly when the two-sided search meets at an intermediate node. Lao's dynamic programming technique is only applicable when the target node is known, however, and only cuts the exponent in half—this is still quite computationally intensive. Lastly, we could replace the BFS with a multiplication of adjacency matrices, which performs the same computation. The efficiency gain comes from the fact that we can just do the multiplication once per path type, instead of once per path type per source node. However, to correctly compute the probabilities for a (source, target) pair, we need to exclude from the graph the edge connecting that training instance. This means that the matrix computed for each path type *should* be different for each training instance, and so we either lose our efficiency gain or we accept incorrect probability estimates. In this work we use the rejection sampling technique.

As mentioned above, once the feature matrix has been computed in the second step of PRA, one can use any kind of classifier desired to learn a model and make predictions on test data.

3 Related Work

The task of knowledge base completion has seen a lot of attention in recent years, with entire workshops devoted to it (Suchanek et al., 2013). We will touch on three broad categories related to KB completion: the task of relation extraction, embedding methods for KB completion, and graph methods for KB completion.

Relation extraction. Relation extraction and knowledge base completion have the same goal: to predict new instances of relations in a formal knowledge base such as Freebase or NELL. The difference is that relation extraction focuses on determining what relationship is expressed by a particular sentence, while knowledge base completion tries to predict which relationships hold between which entities. A relation extraction system can be used for knowledge base completion, but typical KB completion methods do not make predictions on single sentences. This is easily seen in the line of work known as distantly-supervised relation extraction (Mintz et al., 2009; Hoffmann et al., 2011; Surdeanu et al., 2012); these models use the relation instances in a knowledge base as their only supervision, performing some heuristic mapping of the entities in text to the knowledge base, then using that mapping to train extractors for each relation in the KB. The cost of using these methods is that is it generally difficult to incorporate richer features from the knowledge base when predicting whether a particular sentence expresses a relation, and so techniques that make fuller use of the KB can perform better on the KB completion task (Weston et al., 2013; Riedel et al., 2013).

Embedding methods for KB completion. There has been much recent work that attempts to perform KB completion by learning an embedded representation of entities and relations in the KB and then using these representations to infer missing relationships. Some of earliest work along these lines were the RESCAL model (Nickel et al., 2011) and Structured Embeddings (Bordes et al., 2011). These were soon followed by TransE (Bordes et al., 2013), Neural Tensor Networks (Socher et al., 2013), and many variants on all of these algorithms (Chang et al., 2014; García-Durán et al., 2014; Wang et al., 2014). These methods perform well when there is structural redundancy in the knowledge base tensor, but when the tensor (or individual relations in the tensor) has high rank, learning good embeddings can be challenging. The ARE model (Nickel et al., 2014) attempted to address this by only making the embeddings capture the residual of the tensor that cannot be readily predicted from the graph-based techniques mentioned below.

Dataset	Method	MAP
Freebase	Probabilities	.337
	Binarized	.344
NELL	Probabilities	.303
	Binarized	.319

Table 1: Using binary feature values instead of random walk probabilities gives statistically indistinguishable performance. The p-value on the Freebase data is .55, while it is .25 for NELL.

Graph-based methods for KB completion. A separate line of research into KB completion can be broadly construed as performing some kind of inference over graphs in order to predict missing instances in a knowledge base. Markov logic networks (Richardson and Domingos, 2006) fall into this category, as does ProPPR (Wang et al., 2013) and many other logic-based systems. PRA, the main subject of this paper, also fits in this line of work. Work specifically with PRA has ranged from incorporating a parsed corpus as additional evidence when doing random walk inference (Lao et al., 2012), to introducing better representations of the text corpus (Gardner et al., 2013; Gardner et al., 2014), and using PRA in a broader context as part of Google's Knowledge Vault (Dong et al., 2014). An interesting piece of work that combines embedding methods with graph-based methods is that of Neelakantan et al. (2015), which uses a recursive neural network to create embedded representations of PRA-style paths.

4 Motivation

We motivate our modifications to PRA with three observations. First, it appears that binarizing the feature matrix produced by PRA, removing most of the information gained in PRA's second step, has no significant impact on prediction performance in knowledge base completion tasks. We show this on the NELL KB and the Freebase KB in Table 1.[3] The fact that random walk probabilities carry no additional information for this task over binary features is surprising, and it shows that the second step of PRA spends a lot of its computation for no discernible gain in performance.

Second, Neelakantan et al. (2015) presented experiments showing a substantial increase in performance from using a much larger set of features in a PRA-like model.[4] All of their experiments used binary features, so this is not a direct comparison of random walk probabilities versus binarized features, but it shows that increasing the feature size beyond the point that is computationally feasible with random walk probabilities seems useful. Additionally, they showed that using path bigram features, where each sequential pair of edges types in each path was added as an additional feature to the model, gave a significant increase in performance. These kind of features are not representable in the traditional formulation of PRA.

Lastly, the method used to compute the random walk probabilities—rejection sampling—makes the inclusion of more expressive features problematic. Consider the path bigrams mentioned above; one could conceivably compute a probability for a path type that only specifies that the last edge type in the path must be r, but it would be incredibly inefficient with rejection sampling, as most of the samples would end up rejected (leaving aside the additional issues of an unspecified path length). In contrast, if the features simply signify whether a particular path type exists in the graph, without any associated probability, these kinds of features are very easy to compute.

Given this motivation, our work attempts to improve both the efficiency and the expressivity of PRA by removing the second step of the algorithm. Efficiency is improved because the second step is the most computationally expensive, and expressivity is improved by allowing features that cannot be reasonably computed with rejection sampling. We show experimentally that the techniques we introduce do indeed improve performance quite substantially.

5 Subgraph Feature Extraction

In this section we discuss how SFE constructs feature matrices over node pairs in a graph using just a single search over the graph for each node (which is comparable to only using the first step of PRA). As outlined in Section 2, the first step of PRA does a series of random walks from each source and target node (s_j, t_j) in a dataset $\mathcal{D}$. In

[3]The NELL data and experimental protocol is described in Section 6.1. The Freebase data consists of 24 relations from the Freebase KB; we used the same data used by Gardner et al. (2014).

[4]Note that while Neelakantan et al. called the baseline they were comparing to "PRA", they only used the first step of the algorithm to produce path types, and thus did not really compare against PRA per se. It is their version of "PRA" that we formalize and expand as SFE in this work.

PRA these random walks are used to find a relatively small set of potentially useful path types for which more specific random walk probabilities are then computed, at great expense. In our method, subgraph feature extraction (SFE), we stop after this first set of random walks and instead construct a binary feature matrix.

More formally, for each node n in the data (where n could be either a source node or a target node), SFE constructs a subgraph centered around that node using k random walks. Each random walk that leaves n follows some path type π and ends at some intermediate node i. We keep all of these (π, i) pairs as the characterization of the subgraph around n, and we will refer to this subgraph as G_n. To construct a feature vector for a source-target pair (s_j, t_j), SFE takes the subgraphs G_{s_j} and G_{t_j} and merges them on the intermediate nodes i. That is, if an intermediate node i is present in both G_{s_j} and G_{t_j}, SFE takes the path types π corresponding to i and combines them (reversing the path type coming from the target node t_j). If some intermediate node for the source s_j happens to be t_j, no combination of path types is necessary (and similarly if an intermediate node for the target t_j is s_j—the path only needs to be reversed in this case). This creates a feature space that is exactly the same as that constructed by PRA: sequences of edge types that connect a source node to a target node. To construct the feature vector SFE just takes all of these combined path types as binary features for (s_j, t_j). Note, however, that we need not restrict ourselves to only using the same feature space as PRA; Section 5.1 will examine extracting more expressive features from these subgraphs.

This method for generating a feature matrix over node pairs in a graph is much simpler and less computationally expensive than PRA, and from looking at Table 1 we would expect that it would perform on par with PRA with drastically reduced computation costs. Some experimentation shows that it is not that simple. Table 2 shows a comparison between PRA and SFE on 10 NELL relations.[5] SFE has a higher mean average precision, but the difference is not statistically significant. There is a large variance in SFE's performance, and on some relations PRA performs better.

We examined the feature matrices computed by these methods and discovered that the reason for the inconsistency of SFE's improvement is because its random walks are all *unconstrained*. Consider the case of a node with a very high degree, say 1000. If we only do 200 random walks from this node, we cannot possibly get a complete characterization of the graph even one step away from the node. If a particularly informative path is <CITYINSTATE, STATEINCOUNTRY>, and both the city from which a random walk starts and the intermediate state node have very high degree, the probability of actually finding this path type using unconstrained random walks is quite low. This is the benefit gained by the *path-constrained* random walks performed by PRA; PRA leverages training instances with relatively low degree and aggregation across a large number of instances to find path types that are potentially useful. Once they are found, significant computational effort goes into discovering whether each path type exists for *all* (s, t) pairs. It is this computational effort that allows the path type <CITYINSTATE, STATEINCOUNTRY> to have a non-zero value even for very highly connected nodes.

Method	MAP	Ave. Features
PRA	.3704	835
SFE	.4007	8275

Table 2: Comparison of PRA and SFE on 10 NELL relations. The difference shown is not statistically significant.

How do we mitigate this issue, so that SFE can consistently find these path types? It seems the only option without resorting to a similar two-step process to what PRA uses is to do a more exhaustive search. PRA uses random walks to improve scalability on very large graphs, particularly because the second step of the algorithm is so expensive. However, if we are only doing a single search, and the graph fits in memory, a few steps of a breadth-first search (BFS) per node is not infeasible. We can make the BFS more tractable by excluding edge types whose fan out is too high. For example, at a type node in Freebase, there could be thousands of edges of type /TYPE/OBJECT/TYPE; if there are a large number of edges of the same type leaving a node, we do not include those edges in the BFS. Note that because the type node will still be counted as an intermediate node in the subgraph, we can still find paths that go through that

[5]The data and evaluation methods are described more fully in Section 6.1. These experiments were conducted on a different development split of the same data.

Method	MAP	Ave. Features	Time
PRA	.3704	835	44 min.
SFE-RW	.4007	8275	6 min.
SFE-BFS	.4799	237853	5 min.

Table 3: Comparison of PRA and SFE (with PRA-style features) on 10 NELL relations. SFE-RW is not statistically better than PRA, but SFE-BFS is ($p < 0.05$).

node; we just do not continue searching if the out-degree of a particular edge type is too high.

When using a BFS instead of random walks to obtain the subgraphs G_{s_j} and G_{t_j} for each node pair, we saw a dramatic increase in the number of path type features found and a substantial increase in performance.[6] These results are shown in Table 3; SFE-RW is our SFE implementation using random walks, and SFE-BFS uses a BFS.

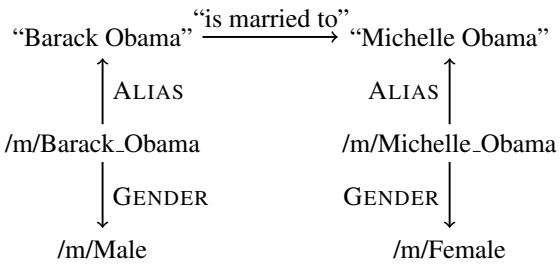
5.1 More expressive features

The description above shows how to recreate the feature space used by PRA using our simpler subgraph feature extraction technique. As we have mentioned, however, we need not restrict ourselves to merely recreating PRA's feature space. Eliminating random walk probabilities allows us to extract a much richer set of features from the subgraphs around each node, and here we present the feature extractors we have experimented with. Figure 1 contains an example graph that we will refer to when describing these features.

PRA-style features. We explained these features in Section 5, but we repeat them here for consistency, and use the example to make the feature extraction process more clear. Relying on the notation introduced earlier, these features are generated by intersecting the subgraphs G_s and G_t on the intermediate nodes. That is, when the subgraphs share an intermediate node, we combine the path types found from the source and target to that node. In the example in Figure 1, there are two common intermediate nodes ("Barack Obama" and "Michelle Obama"), and combining the path types corresponding to those nodes gives the same path type: -ALIAS-"is married to"-ALIAS^{-1}-.

Path bigram features. In Section 4, we mentioned that Neelakantan et al. (2015) experimented with using path bigrams as features. We include those features here as well. For any path π between a source node s and a target node t, we create a feature for each relation bigram in the path type. In the example in Figure 1, this would result in the features "BIGRAM:@START@-ALIAS", "BIGRAM:ALIAS-is married to", "BIGRAM:is married to-ALIAS", and "BIGRAM:ALIAS-@END@".

[6] One should not read too much into the decrease in running time between SFE-RW and SFE-BFS, however, as it was mostly an implementation detail.



Subgraph for /m/Barack_Obama	
π	i
-ALIAS-	"Barack Obama"
-GENDER-	/m/Male
-ALIAS-"is married to"-	"Michelle Obama"

Subgraph for /m/Michelle_Obama	
π	i
-ALIAS-	"Michelle Obama"
-GENDER-	/m/Female
-ALIAS-"is married to"$^{-1}$-	"Barack Obama"

Figure 1: An example graph, with subgraphs extracted for two nodes.

One-sided features. We use *one-sided path* to describe a sequence of edges that starts at a source or target node in the data, but does not necessarily terminate at a corresponding target or source node, as PRA features do. Following the notation introduced in Section 5, we use as features each (π, i) pair in the subgraph characterizations G_s and G_t, along with whether the feature came from the source node or the target node. The motivation for these one-sided path types is to better model which sources and targets are good candidates for participating in a particular relation. For example, not all cities participate in the relation CITYCAPITALOFCOUNTRY, even though the domain of the relation is all cities. A city that has a large number of sports teams may be more likely to be a capital city, and these one-sided features could easily capture that kind of information.

Example one-sided features from the example in Figure 1 would be "SOURCE:-GENDER-:male", "TARGET:-GENDER-:female",

"SOURCE:-ALIAS-:Barack Obama", and "SOURCE:-ALIAS-is married to-:Michelle Obama".

One-sided feature comparisons. We can expand on the one-sided features introduced above by allowing for comparisons of these features in certain circumstances. For example, if both the source and target nodes have an age or gender encoded in the graph, we might profitably use comparisons of these values to make better predictions.

Drawing again on the notation from Section 5, we can formalize these features as analogous to the pairwise PRA features. To get the PRA features, we intersect the intermediate nodes i from the subgraphs G_s and G_t, and combine the path types π when we find common intermediate nodes. To get these comparison features, we instead intersect the subgraphs on the path types, and combine the intermediate nodes when there are common path types. That is, if we see a common path type, such as -GENDER-, we will construct a feature representing a comparison between the intermediate node for the source and the target. If the values are the same, this information can be captured with a PRA feature, but it cannot be easily captured by PRA when the values are different.

In the example in Figure 1, there are two common path types: -ALIAS-, and -GENDER-. The feature generated from the path type -GENDER- would be "COMPARISON:-GENDER-:/m/Male:/m/Female".

Vector space similarity features. Gardner et al. (2014) introduced a modification of PRA's random walks to incorporate vector space similarity between the relations in the graph. On the data they were using, a graph that combined a formal knowledge base with textual relations extracted from text, they found that this technique gave a substantial performance improvement. The vector space random walks only affected the second step of PRA, however, and we have removed that step in SFE. While it is not as conceptually clean as the vector space random walks, we can obtain a similar effect with a simple feature transformation using the vectors for each relation. We obtain vector representations of relations through factorization of the knowledge base tensor as did Gardner et al., and replace each edge type in a PRA-style path with edges that are similar to it in the vector space. We also introduce a special "any edge" symbol, and say that all other edge types are similar to this edge type.

To reduce the combinatorial explosion of the feature space that this feature extractor creates, we only allow replacing one relation at a time with a similar relation. In the example graph in Figure 1, and assuming that "spouse of" is found to be similar to "is married to", some of the features extracted would be the following: "VECSIM:-ALIAS-is married to-ALIAS-", "VECSIM:-ALIAS-spouse of-ALIAS-", "VECSIM:-ALIAS-@ANY_REL@-ALIAS-", and "VECSIM:-@ANY_REL@-is married to-ALIAS-". Note that the first of those features, "VECSIM:-ALIAS-is married to-ALIAS-", is necessary even though it just duplicates the original PRA-style feature. This allows path types with different but similar relations to generate the same features.

Any-Relation features. It turns out that much of the benefit gained from Gardner et al.'s vector space similarity features came from allowing any path type that used a surface edge to match *any* other surface edge with non-zero probability.[7] To test whether the vector space similarity features give us any benefit over just replacing relations with dummy symbols, we add a feature extractor that is identical to the one above, assuming an empty vector similarity mapping. The features extracted from Figure 1 would thus be "ANYREL:-@ANY_REL@-is married to-ALIAS", "ANYREL:-ALIAS-@ANY_REL@-ALIAS", "ANYREL:-ALIAS-is married to-@ANY_REL@".

6 Experiments

Here we present experimental results evaluating the feature extractors we presented, and a comparison between SFE and PRA. As we showed in Section 5 that using a breadth-first search to obtain subgraphs is superior to using random walks, all of the experiments presented here use the BFS implementation of SFE.

6.1 Data

To evaluate SFE and the feature extractors we introduced, we learned models for 10 relations in the NELL KB. We used the same data as Gardner et al. (2014), using both the formal KB relations and the surface relations extracted from text in our

[7] Replacing all surface edges with a single dummy relation gives performance close to vector space PRA. The vector space walks do statistically outperform this, but the extra gain is small.

graph. We used logistic regression with elastic net (L1 and L2) regularization. We tuned the L1 and L2 parameters for each method on a random development split of the data, then used a new split of the data to run the final tests presented here.

The evaluation metrics we use are mean average precision (MAP) and mean reciprocal rank (MRR). We judge statistical significance using a paired permutation test, where the average precision[8] on each relation is used as paired data.

6.2 On Obtaining Negative Evidence

One important practical issue for most uses of PRA is the selection of negative examples for training a model. Typically a knowledge base only contains positive examples of a relation, and it is not clear a priori what the best method is for obtaining negative evidence. Prior work with PRA makes a closed world assumption, treating any (s, t) pair not seen in the knowledge base as a negative example. Negative instances are selected when performing the second step of PRA—if a random walk from a source ends at a target that is not a known correct target for that source, that source-target pair is used as a negative example.

SFE only scores (source, target) pairs; it has no mechanism similar to PRA's that will find potential targets given a source node. We thus need a new way of finding negative examples, both at training time and at test time. We used a simple technique to find negative examples from a graph given a set of positive examples, and we used this to obtain the training and testing data used in the experiments below. Our technique takes each source and target node in the given positive examples and finds other nodes in the same category that are close in terms of personalized page rank (PPR). We then sample new (source, target) pairs from these lists of similar nodes, weighted by their PPR score (while also allowing the original source and target to be sampled). These become our negative examples, both at training and at testing time.

Because this is changing the negative evidence available to PRA at training time, we wanted to be sure we were not unfairly hindering PRA in our comparisons. If it is in fact better to let PRA find its own negative examples at training time, instead of the ones sampled based on personalized page rank, then we should let PRA get its own negative evidence. We thus ran an experiment to see under which training regime PRA performs better. We created a test set with both positive and negative examples as described in the paragraph above, and at training time we compared two techniques: (1) letting PRA find its own negative examples through its random walks, and (2) only using the negative examples selected by PPR. As can be seen in Table 4, the difference between the two training conditions is very small, and it is not statistically significant. Because there is no significant difference between the two conditions, in the experiments that follow we give both PRA and SFE the same training data, created through the PPR-based sampling technique described above.

Method	MAP
PRA's random walks	.359
PPR-based sampling	.363

Table 4: Comparing methods for obtaining negative evidence available at training time. The difference seen is not statistically significant ($p = .77$).

6.3 Results

We first examine the effect of each of the feature types introduced in Section 5.1. The results are shown in Table 5. We can see that, for this data, the comparisons and one-sided features did not improve performance (and the decreases are not statistically significant). Bigram features do appear to improve performance, though the improvement was not consistent enough across relations to achieve statistical significance. The vector similarity features do improve performance, with p-values hovering right at 0.05 when comparing against only PRA features and PRA + bigram features. The any rel features, however, do statistically improve over all other methods ($p <= 0.01$) except the PRA + vec sim result ($p = .21$).

Finally, we present a comparison between PRA, PRA with vector space random walks, and the best SFE result from the ablation study. This is shown in Table 6. SFE significantly outperforms PRA, both with and without the vector space random walks presented by Gardner et al. (2014).

6.4 Discussion

When using only PRA-style features with SFE, the highest weighted features were almost always those of the form -ALIAS-[some textual relation]-ALIAS^{-1}-. For example, for the relation WRITER-

[8] Average precision is equivalent to the area under a precision/recall curve.

Feature Types	MAP	MRR	Features
PRA-style features	.431	.806	240k
+ Comparisons	.405	.833	558k
+ One-sided	.389	.800	1,227k
+ One-sided + Comps.	.387	.817	1,544k
+ Bigrams	.483	1.00	320k
+ Vector similarity	.514	.910	3,993k
+ Bigrams + vec sim.	.490	.950	4,073k
+ Any Rel	**.528**	.933	649k

Table 5: SFE feature ablation study. All rows use PRA features. PRA + any rel is statistically better than all other methods except PRA + vec sim, and most of the other differences are not significant.

Method	MAP	MRR
PRA	.362	.717
Vector space PRA	.432	.850
SFE (PRA + any rel features)	**.528**	.933

Table 6: Results of final comparison between SFE and PRA, with and without vector space similarity features. SFE is statistically better than both PRA methods ($p < 0.005$).

WROTEBOOK, the textual relations used in this feature might be "wrote", "describes in", "writes in", and "expresses in". These are the same feature types that PRA itself finds to have the highest weight, also, though SFE finds many more of them than PRA does, as PRA has to do aggressive feature selection. For this particular dataset, where the graph consists of edges from a formal KB mixed with edges from extracted textual relations, these kinds of features are by far the most useful, and most of the improvements seen by the additional feature types we used with SFE come from more compactly encoding these features.

For example, the path bigram features can encode the fact that there exists a path from the source to the target that begins or ends with an ALIAS edge. This captures in just two features all path types of the form -ALIAS-[some textual relation]-ALIAS^{-1}-, and those two bigram features are almost always the highest weighted features in models where they are used.

However, the bigram features do not capture those path types exactly. The Any-Rel features were designed in part specifically for this path type, and they capture it exactly with a single feature. For all 10 relations, the feature "ANYREL:-ALIAS-@ANY_REL@-ALIAS^{-1}" is the highest weighted feature. This is because, for the relations we experimented with, knowing that *some* relationship is expressed in text between a particular pair of KB entities is a very strong indication of a single KB relation. There are only so many possible relationships between cities and countries, for instance. These features are much less informative between entity types where more than one relation is possible, such as between people.

While the bigram and any-rel features capture succintly whether textual relations are present between two entities, the one-sided features are more useful for determining whether an entity fits into the domain or range of a particular relation. We saw a few features that did this, capturing fine-grained entity types. Most of the features, however, tended towards memorizing (and thus overfitting) the training data, as these features contained the names of the training entities. We believe this overfitting to be the main reason these features did not improve performance, along with the fact that the relations we tested do not need much domain or range modeling (as opposed to, e.g., SPOUSEOF or CITYCAPITALOFCOUNTRY).

7 Conclusion

We have explored several practical issues that arise when using the path ranking algorithm for knowledge base completion. An analysis of several of these issues led us to propose a simpler algorithm, which we called subgraph feature extraction, which characterizes the subgraph around node pairs and extracts features from that subgraph. SFE is both significantly faster and performs better than PRA on this task. We showed experimentally that we can reduce running time by an order of magnitude, while at the same time improving mean average precision from .432 to .528 and mean reciprocal rank from .850 to .933. This thus constitutes the best published results for knowledge base completion on NELL data. The code and data used in the experiments in this paper are available at http://rtw.ml.cmu.edu/emnlp2015_sfe/.

Abstract

Models that learn to represent textual and knowledge base relations in the same continuous latent space are able to perform joint inferences among the two kinds of relations and obtain high accuracy on knowledge base completion (Riedel et al., 2013). In this paper we propose a model that captures the compositional structure of textual relations, and jointly optimizes entity, knowledge base, and textual relation representations. The proposed model significantly improves performance over a model that does not share parameters among textual relations with common sub-structure.

1 Introduction

Representing information about real-world entities and their relations in structured knowledge base (KB) form enables numerous applications. Large, collaboratively created knowledge bases have recently become available e.g., Freebase (Bollacker et al., 2008), YAGO (Suchanek et al., 2007), and DBPedia (Auer et al., 2007), but even though they are impressively large, their coverage is far from complete. This has motivated research in automatically deriving new facts to extend a manually built knowledge base, by using information from the existing knowledge base, textual mentions of entities, and semi-structured data such as tables and web forms (Nickel et al., 2015).

In this paper we build upon the work of Riedel et al. (2013), which jointly learns continuous representations for knowledge base and textual relations. This common representation in the same vector space can serve as a kind of "universal schema" which admits joint inferences among

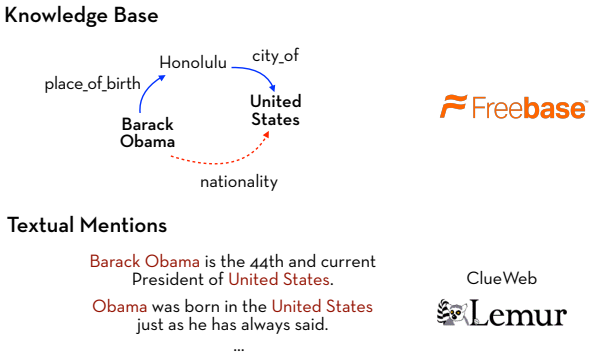

Figure 1: A knowledge base fragment coupled with textual mentions of pairs of entities.

KBs and text. The textual relations represent the relationships between entities expressed in individual sentences (see Figure 1 for an example). Riedel et al. (2013) represented each textual mention of an entity pair by the lexicalized dependency path between the two entities (see Figure 2). Each such path is treated as a separate relation in a combined knowledge graph including both KB and textual relations. Following prior work in latent feature models for knowledge base completion, every textual relation receives its own continuous representation, learned from the pattern of its co-occurrences in the knowledge graph.

However, largely synonymous textual relations often share common sub-structure, and are composed of similar words and dependency arcs. For example, Table 1 shows a collection of dependency paths co-occurring with the *person/organizations_founded* relation.

In this paper we model this sub-structure and share parameters among related dependency paths, using a unified loss function learning entity and relation representations to maximize performance on the knowledge base link prediction task.

We evaluate our approach on the FB15k-237 dataset, a knowledge base derived from the Free-

Lisbon, Portugal, 17-21 September 2015.

base subset FB15k (Bordes et al., 2013) and filtered to remove highly redundant relations (Toutanova and Chen, 2015). The knowledge base is paired with textual mentions for all entity pairs derived from ClueWeb12[1] with Freebase entity mention annotations (Gabrilovich et al., 2013).

We show that using a convolutional neural network to derive continuous representations for textual relations boosts the overall performance on link prediction, with larger improvement on entity pairs that have textual mentions.

2 Related Work

There has been a growing body of work on learning to predict relations between entities without requiring sentence-level annotations of textual mentions at training time. We group such related work into three groups based on whether KB, text, or both sources of information are used. Additionally, we discuss related work in the area of supervised relation extraction using continuous representations of text, even though we do not use supervision at the level of textual mentions.

Knowledge base completion

Nickel et al. (2015) provide a broad overview of machine learning models for knowledge graphs, including models based on observed graph features such as the path ranking algorithm (Lao et al., 2011), models based on continuous representations (latent features), and model combinations (Dong et al., 2014). These models predict new facts in a given knowledge base, based on information from existing entities and relations. From this line of work, most relevant to our study is prior work evaluating continuous representation models on the FB15k dataset. Yang et al. (2015) showed that a simple variant of a bilinear model DISTMULT outperformed TRANSE (Bordes et al., 2013) and more richly parameterized models on this dataset. We therefore build upon the best performing prior model DISTMULT from this line of work, as well as additional models E and F developed in the context of text-augmented knowledge graphs (Riedel et al., 2013), and extend them to incorporate compositional representations of textual relations.

[1] http://lemurproject.org/clueweb12/FACC1/

Relation extraction using distant supervision

A number of works have focused on extracting new instances of relations using information from textual mentions, without sophisticated modeling of prior knowledge from the knowledge base. Mintz et al. (2009) demonstrated that both surface context and dependency path context were helpful for the task, but did not model the compositional sub-structure of this context. Other work proposed more sophisticated models that reason about sentence-level hidden variables (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012) or model the noise arising from the incompleteness of knowledge bases and text collections (Ritter et al., 2013), *inter alia*. Our work focuses on representing the compositional structure of sentential context for learning joint continuous representations of text and knowledge bases.

Combining knowledge base and text information

A combination of knowledge base and textual information was first shown to outperform either source alone in the framework of path-ranking algorithms in a combined knowledge base and text graph (Lao et al., 2012). To alleviate the sparsity of textual relations arising in such a combined graph, (Gardner et al., 2013; Gardner et al., 2014) showed how to incorporate clusters or continuous representations of textual relations. Note that these vector representations are based on the co-occurrence patterns for the textual relations and not on their compositional structure. Co-occurrence based textual relation representations were also learned in (Neelakantan et al., 2015). Wang et al. (2014a) combined knowledge base and text information by embedding knowledge base entities and the words in their names in the same vector space, but did not model the textual co-occurrences of entity pairs and the expressed textual relations. Weston et al. (2013) combined continuous representations from a knowledge base and textual mentions for prediction of new relations. The two representations were trained independently of each other and using different loss functions, and were only combined at inference time. Additionally, the employed representations of text were non-compositional.

In this work we train continuous representations of knowledge base and textual relations jointly, which allows for deeper interactions between the

sources of information. We directly build on the universal schema approach of Riedel et al. (2013) as well as the universal schema extension of the DISTMULT model mentioned previously, to improve the representations of textual relations by capturing their compositional structure. Additionally, we evaluate the approach on a dataset that contains rich prior information from the training knowledge base, as well as a wealth of textual information from a large document collection.

Continuous representations for supervised relation extraction

In contrast to the work reviewed so far, work on sentence-level relation extraction using direct supervision has focused heavily on representing sentence context. Models using hand-crafted features have evolved for more than a decade, and recently, models using continuous representations have been found to achieve new state-of-the-art performance (Zeng et al., 2014; Gormley et al., 2015). Compared to work on representation learning for sentence-level context, such as this recent work using LSTM models on constituency or dependency trees (Tai et al., 2015), our approach using a one-hidden-layer convolutional neural network is relatively simple. However, even such a simple approach has been shown to be very competitive (Kim, 2014).

3 Models for knowledge base completion

We begin by introducing notation to define the task, largely following the terminology in Nickel et al. (2015). We assume knowledge bases are represented using RDF triples, in the form (*subject*, *predicate*, *object*), where the subject and object are entities and the predicate is the type of relation. For example, the KB fragment shown in Figure 1 is shown as a knowledge graph, where the entities are the nodes, and the relations are shown as directed labeled edges: we see three entities participating in three relation instances indicated by the edges. For brevity, we will denote triples by (e_s, r, e_o), where e_s and e_o denote the subject and object entities, respectively.

The task is, given a training KB consisting of entities with some relations between them, to predict new relations (links) that do not appear in the training KB. More specifically, we will build models that rank candidate entities for given queries $(e_s, r, ?)$ or $(?, r, e_o)$, which ask about the object or subject of a given relation.

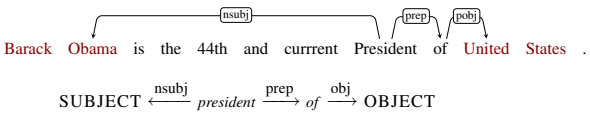

Figure 2: Textual relation extracted from an entity pair mention.

This task setting has been used in models for KB completion previously, e.g. (Dong et al., 2014; Gardner et al., 2014), even though it has not been standard in evaluations of distant supervision for relation extraction (Mintz et al., 2009; Riedel et al., 2013). The advantage of this evaluation setting is that it enables automatic evaluation without requiring humans to label candidate extractions, while making only a *local* closed world assumption for the completeness of the knowledge base — i.e., if one object e_o for a certain subject / relation pair (e_s, r) is present in the knowledge base, it is assumed likely that all other objects (e_s, r, e'_o) will be present. Such an assumption is particularly justified for nearly functional relations.

To incorporate textual information, we follow prior work (Lao et al., 2012; Riedel et al., 2013) and represent both textual and knowledge base relations in a single graph of "universal" relations. The textual relations are represented as full lexicalized dependency paths, as illustrated in Figure 2. An instance of the textual relation SUBJECT $\xleftarrow{\text{nsubj}}$ *president* $\xrightarrow{\text{prep}}$ *of* $\xrightarrow{\text{obj}}$ OBJECT connecting the entities BARACK OBAMA and UNITED STATES, is added to the knowledge graph based on this sentential occurrence.

To present the models for knowledge base completion based on such combined knowledge graphs, we first introduce some notation. Let $\mathcal{E}$ denote the set of entities in the knowledge graph and let $\mathcal{R}$ denote the set of relation types. We denote each possible triple as $T = (e_s, r, e_o)$ where $e_s, e_o \in \mathcal{E}, r \in \mathcal{R}$, and model its presence with a binary random variable $y_T \in \{0, 1\}$ which indicates whether the triple exists. The models we build score possible triples (e_s, r, e_o) using *continuous representations* (*latent features*) of the three elements of the triple. The models use scoring function $f(e_s, r, e_o)$ to represent the model's confidence in the existence of the triple. We present the models and then the loss function used to train

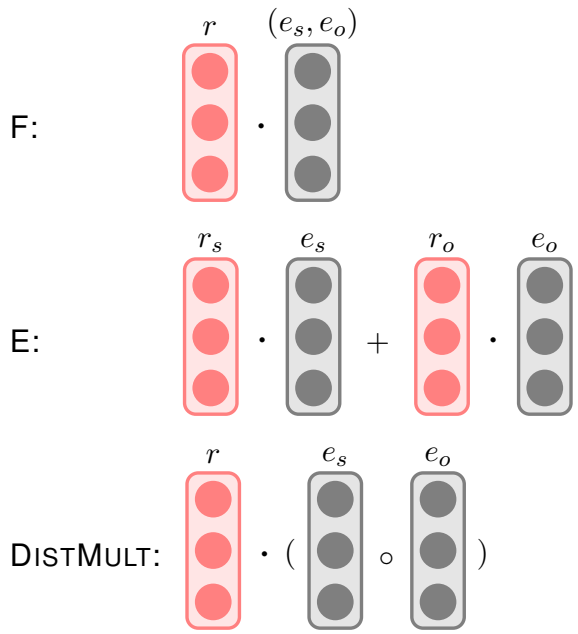

Figure 3: The continuous representations for model F, E and DISTMULT.

their parameters.

3.1 Basic Models

We begin with presenting the three models from prior work that this research builds upon. They all learn latent continuous representations of relations and entities or entity pairs, and score possible triples based on the learned continuous representations. Each of the models can be defined on a knowledge graph containing entities and KB relations only, or on a knowledge graph additionally containing textual relations. We use models F and E from (Riedel et al., 2013) where they were used for a combined KB+text graph, and model DISTMULT from (Yang et al., 2015), which was originally used for a knowledge graph containing only KB relations.

As shown in Figure 3, model F learns a K-dimensional latent feature vector for each candidate entity pair (e_s, e_o), as well as a same-dimensional vector for each relation r, and the scoring function is simply defined as their inner product: $f(e_s, r, e_o) = v(r)^\intercal v(e_s, e_o)$. Therefore, different pairs sharing the same entity would not share parameters in this model.

Model E does not have parameters for entity pairs, and instead has parameters for individual entities. It aims to capture the compatibility between entities and the subject and object positions of relations. For each relation type r, the model learns two latent feature vectors $v(r_s)$ and $v(r_o)$ of dimension K. For each entity (node) e_i, the model also learns a latent feature vector of the same dimensionality. The score of a candidate triple (e_s, r, e_o) is defined as $f(e_s, r, e_o) = v(r_s)^\intercal v(e_s) + v(r_o)^\intercal v(e_o)$. It can be seen that when a subject entity is fixed in a query $(e_s, r, ?)$, the ranking of candidate object entity fillers according to f does not depend on the subject entity but only on the relation type r.

The third model DISTMULT, is a special form of a bilinear model like RESCAL (Nickel et al., 2011), where the non-diagonal entries in the relation matrices are assumed to be zero. This model was proposed in Yang et al. (2015) and was shown to outperform prior work on the FB15k dataset. In this model, each entity e_i and each relation r is assigned a latent feature vector of dimension K. The score of a candidate triple (e_s, r, e_o) is defined as $f(e_s, r, e_o) = v(r)^\intercal \left(v(e_s) \circ v(e_o)\right)$, where $\circ$ denotes the element-wise vector product. In this model, entity pairs which share an entity also share parameters, and the ranking of candidate objects for queries $(e_s, r, ?)$ depends on the subject entity.

Denote $N_e = |\mathcal{E}|, N_r = |\mathcal{R}|$, and K = dimension of latent feature vectors, then model E has $KN_e + 2KN_r$ parameters and model DISTMULT has $KN_e + KN_r$ parameters. Model F has $KN_e^2 + KN_r$ parameters, although most entity pairs will not co-occur in the knowledge base or text.

In the basic models, knowledge base and textual relations are treated uniformly, and each textual relation receives its own latent representation of dimensionality K. When textual relations are added to the training knowledge graph, the total number of relations $|\mathcal{R}|$ grows substantially (it increases from 237 to more than 2.7 million for the dataset in this study), resulting in a substantial increase in the total number of independent parameters.

Note that in all of these models queries about the arguments of knowledge base relations $(e_s, r, ?)$ are answered by scoring functions looking only at the entity and KB relation representations, without using representations of textual mentions. The textual mention information and representations are only used at training time to improve the learned representations of KB relations and entities.

3.2 CONV: Compositional Representations of Textual Relations

In the standard latent feature models discussed above, each textual relation is treated as an atomic unit receiving its own set of latent features. However, many textual relations differ only slightly in the words or dependency arcs used to express the relation. For example, Table 1 shows several textual patterns that co-occurr with the relation *person/organizations_founded* in the training KB. While some dependency paths occur frequently, many very closely related ones have been observed only once. The statistical strength of the model could be improved if similar dependency paths have a shared parameterization. We build on work using similar intuitions for other tasks and learn compositional representations of textual relations based on their internal structure, so that the derived representations are accurate for the task of predicting knowledge base relations.

We use a convolutional neural network applied to the lexicalized dependency paths treated as a sequence of words and dependency arcs with direction. Figure 4 depicts the neural network architecture. In the first layer, each word or directed labeled arc is mapped to a continuous representation using an embedding matrix $\mathbf{V}$. In the hidden layer, every window of three elements is mapped to a hidden vector using position-specific maps $\mathbf{W}$, a bias vector $\mathbf{b}$, and a $\tanh$ activation function. A max-pooling operation over the sequence is applied to derive the final continuous representation for the dependency path.

The CONV representation of textual relations can be used to augment any of the three basic models. The difference between a basic model and its CONV-augmented variant is in the parameterization of textual mentions. The basic models learn distinct latent feature vectors of dimensionality K for all textual relation types, whereas the CONV models derive the K-dimensional latent feature vectors for textual relation types as the activation at the top layer of the convolutional network in Figure 4, given the corresponding lexicalized dependency path as input.

3.3 Training loss function

All basic and CONV-augmented models use the same training loss function. Our loss function is motivated by the link prediction task and the performance measures used. As previously mentioned, the task is to predict the subject or object entity for given held-out triples (e_s, r, e_o), i.e., to rank all entities with respect to their likelihood of filling the respective position in the triple[2]. We would thus like the model to score correct triples (e_s, r, e_o) higher than incorrect triples (e', r, e_o) and (e_s, r, e') which differ from the correct triple by one entity. Several approaches (Nickel et al., 2015) use a margin-based loss function. We use an approximation to the negative log-likelihood of the correct entity filler instead[3]. We define the conditional probabilities $p(e_o|e_s, r)$ and $p(e_s|r, e_o)$ for object and subject entities given the relation and the other argument as follows:

$$p(e_o|e_s, r; \Theta) = \frac{e^{f(e_s,r,e_o;\Theta)}}{\sum_{e' \in Neg(e_s,r,?)} e^{f(e_s,r,e';\Theta)}}$$

Conditional probabilities for subject entities $p(e_s|e_o, r; \Theta)$ are defined analogously. Here Θ denotes all the parameters of latent features. The denominator is defined using a set of entities that do not fill the object position in any relation triple $(e_s, r, ?)$ in the training knowledge graph. Since the number of such entities is impractically large, we sample negative triples from the full set. We also limit the candidate entities to ones that have types consistent with the position in the relation triple (Chang et al., 2014; Yang et al., 2015), where the types are approximated following Toutanova and Chen (2015). Additionally, since the task of predicting textual relations is auxiliary to the main task, we use a weighting factor τ for the loss on predicting the arguments of textual relations (Toutanova and Chen, 2015).

Denote $\mathcal{T}$ as a set of triples, we define the loss $L(\mathcal{T}; \Theta)$ as:

$$\begin{aligned} L(\mathcal{T}; \Theta) \;=\; & -\sum_{(e_s,r,e_o) \in \mathcal{T}} \log p(e_o|e_s, r; \Theta) \\ & -\sum_{(e_s,r,e_o) \in \mathcal{T}} \log p(e_s|e_o, r; \Theta) \end{aligned}$$

Let $\mathcal{T}_{\text{KB}}$ and $\mathcal{T}_{\text{text}}$ represent the set of knowledge base triples and textual relation triples respectively. The final training loss function is de-

[2] Our experimental comparison focuses on predicting object entities only, but we consider both argument types in the training loss function.

[3] Note that both margin-based and likelihood-based loss functions are susceptible to noise from potential selection of false negative examples. An empirical comparison of training loss functions would be interesting.

Table 1: Textual patterns occurring with entity pairs in a *person/organizations_founded* relationship. The count indicates the number of training set instances that have this KB relation, which co-occur with each textual pattern.

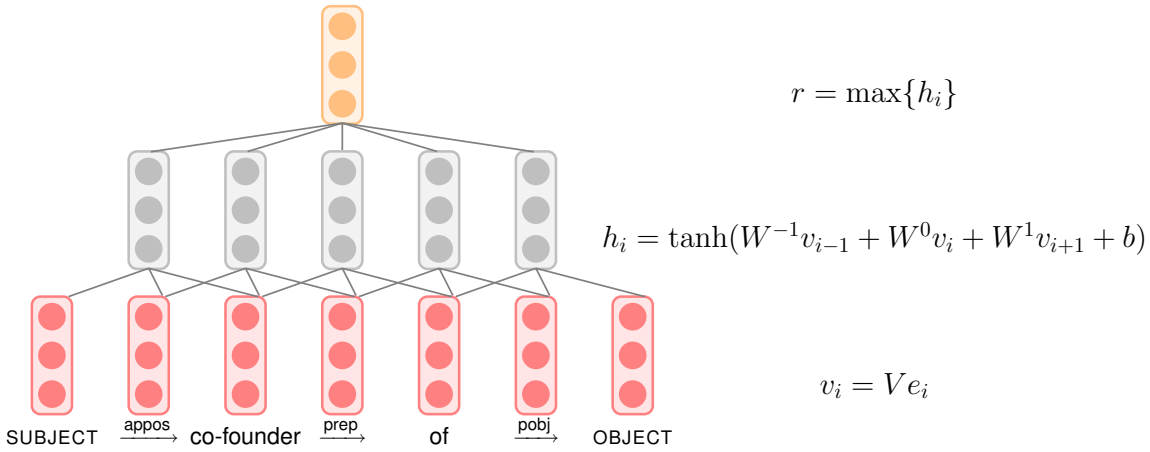

Figure 4: The convolutional neural network architecture for representing textual relations.

fined as:

$$L(\mathcal{T}_{\text{KB}}; \Theta) + \tau L(\mathcal{T}_{\text{text}}; \Theta) + \lambda \|\Theta\|^2,$$

where λ is the regularization parameter, and τ is the weighing factor of the textual relations.

The parameters of all models are trained using a batch training algorithm. The gradients of the basic models are straightforward to compute, and the gradients of the convolutional network parameters for the CONV-augmented models are also not hard to derive using back-propagation.

4 Experiments

Dataset and Evaluation Protocol

We use the FB15k-237 [4] dataset, which is a subset of FB15k (Bordes et al., 2013) that excludes redundant relations and direct training links for held-out triples, with the goal of making the task more realistic (Toutanova and Chen, 2015). The FB15k dataset has been used in multiple studies on knowledge base completion (Wang et al., 2014b; Yang et al., 2015). Textual relations for

[4] Check the first author's website for a release of the dataset.

FB15k-237 are extracted from 200 million sentences in the ClueWeb12 corpus coupled with Freebase mention annotations (Gabrilovich et al., 2013), and include textual links of all co-occurring entities from the KB set. After pruning[5], there are 2.7 million unique textual relations that are added to the knowledge graph. The set of textual relations is larger than the set used in Toutanova and Chen (2015) (25,000 versus 2.7 million), leading to improved performance.

The number of relations and triples in the training, validation and test portions of the data are given in Table 2. The two rows list statistics for the KB and text portions of the data separately. The 2.7 million textual relations occur in 3.9 million text triples. Almost all entities occur in textual relations (13,937 out of 14,541). The numbers of triples for textual relations are shown as zero for the validation and test sets because we don't evaluate on prediction of textual relations (all text triples are used in training). The percentage of KB triples that have textual relations for their pair of entities is 40.5% for the training, 26.6% for the validation, and 28.1% for the test set. While 26.6% of the validation set triples have textual mentions, the percentage with textual relations that have been seen in the training set is 18.4%. Having a mention increases the chance that a random entity pair has a relation from 0.1% to 5.0% — a fifty-fold increase.

Given a set of triples in a set disjoint from a training knowledge graph, we test models on predicting the object of each triple, given the subject and relation type. We rank all entities in the training knowledge base in order of their likelihood of filling the argument position. We report the mean reciprocal rank (MRR) of the correct entity, as well as HITS@10 — the percentage of test triples for which the correct entity is ranked in the top 10. We use *filtered* measures following the protocol proposed in Bordes et al. (2013) — that is, when we rank entities for a given position, we remove all other entities that are known to be part of an existing triple in the training, validation, or test set. This avoids penalizing the model for ranking other correct fillers higher than the tested entity.

[5]The full set of 37 million textual patterns connecting the entity pairs of interest was pruned based on the count of patterns and their tri-grams, and their precision in indicating that entity pairs have KB relations.

Implementation details

We used a value of $\lambda = 1$ for the weight of the L_2 penalty for the main results in Table 3, and present some results on the impact of λ at the end of this section. We used batch optimization after initial experiments with AdaGrad showed inferior performance. L-BFGS (Liu and Nocedal, 1989) and RProp (Riedmiller and Braun, 1993) were found to converge to similar function values, with RProp converging significantly faster. We thus used RProp for optimization. We initialized the KB+text models from the KB-only models and also from random initial values (sampled from a Gaussian distribution), and stopped optimization when the overall MRR on the validation set decreased. For each model type, we chose the better of random and KB-only initialization. The word embeddings in the CONV models were initialized using the 50-dimensional vectors from Turian et al. (2010) in the main experiments, with a slight positive impact. The effect of initialization is discussed at the end of the section.

The number of negative examples for each triple was set to 200. Performance improved substantially when the number of negative examples was increased and reached a plateau around 200. We chose the optimal number of latent feature dimensions via a grid search to optimize MRR on the validation set, testing the values 5, 10, 15, 35, 50, 100, 200 and 500. We also performed a grid search over the values of the parameter τ, testing values in the set $\{0.01, 0.1, 0.25, 0.5, 1\}$. The best dimension for latent feature vectors was 10 for most KB-only models (not including model F), and 5 for the two model configurations including F. We used $K = 10$ for all KB+text models, as higher dimension was also not helpful for them.

Experimental results

In Table 3 we show the performance of different models and their combinations[6], both when using textual mentions (*KB+text*), and when using only knowledge base relations (*KB only*). In the KB+text setting, we evaluate the contribution of the CONV representations of the textual relations. The upper portion of the Table shows the performance of models that have been trained using knowledge graphs including only knowledge

[6]Different models are combined by simply defining a combined scoring function which adds the scores from individual models. Combined models are trained jointly.

	# Relations	# Entities	# Triples in Train / Validation / Test
KB	237	14,541	272,115 / 17,535 / 20, 466
Text	2,740k	13,937	3,978k / 0 / 0

Table 3: Results on FB15k-237 for KB only and KB+text inference, with basic models versus the proposed CONV-augmented models. The values of the hyper-parameter τ (as shown in the Table) were chosen to maximize MRR on the validation set. The reported numbers were obtained for the test set.

base relations, and are not using any information from textual mentions. The lower portion of the Table shows the performance when textual relations are added to the training knowledge graph and the corresponding training loss function. Note that all models predict based on the learned knowledge base relation and entity representations, and the textual relations are only used at training time when they can impact these representations.

The performance of all models is shown as an overall MRR (scaled by 100) and HITS@10, as well as performance on the subset of triples that have textual mentions (column *With mentions*), and ones that do not (column *Without mentions*). Around 28% of the test triples have mentions and contribute toward the measures in the *With mentions* column, and the other 72% of the test triples contribute to the *Without mentions* column.

For the KB-only models, we see the performance of each individual model F, E, and DISTMULT. Model F was the best performing single model from (Riedel et al., 2013), but it does not perform well when textual mentions are not used. In our implementation of model F, we created entity pair parameters only for entity pairs that co-occur in the text data (Riedel et al. (2013) also trained pairwise vectors for co-occuring entities only, but all of the training and test tuples in their study were co-occurring)[7]. Without textual information, model F is performing essentially randomly, because entity pairs in the test sets do not occur in training set relations (by construction of the dataset). Model E is able to do surprisingly well, given that it is making predictions for each object position of a relation without considering the given subject of the relation. DISTMULT is the best performing single model. Unlike model F, it is able to share parameters among entity pairs with common subject or object entities, and, unlike model E, it captures some dependencies between the subject and object entities of a relation. The combination of models E+DISTMULT improves performance, but combining model F with the other two is not helpful.

The lower portion of Table 3 shows results when textual relations are added to the training knowledge graph. The basic models treat the textual relations as atomic and learn a separate latent feature vector for each textual relation. The CONV- models use the compositional representations of tex-

[7]Learning entity pair parameters for all entity pairs would result in 2.2 billion parameters for vectors with dimensionality 10 for our dataset. This was infeasible and was also not found useful based on experiments with vectors of lower dimensionality.

tual relations learned using the convolutional neural network architecture shown in Figure 4. We show the performance of each individual model and its corresponding variant with a CONV parameterization. For each model, we also show the optimal value of τ, the weight of the textual relations loss. Model F is able to benefit from textual relations and its performance increases by 2.5 points in MRR, with the gain in performance being particularly large on test triples with textual mentions. Model F is essentially limiting its space of considered argument fillers to ones that have co-occurred with the given subject entity. This gives it an advantage on test triples with textual mentions, but model F still does relatively very poorly overall when taking into account the much more numerous test triples without textual mentions. The CONV parameterization performs slightly worse in MRR, but slightly better in HITS@10, compared to the atomic parameterization. For model E and its CONV variant, we see that text does not help as its performance using text is the same as that when not using text and the optimal weight of the text is zero. Model DISTMULT benefits from text, and its convolutional text variant CONV-DISTMULT outperforms the basic model, with the gain being larger on test triples with mentions.

The best model overall, as in the KB-only case, is E+DISTMULT. The basic model benefits from text slightly and the model with compositional representations of textual patterns CONV-E+CONV-DISTMULT, improves the performance further, by 2.4 MRR overall, and by 5 MRR on triples with textual mentions. It is interesting that the text and the compositional representations helped most for this combined model. One hypothesis is that model E, which provides a prior over relation arguments, is needed in combination with DISTMULT to prevent the prediction of unlikely arguments based on noisy inference from textual patterns and their individual words and dependency links.

Hyperparameter Sensitivity

To gain insight into the sensitivity of the model to hyper-parameters and initialization, we report on experiments starting with the best model CONV-E + CONV-DISTMULT from Table 3 and varying one parameter at a time. This model has weight of the textual relations loss $\tau = 0.25$, weight of the L_2 penalty $\lambda = 1$, convolution window size of three, and is initialized randomly for the entity and KB relation vectors, and from pre-trained embeddings for word vectors (Turian et al., 2010). The overall MRR of the model is 40.4 on the validation set (test results are shown in the Table).

When the weight of τ is changed to 1 (i.e., equal contribution of textual and KB relations), the overall MRR goes down to 39.6 from 40.4, indicating the usefulness of weighting the two kinds of relations non-uniformly. When λ is reduced to 0.04, MRR is 40.0 and when λ is increased to 25, MRR goes down to 38.9. This indicates the L_2 penalty hyper-parameter has a large impact on performance. When we initialize the word embeddings randomly instead of using pre-trained word vectors, performance drops only slightly to 40.3. If we initialize from a model trained using KB-only information, performance goes down substantially to 38.7. This indicates that initialization is important and there is a small gain from using pre-trained word embeddings. There was a drop in performance to MRR 40.2 when using a window size of one for the convolutional architecture in Figure 4, and an increase to 40.6 when using a window size of five.

5 Conclusion and Future Work

Here we explored an alternative representation of textual relations for latent feature models that learn to represent knowledge base and textual relations in the same vector space. We showed that given the large degree of sharing of sub-structure in the textual relations, it was beneficial to compose their continuous representations out of the representations of their component words and dependency arc links. We applied a convolutional neural network model and trained it jointly with a model mapping entities and knowledge base relations to the same vector space, obtaining substantial improvements over an approach that treats the textual relations as atomic units having independent parameterization.

Abstract

Authoring a scientific paper is a complex process involving many decisions. We introduce a probabilistic model of some of the important aspects of that process: that authors have individual preferences, that writing a paper requires trading off among the preferences of authors as well as extrinsic rewards in the form of community response to their papers, that preferences (of individuals and the community) and tradeoffs vary over time. Variants of our model lead to improved predictive accuracy of citations given texts and texts given authors. Further, our model's posterior suggests an interesting relationship between seniority and author choices.

1 Introduction

Why do we write? As researchers, we write papers to report new scientific findings, but this is not the whole story. Authoring a paper involves a huge amount of decision-making that may be influenced by factors such as institutional incentives, attention-seeking, and pleasure derived from research on topics that excite us.

We propose that text collections and associated metadata can be analyzed to reveal optimizing behavior by authors. Specifically, we consider the ACL Anthology Network Corpus (Radev et al., 2013), along with author and citation metadata. Our main contribution is a method that infers two kinds of quantities about an author: her associations with interpretable research topics, which might correspond to relative expertise or merely to preferences among topics to write about; and a tradeoff coefficient that estimates the extent to which she writes papers that will be cited versus papers close to her preferences.

The method is based on a probabilistic model that incorporates assumptions about how authors decide what to write, how joint decisions work when papers are coauthored, and how individual and community preferences shift over time. Central to our model is a low-dimensional topic representation shared by authors (in defining preferences), papers (i.e., what they are "about"), and the community as a whole (in responding with citations). This method can be used to make predictions; empirically, we find that:

1. topics discovered by generative models outperform a strong text regression baseline (Yogatama et al., 2011) for citation count prediction;
2. such models do better at that task *without* modeling author utility as we propose; and
3. the author utility model leads to better predictive accuracy when answering the question, "given a set of authors, what are they likely to write?"

This method can also be used for exploration and to generate hypotheses. We provide an intriguing example relating author tradeoffs to age within the research community.

2 Notation and Representations

In the following, a document d will be represented by a vector $\boldsymbol{\theta}_d \in \mathbb{R}^K$. The dimensions of this vector might correspond to elements of a vocabulary, giving a "bag of words" encoding; in this work they correspond to latent topics.

Document d is assumed to elicit from the scientific community an observable response y_d, which might correspond to the number of citations (or downloads) of the paper.

Each author a is associated with a vector $\boldsymbol{\eta}_a \in \mathbb{R}^K$, with dimensions indexed the same as documents. Below, we will refer to this vector as a's "preferences," though it is important to remember that they could also capture an author's *expertise*,

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1510–1519,
Lisbon, Portugal, 17-21 September 2015.

and the model makes no attempt to distinguish between them. We use "preferences" because it is a weaker theoretical commitment.

3 Author Utility Model

We describe the components of our model—author utility (§3.1), coauthorship (§3.2), topics (§3.3), and temporal dynamics (§3.4)—then give the full form in §3.5.

3.1 Modeling Utility

Our main assumption about author a is that she is an optimizer: when writing document d she seeks to increase the response y_d while keeping the contents of d, $\boldsymbol{\theta}_d$, "close" to her preferences $\boldsymbol{\eta}_a$. We encode her objectives as a utility function to be maximized with respect to $\boldsymbol{\theta}_d$:

$$U(\boldsymbol{\theta}_d) = \kappa_a y_d - \frac{1}{2}\|\boldsymbol{\theta}_d - (\boldsymbol{\eta}_a + \boldsymbol{\epsilon}_{d,a})\|_2^2 \quad (1)$$

where $\boldsymbol{\epsilon}_{d,a}$ is an author-paper-specific idiosyncratic randomness that is unobserved to us but assumed known to the author. (This is a common assumption in discrete choice models. It is often called a "random utility model.")

Notice the tradeoff between maximizing the response y_d and staying close to one's preferences. We capture these competing objectives by formulating the latter as a squared Euclidean distance between $\boldsymbol{\eta}_a$ and $\boldsymbol{\theta}_d$, and encoding the tradeoff between extrinsic (citation-seeking) and intrinsic (preference-satisfying) objectives as the (positive) coefficient κ_a. If κ_a is large, a might be understood as a citation-maximizing agent; if κ_a is small, a might appear to care much more about certain kinds of papers ($\boldsymbol{\eta}_a$) than about citation.

This utility function considers only two particular facets of author writing behavior; it does not take into account other factors that may contribute to an author's objective. For this reason, some care is required in interpreting quantities like κ_a. For example, divergence between a particular $\boldsymbol{\eta}_a$ and $\boldsymbol{\theta}_d$ might suggest that a is open to new topics, not merely hungry for citations. Other motivations, such as reputation (notoriously difficult to measure), funding maintenance, and the preferences of peer referees are not captured in this model. Similarly for preferences $\boldsymbol{\eta}_a$, a large value in this vector might reflect a's skill or the preferences of a's sponsors rather than a's personal interest the topic.

Next, we model the response y_d. We assume that responses are driven largely by topics, with some noise, so that

$$y_d = \boldsymbol{\beta}^\top \boldsymbol{\theta}_d + \xi_d \quad (2)$$

where $\xi_d \sim \mathcal{N}(0, 1)$. Because the community's interest in different topics varies over time, $\boldsymbol{\beta}$ is given temporal dynamics, discussed in §3.4.

Under this assumption, the author's *expected* utility assuming she is aware of $\boldsymbol{\beta}$ (often called "rational expectations" in discrete choice models), is:

$$\mathbb{E}[U(\boldsymbol{\theta}_d)] = \kappa_a \boldsymbol{\beta}^\top \boldsymbol{\theta}_d - \frac{1}{2}\|\boldsymbol{\theta}_d - (\boldsymbol{\eta}_a + \boldsymbol{\epsilon}_{d,a})\|_2^2 \quad (3)$$

(This is obtained by plugging the expected value of y_d, from Eq. 2, into Eq. 1.)

An author's decision will therefore be

$$\hat{\boldsymbol{\theta}}_d = \arg\max_{\boldsymbol{\theta}} \kappa_a \boldsymbol{\beta}^\top \boldsymbol{\theta} - \frac{1}{2}\|\boldsymbol{\theta} - (\boldsymbol{\eta}_a + \boldsymbol{\epsilon}_{d,a})\|_2^2 \quad (4)$$

Optimality implies that $\hat{\boldsymbol{\theta}}_d$ solves the first-order equations

$$\kappa_a \beta_j - (\hat{\theta}_{d,j} - (\eta_{a,j} + \epsilon_{d,a,j})) = 0, \ \forall 1 \le j \le K \quad (5)$$

Eq. 5 highlights the tradeoff the author faces: when $\beta_j > 0$, the author will write more on $\theta_{d,j}$, while straying too far from $\eta_{a,j}$ incurs a penalty.

3.2 Modeling Coauthorship

Matters become more complicated when multiple authors write a paper together. Suppose the document d is authored by set of authors $\boldsymbol{a}_d$. We model the joint expected utility of $\boldsymbol{a}_d$ in writing $\boldsymbol{\theta}_d$ as the average of the group's utility.[1]

$$\mathbb{E}[U(\boldsymbol{\theta}_d)] = \frac{1}{|\boldsymbol{a}_d|}\sum_{a \in \boldsymbol{a}_d}\Big(\kappa_a \boldsymbol{\beta}^\top \boldsymbol{\theta}_d - \frac{1}{2} c_{d,a}\|\boldsymbol{\theta}_d - (\boldsymbol{\eta}_a + \boldsymbol{\epsilon}_{d,a})\|_2^2\Big) \quad (6)$$

where the "cost" term is scaled by $c_{d,a}$, denoting the fractional "contribution" of author a to document d. Thus, $\sum_{a \in \boldsymbol{a}_d} c_{d,a} = 1$, and we treat $\boldsymbol{c}_d$ as a latent categorical distribution to be inferred. The first-order equation becomes

$$\sum_{a \in \boldsymbol{a}_d} \kappa_a \boldsymbol{\beta} - c_{d,a}(\boldsymbol{\theta}_d - (\boldsymbol{\eta}_a + \boldsymbol{\epsilon}_{d,a})) = \mathbf{0} \quad (7)$$

[1] This assumption is a convenient starting place, but we can imagine revisiting it in future work. For example, an economist and a linguist with different expertise might derive "utility" from the collaboration that is non-linear in each one's individual preferences (Anderson, 2012). Further, contributions by complementary authors are not expected to be independent of each other.

3.3 Modeling Document Content

As noted before, there are many possible ways to represent and model document content $\boldsymbol{\theta}_d$. We treat $\boldsymbol{\theta}_d$ as (an encoding of) a mixture of topics. Following considerable past work, a "topic" is defined as a categorical distribution over observable tokens (Blei et al., 2003; Hofmann, 1999). Let $\boldsymbol{w}_d$ be the observed bag of tokens constituting document d. We assume each token is drawn from a mixture over topics:

$$p(\boldsymbol{w}_d \mid \boldsymbol{\theta}_d) = \sum_{\boldsymbol{z}_d} \prod_{i=1}^{N_d} p(z_{d,i} \mid \boldsymbol{\theta}_d) p(w_{d,i} \mid \boldsymbol{\phi}_{z_{d,i}})$$

where N_d is the number of tokens in document d, $z_{d,i}$ is the topic assignment for d's ith token $w_{d,i}$, and $\boldsymbol{\phi}_1, \ldots, \boldsymbol{\phi}_K$ are topic-term distributions. Note that $\boldsymbol{\theta}_d \in \mathbb{R}^K$; we define $p(z \mid \boldsymbol{\theta}_d)$ as a categorical draw from the softmax-transformed $\boldsymbol{\theta}_d$ (Blei and Lafferty, 2007).

Using topic mixtures instead of a bag of words provides us with a low-dimensional interpretable representation that is useful for analyzing authors' behaviors and preferences. Each dimension j of an author's preference is grounded in topic j. If we ignore document responses, this component of model closely resembles the author-topic model (Rosen-Zvi et al., 2004), except that we assume a different prior for the topic mixtures.

3.4 Modeling Temporal Dynamics

Individual preferences shift over time, as do those of the research community. We extend our model to allow variation at different timesteps. Let $t \in \langle 1, \ldots, T \rangle$ index timesteps (in our experiments, each t is a calendar year). We let $\boldsymbol{\beta}^{(t)}$, $\boldsymbol{\eta}_a^{(t)}$, and $\kappa_a^{(t)}$ denote the community's response coefficients, author a's preferences, and author a's tradeoff coefficient at timestep t.

Again, we must take care in interpreting these quantities. Do changes in community interest drive authors to adjust their preferences or expertise? Or do changing author preferences aggregate into community-wide shifts? Or do changes in the economy or funding availability change authors' tradeoffs? Our model cannot differentiate among these different causal patterns. Our method is useful for tracking these changes, but it does not provide an explanation for *why* they take place.

Modeling the temporal dynamics of a vector-valued random variable can be accomplished using a multivariate Gaussian distribution. Following Yogatama et al. (2011), we assume the prior for $\boldsymbol{\beta}_j^{(\cdot)} = \langle \beta_j^{(1)}, \ldots, \beta_j^{(T)} \rangle$ has a tridiagonal precision matrix $\Lambda(\lambda, \alpha) \in \mathbb{R}^{T \times T}$:

$$\Lambda(\lambda, \alpha) = \lambda \begin{pmatrix} 1+\alpha & -\alpha & 0 & 0 & \ldots \\ -\alpha & 1+2\alpha & -\alpha & 0 & \ldots \\ 0 & -\alpha & 1+2\alpha & -\alpha & \ldots \\ 0 & 0 & -\alpha & 1+2\alpha & \ldots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{pmatrix}$$

The two hyperparameters α and λ capture, respectively, autocorrelation (the tendency of $\beta_j^{(t+1)}$ to be similar to $\beta_j^{(t)}$) and overall variance. This approach to modeling time series allows us to capture temporal dynamics while sharing statistical strength of evidence across all time steps.

We use the notation $\mathcal{T}(\lambda, \alpha) \equiv \mathcal{N}(\mathbf{0}, \Lambda(\lambda, \alpha))$ for this multivariate Gaussian distribution, instances of which are used as priors over response coefficients $\boldsymbol{\beta}$, author preferences $\boldsymbol{\eta}_a$, and (transformed) author tradeoffs $\log \kappa_a$.

Latent variables	
$\boldsymbol{\beta}^{(t)}$	response coefficients at time t ($\in \mathbb{R}^K$)
$\boldsymbol{\eta}_a^{(t)}$	author a's topic preferences at time t ($\in \mathbb{R}^K$)
$\boldsymbol{\kappa}_a^{(t)}$	author a's tradeoff coefficient at time t ($\in \mathbb{R}_{\geq 0}$)
$\boldsymbol{\theta}_d$	document d topic associations ($\in \mathbb{R}^K$)
$c_{d,a}$	author a contrtibution to document d ($\sum_{a \in \boldsymbol{a}_d} c_{d,a} = 1$)
$\boldsymbol{\phi}_k$	distribution over terms for topic k
$z_{d,i}$	topic assignment of $w_{d,i}$
Constants and hyperparameters	
K	number of topics
ρ	symmetric Dirichlet hyperparameter for $\boldsymbol{\phi}_k$
σ_c^2	variance hyperparameter for author contributions $\boldsymbol{c}_d$
$\{\lambda^{(\beta)}, \alpha^{(\beta)}\}$, $\{\lambda^{(\eta)}, \alpha^{(\eta)}\}$, $\{\lambda^{(\kappa)}, \alpha^{(\kappa)}\}$	hyperparameters for priors of $\boldsymbol{\beta}, \boldsymbol{\eta}$, and $\log \kappa$ respectively

Table 1: Table of notation.

3.5 Full Model

Table 1 summarizes all of the notation. The log-likelihood of our model is:

$$\begin{aligned}\mathcal{L} &= \log p(\boldsymbol{\beta}) + \sum_{d \in \mathcal{D}} \log p(\boldsymbol{c}_d) \\ &+ \sum_{d \in \mathcal{D}} \log p(y_d \mid \boldsymbol{\theta}_d, \boldsymbol{\beta}) + \log p(\boldsymbol{w}_d \mid \boldsymbol{\theta}_d) \\ &+ \sum_{a \in \mathcal{A}} \log p(\boldsymbol{\eta}_a) + \log p(\kappa_a) \\ &+ \sum_{d \in \mathcal{D}} \sum_{a \in \boldsymbol{a}_d} \log p(\boldsymbol{\theta}_d \mid \boldsymbol{\beta}, \boldsymbol{\eta}_a, \kappa_a, c_{d,a}) \qquad (8)\end{aligned}$$

We adopt a Bayesian approach to parameter estimation. The generative story, including all priors, is as follows. Recall that $\mathcal{T}(\cdot, \cdot)$ denotes the time series prior discussed in §3.4. See also the plate diagram for the graphical model in Fig. 1.

1. For each topic $k \in \{1, \ldots, K\}$:
   (a) Draw response coefficients $\boldsymbol{\beta}_k^{(\cdot)} \sim \mathcal{T}(\lambda^{(\beta)}, \alpha^{(\beta)})$ and term distribution $\boldsymbol{\phi}_k \sim \text{Dirichlet}(\rho)$.
   (b) For each author $a \in \mathcal{A}$, draw preference strengths for topic k over time, $\langle \eta_{a,k}^{(1)}, \ldots, \eta_{a,k}^{(t)} \rangle \sim \mathcal{T}(\lambda^{(\eta)}, \alpha^{(\eta)})$.
2. For each author $a \in \mathcal{A}$, draw (transformed) tradeoff parameters $\langle \log \kappa_a^{(1)}, \ldots, \log \kappa_a^{(T)} \rangle \sim \mathcal{T}(\lambda^{(\kappa)}, \alpha^{(\kappa)})$.
3. For each timestep $t \in \{1, \ldots, T\}$, and each document $d \in \mathcal{D}_t$:
   (a) Draw author contributions $\boldsymbol{c}_d \sim \text{Softmax}(\mathcal{N}(\mathbf{0}, \sigma_c^2 \mathbf{I}))$. This is known as a logistic normal distribution (Aitchison, 1986).
   (b) Draw d's topic distributions (this distribution is discussed further below):

$$\boldsymbol{\theta}_d \sim \mathcal{N}\left(\sum_{a \in \boldsymbol{a}_d} \kappa_a^{(t)} \boldsymbol{\beta}^{(t)} + c_{d,a} \boldsymbol{\eta}_a^{(t)}, \|\boldsymbol{c}_d\|_2^2 \mathbf{I} \right) \qquad (9)$$

   (c) For each token $i \in \{1, \ldots, N_d\}$, draw topic $z_{d,i} \sim \text{Categorical}(\text{Softmax}(\boldsymbol{\theta}_d))$ and term $w_{d,i} \sim \text{Categorical}(\boldsymbol{\phi}_{z_{d,i}})$.
   (d) Draw response $y_d \sim \mathcal{N}\left(\boldsymbol{\beta}^{(t_d)\top} \boldsymbol{\theta}_d, 1\right)$; note that it collapses out ξ_d, which is drawn from a standard normal.

Eq. 9 captures the choice by authors $\boldsymbol{a}_d$ of a distribution over topics $\boldsymbol{\theta}_d$. Assuming that the $\boldsymbol{\epsilon}_{d,a}$s are i.i.d. and Gaussian, from Eq. 7, we get

$$\boldsymbol{\theta}_d = \sum_{a \in \boldsymbol{a}_d} \kappa_a \boldsymbol{\beta} + c_{d,a} \boldsymbol{\eta}_a + c_{d,a} \boldsymbol{\epsilon}_{d,a},$$

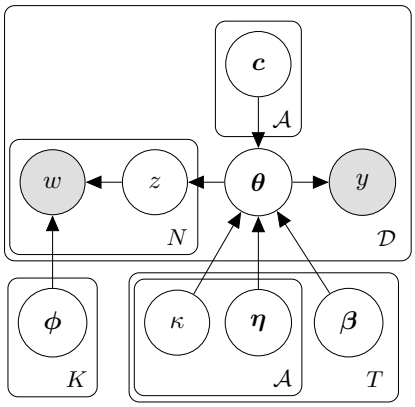

Figure 1: Plate diagram for author utility model. Hyperparameters and edges between consecutive time steps of $\boldsymbol{\beta}, \boldsymbol{\eta}$ and κ are omitted for clarity.

and the linear additive property of Gaussians gives us

$$\boldsymbol{\theta}_d \sim \mathcal{N}\left(\sum_{a \in \boldsymbol{a}_d} \kappa_a \boldsymbol{\beta} + c_{d,a} \boldsymbol{\eta}_a, \|\boldsymbol{c}_d\|_2^2 \mathbf{I} \right)$$

In §3.1 we described a utility function for each author. The model we are estimating is similar to those estimated in discrete choice econometrics (McFadden, 1974). We assumed that authors are utility maximizing (optimizing) and that their optimal topic distribution satisfies the first-order conditions (Eq. 7). However, we cannot see the idiosyncratic component, $\boldsymbol{\epsilon}_{d,a}$, which is assumed to be Gaussian; as noted, this is known as a random utility model. Together, these assumptions give the structure of the distribution over topics in terms of (estimated) utility, which allows us to naturally incorporate the utility function into our probabilistic model in a familiar way (Sim et al., 2015).

4 Learning and Inference

Exact inference in our model is intractable, so we resort to an approximate inference technique based on Monte Carlo EM (Wei and Tanner, 1990). During the E-step, we perform Bayesian inference over latent parameters $(\boldsymbol{\eta}, \boldsymbol{\kappa}, \boldsymbol{z}, \boldsymbol{\theta}, \boldsymbol{c}, \boldsymbol{\phi})$ using a Metropolis-Hastings within Gibbs algorithm (Tierney, 1994), and in the M-step, we compute maximum *a posteriori* estimates of $\boldsymbol{\beta}$ by directly optimizing the log-likelihood function. Since we are using conjugate priors for $\boldsymbol{\phi}$, we can integrate it out. We did not perform Bayesian posterior inference over $\boldsymbol{\beta}$ because the coupling of $\boldsymbol{\beta}$

would slow mixing of the MCMC chain.

E-step. We sample each $\boldsymbol{\eta}_a^{(t_d)}$, $\boldsymbol{c}_d$, $\log \boldsymbol{\kappa}_a^{(\cdot)}$, and $\boldsymbol{\theta}_d$ blockwise using the Metropolis-Hastings algorithm with a multivariate Gaussian proposal distribution, tuning the diagonal covariance matrix to a target acceptance rate of 15-45% (see appendix §A for sampling equations).

For $\boldsymbol{z}$, we integrate out $\boldsymbol{\phi}$ and sample each $z_{d,i}$ directly from

$$p(z_{d,i} = k \mid \boldsymbol{\theta}_d, \boldsymbol{\phi}_k) \propto \exp(\theta_{d,k}) \frac{C_{k,w_{d,i}}^{-d,i} + \rho}{C_{k,\cdot}^{-d,i} + V\rho}$$

where $C_{k,w}^{-d,i}$ and $C_{k,\cdot}^{-d,i}$ are the number of times w is associated with topic k, and the number of tokens associated with topic k respectively.

We run the E-step Gibbs sampler to collect 3,500 samples, discarding the first 500 samples for burn-in and only saving samples at every third iteration.

M-step. We approximate the expectations of our latent variables using the samples collected during the E-step, and directly optimize $\boldsymbol{\beta}^{(t)}$ using L-BFGS (Liu and Nocedal, 1989),[2] which requires a gradient. The gradient of the log-likelihood with respect to $\beta_j^{(t)}$ is

$$\begin{aligned}
\frac{\partial \mathcal{L}}{\partial \beta_j^{(t)}} &= -2\lambda^{(\beta)} \beta_j^{(t)} \\
&\quad - 2\lambda^{(\beta)} \alpha^{(\beta)} \mathbf{1}\{t > 1\} (\beta_j^{(t)} - \beta_j^{(t-1)}) \\
&\quad - 2\lambda^{(\beta)} \alpha^{(\beta)} \mathbf{1}\{t < T\} (\beta_j^{(t)} - \beta_j^{(t+1)}) \\
&\quad + 2 \sum_{d \in \mathcal{D}_t} \theta_{d,j} (y_d - \beta_j^{(t)} \theta_{d,j}) \\
&\quad + 2 \sum_{d \in \mathcal{D}_t} \kappa_d^{(t)} \left(\theta_{d,j} - \kappa_d^{(t)} \beta_j^{(t)} - \sum_{a \in \boldsymbol{a}_d} \frac{\eta_{a,j}^{(t)}}{|\boldsymbol{a}_d|} \right)
\end{aligned} \tag{10}$$

where $\kappa_d^{(t)} = \frac{1}{|\boldsymbol{a}_d|} \sum_{a \in \boldsymbol{a}_d} \kappa_a^{(t)}$.

We ran L-BFGS until convergence[3] and slice sampled the hyperparameters $\lambda^{(\eta)}, \alpha^{(\eta)}, \lambda^{(\kappa)}, \alpha^{(\kappa)}$ (with vague priors) at the end of the M-step. We fix the symmetric Dirichlet hyperparameter $\rho = 1/V$, and tuned $\lambda^{(\beta)}, \alpha^{(\beta)}$ on a held-out developement dataset by grid search over $\{0.01, 0.1, 1, 10\}$.

[2]We used libLBFGS, an open source C++ implementation (`https://github.com/chokkan/liblbfgs`).

[3]Relative tolerance of 10^{-4}.

During initialization, we randomly set the topic assignments, while the other latent parameters are set to 0. We ran the model for 10 EM iterations.

Inference. During inference, we fix the model parameters and only sample $(\boldsymbol{\theta}, \boldsymbol{z})$ for each document. As in the E-step, we discard the first 500 samples, and save samples at every third iteration, until we have 500 posterior samples. In our experiments, we found the posterior samples to be reasonably stable after the initial burn in.

5 Experiments

Data. The ACL Anthology Network Corpus contains 21,212 papers published in the field of computational linguistics between 1965 and 2013 and written by 17,792 authors. Additionally, the corpus provides metadata such as authors, venue and in-community citation networks. For our experiments, we focused on conference papers published between 1980 and 2010.[4] We tokenized the texts, tagged the tokens using the Stanford POS tagger (Toutanova et al., 2003), and extracted n-grams with tags that follow the simple (but effective) pattern of `(Adj|Noun)* Noun` (Justeson and Katz, 1995), representing the dth document as a *bag of phrases* ($\boldsymbol{w}_d$). Note that phrases can also be unigrams. We pruned phrases that appear in $< 1\%$ or $> 95\%$ of the documents, obtaining a vocabulary of V = 6,868 types. The pruned corpus contains 5,498 documents and 2,643,946 phrase tokens written by 5,575 authors. We let responses

$$y_d = \log(1 + \#\text{ of incoming citations in 3 years})$$

For our experiments, we used 3 different random splits of our data (70% train, 20% test, and 10% development) and averaged quantities of interest. Furthermore, we remove an author from a paper in the development or test set if we have not seen him before in the training data.

5.1 Examples of Authors and Topics

Table 2 illustrates ten manually selected topics (out of 64) learned by the author utility model. Each topic is labeled with the top 10 words most likely to be generated conditioned on the topic

[4]The conferences we included are: ACL, CoNLL, EACL, EMNLP, HLT, and NAACL. We ignored journal papers, as well as workshop papers, since they are characteristically different from conference papers.

(ϕ_k). For each topic, we compute an author's topic preference score:

$$\text{TPS}(a, k) = \eta_{a,k}^{(t_d)} \sum_{d \in D_a} [\text{Softmax}(\theta_d)]_k \times y_d$$

where $\text{Softmax}(\boldsymbol{x}) = \frac{\exp(\boldsymbol{x})}{\sum_i \exp(x_i)}$. The TPS scales the author's η preferences by the relative number of citations that the author received for the topic. This way, we can account for different ηs over time, and reduce variance due to authors who publish less frequently.[5] For each topic, the five authors with the highest TPS are displayed in the rightmost column of Table 2. These topics were among the roughly one third (out of 64) that seemed to coherently map to research topics within NLP. Some others corresponded to parts of a paper (e.g., explaining notation and formulae, experiments) or to stylistic groups (e.g., "rational words" including *rather*, *fact*, *clearly*, *argue*, *clear*, *perhaps*). Others were not interpretable to us.

5.2 Predicting Responses

We compare against two baselines for predicting in-community citations. Yogatama et al. (2011) is a strong baseline for predicting responses; they incorporated n-gram features and metadata features in a generalized linear model with the time series prior discussed in §3.4.[6] We also compare against a version of our model without the author utility component. This equates to replacing Yogatama et al.'s features with LDA topic mixtures, and performing joint learning of the topics and citations; we therefore call it "TimeLDA." Without the time series component, TimeLDA would instantiate supervised LDA (McAuliffe and Blei, 2008). Figure 2 shows the mean absolute error (MAE) for the three models.

With sufficiently many topics ($K \geq 16$), topic representations achieve lower error than surface features. Removing the author utility component from our model leads to better predictive performance. This is unsurprising, since our model forces β to explain both the responses (what is evaluated here) and the divergence between author preferences η_a and what is actually written. The utility model is nonetheless competitive with the Yogatama et al. baseline.

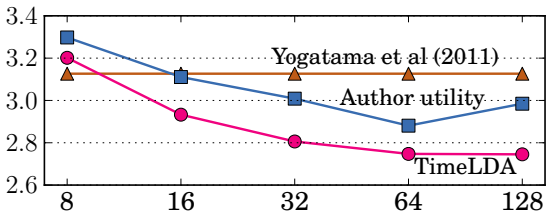

Figure 2: Mean absolute error (in citation counts) for predicted citation counts (y-axis) against the number of topics K (x-axis). Errors are in actual citation counts, while the models are trained with log counts. TimeLDA significantly outperforms Yogatama et al. (2011) for $K \geq 64$ (paired t-test, $p < 0.01$), while the differences between Yogatama et al. (2011) and author utility are not significant. The MAE is calculated over 3 random splits of the data with 809, 812, and 811 documents in the test set respectively.

5.3 Predicting Words

"Given a set of authors, what are they likely to write?" — we use perplexity as a proxy to measure the content predictive ability of our model. Perplexity on a test set is commonly used to quantify the generalization ability of probabilistic models and make comparisons among models over the same observation space. For a document $\boldsymbol{w}_d$ written by authors $\boldsymbol{a}_d$, perplexity is defined as

$$\text{perplexity}(\boldsymbol{w}_d \mid \boldsymbol{a}_d) = \exp\left(-\frac{\log p(\boldsymbol{w}_d \mid \boldsymbol{a}_d)}{N_d}\right)$$

and a lower perplexity indicates better generalization performance. Using S samples from the inference step, we can compute

$$p(\boldsymbol{w}_d \mid \boldsymbol{a}_d) = \frac{1}{S} \sum_{s=1}^{S} \prod_{i=1}^{N_d} \frac{1}{|\boldsymbol{a}_d|} \sum_{a \in \boldsymbol{a}_d, k} \theta_{d,k}^s \phi_{k,w_{di}}^s$$

where θ^s is the sth sample of θ, and ϕ^s is the topic-word distribution estimated from the sth sample of $\boldsymbol{z}$.

We compared the Author-Topic model of Rosen-Zvi et al. (2004). The AT model is similar to setting $\kappa_a = 0$ for all authors, $\boldsymbol{c}_d = \frac{1}{|\boldsymbol{a}_d|}$, and using a Dirichlet prior instead of logistic normal on η_a. Figure 3 present the perplexity of these

[5] The TPS is only a measure of an author's propensity to write papers in a specific topic area and is not meant to be a measure of an author's reputation in a particular research sub-field.

[6] For the ACL dataset, Yogatama et al. (2011)'s model predicts whether a paper will receive at least 1 citation within three years, while here, we train it to predict $\log(1 + \#\text{citations})$ instead.

Topic	Top words	Authors
"MT"	alignment, translation, align, decode, phrase, och, bleu, ney, bleu score, target language	Philipp Koehn, Chris Dyer, Qun Liu, Hermann Ney, David Chiang
"Empirical methods"	model, parameter, learn, iteration, maximize, prior, initialize, distribution, weight, crf	Noah Smith, Dan Klein, Percy Liang, John DeNero, Andrew McCallum
"Parsing"	parse, sentence, parser, accuracy, collins, dependency, tree, parse tree, head, charniak	Michael Collins, Joakim Nivre, Jens Nilsson, Dan Klein, Ryan McDonald
"Dialogue systems"	speak, speech, utterance, user, speaker, dialogue system, turn, act, recognition, transcription	Diane Litman, Marilyn Walker, Julia Hirschberg, Oliver Lemon, Amanda Stent
"NER"	name, entity, identify, person, location, list, organization, system, entity recognition, mention	Jenny Rose Finkel, Satoshi Sekine, Rion Snow, Christopher Manning, Abraham Ittycheriah
"Semantics"	argument, verb, predicate, syntactic, relation, semantic role, annotated, frame, assign	Martha Palmer, Alessandro Moschitti, Daniel Jurafsky, Sanda Harabagiu, Mirella Lapata
"Lexical semantics"	wordnet, noun, sense, concept, context, sens, relation, meaning, pair, disambiguate	Rion Snow, Rob Koeling, Eneko Agirre, Ido Dagan, Patrick Pantel
"Tagging & chunking"	method, sentence, propose, japanese, noun phrase, extract, table, analyze, precision, technology	Yuji Matsumoto, Hitoshi Isahara, Junichi Tsujii, Sadao Kurohashi, Kentaro Torisawa
"Coreference"	mention, instance, create, approach, report, due, text, pair, exist, system	Vincent Ng, Aria Haghighi, Xiaofeng Yang, Claire Cardie, Pascal Denis
"Sentiment classification"	classify, label, accuracy, positive, classification, annotated, annotator, classifier, review, negative	Janyce Wiebe, Soo Min Kim, Eduard Hovy, Carmen Banea, Ryan McDonald

Table 2: Top words from selected topics and authors with preferences in those topics. We manually labeled each of these topics.

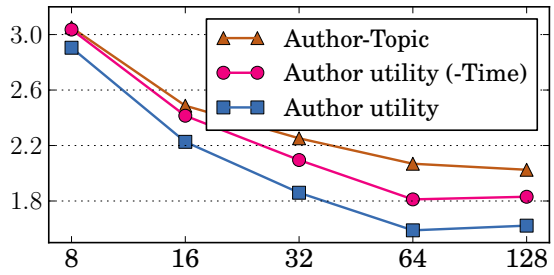

Figure 3: Held-out perplexity ($\times 10^3$, y-axis) with varying number of topics K (x-axis). The differences are significant between all models at $K \geq 64$ (paired t-test, $p < 0.01$). There are 523,381, 529,397, 533,792 phrase tokens in the random test sets.

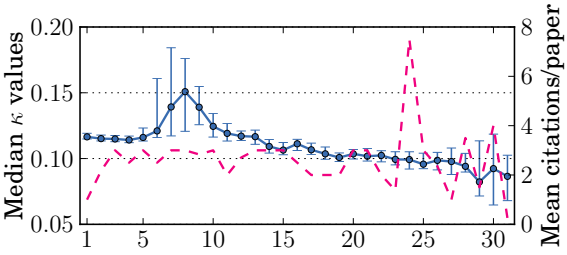

Figure 4: Plot of authors' median κ (blue, solid) and mean citation counts (magenta, dashed) against their academic age in this dataset (see text for explanation).

models at different values of K. We include a version of our author utility model that ignores temporal information ("–time"), i.e., setting $T = 1$ and collapsing all timesteps. We find that perplexity improves with the addition of the utility model as well as the temporal dynamics.

5.4 Exploration: Tradeoffs and Seniority

Recall that κ_a encodes author a's tradeoff between increasing citations (high κ_a) and writing papers on topics a prefers (low κ_a). We do not claim that individual κ_a values consistently represent authors' tradeoffs between citations and writing about preferred topics. We have noted a number of potentially confounding factors that affect authors' choices, for which our data do not allow us to control.

However, in aggregate, κ_a values can be explored in relation to other quantities. Given our model's posterior, one question we can ask is: do an author's tradeoffs tend to change over the course of her career? In Figure 4, we plot the median of κ (and 95% credible intervals) for authors at different "ages." Here, "age" is defined as the number of years since an author's first publication in this dataset.[7]

A general trend over the long term is observed: researchers appear to move from higher to lower κ_a. Statistically, there is significant dependence between κ of an author and her age; the Spearman's rank correlation coefficient is $\rho = -0.870$ with p-value $< 10^{-5}$. This finding is consis-

[7]This means that larger ages correspond to seniority, but smaller ages are a blend of junior researchers and researchers of any seniority new to this publication community.

tent with the idea that greater seniority brings increased and more stable resources and greater freedom to pursue idiosyncratic interests with less concern about extrinsic payoff. It is also consistent with decreased flexibility or openness to shifting topics over time.

To illustrate the importance of our model in making these observations, we also plot the mean number of citations per paper published (across all authors) against their academic age (magenta lines). There is no clear statistical trend between the two variables ($\rho = -0.017$). This suggests that through κ, our model is able to pick up evidence of author's optimizing behaviors, which is not possible using simple citation counts.

There is a noticeable effect during years 5–10, in which κ tends to rise by around 40% and then fall back. (Note that the model maintains considerable uncertainty—wider intervals—about this effect.) Recall that, for a researcher trained within the field and whose primary publication venue is in the ACL community, our measure of age corresponds roughly to academic age. Years 5–10 would correspond to the later part of a Ph.D. program and early postgraduate life, when many researchers begin faculty careers. Insofar as it reflects a true effect, this rise and fall suggests a stage during which a researcher focuses more on writing papers that will attract citations. However, more in-depth study based on data that is not merely observational is required to quantify this effect and, if it persists under scrutiny, determine its cause.

The effect in year 24 of mean citations per paper (magenta line) can be attributed to well cited papers co-authored by senior researchers in the field who published very few papers in their 24th year. Since there are relatively few authors in the dataset at that academic age, there is more variance in mean citations counts.

6 Related Work

Previous work on modeling author interests mostly focused on characterizing authors by their style (Holmes and Forsyth, 1995, *inter alia*),[8] through latent topic mixtures of documents they have co-authored (Rosen-Zvi et al., 2004) and their collaboration networks (Johri et al., 2011). Like our paper, the latter two are based on topic models, which have been popular for modeling the content of scientific articles. For instance, Gerrish and Blei (2010) measured scholarly impact using dynamic topic models, while Hall et al. (2008) analyzed the output of topic models to study the "history of ideas."

Predicting responses to scientific articles was explored in two shared tasks at KDD Cup 2003 (Brank and Leskovec, 2003; McGovern et al., 2003) and by Yogatama et al. (2011), which served as a baseline for our experiments and whose time-series prior we used in our model. Furthermore, there has been considerable research using topic models to predict (or recommend) citations (instead of aggregate counts), such as modeling link probabilities within the LDA framework (Cohn and Hofmann, 2000; Erosheva et al., 2004; Nallapati and Cohen, 2008; Kataria et al., 2010; Zhu et al., 2013) and augmenting topics with discriminative author features (Liu et al., 2009; Tanner and Charniak, 2015).

We modeled both interests of authors and responses to their articles jointly, by assuming authors' text production is an expected utility-maximizing decision. This approach is similar to our earlier work (Sim et al., 2015), where authors are rational agents writing texts to maximize the chance of a favorable decision by a judicial court. In that study, we did not consider the unique preferences of each decision making agent, nor the extrinsic-intrinsic reward tradeoffs that these agents face when authoring a document.

Our utility model can also be viewed as a form of natural language generator, where we take into account the context of an author (i.e., his preferences, the tradeoff coefficient, and what is popular) to generate his document. This is related to natural language pragmatics, where text is influenced by context.[9] Hovy (1990) approached the problem of generating text under pragmatic circumstances from a planning and goal-orientation perspective, while Vogel et al. (2013) used multi-agent decision-theoretic models to show cooperative pragmatic behavior. Vogel et al.'s models suggest an interesting extension of ours for future work: modeling cooperation among co-authors and, perhaps, in the larger scientific discourse.

[8] A closely related problem is that of authorship attribution. There has been extensive research on authorship attribution focusing mainly on learning "stylometric" features of authors; see Stamatatos (2009) for a detailed review.

[9] The $\boldsymbol{\beta}$ vectors can be seen as a naïve representation of world knowledge that motivates an author to select content that reflects his behavioral preferences and intentions.

7 Conclusions

We presented a model of scientific authorship in which authors trade off between seeking citation by others and staying true to their individual preferences among research topics. We find that topic modeling improves over state-of-the-art text regression models for predicting citation counts, and that the author utility model generalizes better than simpler models when predicting what a particular group of authors will write. Inspecting our model suggests interesting patterns in behavior across a researcher's career.

Sim, by a Google research award, and by computing resources from the Pittsburgh Supercomputing Center; it was completed while NAS was at CMU.

A Appendix: Sampling equations

We sample each $\boldsymbol{\eta}_{a,j}$, for $j = 1 \dots K$, and $\boldsymbol{\kappa}_a$ blockwise across time steps using Metropolis-Hastings algorithm with a multivariate Gaussian proposal distribution and likelihood:

$$p(\boldsymbol{\eta}_{a,j} \mid \boldsymbol{\eta}_{-(a,j)}, \boldsymbol{\theta}, \boldsymbol{c}, \boldsymbol{\kappa}, \boldsymbol{\beta}, \Lambda^{(\eta)}) \propto \exp\left(-\frac{1}{2}\boldsymbol{\eta}_{a,j}\Lambda^{(\eta)}\boldsymbol{\eta}_{a,j}^{\top} - \sum_{\substack{t \in T \\ d \in D_t}} \frac{\left(\theta_{d,j} - \sum_{a' \in \boldsymbol{a}_d} \kappa_{a'}^{(t)}\beta_j^{(t)} + c_{d,a'}\eta_{a',j}^{(t)}\right)^2}{2\|\boldsymbol{c}_d\|_2^2} \right)$$

$$p(\boldsymbol{\kappa}_a \mid \boldsymbol{\kappa}_{-(a)}, \boldsymbol{\theta}, \boldsymbol{c}, \boldsymbol{\eta}, \boldsymbol{\beta}, \Lambda^{(\kappa)}) \propto \exp\left(-\frac{1}{2}\log(\boldsymbol{\kappa}_a)\Lambda^{(\kappa)}\log(\boldsymbol{\kappa}_a^{\top}) - \sum_{\substack{t \in T \\ d \in D_t}} \frac{\|\boldsymbol{\theta}_d - \sum_{a' \in \boldsymbol{a}_d} \kappa_{a'}^{(t)}\boldsymbol{\beta}^{(t)} + c_{d,a'}\boldsymbol{\eta}_{a'}^{(t)}\|_2^2}{2\|\boldsymbol{c}_d\|_2^2} \right)$$

$\Lambda^{(\eta)}$ and $\Lambda^{(\kappa)}$ are shorthands for the precision matrices $\Lambda(\lambda^{(\eta)}, \alpha^{(\eta)})$ and $\Lambda(\lambda^{(\kappa)}, \alpha^{(\kappa)})$ respectively. Likewise, $\boldsymbol{\theta}_d$ is sampled blockwise for each document with a multivariate Gaussian distribution and likelihood:

$$p(\boldsymbol{\theta}_d \mid \boldsymbol{c}_d, \boldsymbol{\eta}, \boldsymbol{\kappa}, \boldsymbol{\beta}) \propto \exp\left(-\frac{(y_d - \boldsymbol{\beta}^{(t_d)\top}\boldsymbol{\theta}_d)^2}{2} - \frac{\|\boldsymbol{\theta}_d - \sum_{a \in \boldsymbol{a}_d} \kappa_a^{(t_d)}\boldsymbol{\beta}^{(t_d)} + c_{d,a}\boldsymbol{\eta}_a^{(t_d)}\|_2^2}{2\|\boldsymbol{c}_d\|_2^2} \right)$$

For $\boldsymbol{c}_d$, we first sampled each $\boldsymbol{c}_d$ from a multivariate Gaussian distribution, and applied a logistic transformation to map it onto the simplex. The likelihood for $\boldsymbol{c}_d$ is:

$$p(\boldsymbol{c}_d \mid \boldsymbol{\theta}_d, \boldsymbol{\eta}, \boldsymbol{\kappa}, \boldsymbol{\beta}) \propto \exp\left(-\frac{1}{2\sigma_c^2}\left\|\log\left(\frac{\boldsymbol{c}_d}{c_{d,|\boldsymbol{a}_d|}}\right)\right\|_2^2 - \frac{\|\boldsymbol{\theta}_d - \sum_{a \in \boldsymbol{a}_d} \kappa_a^{(t_d)}\boldsymbol{\beta}^{(t_d)} + c_{d,a}\boldsymbol{\eta}_a^{(t_d)}\|_2^2}{2\|\boldsymbol{c}_d\|_2^2} \right)$$

Abstract

We introduce a model for constructing vector representations of words by composing characters using bidirectional LSTMs. Relative to traditional word representation models that have independent vectors for each word type, our model requires only a single vector per character type and a fixed set of parameters for the compositional model. Despite the compactness of this model and, more importantly, the arbitrary nature of the form–function relationship in language, our "composed" word representations yield state-of-the-art results in language modeling and part-of-speech tagging. Benefits over traditional baselines are particularly pronounced in morphologically rich languages (e.g., Turkish).

1 Introduction

Good representations of words are important for good generalization in natural language processing applications. Of central importance are vector space models that capture functional (i.e., semantic and syntactic) similarity in terms of geometric locality. However, when word vectors are learned—a practice that is becoming increasingly common—most models assume that each word type has its own vector representation that can vary independently of other model components. This paper argues that this independence assumption is inherently problematic, in particular in morphologically rich languages (e.g., Turkish). In such languages, a more reasonable assumption would be that orthographic (formal) similarity is evidence for functional similarity.

However, it is manifestly clear that similarity in form is neither a necessary nor sufficient condition for similarity in function: small orthographic differences may correspond to large semantic or syntactic differences (*butter* vs. *batter*), and large orthographic differences may obscure nearly perfect functional correspondence (*rich* vs. *affluent*). Thus, any orthographically aware model must be able to capture *non-compositional* effects in addition to more regular effects due to, e.g., morphological processes. To model the complex form–function relationship, we turn to long short-term memories (LSTMs), which are designed to be able to capture complex non-linear and non-local dynamics in sequences (Hochreiter and Schmidhuber, 1997). We use bidirectional LSTMs to "read" the character sequences that constitute each word and combine them into a vector representation of the word. This model assumes that each character type is associated with a vector, and the LSTM parameters encode both idiosyncratic lexical and regular morphological knowledge.

To evaluate our model, we use a vector-based model for part-of-speech (POS) tagging and for language modeling, and we report experiments on these tasks in several languages comparing to baselines that use more traditional, orthographically-unaware parameterizations. These experiments show: (i) our character-based model is able to generate similar representations for words that are semantically and syntactically similar, even for words are orthographically distant (e.g., *October* and *January*); our model achieves improvements over word lookup tables using only a fraction of the number of parameters in two tasks; (iii) our model obtains state-of-the-art performance on POS tagging (including establishing a new best performance in English); and

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1520–1530,
Lisbon, Portugal, 17-21 September 2015.

(iv) performance improvements are especially dramatic in morphologically rich languages.

The paper is organized as follows: Section 2 presents our character-based model to generate word embeddings. Experiments on Language Modeling and POS tagging are described in Sections 4 and 5. We present related work in Section 6; and we conclude in Section 7.

2 Word Vectors and Wordless Word Vectors

It is commonplace to represent words as vectors. In contrast to naïve models in which all word types in a vocabulary V are equally different from each other, vector space models capture the intuition that words may be different or similar along a variety of dimensions. Learning vector representations of words by treating them as optimizable parameters in various kinds of language models has been found to be a remarkably effective means for generating vector representations that perform well in other tasks (Collobert et al., 2011; Kalchbrenner and Blunsom, 2013; Liu et al., 2014; Chen and Manning, 2014). Formally, such models define a matrix $\mathbf{P} \in \mathbb{R}^{d \times |V|}$, which contains d parameters for each word in the vocabulary V. For a given word type $w \in V$, a column is selected by right-multiplying $\mathbf{P}$ by a one-hot vector of length $|V|$, which we write $\mathbf{1}_w$, that is zero in every dimension except for the element corresponding to w. Thus, $\mathbf{P}$ is often referred to as word lookup table and we shall denote by $\mathbf{e}_w^W \in \mathbb{R}^d$ the embedding obtained from a word lookup table for w as $\mathbf{e}_w^W = \mathbf{P} \cdot \mathbf{1}_w$. This allows tasks with low amounts of annotated data to be trained jointly with other tasks with large amounts of data and leverage the similarities in these tasks. A common practice to this end is to initialize the word lookup table with the parameters trained on an unsupervised task. Some examples of these include the skip-n-gram and CBOW models of Mikolov et al. (2013).

2.1 Problem: Independent Parameters

There are two practical problems with word lookup tables. Firstly, while they can be pretrained with large amounts of data to learn semantic and syntactic similarities between words, each vector is independent. That is, even though models based on word lookup tables are often observed to learn that *cats*, *kings* and *queens* exist in roughly the same linear correspondences to each other as *cat*, *king* and *queen* do, the model does not represent the fact that adding an *s* at the end of the word is evidence for this transformation. This means that word lookup tables cannot generate representations for previously unseen words, such as *Frenchification*, even if the components, *French* and *-ification*, are observed in other contexts.

Second, even if copious data is available, it is impractical to actually store vectors for all word types. As each word type gets a set of parameters d, the total number of parameters is $d \times |V|$, where $|V|$ is the size of the vocabulary. Even in relatively morphological poor English, the number of word types tends to scale to the order of hundreds of thousands, and in noisier domains, such as online data, the number of word types raises considerably. For instance, in the English wikipedia dump with 60 million sentences, there are approximately 20 million different lowercased and tokenized word types, each of which would need its own vector. Intuitively, it is not sensible to use the same number of parameters for each word type.

Finally, it is important to remark that it is uncontroversial among cognitive scientists that our lexicon is structured into related forms—i.e., their parameters are not independent. The well-known "past tense debate" between connectionists and proponents of symbolic accounts concerns disagreements about how humans represent knowledge of inflectional processes (e.g., the formation of the English past tense), not whether such knowledge exists (Marslen-Wilson and Tyler, 1998).

2.2 Solution: Compositional Models

Our solution to these problems is to construct a vector representation of a word by composing smaller pieces into a representation of the larger form. This idea has been explored in prior work by composing *morphemes* into representations of words (Luong et al., 2013; Botha and Blunsom, 2014; Soricut and Och, 2015). Morphemes are an ideal primitive for such a model since they are—by definition—the minimal meaning-bearing (or syntax-bearing) units of language. The drawback to such approaches is they depend on a morphological analyzer.

In contrast, we would like to compose representations of *characters* into representations of words. However, the relationship between words

forms and their meanings is non-trivial (de Saussure, 1916). While some compositional relationships exist, e.g., morphological processes such as adding *-ing* or *-ly* to a stem have relatively regular effects, many words with lexical similarities convey different meanings, such as, the word pairs *lesson* $\Longleftrightarrow$ *lessen* and *coarse* $\Longleftrightarrow$ *course*.

3 C2W Model

Our compositional character to word (C2W) model is based on bidirectional LSTMs (Graves and Schmidhuber, 2005), which are able to learn complex non-local dependencies in sequence models. An illustration is shown in Figure 1. The input of the C2W model (illustrated on bottom) is a single word type w, and we wish to obtain is a d-dimensional vector used to represent w. This model shares the same input and output of a word lookup table (illustrated on top), allowing it to easily replace then in any network.

As input, we define an alphabet of characters C. For English, this vocabulary would contain an entry for each uppercase and lowercase letter as well as numbers and punctuation. The input word w is decomposed into a sequence of characters $c_1, \ldots, c_m$, where m is the length of w. Each c_i is defined as a one hot vector $\mathbf{1}_{c_i}$, with one on the index of c_i in vocabulary M. We define a projection layer $\mathbf{P}_C \in \mathbb{R}^{d_C \times |C|}$, where d_C is the number of parameters for each character in the character set C. This of course just a character lookup table, and is used to capture similarities between characters in a language (e.g., vowels *vs.* consonants). Thus, we write the projection of each input character c_i as $\mathbf{e}_{c_i} = \mathbf{P}_C \cdot \mathbf{1}_{c_i}$.

Given the input vectors $\mathbf{x}_1, \ldots, \mathbf{x}_m$, a LSTM computes the state sequence $\mathbf{h}_1, \ldots, \mathbf{h}_{m+1}$ by iteratively applying the following updates:

$$
\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_{ix}\mathbf{x}_t + \mathbf{W}_{ih}\mathbf{h}_{t-1} + \mathbf{W}_{ic}\mathbf{c}_{t-1} + \mathbf{b}_i) \\
\mathbf{f}_t &= \sigma(\mathbf{W}_{fx}\mathbf{x}_t + \mathbf{W}_{fh}\mathbf{h}_{t-1} + \mathbf{W}_{fc}\mathbf{c}_{t-1} + \mathbf{b}_f) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \\
&\qquad \mathbf{i}_t \odot \tanh(\mathbf{W}_{cx}\mathbf{x}_t + \mathbf{W}_{ch}\mathbf{h}_{t-1} + \mathbf{b}_c) \\
\mathbf{o}_t &= \sigma(\mathbf{W}_{ox}\mathbf{x}_t + \mathbf{W}_{oh}\mathbf{h}_{t-1} + \mathbf{W}_{oc}\mathbf{c}_t + \mathbf{b}_o) \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t),
\end{aligned}
$$

where σ is the component-wise logistic sigmoid function, and $\odot$ is the component-wise (Hadamard) product. LSTMs define an extra cell memory $\mathbf{c}_t$, which is combined linearly at each timestamp t. The information that is propagated from $\mathbf{c}_{t-1}$ to $\mathbf{c}_t$ is controlled by the three gates $\mathbf{i}_t$, $\mathbf{f}_t$, and $\mathbf{o}_t$, which determine the what to include from the input $\mathbf{x}_t$, the what to forget from $\mathbf{c}_{t-1}$ and what is relevant to the current state $\mathbf{h}_t$. We write $\mathcal{W}$ to refer to all parameters the LSTM ($\mathbf{W}_{ix}$, $\mathbf{W}_{fx}$, $\mathbf{b}_f$, ...). Thus, given a sequence of character representations $\mathbf{e}^C_{c_1}, \ldots, \mathbf{e}^C_{c_m}$ as input, the forward LSTM, yields the state sequence $\mathbf{s}^f_0, \ldots, \mathbf{s}^f_m$, while the backward LSTM receives as input the reverse sequence, and yields states $\mathbf{s}^b_m, \ldots, \mathbf{s}^b_0$. Both LSTMs use a different set of parameters $\mathcal{W}^f$ and $\mathcal{W}^b$. The representation of the word w is obtained by combining the forward and backward states:

$$\mathbf{e}^C_w = \mathbf{D}^f\mathbf{s}^f_m + \mathbf{D}^b\mathbf{s}^b_0 + \mathbf{b}_d,$$

where $\mathbf{D}^f$, $\mathbf{D}^b$ and $\mathbf{b}_d$ are parameters that deter-

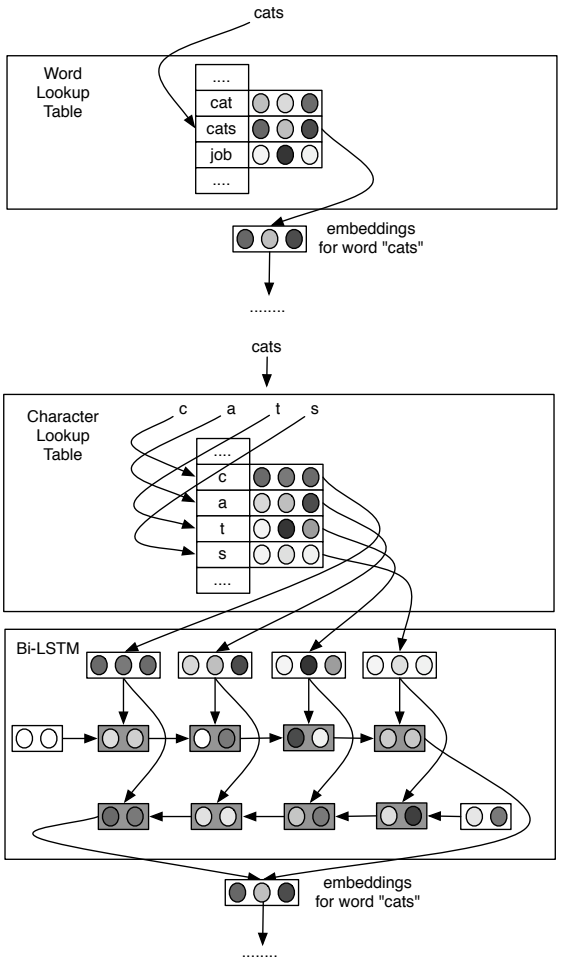

Figure 1: Illustration of the word lookup tables (top) and the lexical Composition Model (bottom). Square boxes represent vectors of neuron activations. Shaded boxes indicate that a non-linearity.

mine how the states are combined.

Caching for Efficiency. Relative to $\mathbf{e}_w^W$, computing $\mathbf{e}_w^C$ is computational expensive, as it requires two LSTMs traversals of length m. However, $\mathbf{e}_w^C$ only depends on the character sequence of that word, which means that unless the parameters are updated, it is possible to cache the value of $\mathbf{e}_w^C$ for each different w's that will be used repeatedly. Thus, the model can keep a list of the most frequently occurring word types in memory and run the compositional model only for rare words. Obviously, caching all words would yield the same performance as using a word lookup table $\mathbf{e}_w^W$, but also using the same amount of memory. Consequently, the number of word types used in cache can be adjusted to satisfy memory vs. performance requirements of a particular application.

At training time, when parameters are changing, repeated words within the same batch only need to be computed once, and the gradient at the output can be accumulated within the batch so that only one update needs to be done per word type. For this reason, it is preferable to define larger batches.

4 Experiments: Language Modeling

Our proposed model is similar to models used to compute composed representations of sentences from words (Cho et al., 2014; Li et al., 2015). However, the relationship between the meanings of individual words and the composite meaning of a phrase or sentence is arguably more regular than the relationship of representations of characters and the meaning of a word. Is our model capable of learning such an irregular relationship? We now explore this question empirically.

Language modeling is a task with many applications in NLP. An effective LM requires syntactic aspects of language to be modeled, such as word orderings (e.g., "John is smart" *vs.* "John smart is"), but also semantic aspects (e.g., "John ate fish" *vs.* "fish ate John"). Thus, if our C2W model only captures regular aspects of words, such as, prefixes and suffixes, the model will yield worse results compared to word lookup tables.

4.1 Language Model

Language modeling amounts to learning a function that computes the log probability, $\log p(\boldsymbol{w})$, of a sentence $\boldsymbol{w} = (w_1, \ldots, w_n)$. This quantity can be decomposed according to the chain rule into the sum of the conditional log probabilities $\sum_{i=1}^{n} \log p(w_i \mid w_1, \ldots, w_{i-1})$. Our language model computes $\log p(w_i \mid w_1, \ldots, w_{i-1})$ by composing representations of words $w_1, \ldots, w_{i-1}$ using an recurrent LSTM model (Mikolov et al., 2010; Sundermeyer et al., 2012).

The model is illustrated in Figure 2, where we observe on the first level that each word w_i is projected into their word representations. This can be done by using word lookup tables $\mathbf{e}_{w_i}^W$, in which case, we will have a regular recurrent language model. To use our C2W model, we can simply replace the word lookup table with the model $f(w_i) = \mathbf{e}_{w_i}^C$. Each LSTM block $\mathbf{s}_i$, is used to predict word w_{i+1}. This is performed by projecting the s_i into a vector of size of the vocabulary V and performing a softmax.

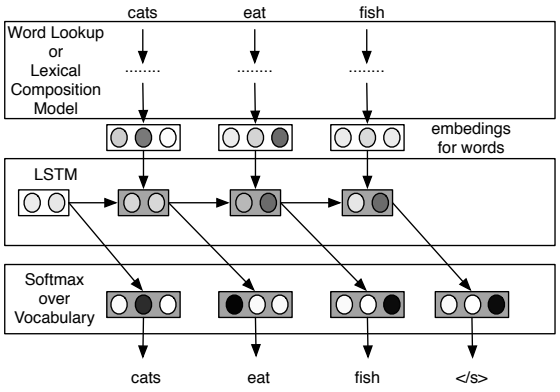

Figure 2: Illustration of our neural network for Language Modeling.

The softmax is still simply a $d \times V$ table, which encodes the likelihood of every word type in a given context, which is a closed-vocabulary model. Thus, at test time out-of-vocabulary (OOV) words cannot be addressed. A strategy that is generally applied is to prune the vocabulary V by replacing word types with lower frequencies as an OOV token. At test time, the probability of words not in vocabulary is estimated as the OOV token. Thus, depending on the number of word types that are pruned, the global perplexities may decrease, since there are fewer outcomes in the softmax, which makes the absolute value of perplexity not informative when comparing models of different vocabulary sizes. Yet, the relative perplexity between different models indicates which models can better predict words based on their contexts.

To address OOV words in the baseline setup, these are replaced by an unknown token, and also associated with a set of embeddings. During training, word types that occur once are replaced with the unknown token stochastically with 0.5 probability. The same process is applied at the character level for the C2W model.

4.2 Experiments

Datasets We look at the language model performance on English, Portuguese, Catalan, German and Turkish, which have a broad range of morphological typologies. While all these languages contain inflections, in agglutinative languages affixes tend to be unchanged, while in fusional languages they are not. For each language, Wikipedia articles were randomly extracted until 1 million words are obtained and these were used for training. For development and testing, we extracted an additional set of 20,000 words.

Setup We define the size of the word representation d to 50. In the C2W model requires setting the dimensionality of characters d_C and current states d_{CS}. We set $d_C = 50$ and $d_{CS} = 150$. Each LSTM state used in the language model sequence s_i is set to 150 for both states and cell memories. Training is performed with mini-batch gradient descent with 100 sentences. The learning rate and momentum were set to 0.2 and 0.95. The softmax over words is always performed on lowercased words. We restrict the output vocabulary to the most frequent 5000 words. Remaining word types will be replaced by an unknown token, which must also be predicted. The word representation layer is still performed over all word types (i.e., completely open vocabulary). When using word lookup tables, the input words are also lowercased, as this setup produces the best results. In the C2W, case information is preserved.

Evaluation is performed by computing the perplexities over the test data, and the parameters that yield the highest perplexity over the development data are used.

Perplexities Perplexities over the testset are reported on Table 4. From these results, we can see that in general, it is clear that C2W always outperforms word lookup tables (row "Word"), and that improvements are especially pronounced in Turkish, which is a highly morphological language, where word meanings differ radically depending on the suffixes used (*evde → in the house vs. evden → from the house*).

	Fusional			Agglutinative	
Perplexity	EN	PT	CA	DE	TR
5-gram KN	70.72	58.73	39.83	59.07	52.87
Word	59.38	46.17	35.34	43.02	44.01

#Parameters					
Word	4.3M	4.2M	4.3M	6.3M	5.7M
C2W	**180K**	**178K**	**182K**	**183K**	**174K**

Table 1: Language Modeling Results

Number of Parameters As for the number of parameters (illustrated for block "#Parameters"), the number of parameters in word lookup tables is $V \times d$. If a language contains 80,000 word types (a conservative estimate in morphologically rich languages), 4 million parameters would be necessary. On the other hand, the compositional model consists of 8 matrices of dimensions $d_{CS} \times d_C + 2d_{CS}$. Additionally, there is also the matrix that combines the forward and backward states of size $d \times 2d_{CS}$. Thus, the number of parameters is roughly 150,000 parameters—substantially fewer. This model also needs a character lookup table with d_C parameters for each entry. For English, there are 618 characters, for an additional 30,900 parameters. So the total number of parameters for English is roughly 180,000 parameters (2 to 3 parameters per word type), which is an order of magnitude lower than word lookup tables.

Performance As for efficiency, both representations can label sentences at a rate of approximately 300 words per second during training. While this is surprising, due to the fact that the C2W model requires a composition over characters, the main bottleneck of the system is the softmax over the vocabulary. Furthermore, caching is used to avoid composing the same word type twice in the same batch. This shows that the C2W model, is relatively fast compared operations such as a softmax.

Representations of (nonce) words While is is promising that the model is not simply learning lexical features, what is most interesting is that the model can propose embeddings for nonce words, in stark contrast to the situation observed with lookup table models. We show the 5-most-similar in-vocabulary words (measured with cosine similarity) as computed by our character model on two

Table 2: Most-similar in-vocabular words under the C2W model; the two query words on the left are in the training vocabulary, those on the right are nonce (invented) words.

in-vocabulary words and two nonce words[1].This makes our model generalize significantly better than lookup tables that generally use unknown tokens for OOV words. Furthermore, this ability to generalize is much more similar to that of human beings, who are able to infer meanings for new words based on its form.

5 Experiments: Part-of-speech Tagging

As a second illustration of the utility of our model, we turn to POS tagging. As morphology is a strong indicator for syntax in many languages, a much effort has been spent engineering features (Nakagawa et al., 2001; Mueller et al., 2013). We now show that some of these features can be learnt automatically using our model.

5.1 Bi-LSTM Tagging Model

Our tagging model is likewise novel, but very straightforward. It builds a Bi-LSTM over words as illustrated in Figure 3. The input of the model is a sequence of features $f(w_1), \ldots, f(w_n)$. Once again, word vectors can either be generated using the C2W model $f(w_i) = \mathbf{e}^C_{w_i}$, or word lookup tables $f(w_i) = \mathbf{e}^W_{w_i}$. We also test the usage of hand-engineered features, in which case $f_1(w_i), \ldots, f_n(w_i)$. Then, the sequential features $f(w_1), \ldots, f(w_n)$ are fed into a bidirectional LSTM model, obtaining the forward states $\mathbf{s}^f_0, \ldots, \mathbf{s}^f_n$ and the backward states $\mathbf{s}^b_{N+1}, \ldots, \mathbf{s}^b_0$. Thus, state $\mathbf{s}^f_i$ contains the information of all words from 0 to i and $\mathbf{s}^b_i$ from n to i. The forward and backward states are combined, for each index from 1 to n, as follows:

$$\mathbf{l}_i = \tanh(\mathbf{L}^f \mathbf{s}^f_i + \mathbf{L}^b \mathbf{s}^b_i + \mathbf{b}_l),$$

where $\mathbf{L}^f$, $\mathbf{L}^b$ and $\mathbf{b}_l$ are parameters defining how the forward and backward states are combined.

[1] software submitted as supplementary material

The size of the forward $\mathbf{s}^f$ and backward states $\mathbf{s}^b$ and the combined state $\mathbf{l}$ are hyperparameters of the model, denoted as d^f_{WS}, d^b_{WS} and d_{WS}, respectively. Finally, the output labels for index i are obtained as a softmax over the POS tagset, by projecting the combined state $\mathbf{l}_i$.

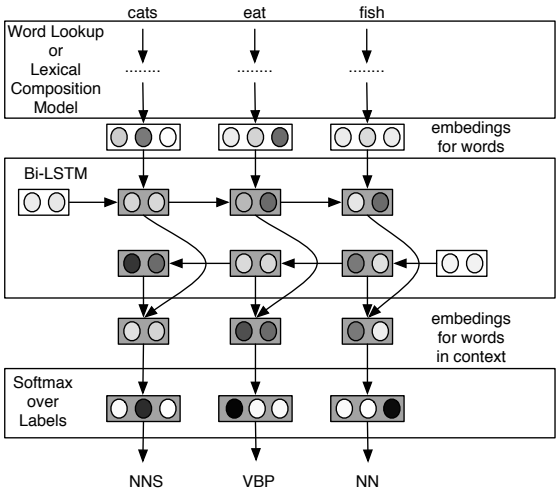

Figure 3: Illustration of our neural network for POS tagging.

5.2 Experiments

Datasets For English, we conduct experiments on the Wall Street Journal of the Penn Treebank dataset (Marcus et al., 1993), using the standard splits (sections 1–18 for train, 19–21 for tuning and 22–24 for testing). We also perform tests on 4 other languages, which we obtained from the CoNLL shared tasks (Martí et al., 2007; Brants et al., 2002; Afonso et al., 2002; Atalay et al., 2003). While the PTB dataset provides standard train, tuning and test splits, there are no tuning sets in the datasets in other languages, so we withdraw the last 100 sentences from the training dataset and use them for tuning.

Setup The POS model requires two sets of hyperparameters. Firstly, words must be converted into continuous representations and the same hyperparametrization as in language modeling (Section 4) is used. Additionally, we also compare to the convolutional model of Santos and Zadrozny (2014), which also requires the dimensionality for characters and the word representation size, which are set to 50 and 150, respectively. Secondly, words representations are combined to en-

code context. Our POS tagger has three hyperparameters d^f_{WS}, d^b_{WS} and d_{WS}, which correspond to the sizes of LSTM states, and are all set to 50. As for the learning algorithm, use the same setup (learning rate, momentum and mini-batch sizes) as used in language modeling.

Once again, we replace OOV words with an unknown token, in the setup that uses word lookup tables, and the same with OOV characters in the C2W model. In setups using pre-trained word embeddings, we consider a word an OOV if it was not seen in the labelled training data as well as in the unlabeled data used for pre-training.

Compositional Model Comparison A comparison of different recurrent neural networks for the C2W model is presented in Table 3. We used our proposed tagger tagger in all experiments and results are reported for the English Penn Treebank. Results on label accuracy test set is shown in the column "acc". The number of parameters in the word composition model is shown in the column "parameters". Finally, the number of words processed at test time per second are shown in column "words/sec".

We observe that approaches using RNN yield worse results than their LSTM counterparts with a difference of approximately 2%. This suggests that while regular RNNs can learn shorter character sequence dependencies, they are not ideal to learn longer dependencies. LSTMs, on the other hand, seem to effectively obtain relatively higher results, on par with using word look up tables (row "Word Lookup"), even when using forward (row "Forward LSTM") and backward (row "Backward LSTM") LSTMs individually. The best results are obtained using the bidirectional LSTM (row "Bi-LSTM"), which achieves an accuracy of 97.29% on the test set, surpassing the word lookup table. The convolution model (Santos and Zadrozny, 2014) obtained slightly lower results (row "Convolutional (S&Z)"), we think this is because the convolutional model uses a max-pooling layer over series of window convolutions. As order is only perserved within windows, longer distance dependences are unobserved.

There are approximately 40k lowercased word types in the training data in the PTB dataset. Thus, a word lookup table with 50 dimensions per type contains approximately 2 million parameters. In the C2W models, the number of characters types (including uppercase and lowercase) is approximately 80. Thus, the character look up table consists of only 4k parameters, which is negligible compared to the number of parameters in the compositional model, which is once again 150k parameters. One could argue that results in the Bi-LSTM model are higher than those achieved by other models as it contains more parameters, so we set the state size $d_{CS} = 50$ (row "Bi-LSTM $d_{CS} = 50$") and obtained similar results.

	acc	parameters	words/sec
Word Lookup	96.97	2000k	6K
Convolutional (S&Z)	96.80	42.5k	4K

Backward RNN	95.52	17.5k	4K
Bi-RNN	95.93	40k	3K
Forward LSTM	97.12	80k	3K
Backward LSTM	97.08	80k	3K
Bi-LSTM $d_{CS} = 50$	97.22	70k	3K
Bi-LSTM	**97.36**	150k	2K

Table 3: POS accuracy results for the English PTB using word representation models.

In terms of computational speed, we can observe that there is a more significant slowdown when applying the C2W models compared to language modeling. This is because there is no longer a softmax over the whole word vocabulary as the main bottleneck of the network. However, we can observe that while the Bi-LSTM system is 3 times slower, it is does not significantly hurt the performance of the system.

Results on Multiple Languages Results on 5 languages are shown in Table 4. In general, we can observe that the model using word lookup tables (row "Word") performs consistently worse than the C2W model (row "C2W"). We also compare our results with Stanford's POS tagger, with the default set of features, found in Table 4. Results using these tagger are comparable or better than state-of-the-art systems. We can observe that in most cases we can slightly outperform the scores obtained using their tagger. This is a promising result, considering that we use the same training data and do not handcraft any features. Furthermore, we can observe that for Turkish, our results are significantly higher (>4%).

Comparison with Benchmarks Most state-of-the-art POS tagging systems are obtained by either learning or handcrafting good lexical features (Manning, 2011; Sun, 2014) or using ad-

System	Fusional			Agglutinative	
	EN	PT	CA	DE	TR
Word	96.97	95.67	98.09	97.51	83.43
C2W	**97.36**	97.47	**98.92**	**98.08**	**91.59**
Stanford	97.32	**97.54**	98.76	97.92	87.31

Table 4: POS accuracies on different languages

ditional raw data to learn features in an unsupervised fashion. Generally, optimal results are obtained by performing both. Table 5 shows the current Benchmarks in this task for the English PTB. Accuracies on the test set is reported on column "acc". Columns "+feat" and "+data" define whether hand-crafted features are used and whether additional data was used. We can see that even without feature engineering or unsupervised pretraining, our C2W model (row "C2W") is on par with the current state-of-the-art system (row "structReg"). However, if we add hand-crafted features, we can obtain further improvements on this dataset (row "C2W + features").

However, there are many words that do not contain morphological cues to their part-of-speech. For instance, the word *snake* does not contain any morphological cues that determine its tag. In these cases, if they are not found labelled in the training data, the model would be dependent on context to determine their tags, which could lead to errors in ambiguous contexts. Unsupervised training methods such as the Skip-n-gram model (Mikolov et al., 2013) can be used to pretrain the word representations on unannotated corpora. If such pretraining places *cat*, *dog* and *snake* near each other in vector space, and the supervised POS data contains evidence that *cat* and *dog* are nouns, our model will be likely to label *snake* with the same tag.

We train embeddings using English wikipedia with the dataset used in (Ling et al., 2015), and the Structured Skip-n-gram model. Results using pre-trained word lookup tables and the C2W with the pre-trained word lookup tables as additional parameters are shown in rows "word(sskip)" and "C2W + word(sskip)". We can observe that both systems can obtain improvements over their random initializations (rows "word" and (C2W)).

Finally, we also found that when using the C2W model in conjunction pre-trained word embeddings, that adding a non-linearity to the representations extracted from the C2W model $\mathbf{e}_w^C$ improves the results over using a simple linear transformation (row "C2W(tanh)+word (sskip)"). This setup, obtains 0.28 points over the current state-of-the-art system(row "SCCN").

5.3 Discussion

It is important to refer here that these results do not imply that our model always outperforms existing benchmarks, in fact in most experiments, results are typically fairly similar to existing systems. Even in Turkish, using morphological analysers in order to extract additional features could also accomplish similar results. The goal of our work is not to overcome existing benchmarks, but show that much of the feature engineering done in the benchmarks can be learnt automatically from the task specific data. More importantly, we wish to show large dimensionality word look tables can be compacted into a lookup table using characters and a compositional model allowing the model scale better with the size of the training data. This is a desirable property of the model as data becomes more abundant in many NLP tasks.

6 Related Work

Our work, which learns representations without relying on word lookup tables has not been explored to our knowledge. In essence, our model attempts to learn lexical features automatically while compacting the model by reducing the redundancy found in word lookup tables. Individually, these problems have been the focus of research in many areas.

Lexical information has been used to augment word lookup tables. Word representation learning can be thought of as a process that takes a string as input representing a word and outputs a set of values that represent a word in vector

space. Using word lookup tables is one possible approach to accomplish this. Many methods have been used to augment this model to learn lexical features with an additional model that is jointly maximized with the word lookup table. This is generally accomplished by either performing a component-wise addition of the embeddings produced by word lookup tables (Chen et al., 2015), and that generated by the additional lexical model, or simply concatenating both representations (Santos and Zadrozny, 2014). Many models have been proposed, the work in (Collobert et al., 2011) refers that additional features sets F_i can be added to the one-hot representation and multiple lookup tables $\mathbf{I}_{F_i}$ can be learnt to project each of the feature sets to the same low-dimensional vector $\mathbf{e}_w^W$. For instance, the work in (Botha and Blunsom, 2014) shows that using morphological analyzers to generate morphological features, such as stems, prefixes and suffixes can be used to learn better representations for words. A problem with this approach is the fact that the model can only learn from what has been defined as feature sets. The models proposed in (Santos and Zadrozny, 2014; Chen et al., 2015) allow the model to arbitrary extract meaningful lexical features from words by defining compositional models over characters. The work in (Chen et al., 2015) defines a simple compositional model by summing over all characters in a given word, while the work in (Santos and Zadrozny, 2014) defines a convolutional network, which combines windows of characters and a max-pooling layer to find important morphological features. The main drawback of these methods is that character order is often neglected, that is, when summing over all character embeddings, words such as *dog* and *god* would have the same representation according to the lexical model. Convolutional model are less susceptible to these problems as they combine windows of characters at each convolution, where the order within the window is preserved. However, the order between extracted windows is not, so the problem still persists for longer words, such as those found in agglutinative languages. Yet, these approaches work in conjunction with a word lookup table, as they compensate for this inability. Aside from neural approaches, character-based models have been applied to address multiple lexically oriented tasks, such as transliteration (Kang and Choi, 2000) and twitter normalization (Xu et al., 2013; Ling et al., 2013).

Compacting models has been a focus of research in tasks, such as language modeling and machine translation, as extremely large models can be built with the large amounts of training data that are available in these tasks. In language modeling, it is frequent to prune higher order n-grams that do not encode any additional information (Seymore and Rosenfeld, 1996; Stolcke, 1998; Moore and Quirk, 2009). The same be applied in machine translation (Ling et al., 2012; Zens et al., 2012) by removing longer translation pairs that can be replicated using smaller ones. In essence our model learns regularities at the subword level that can be leveraged for building more compact word representations.

Finally, our work has been applied to dependency parsing and found similar improvements over word models in morphologically rich languages (Ballesteros et al., 2015).

7 Conclusion

We propose a C2W model that builds word embeddings for words without an explicit word lookup table. Thus, it benefits from being sensitive to lexical aspects within words, as it takes characters as atomic units to derive the embeddings for the word. On POS tagging, our models using characters alone can still achieve comparable or better results than state-of-the-art systems, without the need to manually engineer such lexical features. Although both language modeling and POS tagging both benefit strongly from morphological cues, the success of our models in languages with impoverished morphological cues shows that it is able to learn non-compositional aspects of how letters fit together.

The code for the C2W model and our language model and POS tagger implementations is available from `https://github.com/wlin12/JNN`.

Abstract

Deep compositional models of meaning acting on distributional representations of words in order to produce vectors of larger text constituents are evolving to a popular area of NLP research. We detail a compositional distributional framework based on a rich form of word embeddings that aims at facilitating the interactions between words in the context of a sentence. Embeddings and composition layers are jointly learned against a generic objective that enhances the vectors with syntactic information from the surrounding context. Furthermore, each word is associated with a number of senses, the most plausible of which is selected dynamically during the composition process. We evaluate the produced vectors qualitatively and quantitatively with positive results. At the sentence level, the effectiveness of the framework is demonstrated on the MSRPar task, for which we report results within the state-of-the-art range.

1 Introduction

Representing the meaning of words by using their distributional behaviour in a large text corpus is a well-established technique in NLP research that has been proved useful in numerous tasks. In a distributional model of meaning, the semantic representation of a word is given as a vector in some high dimensional vector space, obtained either by explicitly collecting co-occurrence statistics of the target word with words belonging to a representative subset of the vocabulary, or by directly optimizing the word vectors against an objective function in some neural-network based architecture (Collobert and Weston, 2008; Mikolov et al., 2013).

Regardless their method of construction, distributional models of meaning do not scale up to larger text constituents such as phrases or sentences, since the uniqueness of multi-word expressions would inevitably lead to data sparsity problems, thus to unreliable vectorial representations. The problem is usually addressed by the provision of a compositional function, the purpose of which is to prepare a vectorial representation for a phrase or sentence by combining the vectors of the words therein. While the nature and complexity of these compositional models may vary, approaches based on deep-learning architectures have been shown to be especially successful in modelling the meaning of sentences for a variety of tasks (Socher et al., 2012; Kalchbrenner et al., 2014).

The mutual interaction of distributional word vectors by a means of a compositional model provides many opportunities for interesting research, the majority of which still remains to be explored. One such direction is to investigate in what way lexical ambiguity affects the compositional process. In fact, recent work has shown that shallow multi-linear compositional models that explicitly handle extreme cases of lexical ambiguity in a step prior to composition present consistently better performance than their "ambiguous" counterparts (Kartsaklis and Sadrzadeh, 2013; Kartsaklis et al., 2014). A first attempt to test these observations in a deep compositional setting has been presented by Cheng et al. (2014) with promising results.

Furthermore, a second important question relates to the very nature of the word embeddings used in the context of a compositional model. In a setting of this form, word vectors are not any more just a means for discriminating words based on their underlying semantic relationships; the main goal of a word vector is to contribute to a bigger whole—a task in which syntax, along with semantics, also plays a very important role. It is a central point of this paper, therefore, that in a compositional distributional model of meaning word vectors should be injected with information that reflects their syntactical roles in the training corpus.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1531–1542,
Lisbon, Portugal, 17-21 September 2015.

The purpose of this work is to improve the current practice in deep compositional models of meaning in relation to both the compositional process itself and the quality of the word embeddings used therein. We propose an architecture for jointly training a compositional model and a set of word embeddings, in a way that imposes dynamic word sense induction for each word during the learning process. Note that this is in contrast with recent work in multi-sense neural word embeddings (Neelakantan et al., 2014), in which the word senses are learned without any compositional considerations in mind.

Furthermore, we make the word embeddings syntax-aware by introducing a variation of the hinge loss objective function of Collobert and Weston (2008), in which the goal is not only to predict the occurrence of a target word in a context, but to also predict the *position* of the word within that context. A qualitative analysis shows that our vectors reflect both semantic and syntactic features in a concise way.

In all current deep compositional distributional settings, the word embeddings are internal parameters of the model with no use for any other purpose than the task for which they were specifically trained. In this work, one of our main considerations is that the joint training step should be generic enough to not be tied in any particular task. In this way the word embeddings and the derived compositional model can be learned on data much more diverse than any task-specific dataset, reflecting a wider range of linguistic features. Indeed, experimental evaluation shows that the produced word embeddings can serve as a high quality general-purpose semantic word space, presenting performance on the Stanford Contextual Word Similarity (SCWS) dataset of Huang et al. (2012) competitive to and even better of the performance of well-established neural word embeddings sets.

Finally, we propose a dynamic disambiguation framework for a number of existing deep compositional models of meaning, in which the multi-sense word embeddings and the compositional model of the original training step are further refined according to the purposes of a specific task at hand. In the context of paraphrase detection, we achieve a result very close to the current state-of-the-art on the Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005). An interesting aspect at the sideline of the paraphrase detection experiment is that, in contrast to mainstream approaches that mainly rely on simple forms of classifiers, we approach the problem by following a siamese architecture (Bromley et al., 1993).

2 Background and related work

2.1 Distributional models of meaning

Distributional models of meaning follow the *distributional hypothesis* (Harris, 1954), which states that two words that occur in similar contexts have similar meanings. Traditional approaches for constructing a word space rely on simple counting: a word is represented by a vector of numbers (usually smoothed by the application of some function such as point-wise mutual information) which show how frequently this word co-occurs with other possible context words in a corpus of text.

In contrast to these methods, a recent class of distributional models treat word representations as parameters directly optimized on a word prediction task (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013; Pennington et al., 2014). Instead of relying on observed co-occurrence counts, these models aim to maximize the objective function of a neural net-based architecture; Mikolov et al. (2013), for example, compute the conditional probability of observing words in a context around a target word (an approach known as the *skip-gram model*). Recent studies have shown that, compared to their co-occurrence counterparts, neural word vectors reflect better the semantic relationships between words (Baroni et al., 2014) and are more effective in compositional settings (Milajevs et al., 2014).

2.2 Syntactic awareness

Since the main purpose of distributional models until now was to measure the semantic relatedness of words, relatively little effort has been put into making word vectors aware of information regarding the syntactic role under which a word occurs in a sentence. In some cases the vectors are POS-tag specific, so that 'book' as noun and 'book' as verb are represented by different vectors (Kartsaklis and Sadrzadeh, 2013). Furthermore, word spaces in which the context of a target word is determined by means of grammatical dependencies (Padó and Lapata, 2007) are more effective in capturing syntactic relations than approaches based on simple word proximity.

For word embeddings trained in neural settings, syntactic information is not usually taken explicitly into account, with some notable exceptions. At the lexical level, Levy and Goldberg (2014) propose an extension of the skip-gram model

based on grammatical dependencies. Following a different approach, Mnih and Kavukcuoglu (2013) weight the vector of each context word depending on its distance from the target word. With regard to compositional settings (discussed in the next section), Hashimoto et al. (2014) use dependency-based word embeddings by employing a hinge loss objective, while Hermann and Blunsom (2013) condition their objectives on the CCG types of the involved words.

As we will see in Section 3, the current paper offers an appealing alternative to those approaches that does not depend on grammatical relations or types of any form.

2.3 Compositionality in distributional models

The methods that aim to equip distributional models of meaning with compositional abilities come in many different levels of sophistication, from simple element-wise vector operators such as addition and multiplication (Mitchell and Lapata, 2008) to category theory (Coecke et al., 2010). In this latter work relational words (such as verbs or adjectives) are represented as multi-linear maps acting on vectors representing their arguments (nouns and noun phrases). In general, the above models are shallow in the sense that they do not have functional parameters and the output is produced by the direct interaction of the inputs; yet they have been shown to capture the compositional meaning of sentences to an adequate degree.

The idea of using neural networks for compositionality in language appeared 25 years ago in a seminal paper by Pollack (1990), and has been recently re-popularized by Socher and colleagues (Socher et al., 2011a; Socher et al., 2012). The compositional architecture used in these works is that of a *recursive neural network* (RecNN) (Socher et al., 2011b), where the words get composed by following a parse tree. A particular variant of the RecNN is the *recurrent neural network* (RNN), in which a sentence is assumed to be generated by aggregating words in sequence (Mikolov et al., 2010). Furthermore, some recent work (Kalchbrenner et al., 2014) models the meaning of sentences by utilizing the concept of a convolutional neural network (LeCun et al., 1998), the main characteristic of which is that it acts on small overlapping parts of the input vectors. In all the above models, the word embeddings and the weights of the compositional layers are optimized against a task-specific objective function.

In Section 3 we will show how to remove the restriction of a supervised setting, introducing a generic objective that can be trained on any general-purpose text corpus. While we focus on recursive and recurrent neural network architectures, the general ideas we will discuss are in principle model-independent.

2.4 Disambiguation in composition

Regardless of the way they address composition, all the models of Section 2.3 rely on ambiguous word spaces, in which every meaning of a polysemous word is merged into a single vector. Especially for cases of homonymy (such as 'bank', 'organ' and so on), where the same word is used to describe two or more completely unrelated concepts, this approach is problematic: the semantic representation of the word becomes the average of all senses, inadequate to express any of them in a reliable way.

To address this problem, a prior disambiguation step on the word vectors is often introduced, the purpose of which is to find the word representations that best fit to the given context, before composition takes place (Reddy et al., 2011; Kartsaklis et al., 2013; Kartsaklis and Sadrzadeh, 2013; Kartsaklis et al., 2014). This idea has been tested on algebraic and tensor-based compositional functions with very positive results. Furthermore, it has been also found to provide minimal benefits for a RecNN compositional architecture in a number of phrase and sentence similarity tasks (Cheng et al., 2014). This latter work clearly suggests that explicitly dealing with lexical ambiguity in a deep compositional setting is an idea that is worth to be further explored. While treating disambiguation as only a preprocessing step is a strategy less than optimal for a neural setting, one would expect that the benefits should be greater for an architecture in which the disambiguation takes place in a dynamic fashion during training.

We are now ready to start detailing a compositional model that takes into account the above considerations. The issue of lexical ambiguity is covered in Section 4; Section 3 below deals with generic training and syntactic awareness.

3 Syntax-based generic training

We propose a novel architecture for learning word embeddings and a compositional model to use them in a single step. The learning takes places in the context of a RecNN (or an RNN), and both word embeddings and parameters of the compositional layer are optimized against a generic objective function that uses a hinge loss function.

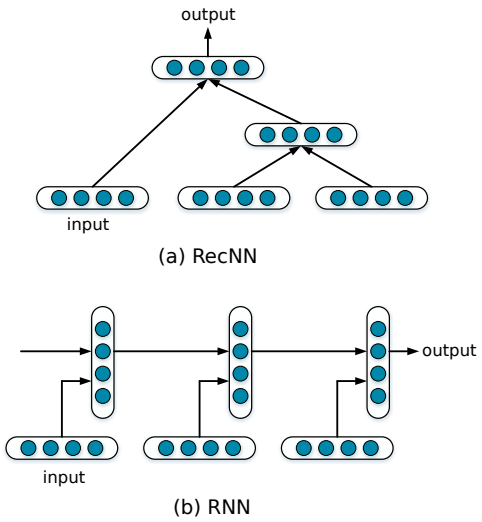

Figure 1: Recursive (a) and recurrent (b) neural networks.

Figure 1 shows the general form of recursive and recurrent neural networks. In architectures of this form, a compositional layer is applied on each pair of inputs $\mathbf{x_1}$ and $\mathbf{x_2}$ in the following way:

$$\mathbf{p} = g(\mathbf{W}\mathbf{x}_{[\mathbf{1:2}]} + \mathbf{b}) \quad (1)$$

where $\mathbf{x}_{[\mathbf{1:2}]}$ denotes the concatenation of the two vectors, g is a non-linear function, and $\mathbf{W}, \mathbf{b}$ are the parameters of the model. In the RecNN case, the compositional process continues recursively by following a parse tree until a vector for the whole sentence or phrase is produced; on the other hand, an RNN assumes that a sentence is generated in a left-to-right fashion, taking into consideration no dependencies other than word adjacency.

We amend the above setting by introducing a novel layer on the top of the compositional one, which scores the linguistic plausibility of the composed sentence or phrase vector with regard to *both* syntax and semantics. Following Collobert and Weston (2008), we convert the unsupervised learning problem to a supervised one by corrupting training sentences. Specifically, for each sentence s we create two sets of negative examples. In the first set, S', the target word within a given context is replaced by a random word; as in the original C&W paper, this set is used to enforce semantic coherence in the word vectors. Syntactic coherence is enforced by a second set of negative examples, S'', in which the words of the context have been randomly shuffled. The objective function is defined in terms of the following hinge losses:

$$\sum_{s \in S} \sum_{s' \in S'} \max(0, m - f(s) + f(s')) \quad (2)$$

$$\sum_{s \in S} \sum_{s'' \in S''} \max(0, m - f(s) + f(s'')) \quad (3)$$

where S is the set of sentences, f the compositional layer, and m a margin we wish to retain between the scores of the positive training examples and the negative ones. During training, all parameters in the scoring layer, the compositional layers and word representations are jointly updated by error back-propagation. As output, we get both general-purpose syntax-aware word representations and weights for the corresponding compositional model.

4 From words to senses

We now extend our model to address lexical ambiguity. We achieve that by applying a gated architecture, similar to the one used in the multi-sense model of Neelakantan et al. (2014), but advancing the main idea to the compositional setting detailed in Section 3.

We assume a fixed number of n senses per word.[1] Each word is associated with a main vector (obtained for example by using an existing vector set, or by simply applying the process of Section 3 in a separate step), as well as with n vectors denoting cluster centroids and an equal number of sense vectors. Both cluster centroids and sense vectors are randomly initialized in the beginning of the process. For each word w_t in a training sentence, we prepare a context vector by averaging the main vectors of all other words in the same context. This context vector is compared with the cluster centroids of w_t by cosine similarity, and the sense corresponding to the closest cluster is selected as the most representative of w_t in the current context. The selected cluster centroid is updated by the addition of the context vector, and the associated sense vector is passed as input to the compositional layer. The selected sense vectors for each word in the sentence are updated by back-propagation, based on the objectives of Equations 2 and 3. The overall architecture of our model, as described in this and the previous section, is illustrated in Figure 2.

5 Task-specific dynamic disambiguation

The model of Figure 2 decouples the training of word vectors and compositional parameters from

[1] Note that in principle the fixed number of senses assumption is not necessary; Neelakantan et al. (2014), for example, present a version of their model in which new senses are added dynamically when appropriate.

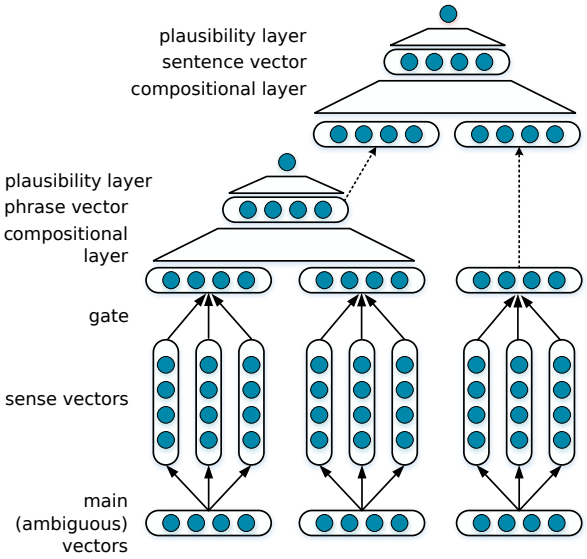

Figure 2: Training of syntax-aware multi-sense embeddings in the context of a RecNN.

a specific task, and as a consequence from any task-specific training dataset. However, note that by replacing the plausibility layer with a classifier trained for some task at hand, you get a task-specific network that transparently trains multi-sense word embeddings and applies dynamic disambiguation on the fly. While this idea of a single-step direct training seems appealing, one consideration is that the task-specific dataset used for the training will not probably reflect the linguistic variety that is required to exploit the expressiveness of the setting in its full. Additionally, in many cases the size of datasets tied to specific tasks is prohibiting for training a deep architecture.

It is a merit of this proposal that, in cases like these, it is possible for one to train the generic model of Figure 2 on any large corpus of text, and then use the produced word vectors and compositional weights to initialize the parameters of a more specific version of the architecture. As a result, the trained parameters will be further refined according to the task-specific objective. Figure 3 illustrates the generic case of a compositional framework applying dynamic disambiguation. Note that here sense selection takes place by a soft-max layer, which can be directly optimized on the task objective.

6 A siamese network for paraphrase detection

We will test the dynamic disambiguation framework of Section 5 in a paraphrase detection task. A *paraphrase* is a restatement of the meaning of a sentence using different words and/or syntax. The goal of a paraphrase detection model, thus, is to examine two sentences and decide if they express the same meaning.

While the usual way to approach this problem is to utilize a classifier that acts (for example) on the concatenation of the two sentence vectors, in this work we follow a novel perspective: specifically, we apply a *siamese architecture* (Bromley et al., 1993), a concept that has been extensively used in computer vision (Hadsell et al., 2006; Sun et al., 2014). While siamese networks have been also used in the past for NLP purposes (for example, by Yih et al. (2011)), to the best of our knowledge this is the first time that such a setting is applied for paraphrase detection.

In our model, two networks sharing the same parameters are used to compute the vectorial representations of two sentences, the paraphrase relation of which we wish to detect; this is achieved by employing a cost function that compares the two vectors. There are two commonly used cost functions: the first is based on the L_2 norm (Hadsell et al., 2006; Sun et al., 2014), while the second on the cosine similarity (Nair and Hinton, 2010; Sun et al., 2014). The L_2 norm variation is capable of handling differences in the magnitude of the vectors. Formally, the cost function is defined as:

$$E_f = \begin{cases} \frac{1}{2}\left\|f(s_1) - f(s_2)\right\|_2^2, & \text{if } y = 1 \\ \frac{1}{2}\max(0, m - \left\|f(s_1) - f(s_2)\right\|_2)^2, & o.w. \end{cases}$$

where s_1, s_2 are the input sentences, f the compositional layer (so $f(s_1)$ and $f(s_2)$ refer to sentence vectors), and $y = 1$ denotes a paraphrase relationship between the sentences; m stands for the margin, a hyper-parameter chosen in advance. On

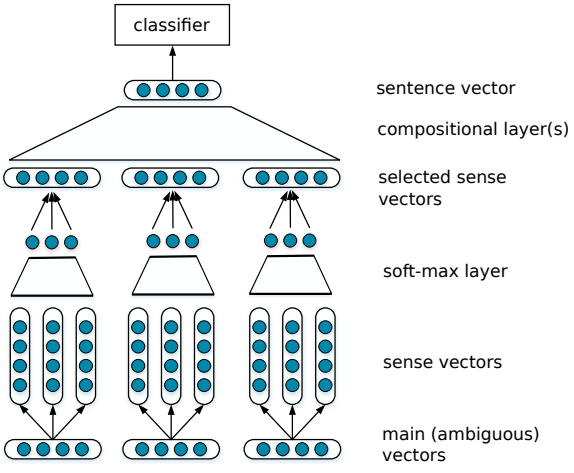

Figure 3: Dynamic disambiguation in a generic compositional deep net.

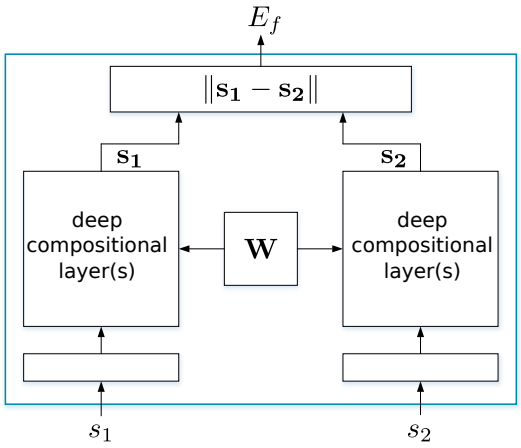

Figure 4: A siamese network for paraphrase detection.

the other hand, the cost function based on cosine similarity handles only directional differences, as follows:

$$E_f = \frac{1}{2}(y - \sigma(wd + b))^2 \quad (4)$$

where $d = \frac{f(s_1) \cdot f(s_2)}{\|f(s_1)\|_2 \|f(s_2)\|_2}$ is the cosine similarity of the two sentence vectors, w and b are the scaling and shifting parameters to be optimized, σ is the sigmoid function and y is the label. In the experiments that will follow in Section 7.4, both of these cost functions are evaluated. The overall architecture is shown in Figure 4.

In Section 7.4 we will use the pre-trained vectors and compositional weights for deriving sentence representations that will be subsequently fed to the siamese network. When the dynamic disambiguation framework is used, the sense vectors of the words are updated during training so that the sense selection process is gradually refined.

7 Experiments

We evaluate the quality of the compositional word vectors and the proposed deep compositional framework in the tasks of word similarity and paraphrase detection, respectively.

7.1 Model pre-training

In all experiments the word representations and compositional models are pre-trained on the British National Corpus (BNC), a general-purpose text corpus that contains 6 million sentences of written and spoken English. For comparison we train two sets of word vectors and compositional models, one ambiguous and one multi-sense (fixing 3 senses per word). The dimension of the embeddings is set to 300.

As our compositional architectures we use a RecNN and an RNN. In the RecNN case, the words are composed by following the result of an external parser, while for the RNN the composition takes place in sequence from left to right. To avoid the exploding or vanishing gradient problem (Bengio et al., 1994) for long sentences, we employ a *long short-term memory* (LSTM) network (Hochreiter and Schmidhuber, 1997). During the training of each model, we minimize the hinge loss in Equations 2 and 3. The plausibility layer is implemented as a 2-layer network, with 150 units at the hidden layer, and is applied at each individual node (as opposed to a single application at the sentence level). All parameters are updated with mini-batches by AdaDelta (Zeiler, 2012) gradient descent method ($\lambda = 0.03$, initial $\alpha = 0.05$).

7.2 Qualitative evaluation of the word vectors

As a first step, we qualitatively evaluate the trained word embeddings by examining the nearest neighbours lists of a few selected words. We compare the results with those produced by the skip-gram model (SG) of Mikolov et al. (2013) and the language model (CW) of Collobert and Weston (2008). We refer to our model as SAMS (Syntax-Aware Multi-Sense). The results in Table 1 show clearly that our model tends to group words that are both semantically and syntactically related; for example, and in contrast with the compared models which group words only at the semantic level, our model is able to retain tenses, numbers (singulars and plurals), and gerunds.

The observed behaviour is comparable to that of embedding models with objective functions conditioned on grammatical relations between words; Levy and Goldberg (2014), for example, present a similar table for their dependency-based extension of the skip-gram model. The advantage of our approach against such models is twofold: firstly, the word embeddings are accompanied by a generic compositional model that can be used for creating sentence representations independently of any specific task; and secondly, the training is quite forgiving to data sparsity problems that in general a dependency-based approach would intensify (since context words are paired with the grammatical relations they occur with the target word). As a result, a small corpus such as the BNC is sufficient for producing high quality syntax-aware word embeddings.

	SG	CW	SAMS
begged	beg, begging, cried	begging, pretended, beg	persuaded, asked, cried
refused	refusing, refuses, refusal	refusing , declined, refuse	declined, rejected, denied
interrupted	interrupting, punctuated, interrupt	interrupts, interrupt, interrupting	punctuated, preceded, disrupted
themes	thematic, theme, notions	theme, concepts, subtext	meanings, concepts, ideas
patiently	impatiently, waited, waits	impatiently, queue, expectantly	impatiently, siliently, anxiously
player	players, football, league	game, club, team	athlete, sportsman, team
prompting	prompted, prompt, sparking	prompt, amid, triggered	sparking, triggering, forcing
reproduce	reproducing, replicate, humans	reproducing, thrive, survive	replicate, produce, repopulate
predictions	prediction, predict, forecasts	predicting, assumption, predicted	expectations, projections, forecasts

Table 1: Nearest neighbours for a number of words with various embedding models.

7.3 Word similarity

We now proceed to a quantitative evaluation of our embeddings on the Stanford Contextual Word Similarity (SCWS) dataset of Huang et al. (2012). The dataset contains 2,003 pairs of words and the contexts they occur in. We can therefore make use of the contextual information in order to select the most appropriate sense for each ambiguous word. Similarly to Neelakantan et al. (2014), we use three different metrics: *globalSim* measures the similarity between two ambiguous word vectors; *localSim* selects a single sense for each word based on the context and computes the similarity between the two sense vectors; *avgSim* represents each word as a weighted average of all senses in the given context and computes the similarity between the two weighted sense vectors.

We compute and report the Spearman's correlation between the embedding similarities and human judgments (Table 2). In addition to the skip-gram and Collobert and Weston models, we also compare against the CBOW model (Mikolov et al., 2013) and the multi-sense skip-gram (MSSG) model of Neelakantan et al. (2014).

Model	globalSim	localSim	avgSim
CBOW	59.5	–	–
SG	**61.8**	–	–
CW	55.3	–	–
MSSG	61.3	56.7	62.1
SAMS	59.9	**58.5**	**62.5**

Table 2: Results for the word similarity task (Spearman's $\rho \times 100$).

Among all methods, only the MSSG model and ours are capable of learning multi-prototype word representations. Our embeddings show top performance for *localSim* and *avgSim* measures, and performance competitive to that of MSSG and SG for *globalSim*, both of which use a hierarchical soft-max as their objective function. Compared to the original C&W model, our version presents an improvement of 4.6%—a clear indication for the effectiveness of the proposed learning method and the enhanced objective.

7.4 Paraphrase detection

In the last set of experiments, the proposed compositional distributional framework is evaluated on the Microsoft Research Paraphrase Corpus (MSRPC) (Dolan and Brockett, 2005), which contains 5,800 pairs of sentences. This is a binary classification task, with labels provided by human annotators. We apply the siamese network detailed in Section 6.

While MSRPC is one of the most used datasets for evaluating paraphrase detection models, its size is prohibitory for any attempt of training a deep architecture. Therefore, for our training we rely on a much larger external dataset, the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013). The PPDB contains more than 220 million paraphrase pairs, of which 73 million are phrasal paraphrases and 140 million are paraphrase patterns that capture syntactic transformations of sentences. We use these phrase- and sentence-level paraphrase pairs as additional training contexts to fine-tune the generic compositional model parameters and word embeddings and to train the baseline models. The original training set of the MSRPC is used as validation set for deciding hyperparameters, such as the margin of the error function and the number of training epochs.

The evaluations were conducted on various aspects, and the models are gradually refined to demonstrate performance within the state-of-the-art range.

Comparison of the two error functions In the first evaluation, we compare the two error functions of the siamese network using only ambigu-

ous vectors. As we can see in Table 3, the cosine error function consistently outperforms the L_2 norm-based one for both compositional models, providing a yet another confirmation of the already well-established fact that similarity in semantic vector spaces is better reflected by length-invariant measures.

Model	L_2	Cosine
RecNN	73.8	**74.9**
RNN	73.0	**74.3**

Table 3: Results with different error functions for the paraphrase detection task (accuracy $\times$ 100).

Effectiveness of disambiguation We now proceed to compare the effectiveness of the two compositional models when using ambiguous vectors and multi-sense vectors, respectively. Our error function is set to cosine similarity, following the results of the previous evaluation. When dynamic disambiguation is applied, we test two methods of selecting sense vectors: in the hard case the vector of the most plausible sense is selected, while in the soft case a new vector is prepared as the weighted average of all sense vectors according to probabilities returned by the soft-max layer (see Figure 3). As a baseline we use a simple compositional model based on vector addition.

The dynamic disambiguation models and the additive baseline are compared with variations that use a simple prior disambiguation step applied on the word vectors. This is achieved by first selecting for each word the sense vector that is the closest to the average of all other word vectors in the same sentence, and then composing the selected sense vectors without further considerations regarding ambiguity. The baseline model and the prior disambiguation variants are trained as separate logistic regression classifiers. The results are shown in Table 4.

Model	Ambig.	Prior	Hard DD	Soft DD
Addition	69.9	71.3	–	–
RecNN	74.9	75.3	75.7	**76.0**
RNN	74.3	74.6	75.1	**75.2**

Table 4: Different disambiguation choices for the paraphrase detection task (accuracy $\times$ 100).

Overall, disambiguated vectors work better than the ambiguous ones, with the improvement to be more significant for the additive model; there, a simple prior disambiguation step produces 1.4% gains. For the deep compositional models, simple prior disambiguation is still helpful with small improvements, a result which is consistent with the findings of Cheng et al. (2014). The small gains of the prior disambiguation models over the ambiguous models clearly show that deep architectures are quite capable of performing this elementary form of sense selection intrinsically, as part of the learning process itself. However, the situation changes when the dynamic disambiguation framework is used, where the gains over the ambiguous version become more significant. Comparing the two ways of dynamic disambiguation (hard method and soft method), the numbers that the soft method gives are slightly higher, producing a total gain of 1.1% over the ambiguous version for the RecNN case.[2]

Note that, at this stage, the advantage of using the dynamic disambiguation framework over simple prior disambiguation is still small (0.7% for the case of RecNN). We seek the reason behind this in the recursive nature of our architecture, which tends to progressively "hide" local features of word vectors, thus diminishing the effect of the fine-tuned sense vectors produced by the dynamic disambiguation mechanism. The next section discusses the problem and provides a solution.

The role of pooling One of the problems of the recursive and recurrent compositional architectures, especially in grammars with strict branching structure such as in English, is that any given composition is usually the product of a terminal and a non-terminal; i.e. a single word can contribute to the meaning of a sentence to the same extent as the rest of a sentence on its whole, as below:

$[[\text{kids}]_{\text{NP}}\ [\text{play ball games in the park}]_{\text{VP}}]_{\text{S}}$

In the above case, the contribution of the words within the verb phrase to the final sentence representation will be faded out due to the recursive composition mechanism. Inspired by related work in computer vision (Sun et al., 2014), we attempt to alleviate this problem by introducing an average pooling layer at the sense vector level and adding the resulting vector to the sentence representation. By doing this we expect that the new sentence vector will reflect local features from all words in the sentence that can help in the classification in a more direct way. The results for the new deep architectures are shown in Table 5, where we see substantial improvements for both deep nets. More importantly, the effect of dynamic

[2]For all subsequent experiments, the reported results are based on the soft selection method.

disambiguation now becomes more significant, as expected by our analysis.

Table 5 also includes results for two models trained in a single step, with word and sense vectors randomly initialized at the beginning of the process. We see that, despite the large size of the training set, the results are much lower than the ones obtained when using the pre-training step. This demonstrates the importance of the initial training on a general-purpose corpus: the resulting vectors reflect linguistic information that, although not obtainable from the task-specific training, can make great difference in the result of the classification.

Model	Ambig.	Prior	Dynamic
RecNN+pooling	75.5	76.3	**77.6**
RNN+pooling	74.8	75.9	**76.6**
1-step RecNN+pooling	74.4	–	72.9
1-step RNN+pooling	73.6	–	73.1

Table 5: Results with average pooling for the paraphrase detection task (accuracy $\times$ 100).

Cross-model comparison In this section we propose a method to further improve the performance of our models, and we present an evaluation against some of the previously reported results.

We notice that using distributional properties alone cannot capture efficiently subtle aspects of a sentence, for example numbers or human names. However, even small differences on those aspects between two sentences can lead to a different classification result. Therefore, we train (using the MSPRC training data) an additional logistic regression classifier which is based not only on the embeddings similarity, but also on a few hand-engineered features. We then ensemble the new classifier (C1) with the original one. In terms of feature selection, we follow Socher et al. (2011a) and Blacoe and Lapata (2012) and add the following features: the difference in sentence length, the unigram overlap among the two sentences, features related to numbers (including the presence or absence of numbers from a sentence and whether or not the numbers in the two sentences are the same). In Table 6 we report results of the original model and the ensembled model, and we compare with the performance of other existing models.

In all of the implemented models (including the additive baseline), disambiguation is performed to guarantee the best performance. We see that by ensembling the original classifier with C1, we improve the result of the previous section by another 1%. This is the second best result reported so far for the specific task, with a 0.6 difference in F-score from the first (Ji and Eisenstein, 2013).[3]

8 Conclusion and future work

The main contribution of this paper is a deep compositional distributional model acting on linguistically motivated word embeddings.[4] The effectiveness of the syntax-aware, multi-sense word vectors and the dynamic compositional disambiguation framework in which they are used was demonstrated by appropriate tasks at the lexical and sentence level, respectively, with very positive results. As an aside, we also demonstrated the benefits of a siamese architecture in the context of a paraphrase detection task. While the architectures tested in this work were limited to a RecNN and an RNN, the ideas we presented are in principle directly applicable to any kind of deep network. As a future step, we aim to test the proposed models on a convolutional compositional architecture, similar to that of Kalchbrenner et al. (2014).

Acknowledgments

The authors would like to thank the three anonymous reviewers for their useful comments, as well as Nal Kalchbrenner and Ed Grefenstette for early discussions and suggestions on the paper, and Simon Šuster for comments on the final draft. Dimitri Kartsaklis gratefully acknowledges financial support by AFOSR.

Conversation Trees: A Grammar Model for Topic Structure in Forums

Annie Louis and Shay B. Cohen

{alouis,scohen}@inf.ed.ac.uk

Abstract

Online forum discussions proceed differently from face-to-face conversations and any single thread on an online forum contains posts on different subtopics. This work aims to characterize the content of a forum thread as a *conversation tree* of topics. We present models that jointly perform two tasks: segment a thread into subparts, and assign a topic to each part. Our core idea is a definition of topic structure using probabilistic grammars. By leveraging the flexibility of two grammar formalisms, Context-Free Grammars and Linear Context-Free Rewriting Systems, our models create desirable structures for forum threads: our topic segmentation is hierarchical, links non-adjacent segments on the same topic, and jointly labels the topic during segmentation. We show that our models outperform a number of tree generation baselines.

1 Introduction

Online forums are commonplace today and used for various purposes: product support and troubleshooting, opining about events and people, and student interaction on online course platforms. Threads in these forums become long, involve posts from multiple users, and the chronological order of the posts in a thread does not represent a continuous flow of dialog. Adding structure to these threads is important for tasks such as information extraction, search, and summarization.

One such aspect of structure is *topic*. Figure 1 shows a computer-troubleshooting related thread with six posts. The first post is the troubleshooting question and the remaining posts can be seen as focusing on either of two topics, the *driver software* (posts p_1, p_2, p_5) or the *speaker hardware* (p_3, p_4). By categorizing posts into such topics, we can provide a useful division of content in a thread and even across multiple threads. Note that the *driver* topic is not a contiguous sequence but present in non-adjacent parts, (p_1, p_2) and (p_5).

p_0 Bob:	When I play a recorded video on my camera, it looks and sounds fine. On my computer, it plays at a really fast rate and sounds like Alvin and the Chipmunks!
p_1 Kate:	I'd find and install the latest audio driver.
p_2 Mary:	The motherboard supplies the clocks for audio feedback. So update the audio and motherboard drivers.
p_3 Chris:	Another fine mess in audio is volume and speaker settings. You checked these?
p_4 Jane:	Yes, under speaker settings, look for hardware acceleration. Turning it off worked for me.
p_5 Matt:	Audio drivers are at this link. Rather than just audio drivers, I would also just do all drivers.

Table 1: Example forum thread conversation

We tackle the problem of joint topic segmentation and topic labeling of forum threads. Given a thread's posts in chronological order (the order in which they were posted), we create a phrase structure tree indicating how the posts are grouped hierarchically into subtopics and super-topics. In these *conversation trees*, leaves span entire posts. Each non-terminal identifies the topic characterizing the posts in its span. Topics are concepts or themes which summarize the content of a group of posts. Specifically, a topic is a set of words which frequently co-occur in posts which are similar in content and other conversation regularities.

Our key insight in this work is to formalize topic structure using probabilistic grammars. We define a base grammar for topic structure of forum threads and refine it to represent finer topics and subtrees. We learn to predict trees under our grammar based on two formalisms: Probabilistic Context-Free Grammars (PCFG) and Probabilistic Linear Context-Free Rewriting Systems (PLCFRS). In the PCFG model, a non-terminal spans a contiguous sequence of posts. In the

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1543–1553,
Lisbon, Portugal, 17-21 September 2015.

PLCFRS model, non-terminals are allowed to span discontinuous segments of posts. We leverage algorithms from probabilistic parsing of natural language sentences and modify them for our domain. We show that our model performs well and sidesteps a number of limitations of prior topic segmentation approaches. In particular:

• Our models perform joint topic segmentation and topic labeling while most existing models identify unlabeled segments. Labeling topics on segments creates richer annotation, and links non-adjacent segments on the same topic.

• Our grammar-based probabilistic models have two key benefits. They naturally create tree structures which are considered linguistically suitable for topic segmentation but were difficult to create under previous approaches. Second, the flexibility of grammars such as PLCFRS allow our models to seamlessly learn to produce trees where non-adjacent segments on the same topic are explicitly linked, an issue that was not addressed before.

We present large-scale experiments on a collection of forum threads from the computer-troubleshooting domain.[1] We show that our grammar models achieve a good balance between identifying when posts should be in the same topic versus a different topic. These grammar models outperform other tree generation baselines by a significant margin especially on short threads.

2 Related work

The ideas in this paper are related to three areas of prior research.

Forum thread analysis. Finding structure in forum threads has been previously addressed in two ways. The first is reply structure prediction where a parent post is linked to its children (replies) which were posted later in time (Wang et al., 2008; Cong et al., 2008). Reply links are sometimes augmented with a dialog act label indicating whether the child post is a question, answer, or confirmation to the parent post (Kim et al., 2010; Wang et al., 2011). The second set of methods partition sentences in emails or blog comments into topical clusters and then show salient words per cluster as topic tags (Joty et al., 2013).

We focus on producing rich hierarchical segmentation going beyond clusters which do not contain any cluster-internal structure. We also believe that topic structure is complementary to dialog act and reply link annotations. Tasks on forum data such as user expertise (Lui and Baldwin, 2009) and post quality prediction (Agichtein et al., 2008), and automatic summarization (Nenkova and Bagga, 2003) can be carried out on a fine-grained level using topic information.

Conversation disentanglement. A related problem of clustering utterances is defined specifically for Internet Relay Chat (IRC) and speech conversations. In this case, multiple conversations, on different topics, are mixed in and systems extract threads which separate out individual conversations (Shen et al., 2006; Adams and Martell, 2008; Elsner and Charniak, 2010).

Disentanglement is typically applied for the coarse-level problem of identifying a coherent conversation. In addition, these methods do not create any structure upon the clustered utterances in contrast to the focus of this work.

Topic Segmentation. is a task which directly focuses on the topic aspect of text and speech. This task is of greater importance for speech which lacks explicit structure such as paragraphs and sections. Many approaches perform linear segmentation where boundaries are inserted in the text or speech to divide it into a flat set of topic segments (Hearst, 1994; Utiyama and Isahara, 2001; Galley et al., 2003; Malioutov and Barzilay, 2006; Eisenstein and Barzilay, 2008). Very few methods recursively combine smaller segments into larger ones. Such hierarchical models (Eisenstein, 2009) have been applied at a coarse level for segmenting very long texts such as books into sections. Other work has focused on linear segmentation for documents within the same domain and having a regular structure (Chen et al., 2009; Jeong and Titov, 2010; Du et al., 2015). These latter approaches rely on three assumptions: that the documents contain a regular set of topics, that these topics are discussed in a fairly regular consensus order, and that the same topic does not recur in the same document.

Our models address two deficiencies in these approaches. First, text is commonly understood to have a hierarchical structure (Grosz and Sidner, 1986) and our grammar model is an ideal framework for this goal. Tree structures also have other advantages, for example, we do not predefine the number of expected topic segments in a conversation tree, a requirement posed by many prior seg-

[1] Our corpus is available from `http://kinloch.inf.ed.ac.uk/public/CTREES/ConversationTrees.html`

mentation algorithms. The second limitation of prior studies is assuming that topics do not recur in the same document. But linguistic theories allow for non-adjacent utterances to belong to the same topic segment (Grosz and Sidner, 1986) and this fact is empirically true in chat and forum conversations (Elsner and Charniak, 2010; Wang et al., 2011). Our models can flexibly handle and link recurring topics within and across threads.

As a final note, because of the annotations required, most prior work on forums or IRC chats have typically used few hundred threads. We present a heuristically derived large corpus of topic structure on which we evaluate our models.

3 Background

Our topic discovery methods are based on two constituency grammar formalisms.

3.1 Probabilistic Context-Free Grammars

A PCFG is defined by a 5-tuple G_C =(N, T, P, S, D) where N is a set of non-terminal symbols, T a set of terminal symbols, and S is the start symbol. P is a set of production rules of the form $A \rightarrow \beta$ where A is a non-terminal and $\beta \in \{N \cup T\}^*$. D is a function that associates each production rule with a conditional probability of the form $p(A \rightarrow \beta|A)$. This probability indicates how often the non-terminal A expands into β. The probabilities of all the rules conditioned on a particular non-terminal should sum to 1.

The joint probability of a tree T with yield Y, $P(T, Y)$, is the product of the probabilities of all the productions used to construct T. The parsing problem is to find the tree $\hat{T}$ which is most likely given the yield Y. $\hat{T} = \arg\max_T P(T|Y) = \arg\max_T P(T, Y)$.

Given training trees, we can enumerate the productions and compute their probabilities using maximum likelihood estimates (MLE):

$$p(A \rightarrow \beta|A) = \frac{\text{count}(A \rightarrow \beta)}{\text{count}(A)}$$

which is the fraction of the times the non-terminal A expands into β.

The most likely parse tree can be found using a number of algorithms. In this work, we use the CYK algorithm for PCFGs in Chomsky Normal Form. This algorithm has complexity $\mathcal{O}(n^3)$ where n is the length of the yield.

PCFGs do not capture a frequently occurring property of forum threads, discontinuous segments on the same topic. Indirectly however, a PCFG may assign the same non-terminal for each of these segments. To model these discontinuities more directly, we present a second model based on PLCFRS where non-terminals are allowed to span discontinuous yield strings.

3.2 Probabilistic Linear Context-Free Rewriting Systems

LCFRS grammars (Vijay-Shanker et al., 1987) generalize CFGs, where non-terminals can span discontinuous constituents. Formally, the span of an LCFRS non-terminal is a tuple, with size $k \geq 1$, of strings, where k is the non-terminal "fan-out". As such, the fan-out of a CFG non-terminal is 1.

An LCFRS G_L =(N, T, P, S, V) where N is the set of non-terminals, T the terminals and S is the start symbol. A function $f : N \rightarrow \mathbb{N}$ gives the fan-out of each non-terminal. P is the set of productions or otherwise called rewriting rules of the LCFRS. V is a set of variables used to indicate the spans of each non-terminal in these rules. A rewriting rule has the form:

$$A(\alpha_1, \alpha_2, \ldots, \alpha_{f(A)}) \rightarrow$$
$$A_1(x_1^1 \ldots, x_{f(A_1)}^1), \ldots, A_m(x_1^m, \ldots, x_{f(A_m)}^m)$$

Here A,A_1,...,$A_m \in N$. Since there are m non-terminals on the RHS, this rule has rank m. $x_j^i \in V$ for $1 \leq i \leq m$ and $1 \leq j \leq f(A_i)$ indicate the $f(A_i)$ discontinuous spans dominated by A_i. $\alpha_i \in (T \cup V)^*$, $1 \leq i \leq f(A)$ are the spans of the LHS non-terminal A.

A rewriting rule explains how the left-hand side (LHS) non-terminal's span can be composed from the yields of the right-hand side (RHS) non-terminals. For example, in the rule $A(x_1x_2, x_3) \rightarrow B(x_1)C(x_2, x_3)$, A and C have fan-out 2, B has fan-out 1. The two spans of A, x_1x_2 and x_3, are composed from the spans of B and C. For comparison, the productions of a CFG take the single spans of each non-terminal on the RHS and concatenate them in the same order to yield a single span of the LHS non-terminal.

A Probabilistic LCFRS (PLCFRS) (Levy, 2005) also contains D, a function which assigns conditional probabilities p($A(\vec{x}) \rightarrow \vec{\phi}|A(\vec{x})$) to the rules. The probabilities conditioned on a particular non-terminal and span configuration, $A(\vec{x})$ should sum to 1. Given a training corpus, LCFRS rules can be read out and probabilities computed similar to CFG rules.

To find the most likely parse tree, we use the parsing algorithm proposed by Kallmeyer and Maier (2013) for binary PLCFRS. The approach uses weighted deduction rules (Shieber et al., 1995; Nederhof, 2003), which specify how to compute a new item from other existing items. Each item is of the form $[A, \vec{\rho}]$ where A is a non-terminal and $\vec{\rho}$ is a vector indicating the spans dominated by A. A weight w is attached to each item which gives the $|\log|$ of the Viterbi inside probability of the subtree under that item. A set of goal items specify the form of complete parse trees. By using the Knuth's generalization (Knuth, 1977) of the shortest paths algorithm, the most likely tree can be found without exhaustive parsing as in Viterbi parsing of CFGs. The complexity of parsing is $\mathcal{O}(n^{3k})$ where k is the fan-out of the grammar (the maximum fan-out of its rules).

4 Problem Formulation

Given a thread consisting of a sequence of posts $(p_1, p_2, \ldots, p_n)$ in chronological order, the task is to produce a constituency tree with yield $(p_1, p_2 \ldots p_n)$. A leaf in this tree spans an entire post. Non-terminals identify the topic of the posts within their span. Non-terminals at higher levels of the tree represent coarser topics in the conversation (the span covered by these nodes contain more posts) than those lower in the tree. The root topic node indicates the overall topic of the thread.

Below we define a Context-Free Grammar (CFG) for such trees.

4.1 A Grammar for Conversation Trees

G_B is our *base grammar* which is context-free and has four non-terminals $\{S, X, T, C\}$. Each post p in the corpus is a terminal symbol (i.e. a terminal symbol is a bag of words). The productions in G_B are: $S \rightarrow T\ X^*$, $X \rightarrow T\ X^*$ and $T \rightarrow p$.

G_B generates trees with the following structure. A root-level topic S characterizes the content of the entire thread. *Thread-starting* rules are of the form, $S \rightarrow T\ X^*$, where X^* indicates a sequence of zero or more X non-terminals. T nodes are pre-terminals analogous to part-of-speech tags in the case of syntactic parsing. In our grammar, the $T \rightarrow p$ rule generates a post in the thread. In the *thread-starting* rules, T generates the first post of the thread which poses the query or comment that elicits the rest of the conversation. The X^* sequence denotes *topic branches*, the subtree under each X is assumed to correspond to a different topic. These X's characterize all but the first post of the thread. The *continuation rules*, $X \rightarrow T\ X^*$, recursively subdivide the X subtrees into topics spanning fewer posts. In each case, the T node on the right-hand side of these rules generates the first post (in terms of posting time) in that subtree. Therefore posts made earlier in time always dominate (in the tree structure) those which come later in the thread. We define the head of a non-terminal as the first post as per the chronological order of posts in the span of the non-terminal.

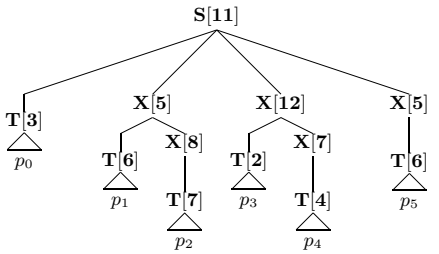

Figure 1: Example conversation tree for the thread in Table 1

This grammar does not generate binary trees. We binarize the tree with C nodes to obtain an equivalent grammar in Chomsky Normal Form (CNF) (CNF yields parsing algorithms with lower complexity)[2]: $S \rightarrow T\ C \mid T$, $X \rightarrow T\ C \mid T$, $T \rightarrow p$ and $C \rightarrow X \mid X\ X \mid X\ C$. The C nodes can be collapsed and its daughters attached to the parent of C to revert back to the non-binary tree.

While this CFG defines the structure of conversation trees, by itself this grammar is insufficient for our task. In particular, it contains a single non-terminal of each type (S, X, T, C) and so does not distinguish between topics. We extend this grammar to create G_E which has a *set* of non-terminals corresponding to each non-terminal in G_B, these fine-grained non-terminals correspond to different topics. G_E is created using latent annotations (Matsuzaki et al., 2005) on the X, T, S and C non-terminals from G_B. The resulting non-terminals for G_E are $S[i]$, $X[j]$, $T[k]$ and $C[l]$, such that $1 \leq i \leq N_S$, $1 \leq j \leq N_X$, $1 \leq k \leq N_T$, $1 \leq l \leq N_C$. i, j, k and l identify specific topics attached to a particular node type.

Our output trees are created with G_E to depict the topic segmentation of the thread and are non-binary. The binary trees produced by our algorithms are converted by collapsing the C. As a result, conversation trees have $S[i]$, $X[j]$ and $T[k]$

[2]Any context-free grammar can be converted to an equivalent CNF grammar. Our algorithms support unary rules.

nodes but no $C[l]$ nodes.

An example conversation tree for the thread in Table 1 is shown in Figure 1. At level 1, $T[3]$ describes the topic of the first post while the remaining posts are under $X[5]$ which may indicate a *driver* topic, and $X[12]$, a *speaker hardware* topic. Note how $X[5]$ may re-occur in the conversation to accommodate post p_5 on the *driver* topic.

4.2 Supervised learning framework

We use a supervised framework for learning the models. We assume that we have training trees according to the base grammar, G_B. The following section describes our data and how we obtain these G_B-based trees. In Section 6, we present a method for creating G_E-type trees with non-terminal refinements. Estimates of rule probabilities from this augmented training corpus are used to develop the parsers for topic segmentation.

5 Data

We collected 13,352 computer-troubleshooting related threads from `http://forums.cnet.com/`. The number of posts per thread varies greatly between 1 and 394, and the average is around 5 posts. We divide these threads into training, development and test sets. The most frequent 100 words from the training set are used as stopwords. After filtering stopwords, a post contains 39 tokens on average and the vocabulary size of our corpus is 81,707. For development and testing, we only keep threads with a minimum of 3 posts (so that the problem is non-trivial) and a maximum of 50 posts (due to complexity of parsing). We have 9,243 training threads, 2,014 for development, and 2,071 for testing.

A particular feature of the forums on `cnet.com` is the explicit reply structure present in the threads. The forum interface elicits these reply relationships as users develop a thread. When a user replies in a particular thread, she has to choose (only) one of the earlier posts in the thread (including the question post) to attach her reply to. In this way, each post is linked to a unique post earlier in time in the same thread. This reply structure forms a dependency tree. Figure 2 (a) is a possible reply tree for the thread in Table 1.

5.1 Deriving conversation trees

Next we convert these reply-link trees into phrase-structure conversation trees. We developed a deterministic conversion method that uses the generative process defined by the base grammar G_B. The key idea is to track when the conversation branches into sub-topics and when the replies are proceeding within the same topic.

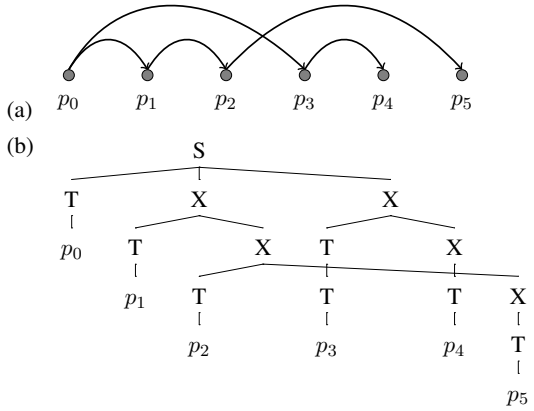

Figure 2: (a) A reply structure tree for the thread in Table 1 and (b) the derived conversation tree

The algorithm traverses the nodes of the dependency tree D in breadth-first order, starting at the root (first) post. We create a root S node in the phrase structure tree H. Then the *thread-starting* rule from G_B, $S \rightarrow T\ X^*$, is used to create one T and k X nodes as children of S. The first post p_0 is attached as a child of the T node. k is equal to the number of replies to p_0 (children of p_0 in D). For each of these k X nodes, we instantiate a $X \rightarrow T\ X^*$ rule in H. The k replies of p_0 are attached one each as a child of the T nodes in these rules. Any set of children are always instantiated in chronological order. So the span of a non-terminal in H always contains posts in non-decreasing time order. We continue the procedure with the next post from D in the traversal order.

This procedure converts the reply tree of Figure 2 (a) into the conversation tree (b). Note that (a) is a possible reply structure for our example thread in Table 1. The conversation tree (b) derived according to this reply structure has a non-projective structure where p_1, p_2 and p_5 are linked under one X node (at level 1). Such a tree can be produced by our LCFRS model. The ideal PCFG tree will repeat the topic branch as in Figure 1.

The derived trees at this stage follow G_B and contain only the S, X, T non-terminals (without any latent annotations). This tree is converted into Chomsky Normal Form using C nodes.

5.2 Discontinuous topic segments

As in our example above, non-projective edges in the *reply structure* are rather frequent. Of the

total threads in our corpus 14.5% contain a non-projective edge. A thread should have a minimum of four posts to have the possibility of non-projective edges. Among the 7,691 threads with at least four posts, the percentage of non-projective trees is even higher, 25%. This finding suggests that in any thread of reasonable size which we wish to summarize or categorize, non-projective edges will be common. Hence a direct approach for addressing discontinuous segments such as our PLCFRS model is important for this domain.

6 Parsers for Conversation Trees

The training data are conversation trees with rules from G_B. We refine the non-terminals to create G_E, extract PCFG or PLCFRS rules from the training trees, and build a CYK parser that predicts the most likely tree according to G_E.

6.1 Refining the non-terminals

We use a clustering approach, akin to the spectral algorithm of Cohen et al. (2013) and Narayan and Cohen (2015),[3] to create finer grained categories corresponding to G_B's non-terminals: S, X, C and T. Each node in each tree in the training data is associated with a feature vector, which is a function of the tree and the anchor node. These vectors are clustered (for each of the non-terminals separately) and then, each node is annotated with the corresponding cluster. This process gives us the non-terminals $S[i]$, $X[j]$, $T[k]$ and $C[l]$ of G_E.

The features for a node n_l are: depth of n_l in the tree, root is at depth 0; maximum depth of the subtree under n_l; number of siblings of n_l; number of children of n_l; number of posts in the span of n_l; average length (in terms of tokens) of the posts in the span of n_l; average similarity of the span of n_l with the span of n_l's siblings[4]; similarity of n_l's span with the span of its left-most sibling; elapsed time between the first and last posts in n_l's span.

We use CLUTO toolkit (Karypis, 2002) to perform clustering. The algorithm maximizes the pairwise cosine similarity between the feature vectors of nodes within the same cluster. The best number of clusters for the four non-terminal node types are tuned jointly to give the best performance on our final topic segmentation task.

6.2 Learning rule probabilities

As mentioned previously, each terminal in our grammar is an entire post's text. For the pre-terminal to terminal productions in our grammar $T[j] \rightarrow p_i$, we compute $p(T[j] \rightarrow p_i|T[j])$ as the probability under a unigram language model L_j which is trained on the collection of the posts from the training corpus which are dominated by $T[j]$ nodes. $p(T[j] \rightarrow p_i|T[j]) = \prod_{k=1}^{N_{p_i}} L_j(w_k^i)$ where $w_1^i, w_2^i ... w_{N_{p_i}}^i$ are the tokens in post p_i.

The rest of the production probabilities are learned using MLE on the training trees. In the case of LCFRS rules, the gap information is also obtained during the extraction.

6.3 CYK parsing

For both PCFG and LCFRS we use CYK style algorithms, as outlined in §3, to obtain the most likely tree. For the more computationally complex LCFRS model, we make a number of additions to improve speed. First, we restrict the fan-out of the grammar to 2, i.e. any non-terminal can only span a maximum of two discontinuous segments. 97% of the productions in fact have only non-terminals with fan-out ≤ 2. Second, we use A^* search (Maier et al., 2012) to prioritize our agenda. Last, we reduce the number of items added to the agenda. An item has the form [A, $\vec{\rho}$], A is a non-terminal and $\vec{\rho}$ is the spans covered by A. For every span, we only keep the top 5 non-terminal items according to the score. In addition, we only allow spans with a gap of at most 2 since 77% of all gaps (dominated by fan-out $\leq$ 2) non-terminals are ≤ 2 posts. Moreover, after a certain number of items (10,000) are added to the chart, we only allow the creation of new items which have a contiguous span.

7 Systems for comparison

We compare our models to two types of systems.

7.1 STRUCTURE ONLY

The first type generate tree structures without considering the content of the threads.

Right-branching tree (RBT). produces a strictly right branching tree where each post is dominated by the immediately previous (according to time) post in the thread. It uses the grammar

[3] The main difference between our algorithm and the algorithm by Narayan and Cohen (2015) is that we do not decompose the trees into "inside" trees and "outside" trees, or use a singular value decomposition step before clustering the features.

[4] The span of n_l and that of a sibling are each represented by binary vectors indicating the presence and absence of a term in the span. The similarity value is computing using cosine overlap between the vectors and the average across all siblings is recorded.

with the rules $\{S \rightarrow TX,\ X \rightarrow TX,\ X \rightarrow T,\ T \rightarrow p\}$. This method does not perform useful topic segmentation as it produces only a single topic branch containing all the posts.

Attach-to-root tree (ART). attaches each post to the root of the tree. The grammar rules are $\{S \rightarrow TX_1...X_n,\ X \rightarrow T,\ T \rightarrow p\}$, where n is the number of posts in the thread. This approach assumes each post belongs to a different topic in the thread. In contrast to RBT, ART contains too many topic branches, one per post in the thread.

Random tree (RAND). mixes decisions to create a new topic branch or continue in the same branch. The generation process is top down, at each step, the algorithm chooses a certain number of topic branches (Xs) to create ($\leq$ number of posts left to add to the tree). Then, the number of posts under each branch is sampled (such that each branch has at least one post). This process is then recursively done at the new topic branches.

7.2 STRUCTURE AND CONTENT

These approaches produce tree structures informed by content. We build these parsers by modifying prior models for chat disentanglement and linear topic segmentation of documents.

Similarity tree (SIM). produces trees by attaching each post as a child of the most similar of the previous (by time) posts (Wang et al., 2008). We use cosine similarity between vector representations of two posts in order to compute similarity. When the similarity exceeds a threshold value, the post is added under the topic branch of the prior post. Otherwise the post is under a new topic branch attached to the root of the tree. A threshold of 0.15 was chosen after tuning on the development data.

Cluster tree (CLUS). uses an approach related to chat disentanglement (Elsner and Charniak, 2010). The posts within *each* thread are clustered *separately* into k_l clusters where $k_l = l/h$ depends on the number of posts in the thread, l. $h = 6$ was chosen by tuning. The posts in each cluster are ordered by time and a right branching tree is created over them. These k_l cluster-level trees are then attached as children of a new node to create a thread-level tree. The cluster-trees are ordered left to right in the thread-tree according to the time of the earliest post in each cluster.

Linear segmentation tree (LSEG). is based on postprocessing the output of a Bayesian linear topic segmentation model (Eisenstein and Barzilay, 2008). Each post's content is treated as a sentence and a document is created for *each* thread by appending its posts in their time order. The model is then used to group consecutive sentences into k_l segments. For each thread of length l, $k_l = l/h$, $h = 6$ was chosen by tuning. For each segment, a right branching tree is created and these segment-level trees are made siblings in a thread-level tree. The segments are added left to right in the thread-tree as per their order in the text.

All STRUCTURE trees contain thread structure but no topic labels. In other words, they have coarse non-terminals (X, T and S) only. The STRUCTURE AND CONTENT trees, LSEG and CLUS contain topics or groups but only at one top level, and further the number and labels of these topics are different per thread. Hence there is no linking across threads. Within a thread, the SIM and CLUS tree can link non-adjacent posts under the same topic. These links are also not available from a LSEG tree.

8 Evaluation metrics

To evaluate the topic segmentation, we develop a node-governance based measure. Our score compares two conversation trees g and h, where g is the gold-standard tree and h is the hypothesized one. We assume that g and h are in dependency format, reversing the transformation from §5.1.

We break g (and h) into a set of pairs, for each pair of nodes in the tree (each node is a post in the thread). For each such pair, p and q, we find their least common ancestor, $\ell(p, q|g)$ (or $\ell(p, q|h)$. If these nodes are in a governing relation (p dominates q or vice versa), then $\ell(p, q)$ is the dominating node. We then define the following sets and quantities for $\cdot \in \{g, h\}$:

- $S_1(\cdot) = \{(p, q, \ell(p, q)) \mid \ell(p, q|\cdot) \in \{p, q\}\}$.
- $S_2(\cdot) = \{(p, q, \ell(p, q)) \mid \ell(p, q|\cdot) \notin \{p, q\}\}$.
- $n_1(g, h) = |S_1(g) \cap S_1(h)|$.
- $n_2(g, h) = |S_2(g) \cap S_2(h)|$.

$s_1(\cdot)$ and $s_2(\cdot)$ are defined as the size of $S_1(\cdot)$ and $S_2(\cdot)$, repsectively. Let $g_1, \ldots, g_n$ and $h_1, \ldots, h_n$ be a corpus of gold-standard conversation trees and their corresponding hypothesized conversation trees. Then the evaluation metric we compute is the harmonic mean (Fscore) of the micro-average of the precision for governing (G-p) and non-governing (NG-p) pairs, and recall for governing (G-r) and non-governing (NG-r) pairs. For example, G-p is calculated as

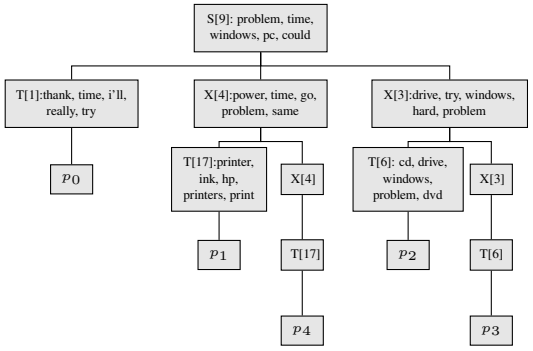
$$\text{G-p} = \frac{\sum_{i=1}^{n} n_1(g_i, h_i)}{\sum_{i=1}^{n} s_1(h_i)}.$$

Traditional parsing evaluation measures such as constituency bracketting and dependency attachment scores were too local for our purpose. For example, if a long chain of posts is placed in a different topic but their local dependencies are maintained, we only penalize one constituent and one node's parent in the constituency and dependency scores respectively. But the topic segmentation created by this change has several posts placed in the wrong topic branch. Our scores overcome this problem by considering the relationship between all pairs of posts and also dividing the relationship in the pair as governing or non-governing.

9 Results and discussion

We tune the number of latent topic annotations for the non-terminals using grid search on the development set. The best settings are 40 S, 100 X, 20 C, 80 T clusters for PCFG and 10 S, 5 X, 15 C, 40 T for LCFRS.

Below we show an example non-projective tree created by our LCFRS parser. The topics are indicated with the most frequent 5 words in the matching cluster.



Here post p_4 though later in posting time is predicted to be on the same topic as p_1.

The non-terminals in our trees enable useful topic segmentation and we found that performance is extremely sensitive to the number of non-terminals of each type S, X, C and T. Currently, we do not have a direct method to evaluate the non-terminals in our tree but we plan to use the information in other applications as an evaluation.

Table 2 and 3 shows the segmentation performance of the models (as percentages). The performance varied greatly depending on the length of the threads and hence we show the results separately for threads with up to 15 posts (SHORT) and those with 16 to 50 posts (LONG). The results are divided into sections based on the subset of test data on which the evaluation is performed. The first section (R1.) is performance on all threads, (R2.) only on the projective threads in the test data, and (R3.) only on the non-projective threads.

Among the baselines, the Right-branching trees (RBT) or Attaching to the root (ART) have some advantages: the RBT receives 100% recall of the governing pairs and the ART tree has high recall of the non-governing pairs. However, their Fscores are 0. Recall that the RBT contains a single topic branch and hence no useful segmentation is done; ART is the other extreme where every post is put in a separate topic branch. RAND is the average performance of 3 randomly generated trees for each thread. This method has a better balance between branching and depth leading to 33.4 Fscore for SHORT and 21.5 for LONG threads.

The PCFG and the LCFRS models clearly outperform these baselines. The Fscore improves up to 15% over RAND on SHORT and LONG threads. The grammar models also consistently outperform SIM systems.

With regard to CLUS and LSEG, there is a difference in performance between SHORT and LONG threads and based on whether the desired structure was projective or non-projective. On SHORT threads, the grammar models outperform LSEG and CLUS particularly on the projective threads (the LCFRS model has a 22% higher Fscore). On the longer threads however, the CLUS and LSEG models perform best overall and for non-projective threads. CLUS and LSEG directly model the content similarity of posts while the grammar models make many decisions at level of topic nodes. Remember that the clustering is done per thread in CLUS and LSEG compared to using a common set of topics across all threads. Making such fine-grained similarity comparison appears to be helpful especially for longer threads and even though LSEG does not make non-projective decisions, its accuracy is high on the attachments it makes leading to good performance on non-projective threads too. In future work, we plan to explore how we can combine the advantages of direct similarity with the grammar models.

Between the two grammar models, the LCFRS model is better than PCFG, even on projective threads, and can produce non-projective trees. Part of this improvement on projective trees could be due to more data being available in the LCFRS model since all the data can be used for training it.

Table 3: Results on threads with > 15 posts

For the PCFG model, only the projective data can be used for training.

Overall, the LCFRS model is powerful on projective threads and SHORT non-projective threads. Compared to PCFG, the LCFRS model has a number of advantages: we can use more data, can predict non-projective trees. Some of the constraints we imposed on the LCFRS parser, such as restricting the gap degree are likely to have limited the ability of the model to generate more flexible non-projective edges. We believe that as we figure out how to make these parsers faster, we will see even more improvements from the LCFRS models.

10 Conclusions

This work represents a first approach to learn discourse structure of forum threads within an explicit grammar framework. We show that a coarse grammar for structure can be refined using latent annotations to indicate the finer topic differences. Our trees have good segmentation performance and provide useful summaries of the thread content at the non-terminal nodes. A main goal for future work is to incorporate further domain specific constraints on the models to improve parsing speed and at the same time allow more flexible trees. We also plan to evaluate the usefulness of conversation trees in tasks such as predicting if a thread is resolved, and user expertise.

Abstract

Weak topic correlation across document collections with different numbers of topics in individual collections presents challenges for existing cross-collection topic models. This paper introduces two probabilistic topic models, *Correlated LDA* (C-LDA) and *Correlated HDP* (C-HDP). These address problems that can arise when analyzing large, asymmetric, and potentially weakly-related collections. Topic correlations in weakly-related collections typically lie in the tail of the topic distribution, where they would be overlooked by models unable to fit large numbers of topics. To efficiently model this long tail for large-scale analysis, our models implement a parallel sampling algorithm based on the Metropolis-Hastings and alias methods (Yuan et al., 2015). The models are first evaluated on synthetic data, generated to simulate various collection-level asymmetries. We then present a case study of modeling over 300k documents in collections of sciences and humanities research from JSTOR.

1 Introduction

Comparing large text collections is a critical task for the curation and analysis of human cultural history. Achievements of research and scholarship are most accessible through textual artifacts, which are increasingly available in digital archives. Text-based research, often undertaken by humanists, historians, lexicographers, and corpus linguists, explores patterns of words in documents across time-periods and distinct collections of text. Here, we introduce two new topic models designed to compare large collections, Correlated LDA (C-LDA) and Correlated HDP (C-HDP), which are sensitive to document-topic asymmetry (where collections have different topic distributions) and topic-word asymmetry (where a single topic has different word distributions in each collection). These models seek to address terminological questions, such as how a topic on physics is articulated distinctively in scientific compared to humanistic research. Accommodating potential collection-level asymmetries is particularly important when researchers seek to analyze collections with little prior knowledge about shared or collection-specific topic structure. Our models extend existing cross-collection approaches to accommodate these asymmetries and implement an efficient parallel sampling algorithm enabling users to examine the long tail of topics in particularly large collections.

Using topic models for comparative text mining was introduced by Zhai et al. (2004), who developed the ccMix model which extended pLSA (Hofmann, 1999). Later work by Paul and Girju (2009) developed ccLDA, which adopted the hierarchical Bayes framework of Latent Dirichlet Allocation or LDA (Blei et al., 2003). These models account for topic-word asymmetry by assuming variation in the vocabularies of topics is due to collection-level differences. Nevertheless, they require the same topics to be present in each collection. These models are useful for comparing collections under specific assumptions, but cannot accommodate collection-topic asymmetry (which

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1554–1564,
Lisbon, Portugal, 17-21 September 2015.

arises in collections that do not share every topic or that have different numbers of topics). In situations where collections do not share all topics, the results often include junk, mixed, or sparse topics, making them difficult to interpret (Paul and Girju, 2009). Such asymmetries make it difficult to use models like ccLDA and ccMix when little is known about collections in advance. This motivates our efforts to model variation in the long tail of topic distributions, where correlations are more likely to appear when collections are weakly related.

C-LDA and C-HDP extend ccLDA (Paul and Girju, 2009) to accommodate collection-topic level asymmetries, particularly by allowing non-common topics to appear in each collection. This added flexibility allows our models to discover topic correlations across arbitrary collections with different numbers of topics, even when there are few (or unknown) numbers of common topics. To demonstrate the effectiveness of our models, we evaluate them on synthetic data and show that they outperform related models such as ccLDA and differential topic models (Chen et al., 2014). We then fit C-LDA to two large collections of humanities and sciences documents from JSTOR. Such historical analyses of text would be intractable without an efficient sampler. An optimized sampler is required in such situations because common topics in weakly-correlated collections are usually found in the tail of the document-topic distribution of a sufficiently large set of topics. To make this feasible on large datasets such as JSTOR, we employ a parallelized Metropolis-Hastings (Kronmal and Peterson Jr, 1979) and alias-table sampling framework, adapted from LightLDA (Yuan et al., 2015). These optimizations, which achieve $\mathcal{O}(1)$ amortized sampling time per token, allow our models to be fit to large corpora with up to thousands of topics in a matter of hours — an order of magnitude speed-up from ccLDA.

After reviewing work related to topic modeling across collections, section 3 describes C-LDA and C-HDP, and then details their technical relationship to existing models. Section 5 introduces the synthetic data and part of the JSTOR corpus used in our evaluations. We then compare our models' performances to other models in terms of held-out perplexity and a measure of distinguishability. The final results section exemplifies the use of C-LDA in a qualitative analysis of humanities and sciences research. We conclude with a brief discussion of the strengths of C-LDA and C-HDP, and outline directions for future work and applications.

2 Related Work

Our models seek to enable users to compare large collections that may only be weakly correlated and that may contain different numbers of topics. While topic models could be fit to separate collections to make post-hoc comparisons (Denny et al., 2014; Yang et al., 2011), our goal is to account for both document-topic asymmetry and topic-word asymmetry "in-model". In short, we seek to model the correlation between *arbitrary* collections. Prioritizing in-model solutions for document-topic asymmetry has been explored elsewhere, such as in hierarchical Dirichlet processes (HDP), which use an additional level to account for collection variations in document-topic distributions (Teh et al., 2006).

One method designed to model topic-word asymmetry is ccMix (Zhai et al., 2004), which models the generative probability of a word in topic z from collection c as a mixture of shared and collection-specific distributions θ_z:

$$p(w) = \lambda_c \, p(w|\theta_z) + (1 - \lambda_c) \, p(w|\theta_{z,c})$$

where $\theta_{z,c}$ is collection-specific and λ_c controls the mixing between shared and collection-specific topics. ccLDA extends ccMix to the LDA framework and adds a beta prior over λ_c that reduces sensitivity to input parameters (Paul and Girju, 2009). Another approach, differential topic models (Chen et al., 2014), is based on hierarchical Bayesian models over topic-word distributions. This method uses the transformed Pitman-Yor process (TPYP) to model topic-word distributions in each collection, with shared common base measures. As (Paul and Girju, 2009) note, ccLDA cannot accommodate a topic if it is not common across collections — an assumption made by ccMix, ccLDA and the TPYP. In a situation where a topic is found in only one collection, it would either dominate the shared topic portion (resulting in a noisy, collection-specific portion), or it would appear as a mixed topic, revealing two sets of unrelated words (Newman et al., 2010b). C-LDA ameliorates this situation by allowing the number of common and non-common topics to be specified separately and by efficiently sampling the tail

of the document-topic distribution, allowing users to examine less prominent regions of the topic space. C-HDP also grants collections document-topic independence using a hierarchical structure to model the differences between collections.

Due to increased demand for scalable topic model implementations, there has been a proliferation of optimized methods for efficient inference, such as SparseLDA (Yao et al., 2009) and AliasLDA (Li et al., 2014). AliasLDA achieves $\mathcal{O}(K_d)$ complexity by using the Metropolis-Hastings-Walker algorithm and an alias table to sample topic-word distributions in $\mathcal{O}(1)$ time. Although this strategy introduces temporal staleness in the updates of sufficient statistics, the lag is overcome by more iterations, and converges significantly faster. A similar technique by Yuan et al. (2015), LightLDA, employs cycle-based Metropolis Hastings mixing with alias tables for both document-topic and topic-word distributions. Despite introducing lag in the sufficient statistics, this method achieves $\mathcal{O}(1)$ amortized sampling complexity and results in even faster convergence than AliasLDA. In addition to being fully parallelized, C-LDA adopts this sampling framework to make comparing large collections more tractable for large numbers of topics. Our models' efficient sampling methods allow users to fit large numbers of topics to big datasets where variation might not be observed in sub-sampled datasets or models with fewer topics.

3 The Models

3.1 Correlated LDA

In ccLDA (and ccMix), each topic has shared and collection-specific components for each collection. C-LDA extends ccLDA to make it more robust with respect to topic asymmetries between collections (Figure 1a). The crucial extension is that by allowing each collection to define a set of non-common topics in addition to common topics, the model removes an assumption imposed by ccLDA and other inter-collection models, namely that collections have the same number of topics. As a result, C-LDA is suitable for collections without a large proportion of common topics, and can also reduce noise (discussed in Section 2). To achieve this, C-LDA assumes document d in collection c has a multinomial document-topic distribution θ with an asymmetric Dirichlet prior for K_c topics, where the first $K^{\emptyset}$ are common across collections. It is also possible to introduce a tree structure into the model that uses a binomial distribution to decide whether a word was drawn from common or non-common topics. This yields collection-specific background topics by using a binomial distribution instead of a multinomial. However, we prefer the simpler, non-tree version because background topics are unnecessary when using an asymmetric α prior (Wallach et al., 2009a).

The generative process for C-LDA is as follows:

1. Sample a distribution ϕ_k (shared component) from Dir(β) and a distribution σ_k from Beta(δ_1, δ_2) for each common topic $k \in \{1, \ldots, K^{\emptyset}\}$;
2. For each collection c, sample a distribution ϕ_k^c (collection-specific component) from Dir(β) for each common topic $k \in \{1, \ldots, K^{\emptyset}\}$ and non-common topic $k \in \{K^{\emptyset} + 1, \ldots, K_c\}$;
3. For each document d in c, sample a distribution θ from Dir(α_c);
4. For each word w_i in d:
   (a) Sample a topic $z_i \in \{1, \ldots, K_c\}$ from Multi(θ);
   (b) If $z_i \leq K^{\emptyset}$, sample y_i from Binomial(σ_{z_i});
   (c) Sample w_i from Multi($\phi_{z_i}^{\xi}$), where
   $$\xi = \begin{cases} \texttt{null} & , z_i \leq K^{\emptyset} \text{ and } y_i = 0; \\ c & , \text{otherwise.} \end{cases}$$

Note that to capture common topics, $K^{\emptyset}$ should be set such that $\exists\ c$ where $K_c = K^{\emptyset}$. Otherwise, words sampled as a non-common topic will not have information about non-common topics in other collections. Then a "common-topic word" is found among non-common topics in all collections (a local minima) and it will take a long time to stabilize as a common topic. To avoid this, when determining the number of topics for sampling, the number of non-common topics for the collection with the smallest number of total topics should be zero. After inference, to distinguish common and non-common topics in this collection, we model σ independently by assuming collections have the same mixing ratio for common topics. With this reasonable assumption and an asymmetric α, common topics become sparse enough that some σ distributions reduce nearly to 0, distinguishing them as non-common topics. Although this may seem counterintuitive, it does not negatively affect results.

Three kinds of collection-level imbalance can confound inter-collection topic models: 1) in the numbers of topics between collections, 2) in the numbers of documents between collections, and 3) in the document-topic distributions. Each of

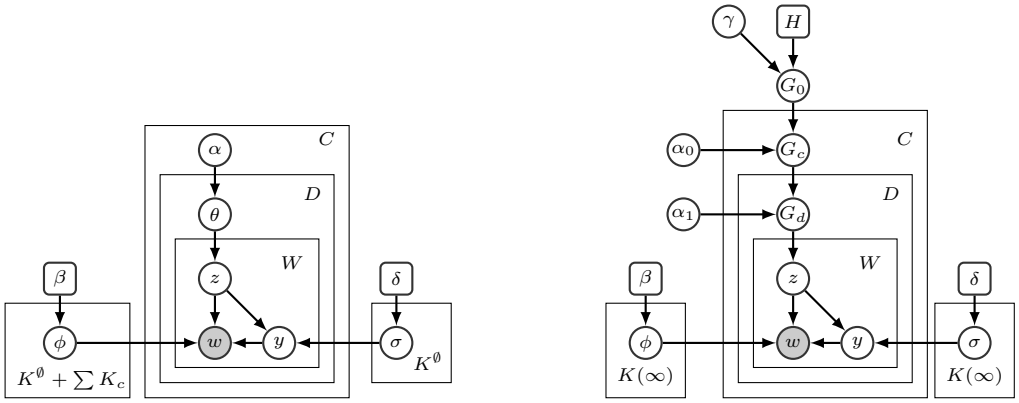

Figure 1: Graphical models of C-LDA (a; left) and C-HDP (b; right).

these can cause topics in different collections to have significantly different numbers of words assigned to the same topic. In this way, a topic can be dominated by the collection comprising most of its words. C-LDA addresses imbalances in the document-topic distributions between collections by estimating α. For imbalance in the number of topics and documents, C-LDA mimics document over-sampling in the Gibbs sampler using a different unit-value in the word count table for each collection. Specifically, a unit η_c is chosen for each collection such that the average equivalent number of assigned words per-topic ($\sum_{d \in c} \eta_c N_d / K_c$, where N_d is the length of document d) is equal. This process both increases the topic quality (in terms of collection balance) in the resulting held-out perplexity of the model.

3.2 Correlated HDP

To alleviate C-LDA's requirement that $\exists\ c$ such that $K_c = K^{\emptyset}$, we introduce a variant of the model, the correlated hierarchical Dirichlet process (C-HDP), that uses a 3-level hierarchical Dirichlet process (Teh et al., 2006). The generative process for C-HDP is the same as C-LDA shown above, except that here we assume a word's topic, z, is generated by a hierarchical Dirichlet process:

$$\begin{aligned} G_0|\gamma, H &\sim \text{DP}(\gamma, H) \\ G_c|\alpha_0, G_0 &\sim \text{DP}(\alpha_0, G_0) \\ G_d|\alpha_1, G_c &\sim \text{DP}(\alpha_1, G_c) \\ z|G_d &\sim G_d \end{aligned}$$

where G_0 is a base measure for each collection-level Dirichlet process, and G_c are base measures of document-level Dirichlet processes in each collection (Figure 1b). Thus, documents from the same collection will have similar topic distributions compared to those from other collections, and collections are allowed to have distinct sets of topics due to the use of HDP.

4 Inference

4.1 Posterior Inference in C-LDA

C-LDA can be trained using collapsed Gibbs sampling with ϕ, θ, and σ integrated out. Given the status assignments of other words, the sampling distribution for word w_i is given by:

$$\begin{aligned} & p(y_i, z_i | \boldsymbol{w}, \boldsymbol{y}_{-i}, \boldsymbol{z}_{-i}, \delta, \alpha, \beta) \\ \propto\ & \underbrace{(N(d, z_i) + \alpha_{c,z_i})}_{q_d} \\ & \times \underbrace{\begin{cases} \frac{N(y_i, z_i) + \delta_{y_i}}{N(z_i) + \sum_k \delta_k} \times \frac{N(w_i, y_i, z_i, \zeta) + \beta}{N(y_i, z_i, \zeta) + V\beta} & z_i \le K^{\emptyset} \\ \frac{N(w_i, z_i, c) + \beta}{N(z_i, c) + V\beta} & z_i > K^{\emptyset} \end{cases}}_{q_w} \end{aligned} \tag{1}$$

where $\zeta = \begin{cases} * & y_i = 0 \\ c & y_i = 1 \end{cases}$, $N(\cdots)$ is the number of status assignments for $(\cdots)$, not including w_i.

Inference in C-LDA employs two optimizations: a parallelized sampler and an efficient sampling algorithm (Algorithm 1). We use the parallel schema in (Smola and Narayanamurthy, 2010; Lu et al., 2013) which applies atomic updates to the sufficient statistics to avoid race conditions. The key idea behind the optimized sampler is the combination of alias tables and the Metropolis-Hastings method (MH), adapted from (Yuan et al., 2015; Li et al., 2014). Metropolis-Hastings is a Markov chain Monte Carlo method that uses a proposal distribution to approximate the true distribu-

      $z \leftarrow z'$
  return z

tion when exact sampling is difficult. In a complimentary way, Walker's alias method (2004) allows one to effectively sample from a discrete distribution by using an alias table, constructed in $\mathcal{O}(K)$ time, from which we can sample in $\mathcal{O}(1)$. Thus, reusing the sampler K times as the proposal distribution for Metropolis-Hastings yields $\mathcal{O}(1)$ amortized sampling time per-token.

Notice that in Eq. 1, the sampling distribution is the product of a single document-dependent term q_d and a single word-dependent term q_w. After burn-in, both terms will be sparse (without the smoothing factor). It is therefore reasonable to use q_d and q_w as cycle proposals (Yuan et al., 2015), alternating them in each Metropolis-Hastings step. Our experiments show that the primary drawback of this method — stale sufficient statistics — does not empirically affect convergence. Our implementation uses proposal distributions q_w and q_d, with y marginalized out. After the Metropolis-Hastings steps, y is sampled to update z, to reduce the size of the alias tables, yielding even faster convergence.

Lastly, the use of an asymmetric α allows C-LDA to discover correlations between less dominant topics across collections (Wallach et al., 2009a). We use Minka's fixed-point method, with a gamma hyper-prior to optimize α_c for each collection separately (Wallach, 2008). All other hyperparameters were fixed during inference.

4.2 Posterior Inference in C-HDP

C-HDP uses the block sampling algorithm described in (Chen et al., 2011), which is based on the Chinese restaurant process metaphor. Here, rather than tracking all assignments (as the samplers given in (Teh et al., 2006)), table indicators are used to track only the start of new tables, which allows us to adopt the same sampling framework as C-LDA. In the Chinese restaurant process, each Dirichlet process in the hierarchical structure is represented as a restaurant with an infinite number of tables, each serving the same dish. New customers can either join a table with existing customers, or start a new table. If a new table is chosen, a proxy customer will be sent to the parent restaurant to determine the dish served to that table.

In the block sampler, indicators are used to denote a customer creating a table (or tables) up to level u (0 as the root, 1 for collection level, and 2 for the document level), and $u = \emptyset$ indicates no table has been created. For example, when a customer creates a table at the collection level, and the proxy customer in the collection level creates a table at the root level, u is 0. With this metaphor, let n_{lz} be the number of customers (including their proxies) served dish z at restaurant l, and let t_{lz} be the number of tables serving dish z at restaurant l ($l = 0$ for root, $l = c$ for collection level or $l = d$ for document level), with $N_0 = \sum_z n_{0z}$ and $N_c = \sum_z n_{cz}$. By the chain rule, the conditional probability of the state assignments for w_i, given all others, is

$$
\begin{aligned}
&p(y_i, z_i, u_i | \boldsymbol{w}, \boldsymbol{y}_{-i}, \boldsymbol{z}_{-i}, \boldsymbol{u}_{-i}, \ldots) \\
\propto &\frac{N(y,z) + \delta_y}{N(z) + \sum_k \delta_k} \times \frac{N(w,y,z,\zeta) + \beta}{N(y,z,\zeta) + V\beta} \\
\times &\begin{cases}
\frac{\gamma\alpha_0}{\gamma + N_0} & u = 0 \\
\frac{\alpha_0}{\gamma+N_0} \frac{S^{n_{cz}+1}_{t_{cz}+1}}{S^{n_{cz}}_{t_{cz}}} \frac{S^{n_{dz}+1}_{t_{dz}+1}}{S^{n_{dz}}_{t_{dz}}} \frac{n^2_{0z}(t_{cz}+1)(t_{dz}+1)}{(n_{0z}+1)(n_{cz}+1)(n_{dz}+1)} & u = 1 \\
\frac{S^{n_{cz}+1}_{t_{cz}}}{S^{n_{cz}}_{t_{cz}}} \frac{S^{n_{dz}+1}_{t_{dz}+1}}{S^{n_{dz}}_{t_{dz}}} \frac{(t_{dz}+1)(n_{cz}-t_{cz}+1)}{(n_{cz}+1)(n_{dz}+1)} & u = 2 \\
\frac{\alpha_0+N_1}{\alpha_1} \frac{S^{n_{dz}+1}_{t_{dz}}}{S^{n_{dz}}_{t_{dz}}} \frac{n_{dz}-t_{dz}+1}{n_{dz}+1} & u = \emptyset
\end{cases}
\end{aligned}
$$

Here, S^n_t is the Stirling number, the ratios of which can be efficiently precomputed (Buntine and Hutter, 2010). The concentration parameters γ, α_0, and α_1 can be sampled using the auxiliary variable method (Teh et al., 2006).

Note that because conditional probability has the same separability as C-LDA (to give term q_w and q_d), the same sampling framework can be used with two alterations: 1) when a new topic is created or removed at the root, collection, or document level, the related alias tables must be reset, which makes the sampling slightly slower

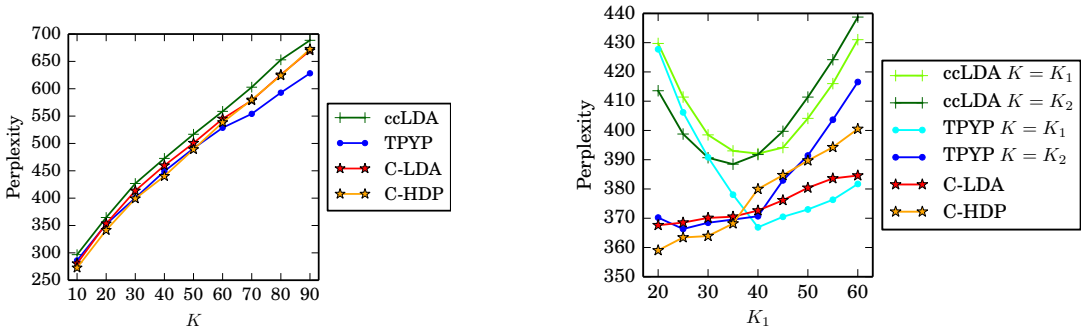

Figure 2: Held-out perplexity of C-LDA, C-HDP, ccLDA and TPYP fit to synthetic data, where $K_1 = K_2 = K$ (a; left) and data with an asymmetric number of topics (b; right).

than $\mathcal{O}(1)$, and 2) while the document alias table samples z and u simultaneously, after sampling z from the word alias table u must be sampled using t_{lc}/n_{lz} (Chen et al., 2011). Parallelizing C-HDP requires an additional empirical method of merging new topics between threads (Newman et al., 2009), which is outside of the scope of this work. Our implementation of both models, C-LDA and C-HDP, are open-sourced online [1].

5 Experiments

5.1 Model Comparison

We use perplexity on held-out documents to evaluate the performance of C-LDA and C-HDP. In all experiments, the gamma prior for α in C-LDA was set to $(1, 1)$, and $(5, 0.1)$, $(5, 0.1)$, $(0.1, 0.1)$ for γ, α_0, α_1 respectively in C-HDP. In the hold-out procedure, 20% of documents were randomly selected as test data. LDA, C-LDA and ccLDA were run for 1,000 iterations and C-HDP and the TII-variant of TPYP for 1,500 iterations (unless otherwise noted), all of which converged to a state where change in perplexity was less than 1% for ten consecutive iterations.

Perplexity was calculated from the marginal likelihood of a held-out document $p(\mathbf{w}|\mathbf{\Phi}, \alpha)$, estimated using the "left-to-right" method (Wallach et al., 2009b). Because it is difficult to validate real-world data that exhibits different kinds of asymmetry, we use synthetic data generated specifically for our evaluation tasks (AlSumait et al., 2009; Wallach et al., 2009b; Kucukelbir and Blei, 2014).

5.1.1 Topic Correlation

C-LDA is unique in the amount of freedom it allows when setting the number of topics for collections. To assess the models' performances with various topic correlations in a fair setting, we generated two collections of synthetic data by following the generative process (varying the number of topics) and measured the models' perplexities against the ground truth parameters. In each experiment, two collections were generated, each with 1,000 documents containing 50 words each, over a vocabulary of 3,000. β and δ were fixed at 0.01 and 1.0 respectively, and α was asymmetrically defined as $1/(i + \sqrt{K_c})$ for $i \in [0, K_c - 1]$.

Completely shared topics The assumptions imposed by ccLDA and TPYP effectively make them a special case of our model where $K^{\emptyset} = K_1 = K_2 = \ldots$. To compare results, data was generated such that all numbers of topics were equal to $K \in [10, 90]$. Additionally, all models were configured to use this ground truth parameter when training. Not surprisingly, ccLDA, C-LDA, and C-HDP have almost the same perplexity with respect to K because their structure is the same when all topics are shared (Figure 2a).

Asymmetric numbers of topics To explore the effect of asymmetry in the number of topics, data was generated such that one collection had $K_1 \in [20, 60]$ topics while a second had a fixed $K_2 = 40$ topics. The number of shared topics was set to $K^{\emptyset} = 20$. The parameters for C-LDA and C-HDP (initial values) were set to ground truths, and, to retain a fair comparison, versions of ccLDA and TPYP were fit with both $K = K_1$ and $K = K_2$.

We find that ccLDA performs nearly as well as C-LDA and C-HDP when there is more symmetry between collection, namely when $K_1 \approx K_2$ (Figure 2b). TPYP, on the other hand, performs well with more topics ($2 \times \max(K_1, K_2)$ where the ground truth is K_1 & K_2). In contrast, C-LDA

[1] https://github.com/iceboal/correlated-lda

and C-HDP perform more consistently than other models across varying degrees of asymmetry.

Partially-shared topics When collections have the same number of topics, C-LDA, C-HDP and ccLDA exhibit adequate flexibility, resulting in similar perplexities. When collections have increasingly few common topics, however, common and non-common topics from ccLDA are considerably less distinguishable than those from C-LDA. To evaluate the models' abilities in such situations, data was generated for two collections having $K_1 = K_2 = 50$ topics, but with the shared number of topics $K^{\emptyset} \in [5, 45]$. We also set $\delta^{(0)} = \delta^{(1)} = 5$, and for comparison to ccLDA we used $K = 50$.

To measure this distinguishability, we examine the inferred σ. Recall that σ indicates what percentage of a common topic is shared. When a topic is actually non-common, the value of σ should be small. We sort σ_k for $k \in [1, K]$ in reverse and use

$$\begin{aligned} \bar{\sigma}_{\text{common}} &= \frac{1}{K^{\emptyset}} \sum_{k=1}^{K^{\emptyset}} \sigma_k \\ \bar{\sigma}_{\text{non-common}} &= \frac{1}{K - K^{\emptyset}} \sum_{k=K^{\emptyset}+1}^{K} \sigma_k \end{aligned} \tag{2}$$

as measures of how well common and non-common topics were learned[2]. $\bar{\sigma}_{\text{common}}$ is the average of the $K^{\emptyset}$ largest σ values, and $\bar{\sigma}_{\text{non-common}}$ is the average of the rest. When $\delta^{(0)} = \delta^{(1)}$ in the synthetic data, σ in the common portion should be 0.5, whereas it should be 0 in the non-common part. Figure 3 shows that C-LDA better distinguishes between common and non-common topics, especially when $K^{\emptyset}$ is small. This allows non-common topics to be separated from the results by examining the value of σ. C-HDP has similar performance but larger σ values. In ccLDA, all topics are shared between collections which means that common and non-common topics are mixed. As expected, ccLDA performs similarly when all topics are common across collections.

5.2 Semantic Coherence

Semantic coherence is a corpus-based metric of the quality of a topic, defined as the average pairwise similarity of the top n words (Newman et al., 2010a; Mimno et al., 2011). A PMI-based form of coherence, which has been found to be the best

[2]TPYP is not comparable using this metric, but its hierarchical structure will cause topics to mix naturally.

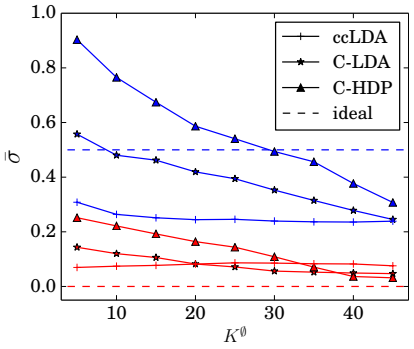

Figure 3: Distinguishability (Eq. 2) of topics fit with C-LDA,C-HDP and ccLDA. Blues lines denote $\bar{\sigma}_{\text{common}}$ and red denote $\bar{\sigma}_{\text{non-common}}$.

proxy human judgements of topic quality, is defined for a topic k as:

$$\text{C}(k) = \frac{2}{n(n-1)} \sum_{\substack{(w_i, w_j) \in k \\ i<j}}^{n} \log \frac{D(w_i, w_j) + 1}{D(w_i) D(w_j)}$$

where $D(\cdot)$ computes the document co-occurrence. To accommodate coherence with common topics in C-LDA that have shared and collection-specific components we define *mutual coherence*, $\text{MC}(k)$, as

$$\text{MC}(k) = \frac{1}{n^2} \sum_{\substack{w_i \in \text{shared}, \\ w_j \in \text{collection-specific}}}^{n} \log \frac{D(w_i, w_j) + 1}{D(w_i) D(w_j)}$$

so that for each collection, $\text{C}(k)$ ($2n$ words) is equal to $\text{C}(k, \text{shared})$ + $\text{C}(k, \text{collection-specific})$ + $\text{MC}(k)$. Table 1 shows the semantic coherence of topics fit with ccLDA and C-LDA. We used a 10% sample of JSTOR due to the limited speed of ccLDA, using 50 (common) topics for ccLDA / C-LDA, and 250 non-common humanities topics for C-LDA. Although these settings are different for the models, the science topics are still comparable because they both have 50 topics. We found that C-LDA provides improved coherence in nearly all situations.

5.2.1 Inference Efficiency

To compare the model efficiency, we timed runs on a sample of 5,036 documents from JSTOR (introduced in the next section) with a 20% held-out and set $K = K_1 = K_2 = 200$ run on a commodity computer with four cores and 16GB of memory. Figure 4a shows the perplexity over

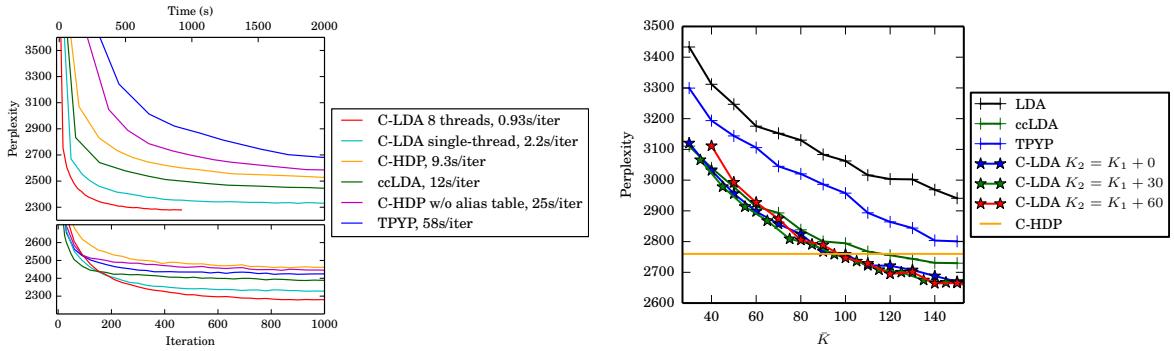

Figure 4: Using JSTOR: perplexity vs. runtime and iterations (a; left) and perplexity vs. K (b; right).

	Coherence					**Mutual Coherence**	
	shared component			collection-specific		shared & collection-specific	
	all documents	science	humanities	science	humanities	science	humanities
C-LDA	-8.83	-7.73	-8.04	-8.38	-8.14	-8.54	-8.37
ccLDA	-9.04	-8.22	-8.27	-8.38	-8.15	-8.69	-8.40
C-LDA	-7.22	-3.68	-6.11	-8.25	-8.09	-7.75	-7.97
ccLDA	-8.11	-5.68	-7.12	-8.24	-7.88	-8.22	-7.95

Table 1: Average semantic coherence of the 50 common topics from JSTOR (top) and the average of the 10 best common topics judged by the mean value of different types of coherence (bottom).

time and iterations. The inference algorithm introduces some staleness, which yields slower convergence in the first 200 iterations. This effect, however, is outweighed in both C-LDA and C-HDP by the increased sampling speed. With 8 threads, C-LDA not only converges faster, but yields lower perplexity, likely due to threads introducing additional stochasticity.

5.3 Performance on JSTOR

To compare our models against slower models, we sampled 2,465 documents from JSTOR, withholding 20% as testing set. We fit a model with 100 common and 50 non-common initial topics using C-HDP, which produced 272 root topics after 2,000 iterations.The perplexity scores are roughly the same when C-LDA uses the same average number of topics per collection (Figure 4b), except when numbers of topics are very asymmetric. Our model begins to outperform ccLDA after 80 topics. C-HDP did not, however, out-perform C-LDA despite the original HDP outperforming LDA. This could be do to the fact that the hierarchical structure of C-HDP is considerably different than the typical 2-level HDP. Held-out perplexity on real data provides a quantitative evaluation of our models' performance in a real-world setting. However, the goal of our models is to enable a deeper analysis of large, weakly-related corpora, which we next discuss.

5.4 Qualitative Analysis

Our models are designed to enable researchers to compare collections of text in a way that is scalable and sensitive to collection-level asymmetries. To demonstrate that C-LDA can fill this role, we fit a model to the entire JSTOR sciences and humanities collections with 100 science topics and 1000 humanities topics (to reveal the less popular science-related topics in the humanities), and $\beta = 0.01, \delta = 1.0$. JSTOR includes books and journal publications in over 9 million documents across nearly 3 thousand journals. We used the journal *Science* to represent a collection of scientific research and 76 humanist journals to represent humanities research[3]. Words were lemmatized, and the most and least frequent words discarded. The final humanities collection contained 149,734 documents and the sciences collection had 160,680 documents, with a combined vocabulary of 21,513 unique words. Together, these collections typify a real-world situation where there is likely some, but not overwhelming correlation.

The results indicate that the sciences and humanities share several topics. Both exhibit an interest in a "non-human" theme (common topic #2; Table 2). This topic is quite similar in both collections (*pig* and *monkey* for science documents; *bird* and *gorilla* for humanities documents), while their shared component forms a cohesive topic (*animal*,

[3]The list is available at http://j.mp/humanities-txt.

Topic 2			Topic 21			Topic 23		
shared	**science**	**humanities**	**shared**	**science**	**humanities**	**shared**	**science**	**humanities**
animal	pig	beast	economic	cost	rural	particle	energy	universe
specie	fly	creature	government	industry	local	physic	electron	quantum
dog	monkey	nonhuman	economy	company	community	physicist	ray	physic
wild	guinea	natural	trade	price	village	energy	ion	technical
wolf	primate	humanity	major	market	region	experiment	atom	scientific
monkey	worm	bird	growth	product	urban	event	particle	relativity
horse	dog	living	capital	income	country	measurement	mass	physical
sheep	cat	gorilla	industry	industrial	area	atom	neutron	mechanic
lion	mammal	brute	institution	business	regional	interaction	proton	law
cat	cattle	ape	support	private	population	atomic	nucleus	reality

Table 2: Three topics from the JSTOR collections with their top words in shared and specific components. Complete results available at http://j.mp/jstor-html.

specie, and *monkey*). This kind of correlation is also evident in topic #23, about physics. While the science documents clearly represent research in particle physics, it is interesting to find the topic is also represented by humanist research focused on cultural representations of science. This reflects a growing interest in science and technology studies that has gained recent traction in the humanities. Despite their differences, both collections engage with a similar theme, seen in the shared component with words like particle, *energy* and *atom*.

The results also indicate that while sciences and humanities documents can share themes, they often diverge in how they are discussed. For example, common topic #21 could be identified as *economic* or *capitalist*, but in the collection-specific components, the two disciplines differ in their articulatation. Science uses terms like *price* and *market*, indicating an acceptance of free-market capitalism (especially as it affects the practice of science), while the humanities, which has long been critical of free-market capitalism, uses terms like *rural* and *community*, highlighting cultural facets of modern economics. These results provide evidence about how ideas move between the sciences and humanities — a phenomenon that constitutes a growing area of research for historians (Galison, 2003; Canales, 2015). C-LDA provides empirical, measurable, and reproducible evidence of the shared research between these disciplines, as well as how concepts are articulated.

6 Discussion

Our models provide a robust way to explore large and potentially weakly-related text collections without imposing assumptions about the data. Like ccLDA and TPYP, our models account for topic-word variation at the collection level. The models accommodate asymmetry in the numbers of topics (set in C-LDA, fit in C-HDP) and provide an efficient inference method which allows them to fit data with large values for K, which can help find correlations in less prevalent topics. Our primary contribution is our models' ability to accommodate asymmetries between arbitrary collections. JSTOR, the world's largest digital collection of humanities research, was an ideal application setting given the size, asymmetry, and comprehensiveness of the humanities collection. As we show, humanities and science research exhibit asymmetries with regard to vocabulary and topic structure — asymmetries that would be systematically overlooked using existing models. By characterizing common topics as mixtures of shared and collection-specific components, we can capture a kind of topic-level homophily, where similar themes are articulated in different ways due to word-, document-, and collection-level variation. Future work on these models could explore methods to fit non-common topics for both collections. In general, C-LDA and C-HDP can be used whenever documents are sampled from ostensibly different populations, where the nature of the difference is unknown.

Molding CNNs for text: non-linear, non-consecutive convolutions

Tao Lei, Regina Barzilay, and Tommi Jaakkola
Computer Science and Artificial Intelligence Laboratory
Massachusetts Institute of Technology
{taolei, regina, tommi}@csail.mit.edu

Abstract

The success of deep learning often derives from well-chosen operational building blocks. In this work, we revise the temporal convolution operation in CNNs to better adapt it to text processing. Instead of concatenating word representations, we appeal to tensor algebra and use low-rank n-gram tensors to directly exploit interactions between words already at the convolution stage. Moreover, we extend the n-gram convolution to non-consecutive words to recognize patterns with intervening words. Through a combination of low-rank tensors, and pattern weighting, we can efficiently evaluate the resulting convolution operation via dynamic programming. We test the resulting architecture on standard sentiment classification and news categorization tasks. Our model achieves state-of-the-art performance both in terms of accuracy and training speed. For instance, we obtain 51.2% accuracy on the fine-grained sentiment classification task.[1]

1 Introduction

Deep learning methods and convolutional neural networks (CNNs) among them have become de facto top performing techniques across a range of NLP tasks such as sentiment classification, question-answering, and semantic parsing. As methods, they require only limited domain knowledge to reach respectable performance with increasing data and computation, yet permit easy architectural and operational variations so as to fine tune them to specific applications to reach top performance. Indeed, their success is often contingent on specific architectural and operational choices.

[1] Our code and data are available at https://github.com/taolei87/text_convnet

CNNs for text applications make use of temporal convolution operators or filters. Similar to image processing, they are applied at multiple resolutions, interspersed with non-linearities and pooling. The convolution operation itself is a *linear* mapping over "n-gram vectors" obtained by concatenating *consecutive* word (or character) representations. We argue that this basic building block can be improved in two important respects. First, the power of n-grams derives precisely from multi-way interactions and these are clearly missed (initially) with linear operations on stacked n-gram vectors. Non-linear interactions within a local context have been shown to improve empirical performance in various tasks (Mitchell and Lapata, 2008; Kartsaklis et al., 2012; Socher et al., 2013). Second, many useful patterns are expressed as *non-consecutive* phrases, such as semantically close multi-word expressions (e.g.,"not that good", "not nearly as good"). In typical CNNs, such expressions would have to come together and emerge as useful patterns after several layers of processing.

We propose to use a feature mapping operation based on *tensor products* instead of linear operations on stacked vectors. This enables us to directly tap into non-linear interactions between adjacent word feature vectors (Socher et al., 2013; Lei et al., 2014). To offset the accompanying parametric explosion we maintain a low-rank representation of the tensor parameters. Moreover, we show that this feature mapping can be applied to all possible *non-consecutive* n-grams in the sequence with an exponentially decaying weight depending on the length of the span. Owing to the low rank representation of the tensor, this operation can be performed efficiently in linear time with respect to the sequence length via dynamic programming. Similar to traditional convolution operations, our non-linear feature mapping can be applied successively at multiple levels.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1565–1575,
Lisbon, Portugal, 17-21 September 2015.

We evaluate the proposed architecture in the context of sentence sentiment classification and news categorization. On the Stanford Sentiment Treebank dataset, our model obtains state-of-the-art performance among a variety of neural networks in terms of both accuracy and training cost. Our model achieves 51.2% accuracy on fine-grained classification and 88.6% on binary classification, outperforming the best published numbers obtained by a deep recursive model (Tai et al., 2015) and a convolutional model (Kim, 2014). On the Chinese news categorization task, our model achieves 80.0% accuracy, while the closest baseline achieves 79.2%.

2 Related Work

Deep neural networks have recently brought about significant advancements in various natural language processing tasks, such as language modeling (Bengio et al., 2003; Mikolov et al., 2010), sentiment analysis (Socher et al., 2013; Iyyer et al., 2015; Le and Zuidema, 2015), syntactic parsing (Collobert and Weston, 2008; Socher et al., 2011a; Chen and Manning, 2014) and machine translation (Bahdanau et al., 2014; Devlin et al., 2014; Sutskever et al., 2014). Models applied in these tasks exhibit significant architectural differences, ranging from recurrent neural networks (Mikolov et al., 2010; Kalchbrenner and Blunsom, 2013) to recursive models (Pollack, 1990; Küchler and Goller, 1996), and including convolutional neural nets (Collobert and Weston, 2008; Collobert et al., 2011; Yih et al., 2014; Shen et al., 2014; Kalchbrenner et al., 2014; Zhang and LeCun, 2015).

Our model most closely relates to the latter. Since these models have originally been developed for computer vision (LeCun et al., 1998), their application to NLP tasks introduced a number of modifications. For instance, Collobert et al. (2011) use the max-over-time pooling operation to aggregate the features over the input sequence. This variant has been successfully applied to semantic parsing (Yih et al., 2014) and information retrieval (Shen et al., 2014; Gao et al., 2014). Kalchbrenner et al. (2014) instead propose (dynamic) k-max pooling operation for modeling sentences. In addition, Kim (2014) combines CNNs of different filter widths and either static or fine-tuned word vectors. In contrast to the traditional CNN models, our method considers non-consecutive n-grams thereby expanding the representation capacity of the model. Moreover, our model captures non-linear interactions within n-gram snippets through the use of tensors, moving beyond direct linear projection operator used in standard CNNs. As our experiments demonstrate these advancements result in improved performance.

3 Background

Let $\mathbf{x} \in \mathbb{R}^{L \times d}$ be the input sequence such as a document or sentence. Here L is the length of the sequence and each $\mathbf{x}_i \in \mathbb{R}^d$ is a vector representing the i^{th} word. The (consecutive) *n-gram* vector ending at position j is obtained by simply concatenating the corresponding word vectors

$$v_j \;=\; [\mathbf{x}_{j-n+1}; \mathbf{x}_{j-n+2}; \cdots; \mathbf{x}_j]$$

Out-of-index words are simply set to all zeros.

The traditional convolution operator is parameterized by filter matrix $\mathbf{m} \in \mathbb{R}^{nd \times h}$ which can be thought of as n smaller filter matrices applied to each $\mathbf{x}_i$ in vector v_j. The operator maps each n-gram vector v_j in the input sequence to $\mathbf{m}^\top v_j \in \mathbb{R}^h$ so that the input sequence $\mathbf{x}$ is transformed into a sequence of feature representations,

$$\left[\mathbf{m}^\top v_1, \cdots, \mathbf{m}^\top v_L\right] \quad \in \quad \mathbb{R}^{L \times h}$$

The resulting feature values are often passed through non-linearities such as the hyper-tangent (element-wise) as well as aggregated or reduced by "sum-over" or "max-pooling" operations for later (similar stages) of processing.

The overall architecture can be easily modified by replacing the basic n-gram vectors and the convolution operation with other feature mappings. Indeed, we appeal to tensor algebra to introduce a non-linear feature mapping that operates on non-consecutive n-grams.

4 Model

N-gram tensor Typical $n-$gram feature mappings where concatenated word vectors are mapped linearly to feature coordinates may be insufficient to directly capture relevant information in the $n-$gram. As a remedy, we replace concatenation with a tensor product. Consider a 3-gram $(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3)$ and the corresponding tensor product $\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3$. The tensor product is a 3-way array of coordinate interactions such that each ijk

entry of the tensor is given by the product of the corresponding coordinates of the word vectors

$$(\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3)_{ijk} = \mathbf{x}_{1i} \cdot \mathbf{x}_{2j} \cdot \mathbf{x}_{3k}$$

Here $\otimes$ denotes the tensor product operator. The tensor product of a 2-gram analogously gives a two-way array or matrix $\mathbf{x}_1 \otimes \mathbf{x}_2 \in \mathbb{R}^{d \times d}$. The n-gram tensor can be seen as a direct generalization of the typical concatenated vector[2].

Tensor-based feature mapping Since each n-gram in the sequence is now expanded into a high-dimensional tensor using tensor products, the set of filters are analogously maintained as high-order tensors. In other words, our filters are linear mappings over the higher dimensional interaction terms rather than the original word coordinates.

Consider again mapping a 3-gram $(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3)$ into a feature representation. Each filter is a 3-way tensor with dimensions $d \times d \times d$. The set of h filters, denoted as T, is a 4-way tensor of dimension $d \times d \times d \times h$, where each d^3 slice of T represents a single filter and h is the number of such filters, i.e., the feature dimension. The resulting $h-$dimensional feature representation $z \in \mathbb{R}^h$ for the 3-gram $(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3)$ is obtained by multiplying the filter $\mathbf{T}$ and the 3-gram tensor as follows. The l^{th} coordinate of z is given by

$$\begin{aligned} z_l &= \sum_{ijk} \mathbf{T}_{ijkl} \cdot (\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3)_{ijk} \\ &= \sum_{ijk} \mathbf{T}_{ijkl} \cdot \mathbf{x}_{1i} \cdot \mathbf{x}_{2j} \cdot \mathbf{x}_{3k} \end{aligned} \quad (1)$$

The formula is equivalent to summing over all the third-order polynomial interaction terms where tensor $\mathbf{T}$ stores the coefficients.

Directly maintaining the filters as full tensors leads to parametric explosion. Indeed, the size of the tensor $\mathbf{T}$ (i.e. $h \times d^n$) would be too large even for typical low-dimensional word vectors where, e.g., $d = 300$. To this end, we assume a *low-rank factorization* of the tensor $\mathbf{T}$, represented in the Kruskal form. Specifically, $\mathbf{T}$ is decomposed into a sum of h rank-1 tensors

$$\mathbf{T} = \sum_{i=1}^{h} \mathbf{P}_i \otimes \mathbf{Q}_i \otimes \mathbf{R}_i \otimes \mathbf{O}_i$$

[2]To see this, consider word vectors with a "bias" term $\mathbf{x}_i{}' = [\mathbf{x}_i; 1]$. The tensor product of n such vectors includes the concatenated vector as a subset of tensor entries but, in addition, contains all up to n^{th}-order interaction terms.

where $\mathbf{P}, \mathbf{Q}, \mathbf{R} \in \mathbb{R}^{h \times d}$ and $\mathbf{O} \in \mathbb{R}^{h \times h}$ are four smaller parameter matrices. $\mathbf{P}_i$ (similarly $\mathbf{Q}_i$, $\mathbf{R}_i$ and $\mathbf{O}_i$) denotes the i^{th} row of the matrix. Note that, for simplicity, we have assumed that the number of rank-1 components in the decomposition is equal to the feature dimension h. Plugging the low-rank factorization into Eq.(1), the feature-mapping can be rewritten in a vector form as

$$z = \mathbf{O}^\top (\mathbf{P}\mathbf{x}_1 \odot \mathbf{Q}\mathbf{x}_2 \odot \mathbf{R}\mathbf{x}_3) \quad (2)$$

where $\odot$ is the element-wise product such that, e.g., $(a \odot b)_k = a_k \times b_k$ for $a, b \in \mathbb{R}^m$. Note that while $\mathbf{P}\mathbf{x}_1$ (similarly $\mathbf{Q}\mathbf{x}_2$ and $\mathbf{R}\mathbf{x}_3$) is a linear mapping from each word $\mathbf{x}_1$ (similarly $\mathbf{x}_2$ and $\mathbf{x}_3$) into a h-dimensional feature space, higher order terms arise from the element-wise products.

Non-consecutive n-gram features Traditional convolution uses consecutive n-grams in the feature map. Non-consecutive n-grams may nevertheless be helpful since phrases such as "not good", "not so good" and "not nearly as good" express similar sentiments but involve variable spacings between the key words. Variable spacings are not effectively captured by fixed n-grams.

We apply the feature-mapping in a weighted manner to all n-grams thereby gaining access to patterns such as "not ... good". Let $z[i, j, k] \in \mathbb{R}^h$ denote the feature representation corresponding to a 3-gram $(\mathbf{x}_i, \mathbf{x}_j, \mathbf{x}_k)$ of words in positions i, j, and k along the sequence. This vector is calculated analogously to Eq.(2),

$$z[i, j, k] = \mathbf{O}^\top (\mathbf{P}\mathbf{x}_i \odot \mathbf{Q}\mathbf{x}_j \odot \mathbf{R}\mathbf{x}_k)$$

We will aggregate these vectors into an $h-$dimensional feature representation at each position in the sequence. The idea is similar to neural bag-of-words models where the feature representation for a document or sentence is obtained by averaging (or summing) of all the word vectors. In our case, we define the aggregate representation $z_3[k]$ in position k as the weighted sum of all 3-gram feature representations ending at position k, i.e.,

$$\begin{aligned} z_3[k] &= \sum_{i<j<k} z[i, j, k] \cdot \lambda^{(k-j-1)+(j-i-1)} \\ &= \sum_{i<j<k} z[i, j, k] \cdot \lambda^{k-i-2} \end{aligned} \quad (3)$$

where $\lambda \in [0, 1)$ is a decay factor that down-weights 3-grams with longer spans (i.e., 3-grams

that skip more in-between words). As $\lambda \to 0$ all non-consecutive 3-grams are omitted, $z_3[k] = z[k-2, k-1, k]$, and the model acts like a traditional model with only consecutive n-grams. When $\lambda > 0$, however, $z_3[k]$ is a weighted average of many 3-grams with variable spans.

Aggregating features via dynamic programming Directly calculating $z_3[\cdot]$ according to Eq.(3) by enumerating all 3-grams would require $O(L^3)$ feature-mapping operations. We can, however, evaluate the features more efficiently by relying on the associative and distributive properties of the feature operation in Eq.(2).

Let $f_3[k]$ be a dynamic programming table representing the sum of 3-gram feature representations before multiplying with matrix $\mathbf{O}$. That is, $z_3[k] = \mathbf{O}^\top f_3[k]$ or, equivalently,

$$f_3[k] = \sum_{i<j<k} \lambda^{k-i-2} \cdot (\mathbf{P}\mathbf{x}_i \odot \mathbf{Q}\mathbf{x}_j \odot \mathbf{R}\mathbf{x}_k)$$

We can analogously define $f_1[i]$ and $f_2[j]$ for 1-grams and 2-grams,

$$f_1[i] = \mathbf{P}\mathbf{x}_i$$
$$f_2[j] = \sum_{i<j} \lambda^{j-i-1} \cdot (\mathbf{P}\mathbf{x}_i \odot \mathbf{Q}\mathbf{x}_j)$$

These dynamic programming tables can be calculated recursively according to the following formulas:

$$\begin{aligned} f_1[i] &= \mathbf{P}\mathbf{x}_i \\ s_1[i] &= \lambda \cdot s_1[i-1] + f_1[i] \end{aligned}$$

$$\begin{aligned} f_2[j] &= s_1[j-1] \odot \mathbf{Q}\mathbf{x}_j \\ s_2[j] &= \lambda \cdot s_2[j-1] + f_2[j] \end{aligned}$$

$$f_3[k] = s_2[k-1] \odot \mathbf{R}\mathbf{x}_k$$

$$z[k] = \mathbf{O}^\top (f_1[k] + f_2[k] + f_3[k])$$

where $s_1[\cdot]$ and $s_2[\cdot]$ are two auxiliary tables. The resulting $z[\cdot]$ is the sum of 1, 2, and 3-gram features. We found that aggregating the 1,2 and 3-gram features in this manner works better than using 3-gram features alone. Overall, the n-gram feature aggregation can be performed in $O(Ln)$ matrix multiplication/addition operations, and remains linear in the sequence length.

The overall architecture The dynamic programming algorithm described above maps the original input sequence to a sequence of feature representations $\mathbf{z} = z[1:L] \in \mathbb{R}^{L \times h}$. As in standard convolutional architectures, the resulting sequence can be used in multiple ways. One can directly aggregate it to a classifier or expose it to non-linear element-wise transformations and use it as an input to another sequence-to-sequence feature mapping.

The simplest strategy (adopted in neural bag-of-words models) would be to average the feature representations and pass the resulting averaged vector directly to a softmax output unit

$$\bar{z} = \frac{1}{L} \sum_{i=1}^{L} z[i]$$
$$\tilde{y} = \text{softmax}\left(\mathbf{W}^\top \bar{z}\right)$$

Our architecture, as illustrated in Figure 1, includes two additional refinements. First, we add a non-linear activation function after each feature representation, i.e. $\mathbf{z}' = \text{ReLU}(\mathbf{z} + b)$, where b is a bias vector and ReLU is the rectified linear unit function. Second, we stack multiple tensor-based feature mapping layers. That is, the input sequence $\mathbf{x}$ is first processed into a feature sequence and passed through the non-linear transformation to obtain $\mathbf{z}^{(1)}$. The resulting feature sequence $\mathbf{z}^{(1)}$ is then analogously processed by another layer, parameterized by a different set of feature-mapping matrices $\mathbf{P}, \cdots, \mathbf{O}$, to obtain a higher-level feature sequence $\mathbf{z}^{(2)}$, and so on. The output feature representations of all these layers are averaged within each layer and concatenated as shown in Figure 1. The final prediction is therefore obtained on the basis of features across the levels.

5 Learning the Model

Following standard practices, we train our model by minimizing the cross-entropy error on a given training set. For a single training sequence $\mathbf{x}$ and the corresponding gold label $y \in [0,1]^m$, the error is defined as,

$$\text{loss}(\mathbf{x}, y) = \sum_{l=1}^{m} y_l \log(\tilde{y}_l)$$

where m is the number of possible output label.

The set of model parameters (e.g. $\mathbf{P}, \cdots, \mathbf{O}$ in each layer) are updated via stochastic gradient

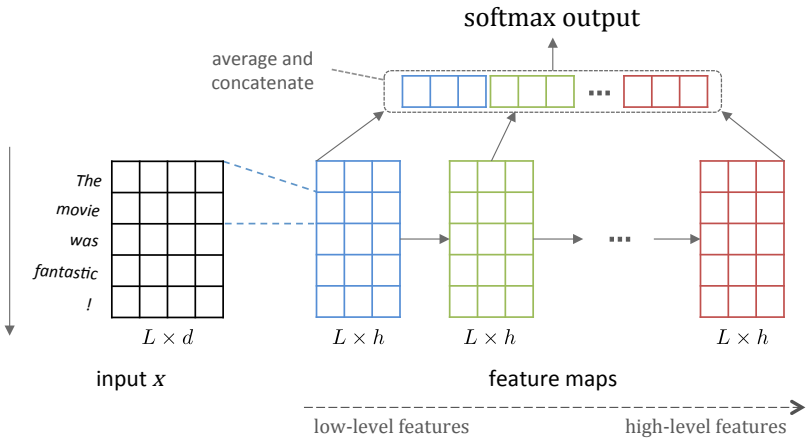

Figure 1: Illustration of the model architecture. The input is represented as a matrix where each row is a d-dimensional word vector. Several feature map layers (as described in Section 4) are stacked, mapping the input into different levels of feature representations. The features are averaged within each layer and then concatenated. Finally a softmax layer is applied to obtain the prediction output.

descent using AdaGrad algorithm (Duchi et al., 2011).

Initialization We initialize matrices $\mathbf{P}, \mathbf{Q}, \mathbf{R}$ from uniform distribution $\left[-\sqrt{3/d}, \sqrt{3/d}\right]$ and similarly $\mathbf{O} \sim \mathrm{U}\left[-\sqrt{3/h}, \sqrt{3/h}\right]$. In this way, each row of the matrices is an unit vector in expectation, and each rank-1 filter slice has unit variance as well,

$$\mathbb{E}\left[\|\mathbf{P}_i \otimes \mathbf{Q}_i \otimes \mathbf{R}_i \otimes \mathbf{O}_i\|^2\right] = 1$$

In addition, the parameter matrix $\mathbf{W}$ in the softmax output layer is initialized as zeros, and the bias vectors b for ReLU activation units are initialized to a small positive constant 0.01.

Regularization We apply two common techniques to avoid overfitting during training. First, we add L2 regularization to all parameter values with the same regularization weight. In addition, we randomly dropout (Hinton et al., 2012) units on the output feature representations $\mathbf{z}^{(i)}$ at each level.

6 Experimental Setup

Datasets We evaluate our model on sentence sentiment classification task and news categorization task. For sentiment classification, we use the Stanford Sentiment Treebank benchmark (Socher et al., 2013). The dataset consists of 11855 parsed English sentences annotated at both the root (i.e. sentence) level and the phrase level using 5-class fine-grained labels. We use the standard 8544/1101/2210 split for training, development and testing respectively. Following previous work, we also evaluate our model on the binary classification variant of this benchmark, ignoring all neutral sentences. The binary version has 6920/872/1821 sentences for training, development and testing.

For the news categorization task, we evaluate on Sogou Chinese news corpora.[3] The dataset contains 10 different news categories in total, including Finance, Sports, Technology and Automobile etc. We use 79520 documents for training, 9940 for development and 9940 for testing. To obtain Chinese word boundaries, we use LTP-Cloud[4], an open-source Chinese NLP platform.

Baselines We implement the standard **SVM** method and the neural bag-of-words model **NBoW** as baseline methods in both tasks. To assess the proposed tensor-based feature map, we also implement a convolutional neural network model **CNN** by replacing our filter with traditional linear filter. The rest of the framework (such as feature averaging and concatenation) remains the same.

In addition, we compare our model with a wide range of top-performing models on the sentence sentiment classification task. Most of these models fall into either the category of recursive neural networks (RNNs) or the category of convolutional neural networks (CNNs). The recursive neural

Ours	49.5	50.6	87.0	87.0	28	33
+ phrase labels	53.4	**51.2**	88.9	**88.6**	445	28

Table 1: Comparison between our model and other baseline methods on Stanford Sentiment Treebank. The top block lists recursive neural network models, the second block are convolutional network models and the third block contains other baseline methods, including the paragraph-vector model (Le and Mikolov, 2014), the deep averaging network model (Iyyer et al., 2015) and our implementation of neural bag-of-words. The training time of baseline methods is taken from (Iyyer et al., 2015) or directly from the authors. For our implementations, timings were performed on a single core of a 2.6GHz Intel i7 processor.

network baselines include standard **RNN** (Socher et al., 2011b), **RNTN** with a small core tensor in the composition function (Socher et al., 2013), the deep recursive model **DRNN** (Irsoy and Cardie, 2014) and the most recent recursive model using long-short-term-memory units **RLSTM** (Tai et al., 2015). These recursive models assume the input sentences are represented as parse trees. As a benefit, they can readily utilize annotations at the phrase level. In contrast, convolutional neural networks are trained on sequence-level, taking the original sequence and its label as training input. Such convolutional baselines include the dynamic CNN with k-max pooling **DCNN** (Kalchbrenner et al., 2014) and the convolutional model with multi-channel **CNN-MC** by Kim (2014). To leverage the phrase-level annotations in the Stanford Sentiment Treebank, all phrases and the corresponding labels are added as separate instances when training the sequence models. We follow this strategy and report results with and without phrase annotations.

Word vectors The word vectors are pre-trained on much larger unannotated corpora to achieve better generalization given limited amount of training data (Turian et al., 2010). In particular, for the English sentiment classification task, we use the publicly available 300-dimensional GloVe word vectors trained on the Common Crawl with 840B tokens (Pennington et al., 2014). This choice of word vectors follows most recent work, such as **DAN** (Iyyer et al., 2015) and **RLSTM** (Tai et al., 2015). For Chinese news categorization, there is no widely-used publicly available word vectors. Therefore, we run `word2vec` (Mikolov et al., 2013) to train 200-dimensional word vectors on the 1.6 million Chinese news articles. Both word vectors are normalized to unit norm (i.e. $\|w\|_2^2 = 1$) and are fixed in the experiments without fine-tuning.

Hyperparameter setting We perform an extensive search on the hyperparameters of our full model, our implementation of the **CNN** model (with linear filters), and the **SVM** baseline. For our model and the **CNN** model, the initial learning rate of AdaGrad is fixed to 0.01 for sentiment classification and 0.1 for news categorization, and the L2 regularization weight is fixed to $1e-5$ and $1e-6$ respectively based on preliminary runs. The rest of the hyperparameters are randomly chosen as follows: number of feature-mapping layers $\in \{1, 2, 3\}$, n-gram order $n \in \{2, 3\}$, hidden feature dimension $h \in \{50, 100, 200\}$, dropout probability $\in \{0.0, 0.1, 0.3, 0.5\}$, and length de-

cay $\lambda \in \{0.0, 0.3, 0.5\}$. We run each configuration 3 times to explore different random initializations. For the **SVM** baseline, we tune L2 regularization weight $C \in \{0.01, 0.1, 1.0, 10.0\}$, word cut-off frequency $\in \{1, 2, 3, 5\}$ (i.e. pruning words appearing less than this times) and n-gram feature order $n \in \{1, 2, 3\}$.

Implementation details The source code is implemented in Python using the Theano library (Bergstra et al., 2010), a flexible linear algebra compiler that can optimize user-specified computations (models) with efficient automatic low-level implementations, including (back-propagated) gradient calculation.

7 Results

7.1 Overall Performance

Table 1 presents the performance of our model and other baseline methods on Stanford Sentiment Treebank benchmark. Our full model obtains the highest accuracy on both the development and test sets. Specifically, it achieves 51.2% and 88.6% test accuracies on fine-grained and binary tasks respectively[5]. As shown in Table 2, our model performance is relatively stable – it remains high accuracies with around 0.5% standard deviation under different initializations and dropout rates.

Our full model is also several times faster than other top-performing models. For example, the convolutional model with multi-channel (**CNN-MC**) runs over 2400 seconds per training epoch. In contrast, our full model (with 3 feature layers) runs on average 28 seconds with only root labels and on average 445 seconds with all labels.

Our results also show that the **CNN** model, where our feature map is replaced with traditional linear map, performs worse than our full model. This observation confirms the importance of the proposed non-linear, tensor-based feature mapping. The **CNN** model also lags behind the **DCNN** and **CNN-MC** baselines, since the latter two propose several advancements over standard CNN.

Table 3 reports the results of **SVM**, **NBoW** and our model on the news categorization task. Since the dataset is much larger compared to the sentiment dataset (80K documents vs. 8.5K sentences), the **SVM** method is a competitive baseline. It achieves 78.5% accuracy compared to 74.4% and 79.2% obtained by the neural bag-of-words model and CNN model. In contrast, our model obtains 80.0% accuracy on both the development and test sets, outperforming the three baselines by a 0.8% absolute margin. The best hyperparameter configuration in this task uses less feature layers and lower n-gram order (specifically, 2 layers and $n = 2$) compared to the sentiment classification task. We hypothesize that the difference is due to the nature of the two tasks: the document classification task requires to handle less compositions or context interactions than sentiment analysis.

[5]Best hyperparameter configuration based on dev accuracy: 3 layers, 3-gram tensors (n=3), feature dimension $d = 200$ and length decay $\lambda = 0.5$

	Dataset	Accuracy
Fine-grained	Dev	52.5 (±0.5) %
	Test	51.4 (±0.6) %
Binary	Dev	88.4 (±0.3) %
	Test	88.4 (±0.5) %

Table 2: Analysis of average accuracy and standard deviation of our model on sentiment classification task.

Model	Dev Acc.	Test Acc.
SVM (1-gram)	77.5	77.4
SVM (2-gram)	78.2	78.0
SVM (3-gram)	78.2	78.5
NBoW	74.4	74.4
CNN	79.5	79.2
Ours	80.0	80.0

Table 3: Performance of various methods on Chinese news categorization task. Our model obtains better results than the SVM, NBoW and traditional CNN baselines.

7.2 Hyperparameter Analysis

We next investigate the impact of hyperparameters in our model performance. We use the models trained on fine-grained sentiment classification task with only root labels.

Number of layers We plot the fine-grained sentiment classification accuracies obtained during hyperparameter grid search. Figure 2 illustrates how the number of feature layers impacts the model performance. As shown in the figure, adding higher-level features clearly improves the classification accuracy across various hyperparameter settings and initializations.

Non-consecutive n-gram features We also analyze the effect of modeling non-consecutive n-

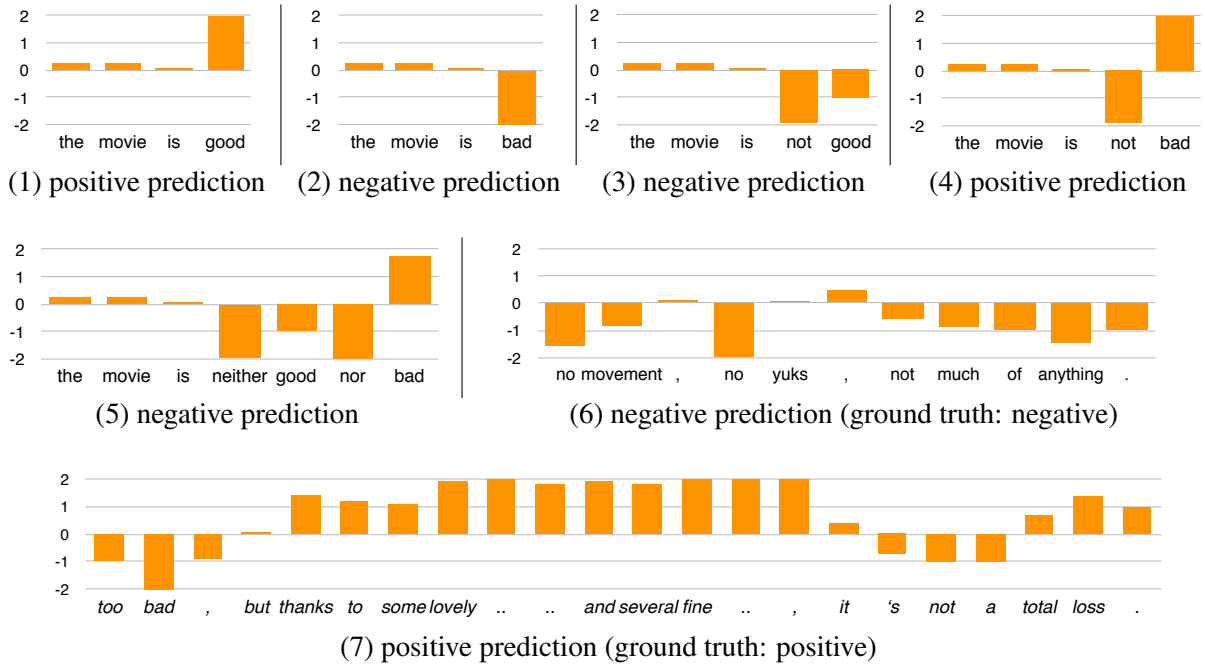

Figure 5: Example sentences and their sentiments predicted by our model trained with root labels. The predicted sentiment scores at each word position are plotted. Examples (1)-(5) are synthetic inputs, (6) and (7) are two real inputs from the test set. Our model successfully identifies negation, double negation and phrases with different sentiment in one sentence.

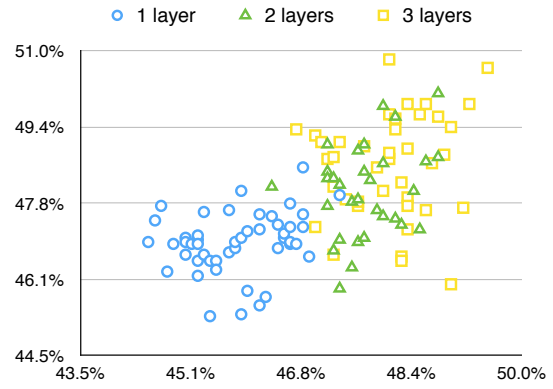

Figure 2: Dev accuracy (x-axis) and test accuracy (y-axis) of independent runs of our model on fine-grained sentiment classification task. Deeper architectures achieve better accuracies.

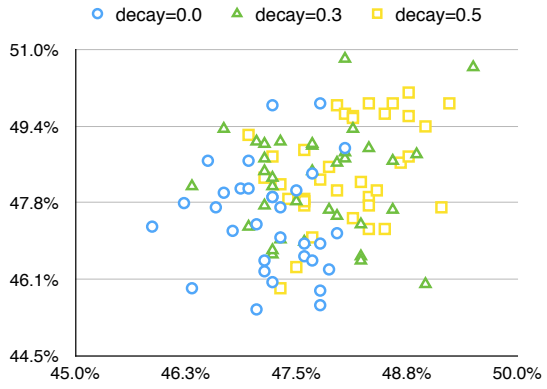

Figure 3: Comparison of our model variations in sentiment classification task when considering consecutive n-grams only (decaying factor $\lambda = 0$) and when considering non-consecutive n-grams ($\lambda > 0$). Modeling non-consecutive n-gram features leads to better performance.

grams. Figure 3 splits the model accuracies according to the choice of span decaying factor λ. Note when $\lambda = 0$, the model applies feature extractions to consecutive n-grams only. As shown in Figure 3, this setting leads to consistent performance drop. This result confirms the importance of handling non-consecutive n-gram patterns.

Non-linear activation Finally, we verify the effectiveness of rectified linear unit activation function (ReLU) by comparing it with no activation (or identity activation $f(x) = x$). As shown in Figure 4, our model with ReLU activation generally outperforms its variant without ReLU. The observation is consistent with previous work on convolutional neural networks and other neural network models.

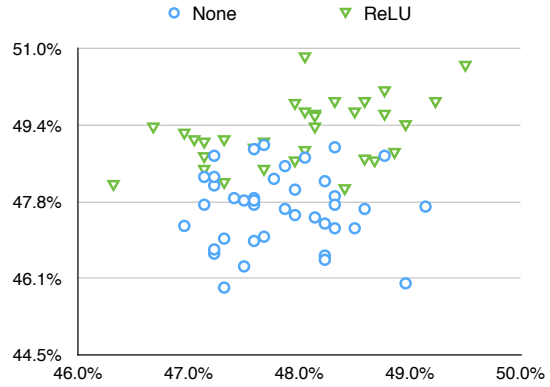

Figure 4: Applying ReLU activation on top of tensor-based feature mapping leads to better performance in sentiment classification task. Runs with no activation are plotted as blue circles.

7.3 Example Predictions

Figure 5 gives examples of input sentences and the corresponding predictions of our model in fine-grained sentiment classification. To see how our model captures the sentiment at different local context, we apply the learned softmax activation to the extracted features at each position without taking the average. That is, for each index i, we obtain the local sentiment $p = \text{softmax}\left(\mathbf{W}^\top \left(z^{(1)}[i] \oplus z^{(2)}[i] \oplus z^{(3)}[i]\right)\right)$. We plot the expected sentiment scores $\sum_{s=-2}^{2} s \cdot p(s)$, where a score of 2 means "very positive", 0 means "neutral" and -2 means "very negative". As shown in the figure, our model successfully learns negation and double negation. The model also identifies positive and negative segments appearing in the sentence.

8 Conclusion

We proposed a feature mapping operator for convolutional neural networks by modeling n-gram interactions based on tensor product and evaluating all non-consecutive n-gram vectors. The associated parameters are maintained as a low-rank tensor, which leads to efficient feature extraction via dynamic programming. The model achieves top performance on standard sentiment classification and document categorization tasks.

Abstract

Modeling sentence similarity is complicated by the ambiguity and variability of linguistic expression. To cope with these challenges, we propose a model for comparing sentences that uses a multiplicity of perspectives. We first model each sentence using a convolutional neural network that extracts features at multiple levels of granularity and uses multiple types of pooling. We then compare our sentence representations at several granularities using multiple similarity metrics. We apply our model to three tasks, including the Microsoft Research paraphrase identification task and two SemEval semantic textual similarity tasks. We obtain strong performance on all tasks, rivaling or exceeding the state of the art without using external resources such as WordNet or parsers.

1 Introduction

Measuring the semantic relatedness of two pieces of text is a fundamental problem in language processing tasks like plagiarism detection, query ranking, and question answering. In this paper, we address the sentence similarity measurement problem: given a query sentence S_1 and a comparison sentence S_2, the task is to compute their similarity in terms of a score $sim(S_1, S_2)$. This similarity score can be used within a system that determines whether two sentences are paraphrases, e.g., by comparing it to a threshold.

Measuring sentence similarity is challenging because of the variability of linguistic expression and the limited amount of annotated training data. This makes it difficult to use sparse, hand-crafted features as in conventional approaches in NLP. Recent successes in sentence similarity have been obtained by using neural networks (Tai et al., 2015; Yin and Schütze, 2015). Our approach is also based on neural networks: we propose a modular functional architecture with two components, sentence modeling and similarity measurement.

For sentence modeling, we use a convolutional neural network featuring convolution filters with multiple granularities and window sizes, followed by multiple types of pooling. We experiment with two types of word embeddings as well as part-of-speech tag embeddings (Sec. 4). For similarity measurement, we compare pairs of local regions of the sentence representations, using multiple distance functions: cosine distance, Euclidean distance, and element-wise difference (Sec. 5).

We demonstrate state-of-the-art performance on two SemEval semantic relatedness tasks (Agirre et al., 2012; Marelli et al., 2014), and highly competitive performance on the Microsoft Research paraphrase (MSRP) identification task (Dolan et al., 2004). On the SemEval-2014 task, we match the state-of-the-art dependency tree Long Short-Term Memory (LSTM) neural networks of Tai et al. (2015) without using parsers or part-of-speech taggers. On the MSRP task, we outperform the recently-proposed convolutional neural network model of Yin and Schütze (2015) without any pretraining. In addition, we perform ablation experiments to show the contribution of our modeling decisions for all three datasets, demonstrating clear benefits from our use of multiple perspectives both in sentence modeling and structured similarity measurement.

2 Related Work

Most previous work on modeling sentence similarity has focused on feature engineering. Several types of sparse features have been found useful, including: (1) string-based, including n-gram overlap features on both the word and character levels (Wan et al., 2006) and features based on machine translation evaluation metrics (Madnani

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1576–1586,
Lisbon, Portugal, 17-21 September 2015.

et al., 2012); (2) knowledge-based, using external lexical resources such as WordNet (Fellbaum, 1998; Fern and Stevenson, 2008); (3) syntax-based, e.g., modeling divergence of dependency syntax between the two sentences (Das and Smith, 2009); (4) corpus-based, using distributional models such as latent semantic analysis to obtain features (Hassan, 2011; Guo and Diab, 2012).

Several strongly-performing approaches used system combination (Das and Smith, 2009; Madnani et al., 2012) or multi-task learning. Xu et al. (2014) developed a feature-rich multi-instance learning model that jointly learns paraphrase relations between word and sentence pairs.

Recent work has moved away from handcrafted features and towards modeling with distributed representations and neural network architectures. Collobert and Weston (2008) used convolutional neural networks in a multitask setting, where their model is trained jointly for multiple NLP tasks with shared weights. Kalchbrenner et al. (2014) introduced a convolutional neural network for sentence modeling that uses dynamic k-max pooling to better model inputs of varying sizes. Kim (2014) proposed several modifications to the convolutional neural network architecture of Collobert and Weston (2008), including the use of both fixed and learned word vectors and varying window sizes of the convolution filters.

For the MSRP task, Socher et al. (2011) used a recursive neural network to model each sentence, recursively computing the representation for the sentence from the representations of its constituents in a binarized constituent parse. Ji and Eisenstein (2013) used matrix factorization techniques to obtain sentence representations, and combined them with fine-tuned sparse features using an SVM classifier for similarity prediction. Both Socher et al. and Ji and Eisenstein incorporated sparse features to improve performance, which we do not use in this work.

Hu et al. (2014) used convolutional neural networks that combine hierarchical sentence modeling with layer-by-layer composition and pooling. While they performed comparisons directly over entire sentence representations, we instead develop a structured similarity measurement layer to compare local regions. A variety of other neural network models have been proposed for similarity tasks (Weston et al., 2011; Huang et al., 2013; Andrew et al., 2013; Bromley et al., 1993).

Most recently, Tai et al. (2015) and Zhu et al. (2015) concurrently proposed a tree-based LSTM neural network architecture for sentence modeling. Unlike them, we do not use syntactic parsers, yet our performance matches Tai et al. (2015) on the similarity task. This result is appealing because high-quality parsers are difficult to obtain for low-resource languages or specialized domains. Yin and Schütze (2015) concurrently developed a convolutional neural network architecture for paraphrase identification, which we compare to in our experiments. Their best results rely on an unsupervised pretraining step, which we do not need to match their performance.

Our model architecture differs from previous work in several ways. We exploit multiple perspectives of input sentences in order to maximize information utilization and perform structured comparisons over particular regions of the sentence representations. We now proceed to describe our model in detail, and we compare to the above related work in our experimental evaluation.

3 Model Overview

Modeling textual similarity is complicated by the ambiguity and variability of linguistic expression. We designed a model with these phenomena in mind, exploiting multiple types of input which are processed by multiple types of convolution and pooling. Our similarity architecture likewise uses multiple similarity functions.

To summarize, our model (shown in Figure 1) consists of two main components:

1. A **sentence model** for converting a sentence into a representation for similarity measurement; we use a convolutional neural network architecture with multiple types of convolution and pooling in order to capture different granularities of information in the inputs.
2. A **similarity measurement layer** using multiple similarity measurements, which compare local regions of the sentence representations from the sentence model.

Our model has a "Siamese" structure (Bromley et al., 1993) with two subnetworks each processing a sentence in parallel. The subnetworks share all of their weights, and are joined by the similarity measurement layer, then followed by a fully connected layer for similarity score output.

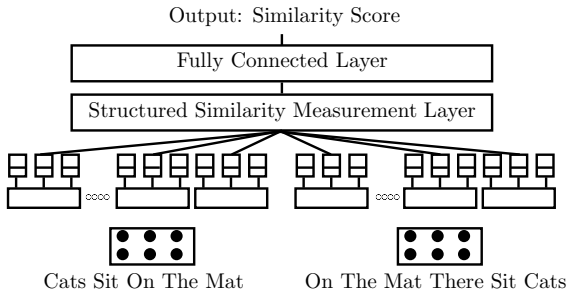

Figure 1: Model overview. Two input sentences (on the bottom) are processed in parallel by identical neural networks, outputting sentence representations. The sentence representations are compared by the structured similarity measurement layer. The similarity features are then passed to a fully-connected layer for computing the similarity score (top).

Importantly, we do not require resources like WordNet or syntactic parsers for the language of interest; we only use optional part-of-speech tags and pretrained word embeddings. The main difference from prior work lies in our use of multiple types of convolution, pooling, and structured similarity measurement over local regions. We show later in our experiments that the bulk of our performance comes from this use of multiple "perspectives" of the input sentences.

We describe our sentence model in Section 4 and our similarity measurement layer in Section 5.

4 Sentence Modeling

In this section we describe our convolutional neural network for modeling each sentence. We use two types of convolution filters defined on different perspectives of the input (Sec. 4.1), and also use multiple types of pooling (Sec. 4.2).

Our inputs are streams of tokens, which can be interpreted as a temporal sequence where nearby words are likely to be correlated. Let $sent \in \mathbf{R}^{len \times Dim}$ be a sequence of len input words represented by Dim-dimensional word embeddings, where $sent_i \in \mathbf{R}^{Dim}$ is the embedding of the i-th word in the sequence and $sent_{i:j}$ represents the concatenation of embeddings from word i up to and including word j. We denote the k-th dimension of the i-th word vector by $sent_i^{[k]}$ and we denote the vector containing the k-th dimension of words i to j by $sent_{i:j}^{[k]}$.

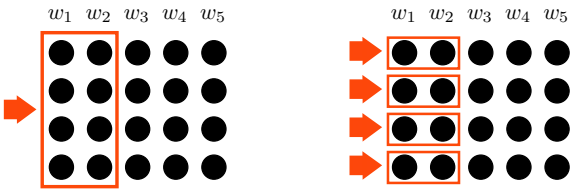

Figure 2: Left: a holistic filter matches entire word vectors (here, $ws = 2$). Right: per-dimension filters match against each dimension of the word embeddings independently.

4.1 Convolution on Multiple Perspectives

We define a convolution filter F as a tuple $\langle ws, w_F, b_F, h_F \rangle$, where ws is the sliding window width, $w_F \in \mathbf{R}^{ws \times Dim}$ is the weight vector for the filter, $b_F \in \mathbf{R}$ is the bias, and h_F is the activation function (a nonlinear function such as $\tanh$). When filter F is applied to sequence $sent$, the inner product is computed between w_F and each possible window of word embeddings of length ws in $sent$, then the bias is added and the activation function is applied. This results in an output vector $out_F \in \mathbf{R}^{1+len-ws}$ where entry i equals

$$out_F[i] = h_F(w_F \cdot sent_{i:i+ws-1} + b_F) \quad (1)$$

where $i \in [1, 1 + len - ws]$. This filter can be viewed as performing "temporal" convolution, as it matches against regions of the word sequence. Since these filters consider the entirety of each word embedding at each position, we call them holistic filters; see the left half of Figure 2.

In addition, we target information at a finer granularity by constructing per-dimension filters $F^{[k]}$ for each dimension k of the word embeddings, where $w_{F^{[k]}} \in \mathbf{R}^{ws}$. See the right half of Figure 2. The per-dimension filters are similar to "spatial convolution" filters except that we limit each to a single, predefined dimension. We include separate per-dimension filters for each dimension of the input word embeddings.

Applying a per-dimension filter $F^{[k]} = \langle ws, w_{F^{[k]}}, b_{F^{[k]}}, h_{F^{[k]}} \rangle$ for dimension k results in an output vector $out_{F^{[k]}} \in \mathbf{R}^{1+len-ws}$ where entry i (for $i \in [1, 1 + len - ws]$) equals

$$out_{F^{[k]}}[i] = h_{F^{[k]}}(w_{F^{[k]}} \cdot sent_{i:i+ws-1}^{[k]} + b_{F^{[k]}})$$

Our use of word embeddings in both ways allows more information to be extracted for richer sentence modeling. While we typically do not expect individual dimensions of neural word embeddings

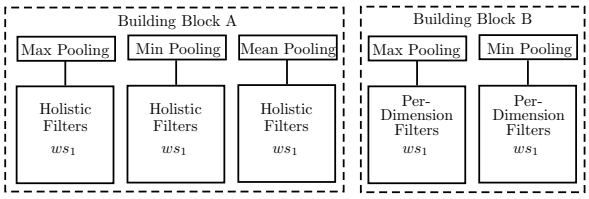

Figure 3: Each building block consists of multiple independent pooling layers and convolution layers with width ws_1. Left: $block_A$ operates on entire vectors of word embeddings. Right: $block_B$ operates on individual dimensions of word vectors to capture information of a finer granularity.

to be interpretable to humans, there may still be distinct information captured by the different dimensions that our model could exploit. Furthermore, if we update the word embeddings during learning, different dimensions could be encouraged further to capture distinct information.

We define a convolution layer as a set of convolution filters that share the same type (holistic or per-dimension), activation function, and width ws. The type, width, activation function, and number of filters $numFilter$ in the layer are chosen by the modeler and the weights of each filter (w_F and b_F) are learned.

4.2 Multiple Pooling Types

The output vector out_F of a convolution filter F is typically converted to a scalar for subsequent use by the model using some method of pooling. For example, "max-pooling" applies a $\max$ operation across the entries of out_F and returns the maximum value. In this paper, we experiment with two additional types of pooling: "min-pooling" and "mean-pooling".

A group, denoted $group(ws, pooling, sent)$, is an object that contains a convolution layer with width ws, uses pooling function $pooling$, and operates on sentence $sent$. We define a building block to be a set of groups. We use two types of building blocks, $block_A$ and $block_B$, as shown in Figure 3. We define $block_A$ as

$$\{group_A(ws_a, p, sent) : p \in \{\max, \min, \text{mean}\}\}.$$

That is, an instance of $block_A$ has three convolution layers, one corresponding to each of the three pooling functions; all have the same window size ws_a. An alternative choice would be to use the multiple types of pooling on the *same* filters (Rennie et al., 2014); we instead use independent sets of filters for the different pooling types.[1] We use blocks of type A for all holistic convolution layers.

We define $block_B$ as

$$\{group_B(ws_b, p, sent) : p \in \{\max, \min\}\}.$$

That is, $block_B$ contains two groups of convolution layers of width ws_b, one with max-pooling and one with min-pooling. Each $group_B(*)$ contains a convolution layer with Dim per-dimension convolution filters. That is, we use blocks of type B for convolution layers that operate on individual dimensions of word vectors.

We use these multiple types of pooling to extract different types of information from each type of filter. The design of each $group(*)$ allows a pooling function to interact with its own underlying convolution layers independently, so each convolution layer can learn to recognize distinct phenomena of the input for richer sentence modeling.

For a $group_A(ws_a, pooling_a, sent)$ with a convolution layer with $numFilter_A$ filters, we define the output oG_A as a vector of length $numFilter_A$ where entry j is

$$oG_A[j] = pooling_a(out_{F_j}) \quad (2)$$

where filters are indexed as F_j. That is, the output of $group_A(*)$ is a $numFilter_A$-length vector containing the output of applying the pooling function on each filter's vector of filter match outputs.[2]

A component $group_B(*)$ of $block_B$ contains Dim filters, each operating on a particular dimension of the word embeddings. We define the output oG_B of $group_B(ws_b, pooling_b, sent)$ as a $Dim \times numFilter_B$ matrix where entry $[k][j]$ is

$$oG_B[k][j] = pooling_b(out_{F_j^{[k]}})$$

where filter $F_j^{[k]}$ is filter j for dimension k.

4.3 Multiple Window Sizes

Similar to traditional n-gram-based models, we use multiple window sizes ws in our building blocks in order to learn features of different lengths. For example, in Figure 4 we use four building blocks, each with one window size $ws =$

[1] We note that $\max$ and $\min$ are not both strictly necessary when using certain activation functions, but they still may help us find a more felicitous local optimum.

[2] We note that there is no pooling across multiple filters in a layer/group, or across groups. Each pooling operation is performed independently on the matches of a single filter.

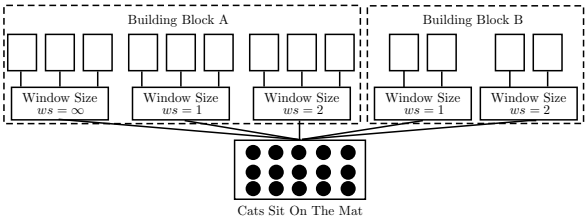

Figure 4: Example neural network architecture for a single sentence, containing 3 instances of $block_A$ (with 3 types of pooling) and 2 instances of $block_B$ (with 2 types) on varying window sizes $ws = 1, 2$ and $ws = \infty$; $block_A$ operates on entire word vectors while $block_B$ contains filters that operate on individual dimensions independently.

1 or 2 for its own convolution layers. In order to retain the original information in the sentences, we also include the entire matrix of word embeddings in the sentence, which essentially corresponds to $ws = \infty$.

The width ws represents how many words are matched by a filter, so using larger values of ws corresponds to matching longer n-grams in the input sentences. The ranges of ws values and the numbers of filters $numFilter$ of $block_A$ and $block_B$ are empirical choices tuned based on validation data.

5 Similarity Measurement Layer

In this section we describe the second part of our model, the similarity measurement layer.

Given two input sentences, the first part of our model computes sentence representations for each of them in parallel. One straightforward way to compare them is to flatten the sentence representations into two vectors, then use standard metrics like cosine similarity. However, this may not be optimal because different regions of the flattened sentence representations are from different underlying sources (e.g., groups of different widths, types of pooling, dimensions of word vectors, etc.). Flattening might discard useful compositional information for computing similarity. We therefore perform structured comparisons over particular regions of the sentence representations.

One important consideration is how to identify suitable local regions for comparison so that we can best utilize the compositional information in the sentence representations. There are many possible ways to group local comparison regions. In doing so, we consider the following four aspects: 1) whether from the same building block; 2) whether from convolutional layers with the same window size; 3) whether from the same pooling layer; 4) whether from the same filter of the underlying convolution layers.[3] We focus on comparing regions that share at least two of these conditions.

To concretize this, we provide two algorithms below to identify meaningful local regions. While there exist other sets of comparable regions that share the above conditions, we do not explore them all due to concerns about learning efficiency; we find that the subset we consider performs strongly in practice.

5.1 Similarity Comparison Units

We define two comparison units for comparing two local regions in the sentence representations:

$$comU_1(\overrightarrow{x}, \overrightarrow{y}) = \{\cos(\overrightarrow{x}, \overrightarrow{y}), L_2Euclid(\overrightarrow{x}, \overrightarrow{y}), |\overrightarrow{x} - \overrightarrow{y}|\} \quad (3)$$

$$comU_2(\overrightarrow{x}, \overrightarrow{y}) = \{\cos(\overrightarrow{x}, \overrightarrow{y}), L_2Euclid(\overrightarrow{x}, \overrightarrow{y})\} \quad (4)$$

Cosine distance (cos) measures the distance of two vectors according to the angle between them, while L_2 Euclidean distance ($L_2Euclid$) and element-wise absolute difference measure magnitude differences.

5.2 Comparison over Local Regions

Algorithms 1 and 2 show how the two sentence representations are compared in our model. Algorithm 1 works on the output of $block_A$ only, while Algorithm 2 deals with both $block_A$ and $block_B$, focusing on regions from the output of the same pooling type and same block type, but with different filters and window sizes of convolution layers.

Given two sentences S_1 and S_2, we set the maximum window size ws of $block_A$ and $block_B$ to be n, let $regM_*$ represent a $numFilter_A$ by $n+1$ matrix, and assume that each $group_*$ outputs its corresponding oG_*. The output features are accumulated in a final vector fea.

5.3 One Simplified Example

We provide a simplified working example to show how the two algorithms compare outputs of $block_A$ only. If we arrange the sentence representations into the shape of sentence matrices as in Figure 5,

[3] We note that since we apply the same network to both sentences, the same filters are used to match both sentences, so we can directly compare filter matches of individual filters across the two sentences.

Algorithm 1 Horizontal Comparison

1: **for** each pooling $p = \max, \min, \text{mean}$ **do**
2: **for** each width $ws_1 = 1...n, \infty$ **do**
3: $regM_1[*][ws_1] = group_A(ws_1, p, S_1)$
4: $regM_2[*][ws_1] = group_A(ws_1, p, S_2)$
5: **end for**
6: **for** each $i = 1...numFilter_A$ **do**
7: $fea_h = comU_2(regM_1[i], regM_2[i])$
8: accumulate fea_h for final layer
9: **end for**
10: **end for**

Algorithm 2 Vertical Comparison

1: **for** each pooling $p = \max, \min, \text{mean}$ **do**
2: **for** each width $ws_1 = 1...n, \infty$ **do**
3: $oG_{1A} = group_A(ws_1, p, S_1)$
4: **for** each width $ws_2 = 1...n, \infty$ **do**
5: $oG_{2A} = group_A(ws_2, p, S_2)$
6: $fea_a = comU_1(oG_{1A}, oG_{2A})$
7: accumulate fea_a for final layer
8: **end for**
9: **end for**
10: **for** each width $ws_1 = 1...n$ **do**
11: $oG_{1B} = group_B(ws_1, p, S_1)$
12: $oG_{2B} = group_B(ws_1, p, S_2)$
13: **for** each $i = 1...numFilter_B$ **do**
14: $fea_b = comU_1(oG_{1B}[*][i], oG_{2B}[*][i])$
15: accumulate fea_b for final layer
16: **end for**
17: **end for**
18: **end for**

then in Algorithms 1 and 2 we are essentially comparing local regions of the two matrices in two directions: along rows and columns.

In Figure 5, each column of the max/min/mean groups is compared with all columns of the same pooling group for the other sentence. This is shown in red dotted lines in the Figure and listed in lines 2 to 9 in Algorithm 2. Note that both ws_1 and ws_2 columns within each pooling group should be compared using red dotted lines, but we omit this from the figure for clarity.

In the horizontal direction, each equal-sized max/min/mean group is extracted as a vector and is compared to the corresponding one for the other sentence. This process is repeated for all rows and comparisons are shown in green solid lines, as performed by Algorithm 1.

5.4 Other Model Details

Output Fully-Connected Layer. On top of the similarity measurement layer (which outputs a vector containing all fea_*), we stack two linear layers with an activation layer in between, followed by a log-softmax layer as the final output layer, which outputs the similarity score.

Activation Layers. We used element-wise tanh as the activation function for all convolution filters and for the activation layer placed between the final two layers.

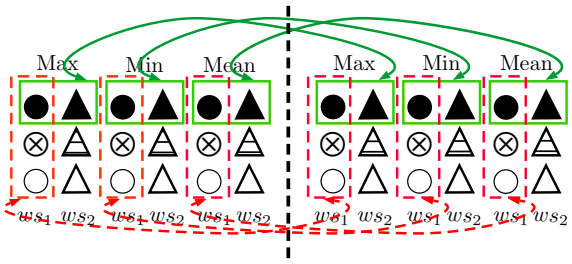

Figure 5: Simplified example of local region comparisons over two sentence representations that use $block_A$ only. The "horizontal comparison" (Algorithm 1) is shown with green solid lines and "vertical comparison" (Algorithm 2) with red dotted lines. Each sentence representation uses window sizes ws_1 and ws_2 with max/min/mean pooling and $numFilter_A = 3$ filters.

6 Experiments and Results

Everything necessary to replicate our experimental results can be found in our open-source code repository.[4]

6.1 Tasks and Datasets

We consider three sentence pair similarity tasks:

1. Microsoft Research Paraphrase Corpus (MSRP). This data was collected from news sources (Dolan et al., 2004) and contains 5,801 pairs of sentences, with 4,076 for training and the remaining 1,725 for testing. Each sentence pair is annotated with a binary label indicating whether the two sentences are paraphrases, so the task here is binary classification.

2. Sentences Involving Compositional Knowledge (SICK) dataset. This data was collected for the 2014 SemEval competition (Marelli et al., 2014) and consists of 9,927 sentence pairs, with 4,500 for training, 500 as a development set, and the remaining 4,927 in the test set. The sentences are drawn from image and video descriptions. Each sentence pair is annotated with a relatedness score $\in [1, 5]$, with higher scores indicating the two sentences are more closely-related.

[4] http://hohocode.github.io/textSimilarityConvNet/

3. Microsoft Video Paraphrase Corpus (MSRVID). This dataset was collected for the 2012 SemEval competition and consists of 1,500 pairs of short video descriptions which were then annotated (Agirre et al., 2012). Half of it is for training and the other half is for testing. Each sentence pair has a relatedness score $\in [0, 5]$, with higher scores indicating the two sentences are more closely-related.

6.2 Training

We use a hinge loss for the MSRP paraphrase identification task. This is simpler than log loss since it only penalizes misclassified cases. The training objective is to minimize the following loss (summed over examples $\langle x, y_{gold} \rangle$):

$$loss(\theta, x, y_{gold}) = \sum_{y' \neq y_{gold}} \max(0, 1 + f_\theta(x, y') - f_\theta(x, y_{gold})) \quad (5)$$

where y_{gold} is the ground truth label, input x is the pair of sentences $x = \{S_1, S_2\}$, θ is the model weight vector to be trained, and the function $f_\theta(x, y)$ is the output of our model.

We use regularized KL-divergence loss for the semantic relatedness tasks (SICK and MSRVID), since the goal is to predict the similarity of the two sentences. The training objective is to minimize the KL-divergence loss plus an L_2 regularizer:

$$loss(\theta) = \frac{1}{m} \sum_{k=1}^{m} KL\left(f^k \,||\, \widehat{f}_\theta^k\right) + \frac{\lambda}{2}||\theta||_2^2 \quad (6)$$

where $\widehat{f}_\theta$ is the predicted distribution with model weight vector θ, f is the ground truth, m is the number of training examples, and λ is the regularization parameter. Note that we use the same KL-loss function and same sparse target distribution technique as Tai et al. (2015).

6.3 Experiment Settings

We conduct experiments with ws values in the range $[1, 3]$ as well as $ws = \infty$ (no convolution).

We use multiple kinds of embeddings to represent each sentence, both on words and part-of-speech (POS) tags. We use the $Dim_g = 300$-dimensional GloVe word embeddings (Pennington et al., 2014) trained on 840 billion tokens. We use $Dim_k = 25$-dimensional PARAGRAM vectors (Wieting et al., 2015) only on the MSRP task since they were developed for paraphrase tasks, having been trained on word pairs from the Paraphrase Database (Ganitkevitch et al., 2013). For POS embeddings, we run the Stanford POS tagger (Manning et al., 2014) on the English side of the Xinhua machine translation parallel corpus, which consists of Xinhua news articles with approximately 25 million words. We then train $Dim_p = 200$-dimensional POS embeddings using the `word2vec` toolkit (Mikolov et al., 2013). Adding POS embeddings is expected to retain syntactic information which is reported to be effective for paraphrase identification (Das and Smith, 2009). We use POS embeddings only for the MSRP task.

Therefore for MSRP, we concatenate all word and POS embeddings and obtain $Dim = Dim_g + Dim_p + Dim_k = 525$-dimension vectors for each input word; for SICK and MSRVID we only use $Dim = 300$-dimension GloVe embeddings.

We use 5-fold cross validation on the MSRP *training* data for tuning, then largely re-use the same hyperparameters for the other two datasets. However, there are two changes: 1) for the MSRP task we update word embeddings during training but not so on SICK and MSRVID tasks; 2) we set the fully connected layer to contain 250 hidden units for MSRP, and 150 for SICK and MSRVID. These changes were done to speed up our experimental cycle on SICK and MSRVID; on SICK data they are the same experimental settings as used by Tai et al. (2015), which makes for a cleaner empirical comparison.

We set the number of holistic filters in $block_A$ to be the same as the input word embeddings, therefore $numFilter_A = 525$ for MSRP and $numFilter_A = 300$ for SICK and MSRVID. We set the number of per-dimension filters in $block_B$ to be $numFilter_B = 20$ per dimension for all three datasets, which corresponds to $20 * Dim$ filters in total.

We perform optimization using stochastic gradient descent (Bottou, 1998). The backpropagation algorithm is used to compute gradients for all parameters during training (Goller and Kuchler, 1996). We fix the learning rate to 0.01 and regularization parameter $\lambda = 10^{-4}$.

6.4 Results on Three Datasets

Results on MSRP Data. We report F1 scores and accuracies from prior work in Table 1. Ap-

Model	Acc.	F1
Hu et al. (2014) ARC-I	69.6%	80.3%
Hu et al. (2014) ARC-II	69.9%	80.9%
Blacoe and Lapata (2012)	73.0%	82.3%
Fern and Stevenson (2008)	74.1%	82.4%
Finch (2005)	75.0%	82.7%
Das and Smith (2009)	76.1%	82.7%
Wan et al. (2006)	75.6%	83.0%
Socher et al. (2011)	76.8%	83.6%
Madnani et al. (2012)	77.4%	84.1%
Ji and Eisenstein (2013)	**80.41**%	**85.96**%
Yin and Schütze (2015) (without pretraining)	72.5%	81.4%
Yin and Schütze (2015) (with pretraining)	78.1%	84.4%
Yin and Schütze (2015) (pretraining+sparse features)	78.4%	84.6%
This work	**78.60**%	**84.73**%

Table 1: Test set results on MSRP for paraphrase identification. Rows in grey are neural network-based approaches.

proaches shown in gray rows of the table are based on neural networks. The recent approach by Yin and Schütze (2015) includes a pretraining technique which significantly improves results, as shown in the table. We do not use any pretraining but still slightly outperform their best results which use both pretraining and additional sparse features from Madnani et al. (2012).

When comparing to their model without pretraining, we outperform them by 6% absolute in accuracy and 3% in F1. Our model is also superior to other recent neural network models (Hu et al., 2014; Socher et al., 2011) without requiring sparse features or unlabeled data as in (Yin and Schütze, 2015; Socher et al., 2011). The best result on MSRP is from Ji and Eisenstein (2013) which uses unsupervised learning on the MSRP test set and rich sparse features.

Results on SICK Data. Our results on the SICK task are summarized in Table 2, showing Pearson's r, Spearman's ρ, and mean squared error (MSE). We include results from the literature as reported by Tai et al. (2015), including prior work using recurrent neural networks (RNNs), the best submissions in the SemEval-2014 competition, and variants of LSTMs. When measured by Pearson's r, the previous state-of-the-art approach uses a tree-structured LSTM (Tai et al., 2015); note that their best results require a dependency parser.

On the contrary, our approach does not rely on parse trees, nor do we use POS/PARAGRAM embeddings for this task. The word embeddings,

Model	r	ρ	MSE
Socher et al. (2014) DT-RNN	0.7863	0.7305	0.3983
Socher et al. (2014) SDT-RNN	0.7886	0.7280	0.3859
Lai and Hockenmaier (2014)	0.7993	0.7538	0.3692
Jimenez et al. (2014)	0.8070	0.7489	0.3550
Bjerva et al. (2014)	0.8268	0.7721	0.3224
Zhao et al. (2014)	0.8414	-	-
LSTM	0.8477	0.7921	0.2949
Bi-LSTM	0.8522	0.7952	0.2850
2-layer LSTM	0.8411	0.7849	0.2980
2-layer Bidirectional LSTM	0.8488	0.7926	0.2893
Tai et al. (2015) Const. LSTM	0.8491	0.7873	0.2852
Tai et al. (2015) Dep. LSTM	0.8676	**0.8083**	**0.2532**
This work	**0.8686**	0.8047	0.2606

Table 2: Test set results on SICK, as reported by Tai et al. (2015), grouped as: (1) RNN variants; (2) SemEval 2014 systems; (3) sequential LSTM variants; (4) dependency and constituency tree LSTMs (Tai et al., 2015). Evaluation metrics are Pearson's r, Spearman's ρ, and mean squared error (MSE).

Model	Pearson's r
Rios et al. (2012)	0.7060
Wang and Cer (2012)	0.8037
Beltagy et al. (2014)	0.8300
Bär et al. (2012)	0.8730
Šarić et al. (2012)	0.8803
This work	**0.9090**

Table 3: Test set results on MSRVID data. The Bär et al. (2012) and Šarić et al. (2012) results were the top two submissions in the Semantic Textual Similarity task at the SemEval-2012 competition.

sparse distribution targets, and KL loss function are exactly the same as used by Tai et al. (2015), therefore representing comparable conditions.

Results on MSRVID Data. Our results on the MSRVID data are summarized in Table 3, which includes the top 2 submissions in the Semantic Textual Similarity (STS) task from SemEval-2012. We find that we outperform the top system from the task by nearly 3 points in Pearson's r.

6.5 Model Ablation Study

We report the results of an ablation study in Table 4. We identify nine major components of our approach, remove one at a time (if applicable), and perform re-training and re-testing for all three tasks. We use the same experimental settings in Sec. 6.3 and report differences (in accuracy for MSRP, Pearson's r for SICK/MSRVID) compared to our results in Tables 1–3.

Gp	ID	Ablation Component	MSRP Accuracy Diff.	MSRVID Pearson Diff.	SICK Pearson Diff.
1	1	Remove POS embeddings (Sec. 6.3)	-0.81	NA	NA
	2	Remove PARAGRAM embeddings (Sec. 6.3)	-1.33	NA	NA
2	3	Remove per-dimension embeddings, building block A only (Sec. 4.1)	-0.75	-0.0067	-0.0014
	4	Remove $\min$ and mean pooling, use $\max$ pooling only (Sec. 4.2)	-0.58	-0.0112	+0.0001
	5	Remove multiple widths, $ws = 1$ and $ws = \infty$ only (Sec. 4.3)	-2.14	-0.0048	-0.0012
3	6	Remove cosine and $L_2 Euclid$ distance in $comU_*$ (Sec. 5.1)	-2.31	-0.0188	-0.0309
4	7	Remove Horizontal Algorithm (Sec. 5.2)	-0.92	-0.0097	-0.0117
	8	Remove Vertical Algorithm (Sec. 5.2)	-2.15	-0.0063	-0.0027
	9	Remove similarity layer (completely flatten) (Sec. 5)	-1.90	-0.0121	-0.0288

Table 4: Ablation study over test sets of all three datasets. Nine components are divided into four groups. We remove components one at a time and show differences.

The nine components can be divided into four groups: (1) input embeddings (components 1–2); (2) sentence modeling (components 3–5); (3) similarity measurement metrics (component 6); (4) similarity measurement layer (components 7–9). For MSRP, we use all nine components. For SICK and MSRVID, we use components 3–9 (as described in Sec. 6.3).

From Table 4 we find drops in performance for all components, with the largest differences appearing when removing components of the similarity measurement layer. For example, conducting comparisons over flattened sentence representations (removing component 9) leads to large drops across tasks, because this ignores structured information within sentence representations. Groups (1) and (2) are also useful, particularly for the MSRP task, demonstrating the extra benefit obtained from our multi-perspective approach in sentence modeling.

We see consistent drops when ablating the Vertical/Horizontal algorithms that target particular regions for comparison. Also, removing group (3) hinders both the Horizontal and Vertical algorithms (as described in Section 5.1), so its removal similarly causes large drops in performance. Though convolutional neural networks already perform strongly when followed by flattened vector comparison, we are able to leverage the full richness of the sentence models by performing structured similarity modeling on their outputs.

7 Discussion and Conclusion

On the SICK dataset, the dependency tree LSTM (Tai et al., 2015) and our model achieve comparable performance despite taking very different approaches. Tai et al. use syntactic parse trees and gating mechanisms to convert each sentence into a vector, while we use large sets of flexible feature extractors in the form of convolution filters, then compare particular subsets of features in our similarity measurement layer.

Our model architecture, with its many paths of information flow, is admittedly complex. Though we have removed hand engineering of features, we have added a substantial amount of functional architecture engineering. This may be necessary when using the small training sets provided for the tasks we consider here. We conjecture that a simpler, deeper neural network architecture may outperform our model when given large amounts of training data, but we leave an investigation of this direction to future work.

In summary, we developed a novel model for sentence similarity based on convolutional neural networks. We improved both sentence modeling and similarity measurement. Our model achieves highly competitive performance on three datasets. Ablation experiments show that the performance improvement comes from our use of multiple perspectives in both sentence modeling and structured similarity measurement over local regions of sentence representations. Future work could extend this model to related tasks including question answering and information retrieval.

Abstract

Many models in natural language processing define probabilistic distributions over linguistic structures. We argue that (1) the quality of a model's posterior distribution can and should be directly evaluated, as to whether probabilities correspond to empirical frequencies; and (2) NLP uncertainty can be projected not only to pipeline components, but also to exploratory data analysis, telling a user when to trust and not trust the NLP analysis. We present a method to analyze calibration, and apply it to compare the miscalibration of several commonly used models. We also contribute a coreference sampling algorithm that can create confidence intervals for a political event extraction task.[1]

1 Introduction

Natural language processing systems are imperfect. Decades of research have yielded analyzers that mis-identify named entities, mis-attach syntactic relations, and mis-recognize noun phrase coreference anywhere from 10-40% of the time. But these systems are accurate enough so that their outputs can be used as soft, if noisy, indicators of language meaning for use in downstream analysis, such as systems that perform question answering, machine translation, event extraction, and narrative analysis (McCord et al., 2012; Gimpel and Smith, 2008; Miwa et al., 2010; Bamman et al., 2013).

To understand the performance of an analyzer, researchers and practitioners typically measure the accuracy of individual labels or edges among a single predicted output structure $\mathbf{y}$, such as a most-probable tagging or entity clustering $\arg\max_{\mathbf{y}} P(\mathbf{y}|x)$ (conditional on text data x).

[1]See the extended version of this paper for software, appendix, and acknowledgments sections:
http://brenocon.com/nlpcalib/
http://arxiv.org/abs/1508.05154

But a probabilistic model gives a probability distribution over many other output structures that have smaller predicted probabilities; a line of work has sought to control cascading pipeline errors by passing on multiple structures from earlier stages of analysis, by propagating prediction uncertainty through multiple samples (Finkel et al., 2006), K-best lists (Venugopal et al., 2008; Toutanova et al., 2008), or explicitly diverse lists (Gimpel et al., 2013); often the goal is to marginalize over structures to calculate and minimize an expected loss function, as in minimum Bayes risk decoding (Goodman, 1996; Kumar and Byrne, 2004), or to perform joint inference between early and later stages of NLP analysis (e.g. Singh et al., 2013; Durrett and Klein, 2014).

These approaches should work better when the posterior probabilities of the predicted linguistic structures reflect actual probabilities of the structures or aspects of the structures. For example, say a model is overconfident: it places too much probability mass in the top prediction, and not enough in the rest. Then there will be little benefit to using the lower probability structures, since in the training or inference objectives they will be incorrectly outweighed by the top prediction (or in a sampling approach, they will be systematically undersampled and thus have too-low frequencies). If we only evaluate models based on their top predictions or on downstream tasks, it is difficult to diagnose this issue.

Instead, we propose to directly evaluate the *calibration* of a model's posterior prediction distribution. A perfectly calibrated model knows how often it's right or wrong; when it predicts an event with 80% confidence, the event empirically turns out to be true 80% of the time. While perfect accuracy for NLP models remains an unsolved challenge, perfect calibration is a more achievable goal, since a model that has imperfect accuracy could, in principle, be perfectly calibrated. In this paper, we develop a method to empirically analyze calibration that is appropriate for NLP models (§3)

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1587–1598,
Lisbon, Portugal, 17-21 September 2015.

and use it to analyze common generative and discriminative models for tagging and classification (§4).

Furthermore, if a model's probabilities are meaningful, that would justify using its probability distributions for any downstream purpose, including exploratory analysis on unlabeled data. In §6 we introduce a representative corpus exploration problem, identifying temporal event trends in international politics, with a method that is dependent on coreference resolution. We develop a coreference sampling algorithm (§5.2) which projects uncertainty into the event extraction, inducing a posterior distribution over event frequencies. Sometimes the event trends have very high posterior variance (large confidence intervals),[2] reflecting when the NLP system genuinely does not know the correct semantic extraction. This highlights an important use of a calibrated model: being able to tell a user when the model's predictions are likely to be incorrect, or at least, not giving a user a false sense of certainty from an erroneous NLP analysis.

2 Definition of calibration

Consider a binary probabilistic prediction problem, which consists of binary labels and probabilistic predictions for them. Each instance has a *ground-truth label* $y \in \{0, 1\}$, which is used for evaluation. The prediction problem is to generate a *predicted probability* or *prediction strength* $q \in [0, 1]$. Typically, we use some form of a probabilistic model to accomplish this task, where q represents the model's posterior probability[3] of the instance having a positive label ($y = 1$).

Let $S = \{(q_1, y_1), (q_2, y_2), \cdots (q_N, y_N)\}$ be the set of prediction-label pairs produced by the model. Many metrics assess the overall quality of how well the predicted probabilities match the data, such as the familiar cross entropy (negative average log-likelihood),

$$L_\ell(\vec{y}, \vec{q}) = \frac{1}{N} \sum_i y_i \log \frac{1}{q_i} + (1 - y_i) \log \frac{1}{1 - q_i}$$

or mean squared error, also known as the *Brier score* when y is binary (Brier, 1950),

$$L_2(\vec{y}, \vec{q}) = \frac{1}{N} \sum_i (y_i - q_i)^2$$

Both tend to attain better (lower) values when q is near 1 when $y = 1$, and near 0 when $y = 0$; and they achieve a perfect value of 0 when all $q_i = y_i$.[4]

Let $\mathbb{P}(y, q)$ be the joint empirical distribution over labels and predictions. Under this notation, $L_2 = \mathbb{E}_{q,y}[y - q]^2$. Consider the factorization

$$\mathbb{P}(y, q) = \mathbb{P}(y \mid q)\, \mathbb{P}(q)$$

where $\mathbb{P}(y \mid q)$ denotes the label empirical frequency, conditional on a prediction strength (Murphy and Winkler, 1987).[5] Applying this factorization to the Brier score leads to the calibration-refinement decomposition (DeGroot and Fienberg, 1983), in terms of expectations with respect to the prediction strength distribution $\mathbb{P}(q)$:

$$L_2 = \underbrace{\mathbb{E}_q[q - p_q]^2}_{\text{Calibration MSE}} + \underbrace{\mathbb{E}_q[p_q(1 - p_q)]}_{\text{Refinement}} \quad (1)$$

where we denote $p_q \equiv \mathbb{P}(y = 1 \mid q)$ for brevity.

Here, *calibration* measures to what extent a model's probabilistic predictions match their corresponding empirical frequencies. Perfect calibration is achieved when $\mathbb{P}(y = 1 \mid q) = q$ for all q; intuitively, if you aggregate all instances where a model predicted q, they should have $y = 1$ at q percent of the time. We define the magnitude of miscalibration using root mean squared error:

Definition 1 (RMS calibration error)**.**

$$CalibErr = \sqrt{\mathbb{E}_q[q - \mathbb{P}(y = 1 \mid q)]^2}$$

The second term of Eq 1 refers to *refinement*, which reflects to what extent the model is able to separate different labels (in terms of the conditional Gini entropy $p_q(1 - p_q)$). If the prediction strengths tend to cluster around 0 or 1, the refinement score tends to be lower. The calibration-refinement breakdown offers a useful perspective on the accuracy of a model posterior. This paper focuses on calibration.

There are several other ways to break down squared error, log-likelihood, and other probabilistic scoring rules.[6] We use the Brier-based calibration error in this work, since unlike cross-entropy

[2] We use the terms *confidence interval* and *credible interval* interchangeably in this work; the latter term is debatably more correct, though less widely familiar.

[3] Whether q comes from a Bayesian posterior or not is irrelevant to the analysis in this section. All that matters is that predictions are numbers $q \in [0, 1]$.

[4] These two loss functions are instances of *proper scoring rules* (Gneiting and Raftery, 2007; Bröcker, 2009).

[5] We alternatively refer to this as *label frequency* or *empirical frequency*. The $\mathbb{P}$ probabilities can be thought of as frequencies from the hypothetical population the data and predictions are drawn from. $\mathbb{P}$ probabilities are, definitionally speaking, completely separate from a probabilistic model that might be used to generate q predictions.

[6] They all include a notion of calibration corresponding to a Bregman divergence (Bröcker, 2009); for example, cross-entropy can be broken down such that KL divergence is the measure of miscalibration.

Algorithm 1 Estimate calibration error using adaptive binning.

Input: A set of N prediction-label pairs $\{(q_1, y_1), (q_2, y_2), \cdots, (q_N, y_N)\}$.

Output: Calibration error.

Parameter: Target bin size β.

Step 1: Sort pairs by prediction values q_k in ascending order.

Step 2: For each, assign bin label $b_k = \left\lfloor \frac{k-1}{\beta} \right\rfloor + 1$.

Step 3: Define each bin B_i as the set of indices of pairs that have the same bin label. If the last bin has size less than β, merge it with the second-to-last bin (if one exists). Let $\{B_1, B_2, \cdots, B_T\}$ be the set of bins.

Step 4: Calculate empirical and predicted probabilities per bin:

$$\hat{p}_i = \frac{1}{|B_i|} \sum_{k \in B_i} y_k \qquad \text{and} \qquad \hat{q}_i = \frac{1}{|B_i|} \sum_{k \in B_i} q_k$$

Step 5: Calculate the calibration error as the root mean squared error per bin, weighted by bin size in case they are not uniformly sized:

$$CalibErr = \sqrt{\frac{1}{N} \sum_{i=1}^{T} |B_i| (\hat{q}_i - \hat{p}_i)^2}$$

it does not tend toward infinity when near probability 0; we hypothesize this could be an issue since both p and q are subject to estimation error.

3 Empirical calibration analysis

From a test set of labeled data, we can analyze model calibration both in terms of the calibration error, as well as visualizing the *calibration curve* of label frequency versus predicted strength. However, computing the label frequencies $\mathbb{P}(y = 1|q)$ requires an infinite amount of data. Thus approximation methods are required to perform calibration analysis.

3.1 Adaptive binning procedure

Previous studies that assess calibration in supervised machine learning models (Niculescu-Mizil and Caruana, 2005; Bennett, 2000) calculate label frequencies by dividing the prediction space into deciles or other evenly spaced bins—e.g. $q \in [0, 0.1)$, $q \in [0.1, 0.2)$, etc.—and then calculating the empirical label frequency in each bin. This procedure may be thought of as using a form of nonparametric regression (specifically, a regressogram; Tukey 1961) to estimate the function $f(q) = \mathbb{P}(y = 1 \mid q)$ from observed data points. But models in natural language processing give very skewed distributions of confidence scores q (many are near 0 or 1), so this procedure performs poorly, having much more variable estimates near the middle of the q distribution (Figure 1).

We propose adaptive binning as an alternative. Instead of dividing the interval $[0, 1]$ into fixed-width bins, adaptive binning defines the bins such that there are an equal number of points in each, after which the same averaging procedure is used. This method naturally gives wider bins to area with fewer data points (areas that require more smoothing), and ensures that these areas have roughly similar standard errors as those near the boundaries, since for a bin with β number of points and empirical frequency p, the standard error is estimated by $\sqrt{p(1-p)/\beta}$, which is bounded above by $0.5/\sqrt{\beta}$. Algorithm 1 describes the procedure for estimating calibration error using adaptive binning, which can be applied to any probabilistic model that predicts posterior probabilities.

Algorithm 2 Estimate calibration error's confidence interval by sampling.

Input: A set of N prediction-label pairs $\{(q_1, y_1), (q_2, y_2), \cdots, (q_N, y_N)\}$.

Output: Calibration error with a 95% confidence interval.

Parameter: Number of samples, S.

Step 1: Calculate $\{\hat{p}_1, \hat{p}_2, \cdots, \hat{p}_T\}$ from step 4 of Algorithm 1.

Step 2: Draw S samples. For each $s = 1..S$,

- For each bin $i = 1..T$, draw $\hat{p}_i^{(s)} \sim \mathcal{N}\left(\hat{p}_i, \hat{\sigma}_i^2\right)$, where $\hat{\sigma}_i^2 = \hat{p}_i(1 - \hat{p}_i)/|B_i|$. If necessary clip to $[0, 1]$: $\hat{p}_i^{(s)} := \min(1, \max(0, \hat{p}_i^{(s)}))$
- Calculate the sample's $CalibErr$ from using the pairs $(\hat{q}_i, \hat{p}_i^{(s)})$ as per Step 5 of Algorithm 1.

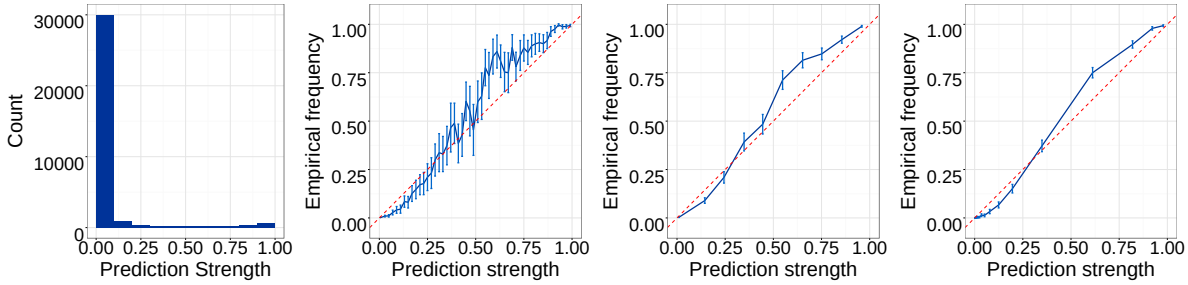
Step 3: Calculate the 95% confidence interval for the calibration error as:

$$CalibErr_{avg} \pm 1.96 \; \hat{s}_{error}$$

where $CalibErr_{avg}$ and $\hat{s}_{error}$ are the mean and the standard deviation, respectively, of the $CalibErr$s calculated from the samples.

3.2 Confidence interval estimation

Especially when the test set is small, estimating calibration error may be subject to error, due to uncertainty in the label frequency estimates. Since how to estimate confidence bands for nonparametric regression is an unsolved problem (Wasserman, 2006), we resort to a simple method based on the binning. We construct a binomial normal approximation for the label frequency estimate in each bin, and simulate from it; every simulation across all bins is used to construct a calibration error; these simulated calibration errors are collected to construct a normal approximation for the calibra-



(a) (b) (c) (d)

Figure 1: (a) A skewed distribution of predictions on whether a word has the NN tag (§4.2.2). Calibration curves produced by equally-spaced binning with bin width equal to 0.02 (b) and 0.1 (c) can have wide confidence intervals. Adaptive binning (with 1000 points in each bin) (d) gives small confidence intervals and also captures the prediction distribution. The confidence intervals are estimated as described in §3.1.

tion error estimate. Since we use bin sizes of at least $\beta \geq 200$ in our experiments, the central limit theorem justifies these approximations. We report all calibration errors along with their 95% confidence intervals calculated by Algorithm 2.[7]

3.3 Visualizing calibration

In order to better understand a model's calibration properties, we plot the pairs $(\hat{p}_1, \hat{q}_1), (\hat{p}_2, \hat{q}_2), \cdots, (\hat{p}_T, \hat{q}_T)$ obtained from the adaptive binning procedure to visualize the *calibration curve* of the model—this visualization is known as a *calibration* or *reliability plot*. It provides finer grained insight into the calibration behavior in different prediction ranges. A perfectly calibrated curve would coincide with the $y = x$ diagonal line. When the curve lies above the diagonal, the model is underconfident ($q < p_q$); and when it is below the diagonal, the model is overconfident ($q > p_q$).

An advantage of plotting a curve estimated from fixed-size bins, instead of fixed-width bins, is that the distribution of the points hints at the refinement aspect of the model's performance. If the points' positions tend to cluster in the bottom-left and top-right corners, that implies the model is making more refined predictions.

4 Calibration for classification and tagging models

Using the method described in §3, we assess the quality of posterior predictions of several classification and tagging models. In all of our experiments, we set the target bin size in Algorithm 1 to be 5,000 and the number of samples in Algorithm 2 to be 10,000.

4.1 Naive Bayes and logistic regression

4.1.1 Introduction

Previous work on Naive Bayes has found its probabilities to have calibration issues, in part due to its incorrect conditional independence assumptions (Niculescu-Mizil and Caruana, 2005; Bennett, 2000; Domingos and Pazzani, 1997). Since logistic regression has the same log-linear representational capacity (Ng and Jordan, 2002) but does not suffer from the independence assumptions, we select it for comparison, hypothesizing it may have better calibration.

We analyze a binary classification task of Twitter sentiment analysis from emoticons. We collect a dataset consisting of tweets identified by the Twitter API as English, collected from 2014 to 2015, with the "emoticon trick" (Read, 2005; Lin and Kolcz, 2012) to label tweets that contain at least one occurrence of the smiley emoticon ":)" as "happy" ($y = 1$) and others as $y = 0$. The smiley emoticons are deleted in positive examples. We sampled three sets of tweets (subsampled from the Decahose/Gardenhose stream of public tweets) with Jan-Apr 2014 for training, May-Dec 2014 for development, and Jan-Apr 2015 for testing. Each set contains 10^5 tweets, split between an equal number of positive and negative instances. We use binary features based on unigrams extracted from the *twokenize.py*[8] tokenization. We use the *scikit-learn* (Pedregosa et al., 2011) implementations of Bernoulli Naive Bayes and L2-regularized logistic regression. The models' hyperparameters (Naive Bayes' smoothing paramter and logistic regression's regularization strength) are chosen to

[7] A major unsolved issue is how to fairly select the bin size. If it is too large, the curve is oversmoothed and calibration looks better than it should be; if it is too small, calibration looks worse than it should be. Bandwidth selection and cross-validation techniques may better address this problem in future work. In the meantime, visualizations of calibration curves help inform the reader of the resolution of a particular analysis—if the bins are far apart, the data is sparse, and the specific details of the curve are not known in those regions.

[8] https://github.com/myleott/ark-twokenize-py

maximize the F-1 score on the development set.

4.1.2 Results

Naive Bayes attains a slightly higher F-1 score (NB 73.8% vs. LR 72.9%), but logistic regression has much lower calibration error: less than half as much RMSE (NB 0.105 vs. LR 0.041; Figure 2). Both models have a tendency to be underconfident in the lower prediction range and overconfident in the higher range, but the tendency is more pronounced for Naive Bayes.

4.2 Hidden Markov models and conditional random fields

4.2.1 Introduction

Hidden Markov models (HMM) and linear chain conditional random fields (CRF) are another commonly used pair of analogous generative and discriminative models. They both define a posterior over tag sequences $P(\mathbf{y}|x)$, which we apply to part-of-speech tagging.

We can analyze these models in the binary calibration framework (§2-3) by looking at marginal distribution of binary-valued outcomes of parts of the predicted structures. Specifically, we examine calibration of predicted probabilities of individual tokens' tags (§4.2.2), and of pairs of consecutive tags (§4.2.3). These quantities are calculated with the forward-backward algorithm.

To prepare a POS tagging dataset, we extract *Wall Street Journal* articles from the English CoNLL-2011 coreference shared task dataset from Ontonotes (Pradhan et al., 2011), using the CoNLL-2011 splits for training, development and testing. This results in 11,772 sentences for training, 1,632 for development, and 1,382 for testing, over a set of 47 possible tags.

We train an HMM with Dirichlet MAP using one pseudocount for every transition and word emission. For the CRF, we use the L_2-regularized L-BFGS algorithm implemented in *CRFsuite* (Okazaki, 2007). We compare an HMM to a CRF that only uses basic transition (tag-tag) and emission (tag-word) features, so that it does not have an advantage due to more features. In order to compare models with similar task performance, we train the CRF with only 3000 sentences from the training set, which yields the same accuracy as the HMM (about 88.7% on the test set). In each case, the model's hyperparameters (the CRF's L_2 regularizer, the HMM's pseudocount) are selected by maximizing accuracy on the development set.

4.2.2 Predicting single-word tags

In this experiment, we measure miscalibration of the two models on predicting tags of single words. First, for each tag type, we produce a set of 33,306 prediction-label pairs (for every token); we then concatenate them across the tags for calibration analysis. Figure 3 shows that the two models exhibit distinct calibration patterns. The HMM tends to be very underconfident whereas the CRF is overconfident, and the CRF has a lower (better) overall calibration error.

We also examine the calibration errors of the individual POS tags (Figure 4(a)). We find that CRF is significantly better calibrated than HMM in most but not all categories (39 out of 47). For example, they are about equally calibrated on predicting the NN tag. The calibration gap between the two models also differs among the tags.

4.2.3 Predicting two-consecutive-word tags

There is no reason to restrict ourselves to model predictions of single words; these models define marginal distributions over larger textual units. Next we examine the calibration of posterior predictions of tag pairs on two consecutive words in the test set. The same analysis may be important for, say, phrase extraction or other chunking/parsing tasks.

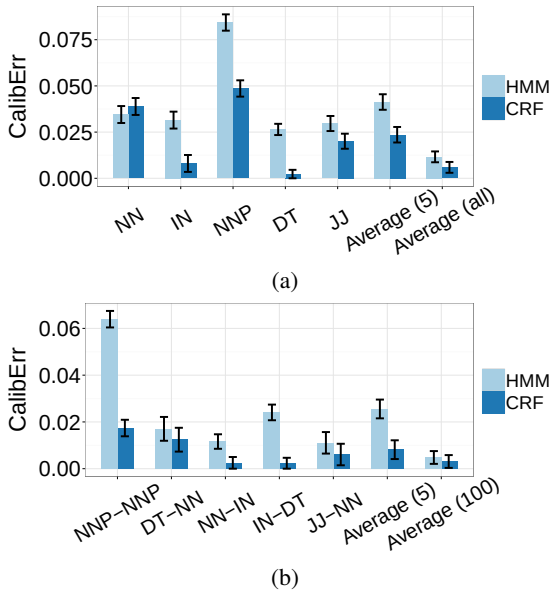

Figure 4: Calibration errors of HMM and CRF on predicting (a) single-word tags and (b) two-consecutive-word tags. Lower errors are better. The last two columns in each graph are the average calibration errors over the most common labels.

We report results for the top 5 and 100 most frequent tag pairs (Figure 4(b)). We observe a similar pattern as seen from the experiment on single tags: the CRF is generally better calibrated than the HMM, but the HMM does achieve better calibration errors in 29 out of 100 categories.

These tagging experiments illustrate that, depending on the application, different models can exhibit different levels of calibration.

5 Coreference resolution

We examine a third model, a probabilistic model for within-document noun phrase coreference, which has an efficient sampling-based inference procedure. In this section we introduce it and analyze its calibration, in preparation for the next section where we use it for exploratory data analysis.

5.1 Antecedent selection model

We use the Berkeley coreference resolution system (Durrett and Klein, 2013), which was originally presented as a CRF; we give it an equivalent a series of independent logistic regressions (see appendix for details). The primary component of this model is a locally-normalized log-linear distribution over clusterings of noun phrases, each cluster denoting an entity. The model takes a fixed input of N mentions (noun phrases), indexed by i in their positional order in the document. It posits that every mention i has a latent antecedent selection decision, $a_i \in \{1, \ldots, i-1, \text{NEW}\}$, denoting which previous mention it attaches to, or NEW if it is starting a new entity that has not yet been seen at a previous position in the text. Such a mention-mention attachment indicates coreference, while the final entity clustering includes more links implied through transitivity. The model's generative process is:

Definition 2 (Antecedent coreference model and sampling algorithm)**.**

- For $i = 1..N$, sample $a_i \sim \frac{1}{Z_i} \exp(\mathbf{w}^\top \mathbf{f}(i, a_i, x))$
- Calculate the entity clusters as $\mathbf{e} := CC(\mathbf{a})$, the connected components of the antecedent graph having edges (i, a_i) for i where $a_i \neq$ NEW.

Here x denotes all information in the document that is conditioned on for log-linear features $\mathbf{f}$. $\mathbf{e} = \{e_1, ...e_M\}$ denotes the entity clusters, where each element is a set of mentions. There are M entity clusters corresponding to the number of connected components in $\mathbf{a}$. The model defines a joint distribution over antecedent decisions $P(\mathbf{a}|x) = \prod_i P(a_i|x)$; it also defines a joint distribution over entity clusterings $P(\mathbf{e}|x)$, where the probability of an $\mathbf{e}$ is the sum of the probabilities of all $\mathbf{a}$ vectors that could give rise to it. In a manner similar to a distance-dependent Chinese restaurant process (Blei and Frazier, 2011), it is non-parametric in the sense that the number of clusters M is not fixed in advance.

5.2 Sampling-based inference

For both calibration analysis and exploratory applications, we need to analyze the posterior distribution over entity clusterings. This distribution is a complex mathematical object; an attractive approach to analyze it is to draw samples from this distribution, then analyze the samples.

This antecedent-based model admits a very straightforward procedure to draw independent $\mathbf{e}$ samples, by stepping through Def. 2: independently sample each a_i then calculate the connected components of the resulting antecedent graph. By construction, this procedure samples from the joint distribution of $\mathbf{e}$ (even though we never compute the probability of any single clustering $\mathbf{e}$).

Unlike approximate sampling approaches, such as Markov chain Monte Carlo methods used in other coreference work to sample $\mathbf{e}$ (Haghighi and Klein, 2007), here there are no questions about burn-in or autocorrelation (Kass et al., 1998). Every sample is independent and very fast to

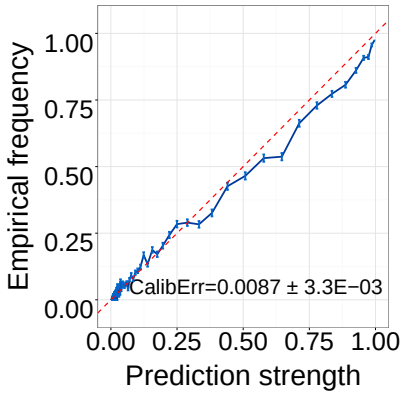

Figure 5: Coreference calibration curve for predicting whether two mentions belong to the same entity cluster.

compute—only slightly slower than calculating the MAP assignment (due to the exp and normalization for each a_i). We implement this algorithm by modifying the publicly available implementation from Durrett and Klein.[9]

5.3 Calibration analysis

We consider the following inference query: for a randomly chosen pair of mentions, are they coreferent? Even if the model's accuracy is comparatively low, it may be the case that it is correctly calibrated—if it thinks there should be great variability in entity clusterings, it may be uncertain whether a pair of mentions should belong together.

Let ℓ_{ij} be 1 if the mentions i and j are predicted to be coreferent, and 0 otherwise. Annotated data defines a gold-standard $\ell_{ij}^{(g)}$ value for every pair i, j. Any probability distribution over $\mathbf{e}$ defines a marginal Bernoulli distribution for every proposition ℓ_{ij}, marginalizing out $\mathbf{e}$:

$$P(\ell_{ij} = 1 \mid x) = \sum_{\mathbf{e}} 1\{(i,j) \in \mathbf{e}\} P(\mathbf{e} \mid x) \quad (2)$$

where $(i,j) \in \mathbf{e}$ is true iff there is an entity in $\mathbf{e}$ that contains both i and j.

In a traditional coreference evaluation of the best-prediction entity clustering, the model assigns 1 or 0 to every ℓ_{ij} and the pairwise precision and recall can be computed by comparing them to the corresponding $\ell_{ij}^{(g)}$. Here, we instead compare the $q_{ij} \equiv P(\ell_{ij} = 1 \mid x, \mathbf{e})$ prediction strengths against $\ell_{ij}^{(g)}$ empirical frequencies to assess pairwise calibration, with the same binary calibration analysis tools developed in §3 by aggregating pairs with similar q_{ij} values. Each q_{ij} is computed by averaging over 1,000 samples, simply taking the fraction of samples where the pair (i,j) is coreferent.

[9]Berkeley Coreference Resolution System, version 1.1: http://nlp.cs.berkeley.edu/projects/coref.shtml

We perform this analysis on the development section of the English CoNLL-2011 data (404 documents). Using the sampling inference method discussed in §5.2, we compute 4.3 millions prediction-label pairs and measure their calibration error. Our result shows that the model produces very well-calibrated predictions with less than 1% $CalibErr$ (Figure 5), though slightly overconfident on middle to high-valued predictions. The calibration error indicates that it is the most calibrated model we examine within this paper. This result suggests we might be able to trust its level of uncertainty.

6 Uncertainty in Entity-based Exploratory Analysis

6.1 Entity-syntactic event aggregation

We demonstrate one important use of calibration analysis: to ensure the usefulness of propagating uncertainty from coreference resolution into a system for exploring unannotated text. Accuracy cannot be calculated since there are no labels; but if the system is calibrated, we postulate that uncertainty information can help users understand the underlying reliability of aggregated extractions and isolate predictions that are more likely to contain errors.

We illustrate with an event analysis application to count the number of "country attack events": for a particular country of the world, how many news articles describe an entity affiliated with that country as the agent of an attack, and how does this number change over time? This is a simplified version of a problem where such systems have been built and used for political science analysis (Schrodt et al., 1994; Schrodt, 2012; Leetaru and Schrodt, 2013; Boschee et al., 2013; O'Connor et al., 2013). A coreference component can improve extraction coverage in cases such as "*Russian troops* were sighted . . . and *they attacked* . . . "

We use the coreference system examined in §5 for this analysis. To propagate coreference uncertainty, we re-run event extraction on multiple coreference samples generated from the algorithm described in §5.2, inducing a posterior distribution over the event counts. To isolate the effects of coreference, we use a very simple syntactic dependency system to identify affiliations and events. Assume the availability of dependency parses for a document d, a coreference resolution $\mathbf{e}$, and a lexicon of country names, which contains a small set of words $w(c)$ for each country c; for example, $w(\text{FRA}) = \{\text{france}, \text{french}\}$. The binary function

$f(c, e; x_d)$ assesses whether an entity e is affiliated with country c and is described as the agent of an attack, based on document text and parses x_d; f returns true iff both:[10]

- There exists a mention $i \in e$ described as country c: either its head word is in $w(c)$ (e.g. "Americans"), or its head word has an *nmod* or *amod* modifier in $w(c)$ (e.g. "American forces", "president of the U.S."); and there is only one unique country c among the mentions in the entity.
- There exists a mention $j \in e$ which is the *nsubj* or *agent* argument to the verb "attack" (e.g. "they attacked", "the forces attacked", "attacked by them").

For a given c, we first calculate a binary variable for whether there is at least one entity fulfilling f in a particular document,

$$a(d, c, \mathbf{e}_d) = \bigvee_{e \in \mathbf{e}_d} f(c, e; x_d) \quad (3)$$

and second, the number of such documents in $d(t)$, the set of *New York Times* articles published in a given time period t,

$$n(t, c, \mathbf{e}_{d(t)}) = \sum_{d \in d(t)} a(d, c, \mathbf{e}_d) \quad (4)$$

These quantities are both random variables, since they depend on $\mathbf{e}$; thus we are interested in the posterior distribution of n, marginalizing out $\mathbf{e}$,

$$P(n(t, c, \mathbf{e}_{d(t)}) \mid x_{d(t)}) \quad (5)$$

If our coreference model was highly certain (only one structure, or a small number of similar structures, had most of the probability mass in the space of all possible structures), each document would have an a posterior near either 0 or 1, and their sum in Eq. 5 would have a narrow distribution. But if the model is uncertain, the distribution will be wider. Because of the transitive closure, the probability of a is potentially more complex than the single antecedent linking probability between two mentions—the affiliation and attack information can propagate through a long coreference chain.

6.2 Results

We tag and parse a 193,403 article subset of the Annotated New York Times LDC corpus (Sandhaus, 2008), which includes articles about world news from the years 1987 to 2007 (details in appendix). For each article, we run the coreference system to predict 100 samples, and evaluate f on every entity in every sample.[11] The quantity of interest is the number of articles mentioning attacks in a 3-month period (quarter), for a given country. Figure 6 illustrates the mean and 95% posterior credible intervals for each quarter. The posterior mean m is calculated as the mean of the samples, and the interval is the normal approximation $m \pm 1.96\ s$, where s is the standard deviation among samples for that country and time period.

Uncertainty information helps us understand whether a difference between data points is real. In the plots of Figure 6, if we had used a 1-best coreference resolution, only a single line would be shown, with no assessment of uncertainty. This is problematic in cases when the model genuinely does not know the correct answer. For example, the 1993-1996 period of the USA plot (Figure 6, top) shows the posterior mean fluctuating from 1 to 5 documents; but when credible intervals are taken into consideration, we see that model does not know whether the differences are real, or were caused by coreference noise.

A similar case is highlighted at the bottom plot of Figure 6. Here we compare the event counts for Yugoslavia and NATO, which were engaged in a conflict in 1999. Did the *New York Times* devote more attention to the attacks by one particular side? To a 1-best system, the answer would be yes. But the posterior intervals for the two countries' event counts in mid-1999 heavily overlap, indicating that the coreference system introduces too much uncertainty to obtain a conclusive answer for this question. Note that calibration of the coreference model is important for the credible intervals to be useful; for example, if the model was badly calibrated by being overconfident (too much probability over a small set of similar structures), these intervals would be too narrow, leading to incorrect interpretations of the event dynamics.

Visualizing this uncertainty gives richer information for a potential user of an NLP-based system, compared to simply drawing a line based on a single 1-best prediction. It preserves the genuine uncertainty due to ambiguities the system was unable to resolve. This highlights an alternative use of Finkel et al. (2006)'s approach of sampling multiple NLP pipeline components, which in that work was used to perform joint inference. Instead

[10] Syntactic relations are Universal Dependencies (de Marneffe et al., 2014); more details for the extraction rules are in the appendix.

[11] We obtained similar results using only 10 samples. We also obtained similar results with a different query function, the total number of entities, across documents, that fulfill f.

of focusing on improving an NLP pipeline, we can pass uncertainty on to exploratory purposes, and try to highlight to a user where the NLP system may be wrong, or where it can only imprecisely specify a quantity of interest.

Finally, calibration can help error analysis. For a calibrated model, the more uncertain a prediction is, the more likely it is to be erroneous. While coreference errors comprise only one part of event extraction errors (alongside issues in parse quality, factivity, semantic roles, etc.), we can look at highly uncertain event predictions to understand the nature of coreference errors relative to our task. We manually analyzed documents with a 50% probability to contain an "attack"ing country-affiliated entity, and found difficult coreference cases.

In one article from late 1990, an "attack" event for IRQ is extracted from the sentence "But some political leaders said that they feared that *Mr. Hussein might attack* Saudi Arabia". The mention "Mr. Hussein" is classified as IRQ only when it is coreferent with a previous mention "President Saddam Hussein of Iraq"; this occurs only 50% of the time, since in some posterior samples the coreference system split apart these two "Hussein" mentions. This particular document is additionally difficult, since it includes the names of more than 10 countries (e.g. United States, Saudi Arabia, Egypt), and some of the Hussein mentions are even clustered with presidents of other countries (such as "President Bush"), presumably because they share the "president" title. These types of errors are a major issue for a political analysis task; further analysis could assess their prevalence and how to address them in future work.

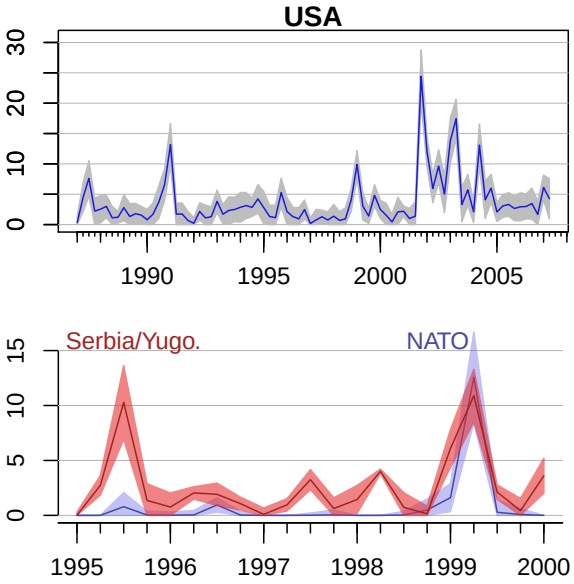

Figure 6: Number of documents with an "attack"ing country per 3-month period, and coreference posterior uncertainty for that quantity. The dark line is the posterior mean, and the shaded region is the 95% posterior credible interval. More examples in appendix.

7 Conclusion

In this work, we argue that the calibration of posterior predictions is a desirable property of probabilistic NLP models, and that it can be directly evaluated. We also demonstrate a use case of having calibrated uncertainty: its propagation into downstream exploratory analysis.

Our posterior simulation approach for exploratory and error analysis relates to *posterior predictive checking* (Gelman et al., 2013), which analyzes a posterior to test model assumptions; Mimno and Blei (2011) apply it to a topic model.

One avenue of future work is to investigate more effective nonparametric regression methods to better estimate and visualize calibration error, such as Gaussian processes or bootstrapped kernel density estimation.

Another important question is: what types of inferences are facilitated by correct calibration? Intuitively, we think that overconfidence will lead to overly narrow confidence intervals; but in what sense are confidence intervals "good" when calibration is perfect? Also, does calibration help joint inference in NLP pipelines? It may also assist calculations that rely on expectations, such as inference methods like minimum Bayes risk decoding, or learning methods like EM, since calibrated predictions imply that calculated expectations are statistically unbiased (though the implications of this fact may be subtle). Finally, it may be interesting to pursue recalibration methods, which readjust a non-calibrated model's predictions to be calibrated; recalibration methods have been developed for binary (Platt, 1999; Niculescu-Mizil and Caruana, 2005) and multiclass (Zadrozny and Elkan, 2002) classification settings, but we are unaware of methods appropriate for the highly structured outputs typical in linguistic analysis. Another approach might be to directly constrain $CalibErr = 0$ during training, or try to reduce it as a training-time risk minimization or cost objective (Smith and Eisner, 2006; Gimpel and Smith, 2010; Stoyanov et al., 2011; Brümmer and Doddington, 2013).

Calibration is an interesting and important property of NLP models. Further work is necessary to address these and many other questions.

A Generative Word Embedding Model and its Low Rank Positive Semidefinite Solution

Abstract

Most existing word embedding methods can be categorized into Neural Embedding Models and Matrix Factorization (MF)-based methods. However some models are opaque to probabilistic interpretation, and MF-based methods, typically solved using Singular Value Decomposition (SVD), may incur loss of corpus information. In addition, it is desirable to incorporate global latent factors, such as topics, sentiments or writing styles, into the word embedding model. Since generative models provide a principled way to incorporate latent factors, we propose a generative word embedding model, which is easy to interpret, and can serve as a basis of more sophisticated latent factor models. The model inference reduces to a low rank weighted positive semidefinite approximation problem. Its optimization is approached by eigendecomposition on a submatrix, followed by online blockwise regression, which is scalable and avoids the information loss in SVD. In experiments on 7 common benchmark datasets, our vectors are competitive to word2vec, and better than other MF-based methods.

1 Introduction

The task of word embedding is to model the distribution of a word and its context words using their corresponding vectors in a Euclidean space. Then by doing regression on the relevant statistics derived from a corpus, a set of vectors are recovered which best fit these statistics. These vectors, commonly referred to as the *embeddings*, capture semantic/syntactic regularities between the words.

The core of a word embedding method is the *link function* that connects the input — the embeddings, with the output — certain corpus statistics. Based on the link function, the objective function is developed. The reasonableness of the link function impacts the quality of the obtained embeddings, and different link functions are amenable to different optimization algorithms, with different scalability. Based on the forms of the link function and the optimization techniques, most methods can be divided into two classes: the traditional *neural embedding models*, and more recent *low rank matrix factorization methods*.

The neural embedding models use the **softmax** link function to model the conditional distribution of a word given its context (or vice versa) as a function of the embeddings. The normalizer in the softmax function brings intricacy to the optimization, which is usually tackled by gradient-based methods. The pioneering work was (Bengio et al., 2003). Later Mnih and Hinton (2007) propose three different link functions. However there are interaction matrices between the embeddings in all these models, which complicate and slow down the training, hindering them from being trained on huge corpora. Mikolov et al. (2013a) and Mikolov et al. (2013b) greatly simplify the conditional distribution, where the two embeddings interact directly. They implemented the well-known "word2vec", which can be trained efficiently on huge corpora. The obtained embeddings show excellent performance on various tasks.

Low-Rank Matrix Factorization (MF in short) methods include various link functions and optimization methods. The link functions are usually not softmax functions. MF methods aim to reconstruct certain corpus statistics matrix by the product of two low rank factor matrices. The objective is usually to minimize the reconstruction error, optionally with other constraints. In this line of research, Levy and Goldberg (2014b) find that "word2vec" is essentially doing stochastic weighted factorization of the word-context pointwise mutual information (PMI) matrix. They then

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1599–1609,
Lisbon, Portugal, 17-21 September 2015.

factorize this matrix directly as a new method. Pennington et al. (2014) propose a bilinear regression function of the conditional distribution, from which a weighted MF problem on the bigram log-frequency matrix is formulated. Gradient Descent is used to find the embeddings. Recently, based on the intuition that words can be organized in semantic hierarchies, Yogatama et al. (2015) add hierarchical sparse regularizers to the matrix reconstruction error. With similar techniques, Faruqui et al. (2015) reconstruct a set of pretrained embeddings using sparse vectors of greater dimensionality. Dhillon et al. (2015) apply Canonical Correlation Analysis (CCA) to the word matrix and the context matrix, and use the canonical correlation vectors between the two matrices as word embeddings. Stratos et al. (2014) and Stratos et al. (2015) assume a Brown language model, and prove that doing CCA on the bigram occurrences is equivalent to finding a transformed solution of the language model. Arora et al. (2015) assume there is a hidden discourse vector on a random walk, which determines the distribution of the current word. The slowly evolving discourse vector puts a constraint on the embeddings in a small text window. The maximum likelihood estimate of the embeddings within this text window approximately reduces to a squared norm objective.

There are two limitations in current word embedding methods. The first limitation is, all MF-based methods map words and their context words to two different sets of embeddings, and then employ Singular Value Decomposition (SVD) to obtain a low rank approximation of the word-context matrix $\boldsymbol{M}$. As SVD factorizes $\boldsymbol{M}^\top \boldsymbol{M}$, some information in $\boldsymbol{M}$ is lost, and the learned embeddings may not capture the most significant regularities in $\boldsymbol{M}$. Appendix A gives a toy example on which SVD does not work properly.

The second limitation is, a generative model for documents parametered by embeddings is absent in recent development. Although (Stratos et al., 2014; Stratos et al., 2015; Arora et al., 2015) are based on generative processes, the generative processes are only for deriving the local relationship between embeddings within a small text window, leaving the likelihood of a document undefined. In addition, the learning objectives of some models, e.g. (Mikolov et al., 2013b, Eq.1), even have no clear probabilistic interpretation. A generative word embedding model for documents is not only easier to interpret and analyze, but more importantly, provides a basis upon which document-level *global* latent factors, such as document topics (Wallach, 2006), sentiments (Lin and He, 2009), writing styles (Zhao et al., 2011b), can be incorporated in a principled manner, to better model the text distribution and extract relevant information.

Based on the above considerations, we propose to unify the embeddings of words and context words. Our link function factorizes into three parts: the interaction of two embeddings capturing linear correlations of two words, a residual capturing nonlinear or noisy correlations, and the unigram priors. To reduce overfitting, we put Gaussian priors on embeddings and residuals, and apply Jelinek-Mercer Smoothing to bigrams. Furthermore, to model the probability of a sequence of words, we assume that the contributions of more than one context word approximately add up. Thereby a generative model of documents is constructed, parameterized by embeddings and residuals. The learning objective is to maximize the corpus likelihood, which reduces to a weighted low-rank positive semidefinite (PSD) approximation problem of the PMI matrix. A Block Coordinate Descent algorithm is adopted to find an approximate solution. This algorithm is based on Eigendecomposition, which avoids information loss in SVD, but brings challenges to scalability. We then exploit the sparsity of the weight matrix and implement an efficient online blockwise regression algorithm. On seven benchmark datasets covering similarity and analogy tasks, our method achieves competitive and stable performance.

The source code of this method is provided at `https://github.com/askerlee/topicvec`.

2 Notations and Definitions

Throughout the paper, we always use a uppercase bold letter as $\boldsymbol{S}, \boldsymbol{V}$ to denote a matrix or set, a lowercase bold letter as $\boldsymbol{v}_{w_i}$ to denote a vector, a normal uppercase letter as N, W to denote a scalar constant, and a normal lowercase letter as s_i, w_i to denote a scalar variable.

Suppose a vocabulary $\boldsymbol{S} = \{s_1, \cdots, s_W\}$ consists of all the words, where W is the vocabulary size. We further suppose $s_1, \cdots, s_W$ are sorted in decending order of the frequency, i.e. s_1 is most frequent, and s_W is least frequent. A document d_i is a sequence of words $d_i = (w_{i1}, \cdots, w_{iL_i}), w_{ij} \in \boldsymbol{S}$. A corpus is a collec-

Name	Description
$\boldsymbol{S}$	Vocabulary $\{s_1, \cdots, s_W\}$
$\boldsymbol{V}$	Embedding matrix $(\boldsymbol{v}_{s_1}, \cdots, \boldsymbol{v}_{s_W})$
$\boldsymbol{D}$	Corpus $\{d_1, \cdots, d_M\}$
$\boldsymbol{v}_{s_i}$	Embedding of word s_i
$a_{s_i s_j}$	Bigram residual for s_i, s_j
$\tilde{P}(s_i,s_j)$	Empirical probability of s_i, s_j in the corpus
$\boldsymbol{u}$	Unigram probability vector $(P(s_1),\cdots,P(s_W))$
$\boldsymbol{A}$	Residual matrix $(a_{s_i s_j})$
$\boldsymbol{B}$	Conditional probability matrix $\Big(P(s_j\|s_i)\Big)$
$\boldsymbol{G}$	PMI matrix $\Big(\text{PMI}(s_i, s_j)\Big)$
$\boldsymbol{H}$	Bigram empirical probability matrix $\Big(\tilde{P}(s_i, s_j)\Big)$

Table 1: Notation Table

tion of M documents $\boldsymbol{D} = \{d_1, \cdots, d_M\}$. In the vocabulary, each word s_i is mapped to a vector $\boldsymbol{v}_{s_i}$ in N-dimensional Euclidean space.

In a document, a sequence of words is referred to as a *text window*, denoted by $w_i, \cdots, w_{i+l}$, or $w_i{:}w_{i+l}$ in shorthand. A text window of chosen size c before a word w_i defines the *context* of w_i as $w_{i-c}, \cdots, w_{i-1}$. Here w_i is referred to as the *focus word*. Each context word w_{i-j} and the focus word w_i comprise a bigram w_{i-j}, w_i.

The *Pointwise Mutual Information* between two words s_i, s_j is defined as

$$\text{PMI}(s_i, s_j) = \log \frac{P(s_i, s_j)}{P(s_i)P(s_j)}.$$

3 Link Function of Text

In this section, we formulate the probability of a sequence of words as a function of their embeddings. We start from the link function of bigrams, which is the building blocks of a long sequence. Then this link function is extended to a text window with c context words, as a first-order approximation of the actual probability.

3.1 Link Function of Bigrams

We generalize the link function of "word2vec" and "GloVe" to the following:

$$P(s_i, s_j) = \exp\Big\{\boldsymbol{v}_{s_j}^\top \boldsymbol{v}_{s_i} + a_{s_i s_j}\Big\} P(s_i)P(s_j) \quad (1)$$

The rationale for (1) originates from the idea of the *Product of Experts* in (Hinton, 2002). Suppose different types of semantic/syntactic regularities between s_i and s_j are encoded in different dimensions of $\boldsymbol{v}_{s_i}, \boldsymbol{v}_{s_j}$. As $\exp\{\boldsymbol{v}_{s_j}^\top \boldsymbol{v}_{s_i}\} = \prod_l \exp\{v_{s_i,l} \cdot v_{s_j,l}\}$, this means the effects of different regularities on the probability are combined by multiplying together. If s_i and s_j are independent, their joint probability should be $P(s_i)P(s_j)$. In the presence of correlations, the actual joint probability $P(s_i, s_j)$ would be a scaling of it. The scale factor reflects how much s_i and s_j are positively or negatively correlated. Within the scale factor, $\boldsymbol{v}_{s_j}^\top \boldsymbol{v}_{s_i}$ captures linear interactions between s_i and s_j, the residual $a_{s_i s_j}$ captures nonlinear or noisy interactions. In applications, only $\boldsymbol{v}_{s_j}^\top \boldsymbol{v}_{s_i}$ is of interest. Hence the bigger magnitude $\boldsymbol{v}_{s_j}^\top \boldsymbol{v}_{s_i}$ is of relative to $a_{s_i s_j}$, the better.

Note that we do *not* assume $a_{s_i s_j} = a_{s_j s_i}$. This provides the flexibility $P(s_i, s_j) \neq P(s_j, s_i)$, agreeing with the asymmetry of bigrams in natural languages. At the same time, $\boldsymbol{v}_{s_j}^\top \boldsymbol{v}_{s_i}$ imposes a symmetric part between $P(s_i, s_j)$ and $P(s_j, s_i)$.

(1) is equivalent to

$$P(s_j|s_i) = \exp\Big\{\boldsymbol{v}_{s_j}^\top \boldsymbol{v}_{s_i} + a_{s_i s_j} + \log P(s_j)\Big\}, \quad (2)$$

$$\log \frac{P(s_j|s_i)}{P(s_j)} = \boldsymbol{v}_{s_j}^\top \boldsymbol{v}_{s_i} + a_{s_i s_j}. \quad (3)$$

(3) of all bigrams is represented in matrix form:

$$\boldsymbol{V}^\top \boldsymbol{V} + \boldsymbol{A} = \boldsymbol{G}, \quad (4)$$

where $\boldsymbol{G}$ is the PMI matrix.

3.1.1 Gaussian Priors on Embeddings

When (1) is employed on the regression of empirical bigram probabilities, a practical issue arises: more and more bigrams have zero frequency as the constituting words become less frequent. A zero-frequency bigram does not necessarily imply negative correlation between the two constituting words; it could simply result from missing data. But in this case, even after smoothing, (1) will force $\boldsymbol{v}_{s_j}^\top \boldsymbol{v}_{s_i} + a_{s_i s_j}$ to be a big negative number, making $\boldsymbol{v}_{s_i}$ overly long. The increased magnitude of embeddings is a sign of overfitting.

To reduce overfitting of embeddings of infrequent words, we assign a Spherical Gaussian prior $\mathcal{N}(0, \frac{1}{2\mu_i}\boldsymbol{I})$ to $\boldsymbol{v}_{s_i}$:

$$P(\boldsymbol{v}_{s_i}) \sim \exp\{-\mu_i \|\boldsymbol{v}_{s_i}\|^2\},$$

where the hyperparameter μ_i increases as the frequency of s_i decreases.

3.1.2 Gaussian Priors on Residuals

We wish $\boldsymbol{v}_{s_j}^\top \boldsymbol{v}_{s_i}$ in (1) captures as much correlations between s_i and s_j as possible. Thus the smaller $a_{s_i s_j}$ is, the better. In addition, the more frequent s_i, s_j is in the corpus, the less noise there is in their empirical distribution, and thus the residual $a_{s_i s_j}$ should be more heavily penalized.

To this end, we penalize the residual $a_{s_i s_j}$ by $f(\tilde{P}(s_i, s_j))a_{s_i s_j}^2$, where $f(\cdot)$ is a nonnegative monotonic transformation, referred to as the *weighting function*. Let h_{ij} denote $\tilde{P}(s_i, s_j)$, then the total penalty of all residuals are the square of the *weighted Frobenius norm* of $\boldsymbol{A}$:

$$\sum_{s_i, s_j \in \boldsymbol{S}} f(h_{ij}) a_{s_i s_j}^2 = \|\boldsymbol{A}\|_{f(\boldsymbol{H})}^2. \quad (5)$$

By referring to "GloVe", we use the following weighting function, and find it performs well:

$$f(h_{ij}) = \begin{cases} \frac{\sqrt{h_{ij}}}{C_{\text{cut}}} & \sqrt{h_{ij}} < C_{\text{cut}}, i \neq j \\ 1 & \sqrt{h_{ij}} \geq C_{\text{cut}}, i \neq j \\ 0 & i = j \end{cases},$$

where C_{cut} is chosen to cut the most frequent 0.02% of the bigrams off at 1. When $s_i = s_j$, two identical words usually have much smaller probability to collocate. Hence $\tilde{P}(s_i, s_i)$ does not reflect the true correlation of a word to itself, and should not put constraints to the embeddings. We eliminate their effects by setting $f(h_{ii})$ to 0.

If the domain of $\boldsymbol{A}$ is the whole space $R^{W \times W}$, then this penalty is equivalent to a Gaussian prior $\mathcal{N}\left(0, \frac{1}{2f(h_{ij})}\right)$ on each $a_{s_i s_j}$. The variances of the Gaussians are determined by the bigram empirical probability matrix $\boldsymbol{H}$.

3.1.3 Jelinek-Mercer Smoothing of Bigrams

As another measure to reduce the impact of missing data, we apply the commonly used Jelinek-Mercer Smoothing (Zhai and Lafferty, 2004) to smooth the empirical conditional probability $\tilde{P}(s_j|s_i)$ by the unigram probability $\tilde{P}(s_j)$ as:

$$\tilde{P}_{\text{smoothed}}(s_j|s_i) = (1-\kappa)\tilde{P}(s_j|s_i) + \kappa P(s_j). \quad (6)$$

Accordingly, the smoothed bigram empirical joint probability is defined as

$$\tilde{P}(s_i, s_j) = (1-\kappa)\tilde{P}(s_i, s_j) + \kappa P(s_i)P(s_j). \quad (7)$$

In practice, we find $\kappa = 0.02$ yields good results. When $\kappa \geq 0.04$, the obtained embeddings begin to degrade with κ, indicating that smoothing distorts the true bigram distributions.

3.2 Link Function of a Text Window

In the previous subsection, a regression link function of bigram probabilities is established. In this section, we adopt a first-order approximation based on Information Theory, and extend the link function to a longer sequence $w_0, \cdots, w_{c-1}, w_c$.

Decomposing a distribution conditioned on n random variables as the conditional distributions on its subsets roots deeply in Information Theory. This is an intricate problem because there could be both (pointwise) *redundant information* and (pointwise) *synergistic information* among the conditioning variables (Williams and Beer, 2010). They are both functions of the PMI. Based on an analysis of the complementing roles of these two types of pointwise information, we assume they are approximately equal and cancel each other when computing the *pointwise interaction information*. See Appendix B for a detailed discussion.

Following the above assumption, we have $\text{PMI}(w_2; w_0, w_1) \approx \text{PMI}(w_2; w_0) + \text{PMI}(w_2; w_1)$:

$$\log \frac{P(w_0, w_1|w_2)}{P(w_0, w_1)} \approx \log \frac{P(w_0|w_2)}{P(w_0)} + \log \frac{P(w_1|w_2)}{P(w_1)}.$$

Plugging (1) and (3) into the above, we obtain

$$P(w_0, w_1, w_2) \approx \exp\left\{ \sum_{\substack{i,j=0 \\ i \neq j}}^{2} (\boldsymbol{v}_{w_i}^\top \boldsymbol{v}_{w_j} + a_{w_i w_j}) + \sum_{i=0}^{2} \log P(w_i) \right\}.$$

We extend the above assumption to that the pointwise interaction information is still close to 0 within a longer text window. Accordingly the above equation extends to a context of size $c > 2$:

$$P(w_0, \cdots, w_c) \approx \exp\left\{ \sum_{\substack{i,j=0 \\ i \neq j}}^{c} (\boldsymbol{v}_{w_i}^\top \boldsymbol{v}_{w_j} + a_{w_i w_j}) + \sum_{i=0}^{c} \log P(w_i) \right\}.$$

From it derives the conditional distribution of w_c, given its context $w_0, \cdots, w_{c-1}$:

$$P(w_c \mid w_0 : w_{c-1}) = \frac{P(w_0, \cdots, w_c)}{P(w_0, \cdots, w_{c-1})} \approx P(w_c) \exp\left\{ \boldsymbol{v}_{w_c}^\top \sum_{i=0}^{c-1} \boldsymbol{v}_{w_i} + \sum_{i=0}^{c-1} a_{w_i w_c} \right\}. \quad (8)$$

4 Generative Process and Likelihood

We proceed to assume the text is generated from a *Markov chain* of order c, i.e., a word only depends on words within its context of size c. Given the hyperparameter $\boldsymbol{\mu} = (\mu_1, \cdots, \mu_W)$, the generative process of the whole corpus is:

1. For each word s_i, draw the embedding $\boldsymbol{v}_{s_i}$ from $\mathcal{N}(0, \frac{1}{2\mu_i}\boldsymbol{I})$;
2. For each bigram s_i, s_j, draw the residual $a_{s_i s_j}$ from $\mathcal{N}\left(0, \frac{1}{2f(h_{ij})}\right)$;
3. For each document d_i, for the j-th word, draw word w_{ij} from $\boldsymbol{S}$ with probability $P(w_{ij} \mid w_{i,j-c} : w_{i,j-1})$ defined by (8).

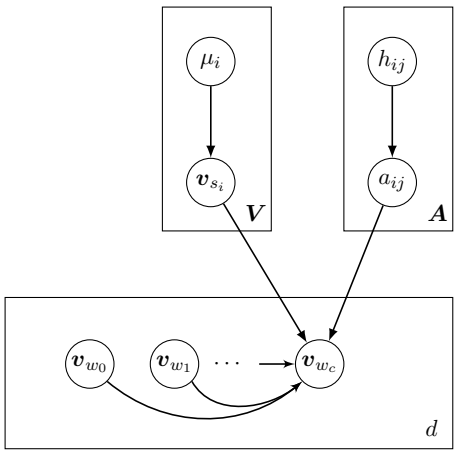

Figure 1: The Graphical Model of PSDVec

The above generative process for a document d is presented as a graphical model in Figure 1.

Based on this generative process, the probability of a document d_i can be derived as follows, given the embeddings and residuals $\boldsymbol{V}, \boldsymbol{A}$:

$$P(d_i|\boldsymbol{V},\boldsymbol{A}) = \prod_{j=1}^{L_i} P(w_{ij}) \exp\left\{ \boldsymbol{v}_{w_{ij}}^\top \sum_{k=j-c}^{j-1} \boldsymbol{v}_{w_{ik}} + \sum_{k=j-c}^{j-1} a_{w_{ik}w_{ij}} \right\}.$$

The complete-data likelihood of the corpus is:

$$\begin{aligned} & p(\boldsymbol{D},\boldsymbol{V},\boldsymbol{A}) \\ =& \prod_{i=1}^{W} \mathcal{N}(0, \frac{\boldsymbol{I}}{2\mu_i}) \prod_{i,j=1}^{W,W} \mathcal{N}\left(0, \frac{1}{2f(h_{ij})}\right) \prod_{i=1}^{M} p(d_i|\boldsymbol{V},\boldsymbol{A}) \\ =& \frac{1}{\mathcal{Z}(\boldsymbol{H},\boldsymbol{\mu})} \exp\Big\{ -\sum_{i,j=1}^{W,W} f(h_{i,j}) a_{s_i s_j}^2 - \sum_{i=1}^{W} \mu_i \|\boldsymbol{v}_{s_i}\|^2 \Big\} \\ & \cdot \prod_{i,j=1}^{M,L_i} P(w_{ij}) \exp\left\{ \boldsymbol{v}_{w_{ij}}^\top \sum_{k=j-c}^{j-1} \boldsymbol{v}_{w_{ik}} + \sum_{k=j-c}^{j-1} a_{w_{ik}w_{ij}} \right\}, \end{aligned}$$

where $\mathcal{Z}(\boldsymbol{H},\boldsymbol{\mu})$ is the normalizing constant.

Taking the logarithm of both sides of $p(\boldsymbol{D},\boldsymbol{A},\boldsymbol{V})$ yields

$$\begin{aligned} & \log p(\boldsymbol{D},\boldsymbol{V},\boldsymbol{A}) \\ =& C_0 - \log \mathcal{Z}(\boldsymbol{H},\boldsymbol{\mu}) - \|\boldsymbol{A}\|_{f(\boldsymbol{H})}^2 - \sum_{i=1}^{W} \mu_i \|\boldsymbol{v}_{s_i}\|^2 \\ & + \sum_{i,j=1}^{M,L_i} \left\{ \boldsymbol{v}_{w_{ij}}^\top \sum_{k=j-c}^{j-1} \boldsymbol{v}_{w_{ik}} + \sum_{k=j-c}^{j-1} a_{w_{ik}w_{ij}} \right\}, \quad (9) \end{aligned}$$

where $C_0 = \sum_{i,j=1}^{M,L_i} \log P(w_{ij})$ is constant.

5 Learning Algorithm

5.1 Learning Objective

The learning objective is to find the embeddings $\boldsymbol{V}$ that maximize the corpus log-likelihood (9).

Let x_{ij} denote the (smoothed) frequency of bigram s_i, s_j in the corpus. Then (9) is sorted as:

$$\begin{aligned} & \log p(\boldsymbol{D},\boldsymbol{V},\boldsymbol{A}) \\ =& C_0 - \log \mathcal{Z}(\boldsymbol{H},\boldsymbol{\mu}) - \|\boldsymbol{A}\|_{f(\boldsymbol{H})}^2 - \sum_{i=1}^{W} \mu_i \|\boldsymbol{v}_{s_i}\|^2 \\ & + \sum_{i,j=1}^{W,W} x_{ij} (\boldsymbol{v}_{s_i}^\top \boldsymbol{v}_{s_j} + a_{s_i s_j}). \quad (10) \end{aligned}$$

As the corpus size increases, $\sum_{i,j=1}^{W,W} x_{ij}(\boldsymbol{v}_{s_i}^\top \boldsymbol{v}_{s_j} + a_{s_i s_j})$ will dominate the parameter prior terms. Then we can ignore the prior terms when maximizing (10).

$$\begin{aligned} & \max \sum x_{ij} (\boldsymbol{v}_{s_i}^\top \boldsymbol{v}_{s_j} + a_{s_i s_j}) \\ =& \Big(\sum x_{ij} \Big) \cdot \max \sum \tilde{P}_{\text{smoothed}}(s_i, s_j) \log P(s_i, s_j). \end{aligned}$$

As both $\{\tilde{P}_{\text{smoothed}}(s_i, s_j)\}$ and $\{P(s_i, s_j)\}$ sum to 1, the above sum is maximized when $P(s_i, s_j) = \tilde{P}_{\text{smoothed}}(s_i, s_j)$.

The maximum likelihood estimator is then:

$$P(s_j|s_i) = \tilde{P}_{\text{smoothed}}(s_j|s_i),$$

$$\boldsymbol{v}_{s_i}^\top \boldsymbol{v}_{s_j} + a_{s_i s_j} = \log \frac{\tilde{P}_{\text{smoothed}}(s_j|s_i)}{P(s_j)}. \quad (11)$$

Writing (11) in matrix form:

$$\begin{aligned} \boldsymbol{B}^* &= \left(\tilde{P}_{\text{smoothed}}(s_j|s_i) \right)_{s_i, s_j \in \boldsymbol{S}} \\ \boldsymbol{G}^* &= \log \boldsymbol{B}^* - \log \boldsymbol{u} \otimes (1 \cdots 1), \quad (12) \end{aligned}$$

where "$\otimes$" is the outer product.

Now we fix the values of $\boldsymbol{v}_{s_i}^\top \boldsymbol{v}_{s_j} + a_{s_i s_j}$ at the above optimal. The corpus likelihood becomes

$$\begin{aligned} \log p(\boldsymbol{D},\boldsymbol{V},\boldsymbol{A}) =& C_1 - \|\boldsymbol{A}\|_{f(\boldsymbol{H})}^2 - \sum_{i=1}^{W} \mu_i \|\boldsymbol{v}_{s_i}\|^2, \\ & \text{subject to} \quad \boldsymbol{V}^\top \boldsymbol{V} + \boldsymbol{A} = \boldsymbol{G}^*, \quad (13) \end{aligned}$$

where $C_1 = C_0 + \sum x_{ij} \log \tilde{P}_{\text{smoothed}}(s_i, s_j) - \log \mathcal{Z}(\boldsymbol{H},\boldsymbol{\mu})$ is constant.

5.2 Learning V as Low Rank PSD Approximation

Once $\boldsymbol{G}^*$ has been estimated from the corpus using (12), we seek $\boldsymbol{V}$ that maximizes (13). This is to find the maximum a posteriori (MAP) estimates of $\boldsymbol{V}, \boldsymbol{A}$ that satisfy $\boldsymbol{V}^\top \boldsymbol{V} + \boldsymbol{A} = \boldsymbol{G}^*$. Applying this constraint to (13), we obtain

Algorithm 1 BCD algorithm for finding a unregularized rank-N weighted PSD approximant.

Input: matrix $\boldsymbol{G}^*$, weight matrix $\boldsymbol{W} = f(\boldsymbol{H})$, iteration number $\mathcal{T}$, rank N

Randomly initialize $\boldsymbol{X}^{(0)}$
for $t = 1, \cdots, \mathcal{T}$ **do**
  $\boldsymbol{G}_t = \boldsymbol{W} \circ \boldsymbol{G}^* + (1 - \boldsymbol{W}) \circ \boldsymbol{X}^{(t-1)}$
  $\boldsymbol{X}^{(t)} = \text{PSD\_Approximate}(\boldsymbol{G}_t, N)$
end for
$\boldsymbol{\lambda}, \boldsymbol{Q} = \text{Eigen\_Decomposition}(\boldsymbol{X}^{(\mathcal{T})})$
$\boldsymbol{V}^* = \text{diag}(\boldsymbol{\lambda}^{\frac{1}{2}}[1{:}N]) \cdot \boldsymbol{Q}^\top[1{:}N]$

Output: $\boldsymbol{V}^*$

$$\arg\max_{\boldsymbol{V}} \log p(\boldsymbol{D}, \boldsymbol{V}, \boldsymbol{A})$$
$$= \arg\min_{\boldsymbol{V}} \|\boldsymbol{G}^* - \boldsymbol{V}^\top \boldsymbol{V}\|_{f(\boldsymbol{H})} + \sum_{i=1}^{W} \mu_i \|\boldsymbol{v}_{s_i}\|^2. \quad (14)$$

Let $\boldsymbol{X} = \boldsymbol{V}^\top \boldsymbol{V}$. Then $\boldsymbol{X}$ is positive semidefinite of rank N. Finding $\boldsymbol{V}$ that minimizes (14) is equivalent to finding a rank-N *weighted positive semidefinite approximant* $\boldsymbol{X}$ of $\boldsymbol{G}^*$, subject to Tikhonov regularization. This problem does not admit an analytic solution, and can only be solved using local optimization methods.

First we consider a simpler case where all the words in the vocabulary are enough frequent, and thus Tikhonov regularization is unnecessary. In this case, we set $\forall \mu_i = 0$, and (14) becomes an unregularized optimization problem. We adopt the Block Coordinate Descent (BCD) algorithm[1] in (Srebro et al., 2003) to approach this problem. The original algorithm is to find a generic rank-N matrix for a weighted approximation problem, and we tailor it by constraining the matrix within the positive semidefinite manifold.

We summarize our learning algorithm in **Algorithm 1.** Here "$\circ$" is the entry-wise product. We suppose the eigenvalues $\boldsymbol{\lambda}$ returned by Eigen_Decomposition($\boldsymbol{X}$) are in descending order. $\boldsymbol{Q}^\top[1{:}N]$ extracts the 1 to N rows from $\boldsymbol{Q}^\top$.

One key issue is how to initialize $\boldsymbol{X}$. Srebro et al. (2003) suggest to set $\boldsymbol{X}^{(0)} = \boldsymbol{G}^*$, and point out that $\boldsymbol{X}^{(0)} = \boldsymbol{0}$ is far from a local optimum, thus requires more iterations. However we find $\boldsymbol{G}^*$ is also far from a local optimum, and this setting converges slowly too. Setting $\boldsymbol{X}^{(0)} = \boldsymbol{G}^*/2$ usually yields a satisfactory solution in a few iterations.

The subroutine PSD_Approximate() computes the *unweighted* nearest rank-N PSD approximation, measured in F-norm (Higham, 1988).

[1]It is referred to as an Expectation-Maximization algorithm by the original authors, but we think this is a misnomer.

5.3 Online Blockwise Regression of $\boldsymbol{V}$

In Algorithm 1, the essential subroutine PSD_Approximate() does eigendecomposition on $\boldsymbol{G}_t$, which is dense due to the logarithm transformation. Eigendecomposition on a $W \times W$ dense matrix requires $O(W^2)$ space and $O(W^3)$ time, difficult to scale up to a large vocabulary. In addition, the majority of words in the vocabulary are infrequent, and Tikhonov regularization is necessary for them.

It is observed that, as words become less frequent, fewer and fewer words appear around them to form bigrams. Remind that the vocabulary $\boldsymbol{S} = \{s_1, \cdots, s_W\}$ are sorted in decending order of the frequency, hence the lower-right blocks of $\boldsymbol{H}$ and $f(\boldsymbol{H})$ are very sparse, and cause these blocks in (14) to contribute much less penalty relative to other regions. Therefore these blocks could be ignored when doing regression, without sacrificing too much accuracy. This intuition leads to the following *online blockwise regression*.

The basic idea is to select a small set (e.g. 30,000) of the most frequent words as the *core words*, and partition the remaining *noncore words* into sets of moderate sizes. Bigrams consisting of two core words are referred to as *core bigrams*, which correspond to the top-left blocks of $\boldsymbol{G}$ and $f(\boldsymbol{H})$. The embeddings of core words are learned approximately using Algorithm 1, on the top-left blocks of $\boldsymbol{G}$ and $f(\boldsymbol{H})$. Then we fix the embeddings of core words, and find the embeddings of each set of noncore words in turn. After ignoring the lower-right regions of $\boldsymbol{G}$ and $f(\boldsymbol{H})$ which correspond to bigrams of two noncore words, the **quadratic terms** of noncore embeddings are ignored. Consequently, finding these embeddings becomes a *weighted ridge regression* problem, which can be solved efficiently in closed-form. Finally we combine all embeddings to get the embeddings of the whole vocabulary. The details are as follows:

1. Partition $\boldsymbol{S}$ into K consecutive groups $\boldsymbol{S}_1, \cdots, \boldsymbol{S}_k$. Take $K = 3$ as an example. The first group is core words;
2. Accordingly partition $\boldsymbol{G}$ into $K \times K$ blocks,

in this example as $\left(\begin{array}{c|cc} \boldsymbol{G}_{11} & \boldsymbol{G}_{12} & \boldsymbol{G}_{13} \\ \hline \boldsymbol{G}_{21} & \boldsymbol{G}_{22} & \boldsymbol{G}_{23} \\ \boldsymbol{G}_{31} & \boldsymbol{G}_{32} & \boldsymbol{G}_{33} \end{array}\right)$. Partition $f(\boldsymbol{H})$,$\boldsymbol{A}$ in the same way. $\boldsymbol{G}_{11}, f(\boldsymbol{H})_{11}, \boldsymbol{A}_{11}$ correspond to core bigrams. Partition $\boldsymbol{V}$ into $\underbrace{(\boldsymbol{V}_1}_{\boldsymbol{S}_1} \mid \underbrace{\boldsymbol{V}_2}_{\boldsymbol{S}_2} \; \underbrace{\boldsymbol{V}_3)}_{\boldsymbol{S}_3}$;

3. Solve $\boldsymbol{V}_1^\top \boldsymbol{V}_1 + \boldsymbol{A}_{11} = \boldsymbol{G}_{11}$ using Algorithm 1, and obtain core embeddings $\boldsymbol{V}_1^*$;
4. Set $\boldsymbol{V}_1 = \boldsymbol{V}_1^*$, and find $\boldsymbol{V}_2^*$ that minimizes the total penalty of the 12-th and 21-th blocks of residuals (the 22-th block is ignored due to its high sparsity):

$$\begin{aligned} &\arg\min_{\boldsymbol{V}_2} \|\boldsymbol{G}_{12} - \boldsymbol{V}_1^\top \boldsymbol{V}_2\|^2_{f(\boldsymbol{H})_{12}} \\ &\quad + \|\boldsymbol{G}_{21} - \boldsymbol{V}_2^\top \boldsymbol{V}_1\|^2_{f(\boldsymbol{H})_{21}} + \sum_{s_i \in \boldsymbol{S}_2} \mu_i \|\boldsymbol{v}_{s_i}\|^2 \\ =&\arg\min_{\boldsymbol{V}_2} \|\overline{\boldsymbol{G}}_{12} - \boldsymbol{V}_1^\top \boldsymbol{V}_2\|^2_{\bar{f}(\boldsymbol{H})_{12}} + \sum_{s_i \in \boldsymbol{S}_2} \mu_i \|\boldsymbol{v}_{s_i}\|^2, \end{aligned}$$

   where $\bar{f}(\boldsymbol{H})_{12} = f(\boldsymbol{H})_{12} + f(\boldsymbol{H})_{21}^\top$; $\overline{\boldsymbol{G}}_{12} = \left(\boldsymbol{G}_{12} \circ f(\boldsymbol{H})_{12} + \boldsymbol{G}_{21}^\top \circ f(\boldsymbol{H})_{21}^\top\right) / \left(f(\boldsymbol{H})_{12} + f(\boldsymbol{H})_{21}^\top\right)$ is the weighted average of $\boldsymbol{G}_{12}$ and $\boldsymbol{G}_{21}^\top$, "$\circ$" and "/" are element-wise product and division, respectively. The columns in $\boldsymbol{V}_2$ are independent, thus for each $\boldsymbol{v}_{s_i}$, it is a separate weighted ridge regression problem, whose solution is (Holland, 1973): $\boldsymbol{v}_{s_i}^* = (\boldsymbol{V}_1^\top \mathrm{diag}(\bar{\boldsymbol{f}}_i) \boldsymbol{V}_1 + \mu_i \boldsymbol{I})^{-1} \boldsymbol{V}_1^\top \mathrm{diag}(\bar{\boldsymbol{f}}_i) \bar{\boldsymbol{g}}_i$, where $\bar{\boldsymbol{f}}_i$ and $\bar{\boldsymbol{g}}_i$ are columns corresponding to s_i in $\bar{f}(\boldsymbol{H})_{12}$ and $\overline{\boldsymbol{G}}_{12}$, respectively;
5. For any other set of noncore words $\boldsymbol{S}_k$, find $\boldsymbol{V}_k^*$ that minimizes the total penalty of the $1k$-th and $k1$-th blocks, ignoring all other kj-th and jk-th blocks;
6. Combine all subsets of embeddings to form $\boldsymbol{V}^*$. Here $\boldsymbol{V}^* = (\boldsymbol{V}_1^*, \boldsymbol{V}_2^*, \boldsymbol{V}_3^*)$.

6 Experimental Results

We trained our model along with a few state-of-the-art competitors on Wikipedia, and evaluated the embeddings on 7 common benchmark sets.

6.1 Experimental Setup

Our own method is referred to as **PSD**. The competitors include:

- (Mikolov et al., 2013b): **word2vec**[2], or SGNS in some literature;
- (Levy and Goldberg, 2014b): the **PPMI** matrix without dimension reduction, and **SVD** of PPMI matrix, both yielded by hyperwords;
- (Pennington et al., 2014): **GloVe**[3];
- (Stratos et al., 2015): **Singular**[4], which does SVD-based CCA on the weighted bigram frequency matrix;
- (Faruqui et al., 2015): **Sparse**[5], which learns new sparse embeddings in a higher dimensional space from pretrained embeddings.

All models were trained on the English Wikipedia snapshot in March 2015. After removing non-textual elements and non-English words, 2.04 billion words were left. We used the default hyperparameters in Hyperwords when training PPMI and SVD. Word2vec, GloVe and Singular were trained with their own default hyperparameters.

The embedding sets PSD-Reg-180K and PSD-Unreg-180K were trained using our online block-wise regression. Both sets contain the embeddings of the most frequent 180,000 words, based on 25,000 core words. PSD-Unreg-180K was traind with all $\mu_i = 0$, i.e. disabling Tikhonov regularization. PSD-Reg-180K was trained with $\mu_i = \begin{cases} 2 & i \in [25001, 80000] \\ 4 & i \in [80001, 130000] \\ 8 & i \in [130001, 180000] \end{cases}$, i.e. increased regularization as the sparsity increases. To contrast with the batch learning performance, the performance of PSD-25K is listed, which contains the core embeddings only. PSD-25K took advantages that it contains much less false candidate words, and some test tuples (generally harder ones) were not evaluated due to missing words, thus its scores are not comparable to others.

Sparse was trained with PSD-180K-reg as the input embeddings, with default hyperparameters.

The benchmark sets are almost identical to those in (Levy et al., 2015), except that (Luong et al., 2013)'s Rare Words is not included, as many rare words are cut off at the frequency 100, making more than 1/3 of test pairs invalid.

Word Similarity There are 5 datasets: WordSim Similarity (**WS Sim**) and WordSim Relatedness (**WS Rel**) (Zesch et al., 2008; Agirre et al., 2009), partitioned from WordSim353 (Finkelstein et al., 2002); Bruni et al. (2012)'s **MEN** dataset;

Table 2: Performance of each method across different tasks.

Radinsky et al. (2011)'s Mechanical **Turk** dataset; and (Hill et al., 2014)'s **SimLex**-999 dataset. The embeddings were evaluated by the Spearman's rank correlation with the human ratings.

Word Analogy The two datasets are **MSR**'s analogy dataset (Mikolov et al., 2013c), with 8000 questions, and **Google**'s analogy dataset (Mikolov et al., 2013a), with 19544 questions. After filtering questions involving out-of-vocabulary words, i.e. words that appear less than 100 times in the corpus, 7054 instances in MSR and 19364 instances in Google were left. The analogy questions were answered using 3CosAdd as well as 3CosMul proposed by Levy and Goldberg (2014a).

6.2 Results

Table 2 shows the results on all tasks. Word2vec significantly outperformed other methods on analogy tasks. PPMI and SVD performed much worse on analogy tasks than reported in (Levy et al., 2015), probably due to sub-optimal hyperparameters. This suggests their performance is unstable. The new embeddings yielded by Sparse systematically *degraded* compared to the old embeddings, contradicting the claim in (Faruqui et al., 2015).

Our method PSD-Reg-180K performed well consistently, and is best in 4 similarity tasks. It performed worse than word2vec on analogy tasks, but still better than other MF-based methods. By comparing to PSD-Unreg-180K, we see Tikhonov regularization brings 1-4% performance boost across tasks. In addition, on similarity tasks, online blockwise regression only degrades slightly compared to batch factorization. Their performance gaps on analogy tasks were wider, but this might be explained by the fact that some hard cases were not counted in PSD-25K's evaluation, due to its limited vocabulary.

7 Conclusions and Future Work

In this paper, inspired by the link functions in previous works, with the support from Information Theory, we propose a new link function of a text window, parameterized by the embeddings of words and the residuals of bigrams. Based on the link function, we establish a generative model of documents. The learning objective is to find a set of embeddings maximizing their posterior likelihood given the corpus. This objective is reduced to weighted low-rank positive-semidefinite approximation, subject to Tikhonov regularization. Then we adopt a Block Coordinate Descent algorithm, jointly with an online blockwise regression algorithm to find an approximate solution. On seven benchmark sets, the learned embeddings show competitive and stable performance.

In the future work, we will incorporate global latent factors into this generative model, such as topics, sentiments, or writing styles, and develop more elaborate models of documents. Through learning such latent factors, important summary information of documents would be acquired, which are useful in various applications.

Appendix A Possible Trap in SVD

Suppose $\boldsymbol{M}$ is the bigram matrix of interest. SVD embeddings are derived from the low rank approximation of $\boldsymbol{M}^\top \boldsymbol{M}$, by keeping the largest singular values/vectors. When some of these singular values correspond to negative eigenvalues, undesirable correlations might be captured. The following is an example of approximating a PMI matrix.

A vocabulary consists of 3 words s_1, s_2, s_3. Two corpora derive two PMI matrices:

$$\boldsymbol{M}^{(1)} = \begin{pmatrix} 1.4 & 0.8 & 0 \\ 0.8 & 2.6 & 0 \\ 0 & 0 & 2 \end{pmatrix}, \quad \boldsymbol{M}^{(2)} = \begin{pmatrix} 0.2 & -1.6 & 0 \\ -1.6 & -2.2 & 0 \\ 0 & 0 & 2 \end{pmatrix}.$$

They have identical left singular matrix and singular values $(3, 2, 1)$, but their eigenvalues are $(3, 2, 1)$ and $(-3, 2, 1)$, respectively.

In a rank-2 approximation, the largest two singular values/vectors are kept, and $\boldsymbol{M}^{(1)}$ and $\boldsymbol{M}^{(2)}$ yield identical SVD embeddings $\boldsymbol{V} = \begin{pmatrix} 0.45 & 0.89 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ (the rows may be scaled depending on the algorithm, without affecting the validity of the following conclusion). The embeddings of s_1 and s_2 (columns 1 and 2 of $\boldsymbol{V}$) point at the same direction, suggesting they are positively correlated. However as $\boldsymbol{M}^{(2)}_{1,2} = \boldsymbol{M}^{(2)}_{2,1} = -1.6 < 0$, they are actually negatively correlated in the second corpus. This inconsistency is because the principal eigenvalue of $\boldsymbol{M}^{(2)}$ is negative, and yet the corresponding singular value/vector is kept.

When using eigendecomposition, the largest two positive eigenvalues/eigenvectors are kept. $\boldsymbol{M}^{(1)}$ yields the same embeddings $\boldsymbol{V}$. $\boldsymbol{M}^{(2)}$ yields $\boldsymbol{V}^{(2)} = \begin{pmatrix} -0.89 & 0.45 & 0 \\ 0 & 0 & 1.41 \end{pmatrix}$, which correctly preserves the negative correlation between s_1, s_2.

Appendix B Information Theory

Redundant information refers to the reduced uncertainty by knowing the value of any one of the conditioning variables (hence redundant). *Synergistic information* is the reduced uncertainty ascribed to knowing all the values of conditioning variables, that cannot be reduced by knowing the value of any variable alone (hence synergistic).

The mutual information $I(y; x_i)$ and the redundant information $\text{Rdn}(y; x_1, x_2)$ are defined as:

$$I(y; x_i) = E_{P(x_i,y)}[\log \frac{P(y|x_i)}{P(y)}]$$

$$\text{Rdn}(y; x_1, x_2) = E_{P(y)}\left[\min_{x_1,x_2} E_{P(x_i|y)}[\log \frac{P(y|x_i)}{P(y)}]\right]$$

The synergistic information $\text{Syn}(y; x_1, x_2)$ is defined as the PI-function in (Williams and Beer, 2010), skipped here.

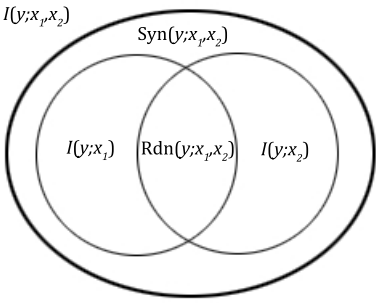

Figure 2: Different types of information among 3 random variables y, x_1, x_2. $I(y; x_1, x_2)$ is the mutual information between y and (x_1, x_2). $\text{Rdn}(y; x_1, x_2)$ and $\text{Syn}(y; x_1, x_2)$ are the redundant information and synergistic information between x_1, x_2, conditioning y, respectively.

The interaction information $\text{Int}(x_1, x_2, y)$ measures the relative strength of $\text{Rdn}(y; x_1, x_2)$ and $\text{Syn}(y; x_1, x_2)$ (Timme et al., 2014):

$$\begin{aligned}
&\text{Int}(x_1, x_2, y) \\
=&\text{Syn}(y; x_1, x_2) - \text{Rdn}(y; x_1, x_2) \\
=&I(y; x_1, x_2) - I(y; x_1) - I(y; x_2) \\
=&E_{P(x_1,x_2,y)}[\log \frac{P(x_1)P(x_2)P(y)P(x_1, x_2, y)}{P(x_1, x_2)P(x_1, y)P(x_2, y)}]
\end{aligned}$$

Figure 2 shows the relationship of different information among 3 random variables y, x_1, x_2 (based on Fig.1 in (Williams and Beer, 2010)).

PMI is the pointwise counterpart of mutual information I. Similarly, all the above concepts have their pointwise counterparts, obtained by dropping the expectation operator. Specifically, the *pointwise interaction information* is defined as $\text{PInt}(x_1, x_2, y) = \text{PMI}(y; x_1, x_2) - \text{PMI}(y; x_1) - \text{PMI}(y; x_2) = \log \frac{P(x_1)P(x_2)P(y)P(x_1,x_2,y)}{P(x_1,x_2)P(x_1,y)P(x_2,y)}$. If we know $\text{PInt}(x_1, x_2, y)$, we can recover $\text{PMI}(y; x_1, x_2)$ from the mutual information over the variable subsets, and then recover the joint distribution $P(x_1, x_2, y)$.

As the pointwise redundant information $\text{PRdn}(y; x_1, x_2)$ and the pointwise synergistic information $\text{PSyn}(y; x_1, x_2)$ are both higher-order interaction terms, their magnitudes are usually much smaller than the PMI terms. We assume they are approximately equal, and thus cancel each other when computing PInt. Given this, PInt is always 0. In the case of three words w_0, w_1, w_2, $\text{PInt}(w_0, w_1, w_2) = 0$ leads to $\text{PMI}(w_2; w_0, w_1) = \text{PMI}(w_2; w_0) + \text{PMI}(w_2; w_1)$.

Abstract

Modeling non-stationary time-series data for making predictions is a challenging but important task. One of the key issues is to identify long-term changes accurately in time-varying data. *Bayesian Online Change Point Detection (BO-CPD)* algorithms efficiently detect long-term changes without assuming the Markov property which is vulnerable to local signal noise. We propose a *Document based BO-CPD (DBO-CPD)* model which automatically detects long-term temporal changes of continuous variables based on a novel dynamic Bayesian analysis which combines a non-parametric regression, the Gaussian Process (GP), with generative models of texts such as news articles and posts on social networks. Since texts often include important clues of signal changes, DBO-CPD enables the accurate prediction of long-term changes accurately. We show that our algorithm outperforms existing BO-CPDs in two real-world datasets: stock prices and movie revenues.

1 Introduction

Time series data depends on the latent dependence structure which changes over time. Thus, stationary parametric models are not appropriate to represent such dynamic non-stationary processes. Change point analysis (Smith, 1975; Stephens, 1994; Chib, 1998; Barry and Hartigan, 1993) focuses on formal frameworks to determine whether a change has taken place without assuming the Markov property which is vulnerable to local signal noise. When change points are identified, each part of the time series is approximated by specified parametric models under the stationary assumptions. Such change point detection models have successfully been applied to a variety of data, such as stock markets (Chen and Gupta, 1997; Hsu, 1977; Koop and Potter, 2007), analyzing bees' behavior (Xuan and Murphy, 2007), forecasting climates (Chu and Zhao, 2004; Zhao and Chu, 2010), and physics experiments (von Toussaint, 2011). However, offline-based change point analysis suffers from slow retrospective inference which prevents real-time analysis.

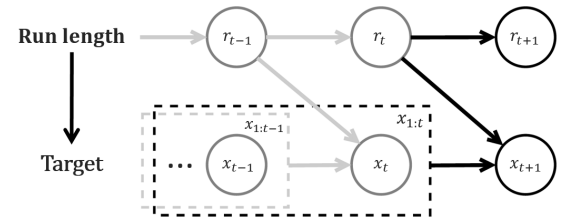
Bayesian Online Change Point Detection (BO-CPD) (Adams and MacKay, 2007; Steyvers and Brown, 2005; Osborne, 2010; Gu et al., 2013) overcomes this restriction by exploiting efficient online inference algorithms. BO-CPD algorithms efficiently detect long-term changes by analyzing continuous target values with the Gaussian Process (GP), a non-parametric regression method. The GP-based CPD model is simple and flexible. However, it is not straightforward to utilize rich external data such as texts in news articles and posts in social networks.

In this paper, we propose a novel BO-CPD model that improves the detection of change points in continuous signals by incorporating the rich external information implicitly written in texts on top of the long-term change analysis of the GP. In particular, our model finds causes of signal changes in news articles which are influential sources of markets of interests.

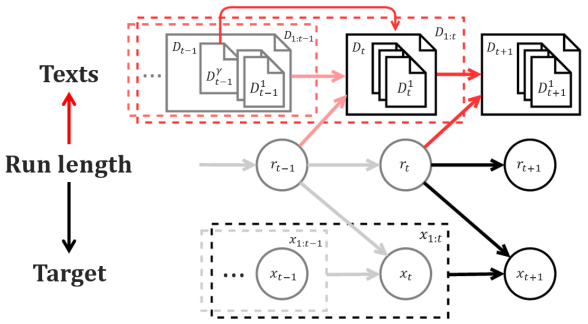
Given a set of news articles extracted from the Google News service and a sequence of target, continuous values, our new model, Document-based Bayesian Online Change Point Detection (DBO-CPD), learns a generative model which represents the probability of a news article given the run length (a length of consecutive observations without a change). By using the new prior, DBO-CPD models a dynamic hazard rate (h) which determines the rate at which change points occur.

In the literature, important information is extracted from news articles (Nothman et al., 2012;

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1610–1619,
Lisbon, Portugal, 17-21 September 2015.



(a) BO-CPD



(b) DBO-CPD (this work)

Figure 1: This figures illustrates a graphical representation of BO-CPD and our DBO-CPD model. x_t, r_t, and D_t represent a continuous variable of interest, the run length (hidden) variable, and documents, respectively. Our modeling contribution is to add texts $D_{1:t}$ for the accurate prediction of the run length r_{t+1}.

Schumaker and Chen, 2009; Gidófalvi and Elkan, 2001; Fung et al., 2003; Fung et al., 2002; Schumaker and Chen, 2006), tweets on Twitter (Si et al., 2013; Wang et al., 2012; Bollen et al., 2011; St Louis et al., 2012), online chats (Kim et al., 2010; Gruhl et al., 2005), and blog posts (Peng et al., 2015; Mishne and Glance, 2006).

In experiments, we show that DBO-CPD can effectively distinguish whether an abrupt change is a change point or not in real-world datasets (see Section 3.1). Compared to previous BO-CPD models which explain the changes by human manual mappings, our DBO-CPD automatically explains the reasons why a change point has occurred by connecting the numerical sequence of data and textual features of news articles.

2 Bayesian Online Change Point Detection

This section will review our research problem, the change point detection (CPD) (Barry and Hartigan, 1993), and the Bayesian Online Change Point Detection (BO-CPD) (Adams and MacKay, 2007) and our model, Document Based Online Change Point Detection (DBO-CPD).

Let $x_t \in \mathbb{R}$ be a data observation at time t. We assume that a sequence of data $(x_1, x_2, ..., x_t)$ is composed of several non-overlapping productive partitions (Barry and Hartigan, 1992). The boundaries that separate the partitions is called the change points. Let r be the random variable that denotes the *run length*, which is the number of time steps since the last change point was detected. r_t is the current run at time t. $x_t^{(r_t)}$ denotes the most recent data corresponding to the run r_t.

2.1 Online Recursive Detection

To make an optimal prediction of the next data x_{t+1}, one may need to consider all possible run lengths $r_t \in \mathbb{N}$ and a probability distribution over run length r_t. Given a sequence of data up to time t, $x_{1:t} = (x_1, x_2, ..., x_t)$, the run length prediction problem is formalized as computing the joint probability of random variables $P(x_{t+1}, x_{1:t})$. This distribution can be calculated in terms of the posterior distribution of run length at time t, $P(r_t|x_{1:t})$, as follows:

$$\begin{aligned} P(x_{t+1}, x_{1:t}) &= \sum_{r_t} P(x_{t+1}|r_t, x_t^{(r_t)}) P(r_t|x_{1:t}) \\ &= \sum_{r_t} P(x_{t+1}|x_t^{(r_t)}) P(r_t|x_{1:t}) \end{aligned} \quad (1)$$

The predictive distribution $P(x_{t+1}|r_t, x_t^{(r_t)})$ depends only on the most recent r_t observations $x_t^{(r_t)}$. The posterior distribution of run length $P(r_t|x_{1:t})$ can be computed recursively:

$$P(r_t|x_{1:t}) = \frac{P(r_t, x_{1:t})}{P(x_{1:t})} \quad (2)$$

where:

$$P(x_{1:t}) = \sum_{r_t} P(r_t, x_{1:t}). \quad (3)$$

The joint distribution over run length r_t and data $x_{1:t}$ can be derived by summing $P(r_t, r_{t-1}, x_{1:t})$ over r_{t-1}:

$$\begin{aligned} P(r_t, x_{1:t}) &= \sum_{r_{t-1}} P(r_t, r_{t-1}, x_{1:t}) \\ &= \sum_{r_{t-1}} P(r_t, x_t|r_{t-1}, x_{1:t-1}) P(r_{t-1}, x_{1:t-1}) \\ &= \sum_{r_{t-1}} P(r_t|r_{t-1}) P(x_t|r_{t-1}, x_t^{(r_t)}) P(r_{t-1}, x_{1:t-1}). \end{aligned}$$

This formulation updates the posterior distribution of the run length given the prior over r_t from r_{t-1} and the predictive distribution of new data.

However, the existing BO-CPD model (Adams and MacKay, 2007) specifies the conditional prior on the change point $P(r_t|r_{t-1})$ in advance. This approach may lead to model biased predictions because the update formula highly relies on the predefined, fixed hazard rate (h). Furthermore, BO-CPD is incapable of incorporating external information that implicitly influences the observation and explains the reasons for the current change of the long-term trend.

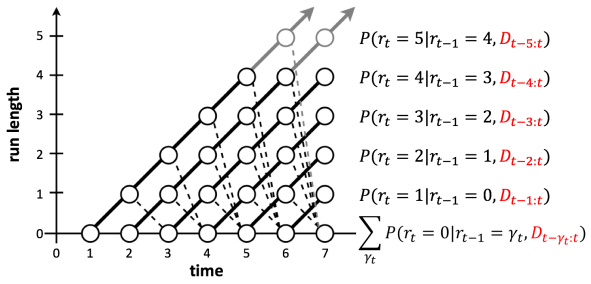


Figure 2: This figure illustrates the recursive updates of the posterior probability in the DBO-CPD model. Even the BO-CPD model only uses current and previous run length to calculate the posterior, DBO-CPD can utilize the series of text documents to compute the conditional probability accurately.

2.2 Document-based Bayesian Online Change Point Detection

This section explains our DBO-CPD model. To represent the text documents, we add a variable $\boldsymbol{D}$ which denotes a series of text documents related to the observed data as shown in Figure 1. Let D_t be a set of N_t text documents $D_t^1, D_t^2, ..., D_t^{N_t}$ that are indexed at time of publication t, where N_t is the number of documents observed at time t. Then, we can rewrite the joint probability over the run length as:

$$P(r_t, x_{1:t}) = \sum_{r_{t-1}} \sum_{D_t^{(r_{t-1})}} P\left(r_t|r_{t-1}, D_t^{(r_{t-1})}\right) \cdot P\left(x_t|r_{t-1}, x_t^{(r_{t-1})}\right) P(r_{t-1}, x_{1:t-1}) \quad (4)$$

where $D_t^{(r_t)}$ $(= D_{t-r_t+1:t})$ is the set of the r_t most recent documents. Figure 2 illustrates the recursive updates of posterior probability where solid lines indicate that the probability mass is passed upwards and dotted lines indicate the probability that the current run length r_t is set to zero.

Given documents $D_t^{(r_t)}$, the conditional probability is represented as follows:

$$\begin{aligned} & P\left(r_t = \gamma{+}1|r_{t-1} = \gamma, D_t^{(\gamma)}\right) \\ &= \frac{P\left(r_{t-1} = \gamma, D_t^{(\gamma)}|r_t = \gamma{+}1\right) P(r_t = \gamma{+}1)}{\sum_{\bar{\gamma}=1}^{\gamma+1} P\left(r_{t-1} = \gamma, D_t^{(\gamma)}|r_t = \bar{\gamma}\right) P(r_t = \bar{\gamma})} \\ &= \frac{P\left(r_{t-1} = \gamma, D_t^{(\gamma)}|r_t = \gamma + 1\right) P_{gap}(\gamma{+}1)}{\sum_{\bar{\gamma}=1}^{\gamma+1} P\left(r_{t-1} = \gamma, D_t^{(\gamma)}|r_t = \bar{\gamma}\right) P_{gap}(\bar{\gamma})} \end{aligned}$$

where P_{gap} is the distribution of intervals between consecutive change-points. As the BO-CPD model (Adams and MacKay, 2007), we assume the simplest case where the probability of a change-point at every step is constant if the length of a segment is modeled by a discrete exponential (geometric) distribution as:

$$P_{gap}(r_t|\lambda) = \lambda exp^{-\lambda r_t} \quad (5)$$

where $\lambda > 0$, a *rate parameter*, is the parameter of the distribution.

The update rule for the prior distribution on r_t makes the computation of the joint distribution tractable, $\sum_{\bar{\gamma}=1}^{\gamma+1} P(r_{t-1}{=}\gamma, D_t^{(\gamma)}|r_t{=}\bar{\gamma}) \cdot P_{gap}(\bar{\gamma})$. Because r_t can only be increased to $\gamma + 1$ or set to 0, the conditional probability is as follows:

$$\begin{aligned} & P(r_t = \gamma + 1|r_{t-1} = \gamma, D_t^{(\gamma)}) \\ &= \frac{T_D(t, \gamma|\gamma{+}1)}{T_D(t, \gamma|\gamma{+}1) + T_D(t, \gamma|0)} \end{aligned} \quad (6)$$

where the function $T_D(t, \alpha|\bar{\alpha})$ is an abbreviation of $P\left(r_{t-1}{=}\alpha, D_t^{(\alpha)}|r_t{=}\bar{\alpha}\right)$. In Equation (6), $T_D(t, \gamma|\gamma{+}1){=}P(r_{t-1}{=}\gamma, D_t^{(\gamma)}|r_t{=}\gamma{+}1)$ is the joint probability of the run length r_{t-1} and a set of documents $D_t^{(\gamma)}$ when no change has occurred at time t and the run length becomes $\gamma + 1$. Therefore, we can simplify the equation by removing $r_{t-1}{=}\gamma$ from the condition as follows:

$$T_D(t, \gamma|\gamma{+}1) = P(D_t^{(\gamma)}|r_t{=}\gamma + 1). \quad (7)$$

We represent the distribution of words by the *bag-of-words* model. Let D_t^i be the set of M words that is part of the ith document at time t, i.e. $D_t^i = \{d_t^{i,1}, d_t^{i,2}, ..., d_t^{i,M}\}$. In the model, we assume that the probability of word $d_t^{i,j}$ is independent and identically distributed (iid) given a run

length parameter r_t. In this setting, the conditional probability of the words takes the following form:

$$P\left(D_t^{(\gamma)}|r_t=\gamma{+}1\right)=\frac{1}{Z}\prod_{i,j}P\left(d_t^{i,j}|r_t=\gamma{+}1\right). \tag{8}$$

The conditional probability $P(d_t^{i,j}|r_t{=}\gamma{+}1)$ is represented by two generative models, $\phi_{\mathbf{wf}}$ and $\phi_{\mathbf{wi}}$ which illustrates *word frequency* and *word impact*, respectively. The key intuition of *word frequency* is that a word tends to close to a change point if a word has been frequently seen in articles, published when there was a rapid change. The key intuition of *word impact* is that how much does a word lose information in time which will be discussed in next section. In our paper, we use the unnormalized beta distribution of the weights of words to represent the exponential decays. The probability $P\left(D_t^{(\gamma)}|r_t{=}\gamma+1\right)$ can be represented recursively as:

$$\begin{aligned}
P\left(D_t^{(\gamma)}|r_t{=}\gamma{+}1\right) &= P\left(D_t^{(\gamma)}|\gamma{+}1\right)\\
&\propto \phi_{\mathbf{wi}}(D_t^{(\gamma)}|\gamma{+}1)\cdot\phi_{\mathbf{wf}}(D_t^{(\gamma)}|\gamma{+}1)\\
&= \phi_{\mathbf{wi}}(D_t|\gamma{+}1)\cdot\phi_{\mathbf{wf}}(D_t|\gamma{+}1)\\
&\quad\cdot\phi_{\mathbf{wi}}(D_{t-1}^{(\gamma-1)}|r_{t-1}{=}\gamma)\cdot\phi_{\mathbf{wf}}(D_{t-1}^{(\gamma-1)}|r_{t-1}{=}\gamma)\\
&= \prod_{i,j}\phi_{\mathbf{wi}}(d_t^{i,j}|\gamma{+}1)\cdot\phi_{\mathbf{wf}}(d_t^{i,j}|\gamma{+}1) \qquad (9)\\
&\quad\cdot\phi_{\mathbf{wi}}(D_{t-1}^{(\gamma-1)}|r_{t-1}{=}\gamma)\cdot\phi_{\mathbf{wf}}(D_{t-1}^{(\gamma-1)}|r_{t-1}{=}\gamma)
\end{aligned}$$

where:

$$\phi_{\mathbf{wf}}(d_t^{x,y}|\gamma)=\frac{count(d_t^{x,y},r_t=\gamma)}{\sum_{i,j}count(d_t^{i,j},r_t=\gamma)}.$$

Here, $\phi_{\mathbf{wi}}(d_t^{x,y}|\gamma)$ and $\phi_{\mathbf{wf}}(d_t^{x,y}|\gamma)$ are empirical potentials which contribute to represent $P(d_t^{i,j}|\gamma)$. $\phi_{\mathbf{wi}}(\cdot)$ is explained in Section 2.3. Here, $count(E)$ is the number of times event E appears in the dataset. In Equation (9), τ_t is the time gap (difference) between t and the time when a document is generated, and $d^{i,j}$ represents a document without considering the time domain.

$T_D(t,\gamma|0)$ is represented as follows:

$$\begin{aligned}
&P(r_{t-1}{=}\gamma, D_t^{(\gamma)}|r_t{=}0)\\
&= P(r_{t-1}{=}\gamma|r_t=0)P(D_t^{(\gamma)}|r_t{=}0)\\
&= H(\gamma{+}1)P(D_t^{(\gamma)}|r_t{=}0)
\end{aligned}$$

where $H(\tau)$ is the *hazard function* (Forbes et al., 2011),

$$H(\tau)=\frac{P_{gap}(\tau)}{\sum_{t=\tau}^{\infty}P_{gap}(t)}. \tag{10}$$

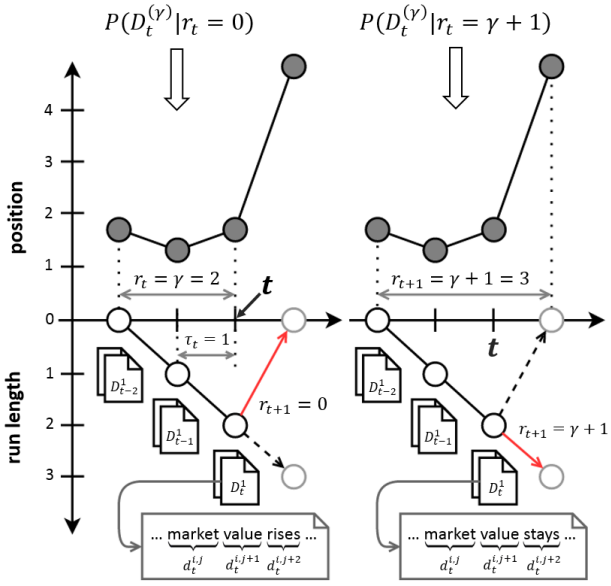

Figure 3: This figure illustrates how our Equation (9) is calculated and how it determines whether a change occurs or not. If the same data is given, BO-CPD gives us the same answer to a question whether an abrupt change at time t is a change point or not. However, DBO-CPD uses documents D_t^{γ} for its prediction to incorporate the external information which cannot be inferred only from the data.

When P_{gap} is the discrete exponential distribution, the hazard function is constant at $H(\tau)=1/\lambda$ (Adams and MacKay, 2007).

As an illustrative example, suppose that we found a rapid change in Google stock three days ago. Today at $t=3$, we want to know how the articles are written and whether it will affect the change tomorrow ($t=4$). As shown in Figure 3, we can calculate what degree a word, for example *rises* or *stays*, is likely to appear in articles published since today, which is $P(D_t^{(\gamma)}|r_t=\gamma{+}1)$, and this probability leads us to predict run lengths from the texts. Documents for each $\tau_t=0,1$ and 2 are generated from the generative models with a given predicted run length through recursive calculation of the Bayesian models which enables online prediction as shown in Equation (9). This is the main contribution of this paper that enables DBO-CPD to infer change points accurately with information included in text documents.

2.3 Generative Models Trained from Regression

Let $D \in \mathbb{R}^{T \times N \times M}$ be N documents of news articles which consist of M vocabulary over time domain T. $D_t^i \in \mathbb{R}^M$ is the ith document of a set of documents generated at time t, and define $r \in \mathbb{R}^N$ as the corresponding set of the run length, which is a time gap between the time when the document is generated and the next change point occurs. Then, given a text document D_t^i, we seek to predict the value of run length r by learning a parameterized function f:

$$\hat{r} = f(D_t^i; \mathbf{w}) \tag{11}$$

where $\mathbf{w} \in \mathbb{R}^d$ are the weights of text features for $d_t^{i,1}, d_t^{i,2}, ..., d_t^{i,M}$ which compose documents D_t^i. From a collection of N documents, we use linear regression which is trained by solving the following optimization problem:

$$\min_{\mathbf{w}, D_t^i} f(D_t^i; \mathbf{w}) \equiv \mathbf{C} \sum_{\mathbf{i=1}}^{\mathbf{N}} \xi(\mathbf{w}, \mathbf{D_t^i}, \mathbf{r_t}) + \mathbf{r}(\mathbf{w}) \tag{12}$$

where $r(\mathbf{w})$ is the regularization term and $\xi(\mathbf{w}, \mathbf{D_t^i}, \mathbf{r_t})$ is the loss function. Parameter $C > 0$ is a user-specified constant for balancing $r(\mathbf{w})$ and the sum of losses.

Let h be a function from a document into a vector-space representation $\in \mathbb{R}^d$. In linear regression, the function f takes the form:

$$f(D_t^i; \mathbf{w}) = h(D_t^i)^\top \mathbf{w} + \epsilon \tag{13}$$

where ϵ is Gaussian noise.

Figure 4 illustrates how we trained a linear regression model on a sample article. One issue is that the run length can not be trained directly. Suppose that we train $r_5 = 0$ into regression, the weight $\mathbf{w}$ of the model will become 0 even though the set of words contained in $D_5^j, \forall j \in \{1, ..., T\}$ is composed of salient words which can incur a possible future change point. To solve this interpretability problem, we trained the weight in the inverse exponential domain for the predicted variable, predicting e^{-r_t} instead of r_t. In this setting, the predicted run-length takes the form:

$$e^{-\hat{r_t}} = h(D_t)^\top \mathbf{w} + \epsilon. \tag{14}$$

By this method, the regression model can give a high weight to a word which often appears close to change points. We can interpret that highly weighted words d are more closely related to an outbreak of changes than lower weighted words.

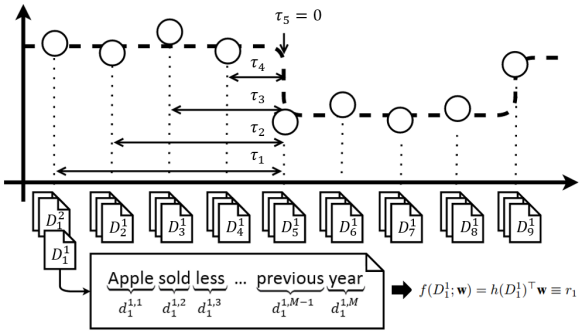

Figure 4: This figure illustrates a graphical representation of how we train a generative model from a regression problem. We use a regression model to predict time gap r_t between the release date of article and the nearest future change point. The weights of regression model are changed into the negative exponential scale to be considered as *word impact*.

With $\mathbf{w}$, we can rewrite the probability of d, τ_t given $\mathbf{w}$ as:

$$\begin{aligned} \phi_{\mathbf{wi}}(d, \tau_t) &\propto \mathbf{w}_d \cdot (\exp(-1/\mathbf{w}_d))^{\tau_t} \\ &= \mathbf{w}_d \cdot \exp(-\tau_t/\mathbf{w}_d). \end{aligned} \tag{15}$$

The potential, $\phi_{\mathbf{wi}}$, can also be represented recursively as follows:

$$\phi_{\mathbf{wi}}(d, \tau_{t+1}) = \phi_{\mathbf{wi}}(d, \tau_t) \cdot \exp(-1/\mathbf{w}_d), \tag{16}$$

since given a word d, $\tau_{t+1} = \tau_t + 1$ holds.

3 Experiments

Now we explain experiments of DBO-CPD in two real-world datasets, stock prices and movie revenues. The first case is the historical end-of-day stock prices of five information technology corporations. In the second dataset, we examine daily film revenues averaged by the number of theaters.

3.1 Datasets

In the stock price dataset, we gather data for five different companies: Apple (AAPL), Google (GOOG), IBM (IBM), Microsoft (MSFT), and Facebook (FB). These companies were selected because they were the top 5 ranked in market value in 2015.

We chose these technology companies because the announcement of new IT products and features and the interests of public media tend to be higher

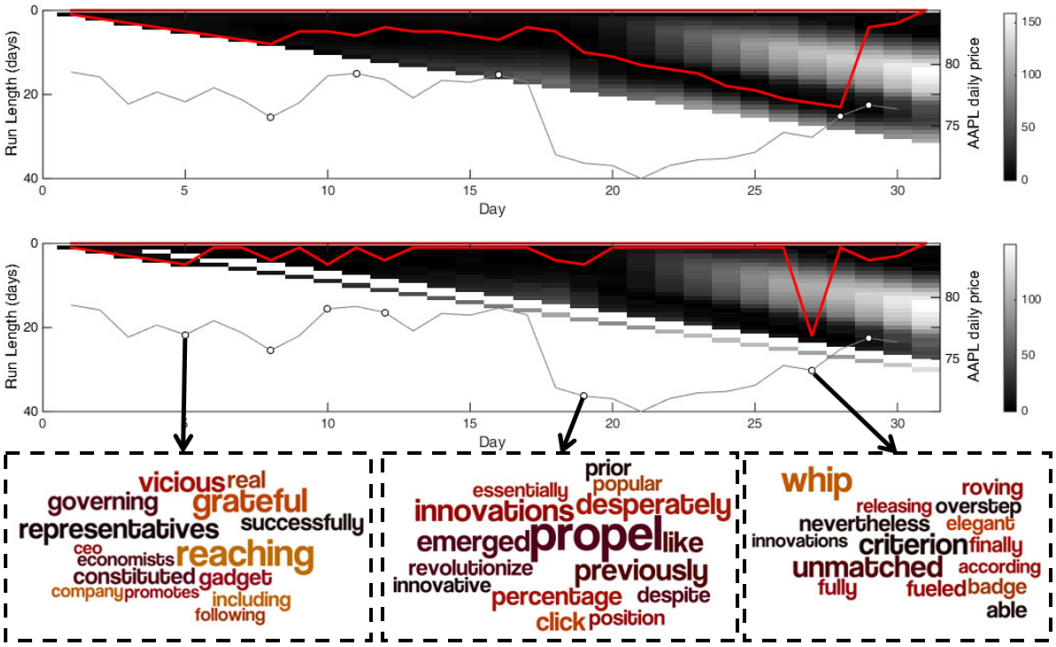

Figure 5: (a) Two plots show the results of BO-CPD (**top**) and DBO-CPD (**middle**) on Apple stock prices in January 2014. The stock price is plotted in light gray, with the predictive change points drawn as small circles. The red line represents the most likely predicted run-lengths for each day. The **bottom** figures are a set of visualizations of the top 15 strongly weighted words which are found at selected change points which BO-CPD is unable to predict. The size of each word represents the weight of its textual features learned during the training of the regression model.

and lead to many news articles. We use the historical stock price data from the Google Finance service.[1].

category	words	documents	words/doc

AVGR	3.5M	6,476	537
FRZ	6.8M	15,021	454
INTRS	4.2M	7,846	538

Table 1: Dimensions of the datasets used in this paper, after tokenizing and filtering the news articles. '**:N**' means the articles are collected with additional 'NASDAQ:' search query.

The second dataset is a set of movie revenues averaged by the number of theaters for five months from the release date of film. We target 5 different movies: The Dark Knight (KNGHT), Inception (INCPT), The Avengers (AVGR), Frozen (FRZ) and Interstellar (INTRS), because these movies are on highest-grossing movie list and also are screened recently. The cumulative daily revenue per theater is collected from 'Box Office Mojo' (www.boxofficemojo.com).

News articles are collected from Google News and we use *Google search queries* to extract specific articles related to each dataset in a specific time period. During the online article crawling, we store not only the titles of articles, HTML documents, and publication dates, but also the number of related articles. The number of articles is used to differentiate the weight of news articles during the training of regression. In the case of stock price data, we use two different queries to decrease noise. First, we search with the company name such as 'Google'. Then, we use queries specific to stock 'NASDAQ:' to make the content of articles to be highly relevant to the stock market. In case of movie data, we search with the movie title with the additional word 'movie' to only collect articles related to the target movie.

With these collected articles, we used two ar-

[1]https://www.google.com/finance

ticle extractors, *newspaper* (Ou-Yang, 2013) and *python-goose* (Grangier, 2013), to automate the text extraction of 291,057 HTML documents. After preprocessing, we could successfully extract texts from 287,389 (98.74%) HTMLs.

3.2 Textual Feature Representation

After extracting texts from HTMLs, we tokenize the texts into words. We use three different tokenization methods which are downcasing the characters, punctuation removal, and removing English stop words. Table 1 shows the statistics on the corpora of collected news articles.

With these article corpora, we use a *bag-of-words* (BoW) representation to change each word into a vector representation where words from articles are indexed and then weighted. Using these vectors, we adopt three document representations, TF, TFIDF, and LOG1P, which extend BoW representation. TF and TFIDF (Sparck Jones, 1972) calculate the importance of a word to a set of documents based on term frequency. LOG1P (Kogan et al., 2009) calculates the logarithm of the word frequencies.

3.3 Training BO-CPD

As we noted earlier, we use BO-CPD to train the regression model to learn high weight for words which are more related to changes. When we choose the parameters for the Gaussian Process of BO-CPD, we try to find the value which makes the distance of intervals between predicted change points around 1-2 weeks. This is because we assume that the information included in the articles will have an immediate effect on the data right after it is published to the public, so the external information in texts will indicate the short-term causes for a future change.

For the reasonable comparison of BO-CPD and DBO-CPD, we use the same parameter for the Gaussian Process in both models. After several experiments we found that $a = 1$ and $b = 1$ for the Gaussian Process and $\lambda_{gap} = 250$ is appropriate to train BO-CPD in the stock and film datasets. We separate the training and testing examples for cross-validation at a ratio of $2 : 1$ for each year. Then we train each model differently by year.

3.4 Learning the strength parameter w from Regression

The weight **w** of the regression model gives us an intuition of how a word is important which affect to the length of the current run. With the predicted run length calculated in Section 3.3, we change the run length domain $r \in \mathbb{R}$ into $0 \leq r \leq 1$ by predicting e^{r_t} rather than r_t to solve the interpretability problem. Therefore, we can think of a high weight w_i as a powerful word which changes the current run length r to 0. To maintain the scalability of **w**, we normalize the weight by rescaling the range into $\mathbf{w} \in [-1, 1]$. With the word representation calculated in Section 3.2, we train the regression model by using the number of relevant articles as the importance weight of training.

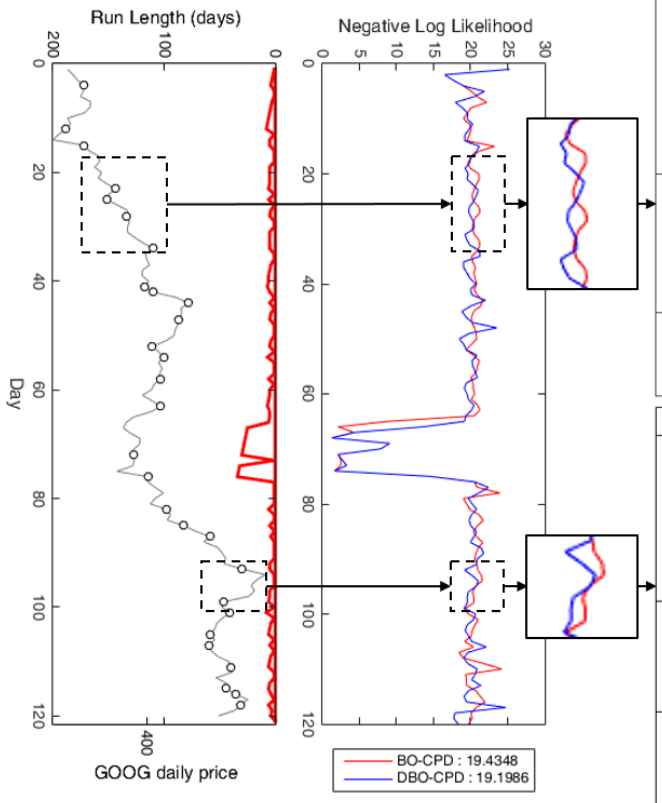
Table 2: Negative log likelihood of five stocks (Apple, Google, IBM, Microsoft, and Facebook) without and with our model per year from 2010 to 2014. DBO-CPD I represents the experiments without 'NASDAQ:' as a search query and DBO-CPD II is the result of articles searched with 'NASDAQ:'. Facebook data is not available before the year 2012.

3.5 Results

We evaluate the performance of BO-CPD and DBO-CPD by comparing the negative log likelihood (NLL) (Turner et al., 2009) of two models at time t as:

$$\log p(x_{1:T}|\mathbf{w}) = \sum_{t=1}^{T} \log p(x_t|x_{1:t-1}, \mathbf{w}).$$

We calculate the marginal NLL by year and the results are described in Table 2 and Table 3. (Facebook data is not available before the year 2012.) The difference between DBO-CPD I and DBO-CPD II is whether the search queries include 'NASDAQ'. In stock data sets of 5 years, our model outperforms BO-CPD in Apple, Google, IBM, Microsoft dataset. The improvements of



Rank	From Jan 25 to Feb 13 at 2013 from GOOG

Figure 6: (b) The **left** plot illustrates daily stock prices of Google in 2013 from early January to late May. The black line represents the stock price, black circles indicate the predicted change points, and the red line shows the predicted run length calculated by DBO-CPD. The **middle** plot shows the negative log likelihood (NLL) of BO-CPD and DBO-CPD on the same data. The overall marginal NLL of DBO-CPD (19.1964) is smaller than BO-CPD (19.3438). The two zoomed intervals are the two longest intervals where the negative log likelihood of DBO-CPD is smaller than BO-CPD. The **right** table shows the sentences whose run length predicted by the regression model (described in Section 2.3) are the highest at the two zoomed points, which means the sentences are likely to appear near feature change points. The boldface words are the top 5 most strongly-weighted terms in the regression model.

DBO-CPD compared to the BO-CPD is statistically significant with 90% confidence in the four stocks except for stock of Facebook. We also found that most of the DBO-CPD II shows better results than DBO-CPD I and BO-CPD in most datasets due to noise reduction of texts through the additional search query 'NASDAQ:'. Out of 23 datasets, APPL in 2010 and FB in 2012 are the only datasets where NLLs of BO-CPD is smaller (better) than NLLs of DBO-CPD.

One of the advantages of using a linear model is that we can investigate what the model discovers about different terms. As shown in Figure 5, we can find negative semantic words such as *vicious*, *whip*, and *desperately*, and words representing the status of a company like *propel*, *innovations*, and *grateful* are the most strongly-weighted terms in the regression model. We analyze and visualize some change points where NLL of DBO-CPD is lower than NLL of BO-CPD. The results are shown in Figure 6 and three sentences are the top 3 most weighted sentences in the regression model for two changes with the boldface words of top 5 strongly weighted terms like the terms *big*, *money*, and *steadily*. A particularly interesting case is the term *earth* which is found between Jan. 25 and Feb. 13 in 2013. After we investigated articles where the sentence is included, we found that Google announced a new tour guide feature in Google Earth on Jan. 31 and after this announce-

ment the stock price increased. We can also find that the word *million* is also a positive term which can predict a new change in the near feature.

4 Conclusions

In this paper, we propose a novel generative model for online inference to find change points from non-stationary time-series data. Unlike previous approaches, our model can incorporate external information in texts which may includes the causes of signal changes. The main contribution of this paper is to combine the generative model for online change points detection and a regression model learned from the weights of words in documents. Thus, our model accurately infers the conditional prior of the change points and automatically explains the reasons of a change by connecting the numerical sequence of data and textual features of news articles.

5 Future work

Our DBO-CPD can be improved further by incorporating more external information beyond documents. In principle, our DBO-CPD can incorporate other features if they are vectorized into a matrix form. Our implementation currently only uses the simple bag of words models (TF, TFIDF and LOG1P) to improve the baseline GP-based CPD models by bringing documents into change point detection. One possible direction of future work would explore ways to fully represent the rich information in texts by extending the text features and language representations like continuous bag-of-words (CBOW) models (Mikolov et al., 2013) or Global vectors for word representation (GloVe) (Pennington et al., 2014).

Abstract

Recognizing Text Entailment (RTE) plays an important role in NLP applications including question answering, information retrieval, etc. In recent work, some research explore "deep" expressions such as discourse commitments or strict logic for representing the text. However, these expressions suffer from the limitation of inference inconvenience or translation loss. To overcome the limitations, in this paper, we propose to use the predicate-argument structures to represent the discourse commitments extracted from text. At the same time, with the help of the YAGO knowledge, we borrow the distant supervision technique to mine the implicit facts from the text. We also construct a probabilistic network for all the facts and conduct inference to judge the confidence of each fact for RTE. The experimental results show that our proposed method achieves a competitive result compared to the previous work.

1 Introduction

For the natural language, a common phenomenon is that there exist a lot of ways to express the same or similar meaning. To discover such different expressions, the Recognising Textual Entailment (RTE) task is proposed to judge whether the meaning of one text (denoted as H) can be inferred (entailed) from the other one (T)(Dagan et al., 2006). For many natural language processing applications like question answering, information retrieval which involve the diversity of natural language, recognising textual entailments is a critical step.

PASCAL Recognizing Textual Entailment (RTE) Challenges (Dagan et al., 2006) have witnessed a variety of excellent systems which intend to recognize the textual entailment instances. These systems mainly employ "shallow" techniques, including heuristics, term overlap, syntactic dependencies(Vanderwende et al., 2006; Jijkoun and de Rijke, 2005; Malakasiotis and Androutsopoulos, 2007; Haghighi et al., 2005). As Hickl (2008) stated, the shallow approaches do not work well for long sentences for the missing of underlying information which needs to be mined from the surface level expression.

Recently, some deep techniques are developed to mine the facts latent in the text. Hickl (2008) proposed the concept of discourse commitments which can be seen as the set of propositions inferred from the text, and used a series of syntax-level and semantic-level rules to extract the commitments from the T-H pairs. Then the RTE task is reduced to the identification of the commitments from T which are most likely to support the inference of the commitments from H. From the work of Hickl (2008), we can see that a deep understanding of text is critical to the RTE performance and discourse commitments can serve a good media to understanding text. However, the limitation of Hickl (2008)'s work is, the extracted discourse commitments are still from the original text and do not explore the implicit meaning latent behind the text.

Another kind of deep methods involves first transferring natural language to logic representation and then conducting strict logic inference based on the logic representations (de Salvo Braz et al., 2006; Tatu and Moldovan, 2006; Wotzlaw and Coote, 2013). Through logic inference, some implicit knowledge behind the text can be mined. However, it is not easy to translate the natural language text into formal logic expressions and the translation process inevitably suffer from great information loss.

Through analysis above, in our work, we pro-

Lisbon, Portugal, 17-21 September 2015.

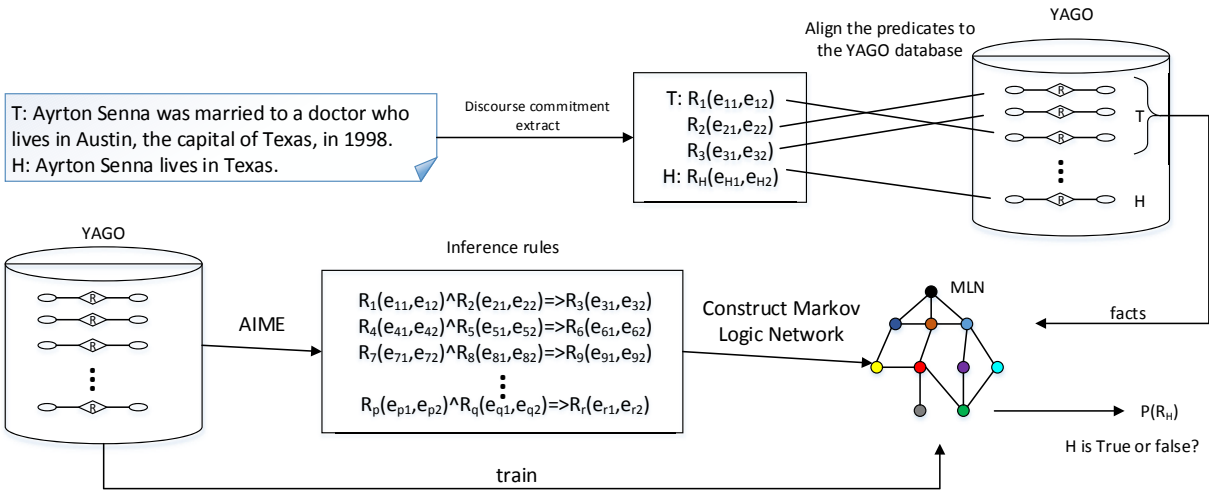

Figure 1: The Framework of our RTE system

pose to use the predicate-argument structure to represent the extracted discourse commitments. Inspired by the work of (Mintz et al., 2009), we make use of the external knowledge YAGO and borrow the distant supervision technique to mine implicit facts for the extracted predicates. For example,

Ayrton Senna was married to a doctor who lives in Austin, the capital of Texas, in 1998.

We translate this example into the predicate-argument structures such as bemarried(Senna, doctor), livein(doctor, Austin), captial(Austin, Texas). Then through distant supervision, we can get some new facts livein(Senna, Austin), livein(Senna, Texas).

To judge the confidence of the new facts, we construct a probabilistic network with all the facts and adopt the Markov Logic Network (MLN) to calculate the probability of each new fact, which can be further used to recognize text entailments.

2 Our RTE System

To make full use of the underlying information in sentences and lessen the effect brought by natural language's vagueness, we design a RTE system which is composed of three stages, as shown in Figure 1.

First, we decompose the sentences in T-H pair to a series of discourse commitments as Hickl (2008) did. Since the syntax of these commitments are very simple, we can directly transform them to predicates (or 3-arg tuples). Then we use YAGO, a large semantic database including several thousands relations, to provide distant supervision. The predicates in T are matched to YAGO facts due to some metrics. At last, we use the Markov Logic Network(MLN) (Richardson and Domingos, 2006) to infer the correctness of the predicates in H. The MLN is constructed using the inference rules ("soft" rules) generated by AMIE system (Galárraga et al., 2013) on YAGO. Each rule has a weight which should be trained by real world facts. Using this framework, we can apply the "soft" logic to the textual entailment recognition task.

2.1 Extracting Predicates from Sentences

Discourse commitment is our baseline system proposed by Hickl (2008) which can decompose one sentence to a series of shorter and simpler sentences which completely contain the origin sentence's information. One of the advantages of discourse commitments is that it can use a lot of syntax-level and semantic level rules to extract the underlying information of one sentence. For example, the following T-H pair can be decomposed as Figure 2. The discourse commitments of T contains the information: Ayrton Senna married in 1998, which is not easy to be captured by "shallow" methods.

T : Ayrton Senna was married to a doctor who lives in Austin, the capital of Texas, in 1998.

H : Ayrton Senna lives in Texas.

Since we need to infer new facts using the extracted commitments, we transfer all the commit-

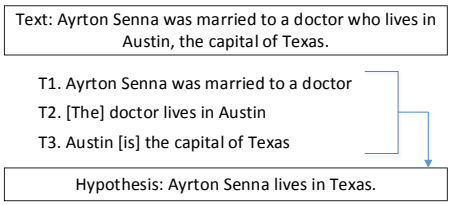

Figure 2: Text Commitments Example

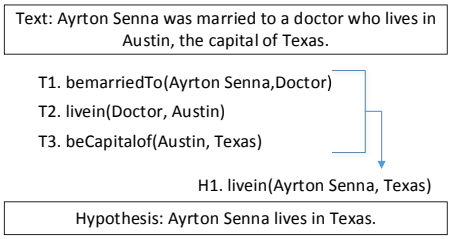

Figure 3: Text Predicates Example

ments to predicates. For example, the commitments in Figure 2 can be transformed to the predicates (or triples) shown in Figure 3. We use REVERB (Fader et al., 2011) to extract the triples (predicate + 2 Arguments). To make the inference process in the next section more convenient, we order that all of the arguments should be NPs. Therefore, we check if the arguments in the triples contain or have overlap with any of the NPs, replace it with that NP, and the predicates are successfully extracted.

2.2 Distant supervision with YAGO

The goal of distant supervision is to use the knowledge of YAGO (Mahdisoltani et al., 2014) to help the textual entailment recognition task. The facts in YAGO have various type of connections with each other. We think this connection is very useful for RTE. Therefore, the predicates in the T-H pair should be matched to the YAGO facts for making advantage of the connection information.

Since YAGO is very large, the common predicates can easily matched to YAGO facts in most cases. However, YAGO cannot contain every predicate in T. We run DIRT (Lin and Pantel, 2001) system on 1GB text random sampled from Gigaword corpus and for each predicate we choose the top-10 similar predicates as its synonymous predicate. If the origin predicate cannot be found in YAGO, we instead check for the top-10 similar predicates. If we still cannot find a match, that means this predicate has very little connection with other predicates and cannot be supervised by YAGO.

2.3 Probabilistic Inference

The goal of MLN (Richardson and Domingos, 2006) is to implement the probabilistic inference, or "soft" logic inference. MLN is constructed by an inference rule base. Each rule has a weight which needs to be well trained by real word facts. We use AMIE to mine inference rules from YAGO.

AMIE[1] (Galárraga et al., 2013) is a state-of-the-art inference rule mining system. The motivation of AMIE is that KBs themselves often already contain enough information to derive and add new facts. If, for example, a KB contains the fact that a child has a mother, then the mother's husband is most likely the father.

$$motherOf(m, c) \wedge marriedTo(m, f) \Rightarrow fatherOf(f, c)$$

AMIE can mine such inference rules from large KBs. The inference rules can be directly used for constructing Markov logic network in the next section. In addition, the process of mining inference rules is quite efficient so that it is very helpful for our RTE task.

We use AMIE only to extract the inference rules. After the inference rules are prepared, we can construct a MLN. We give the related facts in YAGO to the MLN, then the weights of each inference rule can tune to a best fit for these facts. After the weights of each inference rule are well trained, the MLN is well prepared to use. Given the predicates in T, we first select all the related rules to construct a simple MLN, and then give the MLN some facts. After that, the MLN will calculate the probabilities of the unknown new facts. The arguments of the new facts are the permutations of all the ground atoms (or entities). For example, if we give the facts "hasChild (Cliton, Chelsea)" and "IsMarriedto (Cliton, Hillary)", the MLN will output the probability of "hasChild (Cliton, Hillary)", "hasChild (Hillary, Chelsea)", "IsMarriedto (Cliton, Chelsea)", etc. Obviously, the probability of "hasChild (Hillary, Chelsea)" may be the highest, so that it is most likely to be true. The MLN constructing and inferring can be implemented by

Alchemy[2], which provides a series of algorithms for statistical relational learning and probabilistic logic inference, based on the Markov logic representation.

After the new facts are inferred, we check if these facts can cover the predicates in H. If so, we decide T entails H.

3 Experiment

We evaluate the performance of our framework for RTE on the PASCAL RTE-2[3] and RTE-3[4] datasets, which has 1600 examples. We use the YAGO2 for aligning predicates and mining inference rules. YAGO2 contains more than 940K facts and about 470K entities. We run the AMIE system on YAGO2 for only one time to get all inference rules (about more than 1.8K in total). For each T-H pair, we only choose a portion of related inference rules to construct MLN. The chosen rules must contain at least one predicate which occurred in the predicates of T-H pair. We only use the MLN to infer when the discourse commitment paraphrasing cannot identify a T-H pair as "Entailment", which is a back-off method.

We compare our result with 5 baseline systems: (1) Zanzotto and Moschitti (2006)'s simple term-overlap measure, (2) MacCartney et al. (2006)'s semantic graph-mapping approach, (3) Hickl et al. (2006)'s classification-based term alignment approach. (4) Hickl (2008)'s discourse commitment based Alignment, (5) Tatu and Moldovan (2006)'s strict logic based method. The comparison of the 5 baselines and our framework is shown in Table 1. Since we only need to judge "Yes" or "No" for the 1600 examples, the precision is equal to the recall, so that we only report the precision.

According to the Table 1, the performance of our framework is higher than Hickl (2008)'s baseline, which is significant (Wilcoxon signed-rank test, $p < 0.05$). The reason is that we have added the inference portion to Hickl (2008)'s method. Therefore, some T-H pairs which had to be judged by semantic reasoning can be corrected by our framework. For instance, T is "Hughes loved his wife, Gracia, and was absolutely obsessed with his little daughter Elicia." and H is "Gracia's daughter is Elicia." It is not easy for the former baselines to recognize this entailment, but our framework can easily recognize it to be "true". In this way, our framework has achieved a higher result.

4 Related work

Textual Entailment Recognizing (RTE) task has been widely studied by many previous works. Firstly, the method based on similarity and overlap (Malakasiotis and Androutsopoulos, 2007; Jijkoun and de Rijke, 2005; Wan et al., 2006). This kind of methods can help solve the paraphrase recognition problem, which is a subset of RTE. Another important similarity-based method is tree kernel (Zanzotto and Moschitti, 2006), which rely on the cross-pair similarity between two pairs (T', H') and (T'', H'').

Secondly, some approaches extract the knowledge in T-H pair and check if the knowledge in T contains the knowledge in H. Hickl (2008) transformed the T-H pair into discourse commitments, reducing the RTE task to the identification of the commitments from a T which support the inference of the H. Other works map the text to logical meaning representations, and then strict logic entailment methods, possibly by invoking theorem provers.

Thirdly, some works make use of statistical classifiers which leverages a wide variety of features. The language expression of each T-H pair are represented by a feature vector $\langle f_1, f_2 \cdots f_m \rangle$. The feature vector contains the scores of different similarity measures applied to the pair, and possibly other features.

There are also other works based on predicate-argument representations with Markov Logic for RTE, such as Rios et al. (2014) and Beltagy et al. (2013). However, they did not use discourse commitments to extract predicate-argument triples, which may lead to severe information loss.

5 Conclusion

This paper introduced a new framework to solve the Textual Entailment Recognizing task. This

framework makes full use of Markov logic network for probabilistic inference. We hold that probabilistic inference is better than strict logic method since transforming from language form to strict logic form could lose a lot of information. Therefore it is extremely hard for the theorem provers to perform well.

In addition, we use YAGO database for distant supervision. The predicates extracted from T-H pair are first aligned with YAGO. If it succeeds, the inference procedure of MLN will become much more accurate. In addition, the inference rules for constructing MLN are also extracted from YAGO database using AIME system.

This framework can correctly recognize the entailment T-H pairs which must be judged using inference. This is our improvement over the previous work.

Abstract

Traditional approaches to Chinese Semantic Role Labeling (SRL) almost heavily rely on feature engineering. Even worse, the long-range dependencies in a sentence can hardly be modeled by these methods. In this paper, we introduce bidirectional recurrent neural network (RNN) with long-short-term memory (LSTM) to capture bidirectional and long-range dependencies in a sentence with minimal feature engineering. Experimental results on Chinese Proposition Bank (CPB) show a significant improvement over the state-of-the-art methods. Moreover, our model makes it convenient to introduce heterogeneous resource, which makes a further improvement on our experimental performance.

1 Introduction

Semantic Role Labeling (SRL) is defined as the task to recognize arguments for a given predicate and assign semantic role labels to them. Because of its ability to encode semantic information, there has been an increasing interest in SRL on many languages (Gildea and Jurafsky, 2002; Sun and Jurafsky, 2004). Figure 1 shows an example in Chinese Proposition Bank (CPB) (Xue and Palmer, 2003), which is a Chinese corpus annotated with semantic role labels.

Traditional approaches to Chinese SRL often extract a large number of handcrafted features from the sentence, even its parse tree, and feed these features to statistical classifiers such as CRF, MaxEnt and SVM (Sun and Jurafsky, 2004; Xue, 2008; Ding and Chang, 2008; Ding and Chang, 2009; Sun, 2010). However, these methods suffer from three major problems. Firstly, their performances are heavily dependent on feature engineering, which needs domain knowledge and laborious work of feature extraction and selection. Secondly, although sophisticated features are designed, the long-range dependencies in a sentence can hardly be modeled. Thirdly, a specific annotated dataset is often limited in its scalability, but the existence of heterogenous resource, which has very different semantic role labels and annotation schema but related latent semantic meaning, can alleviate this problem. However, traditional methods cannot relate distinct annotation schemas and introduce heterogeneous resource with ease.

WORD:	警察	正在	调查	事故	原因
	Police	now	investigate	accident	cause
ROLE:	[A0]	[AM-TMP]	REL	[A1]	
IOBES:	S-A0	S-AM-TMP	REL	B-A1	E-A1

Figure 1: A sentence with semantic roles labeled from CPB.

Concerning these problems, in this paper, we propose bidirectional recurrent neural network (RNN) with long-short-term memory (LSTM) to solve the problem of Chinese SRL. Our approach makes the following contributions:

- We formulate Chinese SRL with bidirectional LSTM RNN model. With bidirectional RNN, the dependencies in a sentence from both directions can be captured, and with LSTM architecture, long-range dependencies can be well modeled. The test results on the bechmark dataset CPB show a significant improvement over the state-of-the-art methods.
- Compared with previous work that relied on a huge number of handcrafted features, our model can achieve much better performance only with minimal feature engineering.
- The framework of our model makes the introduction of heterogeneous resource efficient

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1626–1631,
Lisbon, Portugal, 17-21 September 2015.

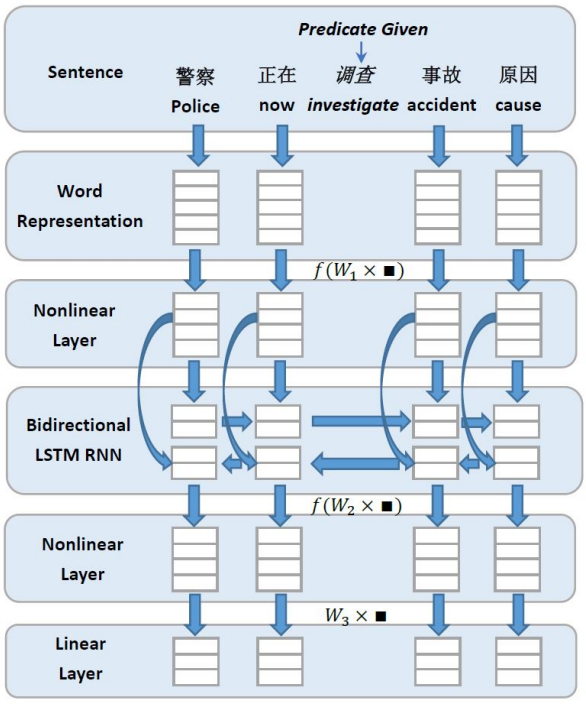

Figure 2: The model architecture.

and convenient, and this can further improve our experimental performance.

2 Chinese SRL with RNN

Following previous work, we regard Chinese SRL as a task of sequence labeling, which assigns a label for each word in the sequence. To identify the boundary information of semantic roles, we adopt the IOBES tagging schema for the labels as shown in Figure 1. For sequence labeling, it is important to capture dependencies in the sequence, especially for the problem of SRL, where the semantic role label for a word not only relies on its local information, but also is determined by long-range dependencies from other words. The advantage of RNN is the ability to better capture the contextual information, which is beneficial to capture dependencies in SRL. Moreover, we enrich the basic RNN model with bidirectional LSTM RNN, which can model bidirectional and long-range dependencies simultaneously.

2.1 Model Architecture

The architecture of our approach is illustrated in Figure 2. Given a sentence, we first get representation for each word to be labeled. Then after a nonlinear transformation, bidirectional LSTM RNN layer is designed to combine the local information of a word and its contextual information from both directions. With a nonlinear layer to form more complex features, a linear output layer follows. For each word to be labeled, there is an output vector, whose each dimension is a score corresponding to a kind of semantic role label.

2.2 Word Representation

Word representation captures the features locally embedded around the word. The features used in our work are: the current word, the current POS tag, the predicate, left and right words, left and right POS tags, distance to the predicate. Note that these features are all basic information about the word, hence we alleviate the heavy job of feature engineering. All these features are introduced by embeddings. After concatenation, we get the word representation feature vector.

To get more complex features, we adopt a nonlinear transformation:

$$z_t = f(W_1 x_t) \quad 1 \leq t \leq N$$

where x_t is the word representation of the t-th word, $W_1 \in \mathbb{R}^{n_1 \times n_0}$, n_0 is the length of word representation, f is an activation function and we use *tanh* in our experiments, N is the number of words to be labeled in the sequence.

2.3 Bidirectional LSTM RNN

Representation z_t only captures the local information. Here we adopt RNN to capture contextual information. Traditional RNN has the problem of vanishing or exploding gradients, which means the long-term dependencies can hardly be modeled. LSTM is designed to mitigate this problem.

At each word position t, the LSTM RNN computes six internal vectors: $\widetilde{C}$, g_i, g_f, g_o, C_t and h_t for the memory cell, which is a structure used in LSTM to store information. $\widetilde{C}$ computes the candidate value for the state of the memory cell:

$$\widetilde{C} = f(W_c z_t + U_c h_{t-1} + b_c)$$

The activations of the memory cell's input gate, forget gate and output gate are defined as:

$$g_j = \sigma(W_j z_i + U_j h_{t-1} + b_j)$$

where j stands for i, f or o. σ is taken $sigmoid$ in experiments. Then we can compute C_t, the memory cell's new state at position t:

$$C_t = g_i \odot \widetilde{C} + g_f \odot C_{t-1}$$

where $\odot$ indicates elementwise vector multiplication. With the new state of the memory cell, we can compute the value of output state h_t:

$$h_t = g_o \odot f(C_t)$$

h_t contains the information not only from local representation z_t, but also from previous output state h_{t-1}, hence can capture dependencies in a sentence. Because the dependencies forward and backward are both important to label semantic roles, we extend LSTM with bidirectional approach, resulting in:

$$a_t = [\overrightarrow{h_t}^T, \overleftarrow{h_t}^T]^T \quad 1 \leq t \leq N$$

Further, a nonlinear transformation follows:

$$v_t = f(W_2 a_t) \quad 1 \leq t \leq N$$

where $W_2 \in \mathbb{R}^{n_3 \times n_2}$, n_2 is the dimension of a_t.

2.4 Output Representation

For each word to be labeled, we adopt linear transformation to get the output vector o_t:

$$o_t = W_3 v_t \quad 1 \leq t \leq N$$

$W_3 \in \mathbb{R}^{n_4 \times n_3}$, where n_4 is the number of semantic role labels in IOBES tagging schema. Therefore, the resulting vector o_t for the t-th word is of length n_4, and each dimension corresponds to the score of a certain semantic role label.

2.5 Training Criteria

Because there are dependencies among word labels in a sentence, isolated training approach which independently considers each word will be inappropriate. Therefore, we adopt sentence tag approach, in which we encourage the correct path of tags, while discouraging all other valid paths.

Given all our training examples:

$$T = (x^{(i)}, y^{(i)})$$

where $x^{(i)}$ denotes the i-th training sentence, $y^{(i)}$ is the corresponding N_i (the number of words to be labeled) dimension vector, which indicates the correct path of tags, and $y_t^{(i)} = k$ means the t-th word has the k-th semantic role label. The score of $x^{(i)}$ along the path $y^{(i)}$ is defined as follows:

$$s(x^{(i)}, y^{(i)}, \theta) = \sum_{t=1}^{N_i} o_{t y_t^{(i)}}$$

where θ is an ensemble of all the parameters in the network.

The log likelihood with a single sample is then:

$$\begin{aligned} logp(y^{(i)}|x^{(i)}, \theta) &= log \frac{\exp\left(s(x^{(i)}, y^{(i)}, \theta)\right)}{\sum_{y\prime} \exp\left(s(x^{(i)}, y\prime, \theta)\right)} \\ &= s(x^{(i)}, y^{(i)}, \theta) - log \sum_{y\prime} \exp\Big(s(x^{(i)}, y\prime, \theta)\Big) \end{aligned}$$

where $y\prime$ ranges from all the valid paths of tags.

The full log likelihood of the whole training corpus is as follows:

$$J(\theta) = \sum_{i=1}^{T} logp(y^{(i)}|x^{(i)}, \theta)$$

To compute the network parameter θ, we maximize the log likelihood $J(\theta)$ using stochastic gradient ascent in the experiments.

2.6 Introducing Heterogeneous Resource

A single annotated corpus with semantic role labels is often limited in its scalability. Heterogeneous resource in our work is defined as another dataset annotated with semantic roles, which also provides predicate-argument structure annotation, but uses very different semantic role labels and annotation schema. However, in spite of these differences, the latent semantic meaning may be highly correlated. Therefore, the introduction of heterogeneous data can alleviate the problem of scalability with a single annotated corpus.

Traditional approaches hardly concern the existence of heterogeneous resource and are difficult to relate different annotation schemas, but in the framework of our model, heterogeneous data can be introduced in a relatively convenient way. Specifically, we learn a bidirectional LSTM RNN model based on heterogeneous data, then with the fine-tuned word embeddings we initialize the model on our experimental dataset. The principle behind is that the words almost convey the same semantic meaning albeit in distinct annotation schemas. The introduction of heterogenous resource in this way is efficient and can lead to performance improvement on our experiment.

3 Experiments

We conduct experiments to compare our model with previous landmark methods on the benchmark dataset CPB for Chinese SRL. The result

reveals that even with our basic model, which does not resort to other resources, our approach can significantly outperform all of the competitors. Moreover, we enrich our work with introducing heterogenous resource to make a further improvement on performance. And the result also shows the influence of heterogeneous resource is more evident than the standard method of pre-training for word embeddings.

3.1 Experimental Setting

To facilitate comparison with previous work, we conduct experiments on the standard benchmark dataset CPB 1.0.[1] We follow the same data setting as previous work (Xue, 2008; Sun et al., 2009), which divided the dataset into three parts: 648 files (from chtb_081.fid to chtb_899.fid) are used as the training set. The development set includes 40 files, from chtb_041.fid to chtb_080.fid. The test set includes 72 files, which are chtb_001.fid to chtb_040.fid, and chtb_900.fid to chtb_931.fid. We use another annotated corpus[2] with distinct semantic role labels and annotation schema, which is designed by ourselves for other projects, as heterogeneous resource. This labeled dataset has 17,308 annotated sentences, and the semantic roles concerned are like "agent" and "patient", resulting in 21 kinds of types, which are all distinct from the semantic roles defined in CPB. We use the development set of CPB for model selection, and the hyper parameter setting of our model is reported in Table 1.

3.2 Chinese SRL Performance

Table 2 summarizes our SRL performance compared to previous landmark results. The work of Collobert and Weston (2008) was conducted on English SRL, we implement their approach on CPB for comparison. As indicated by this table, our approach significantly outperforms previous state-of-the-art methods even with all parameters randomly initialized, that is without introducing other resources. This result can prove the ability of our model to capture useful dependencies for Chinese SRL with minimal feature engineering.

Further, we conduct experiments with the introduction of heterogenous resource. Previous work found that the performance can be improved by pre-training the word embeddings on large unlabeled data and using the obtained embeddings to make initialization. With the result in Table 2, it is true that these pre-trained word embeddings have a good effect on our performance (we use *word2vec*[3] on Chinese Gigaword Corpus for word pre-training). However, as shown in Table 2, compared to standard pre-training, the influence of heterogenous data is more evident. We can explain this difference via the distinction between these two kinds of methods for performance improvement. The information provided by standard pre-training with unlabeled data is more general, while that of heterogenous resource is more relevant to our task, hence is more informative and evident.

4 Related Work

Semantic Role Labeling (SRL) was first defined by Gildea and Jurafsky (2002), who presented a a system based on statistical classifiers trained on hand-annotated corpus FrameNet. Sun and Jurafsky (2004) did the preliminary work on Chinese SRL without any large semantically annotated corpus and produced promising results. After CPB (Xue and Palmer, 2003) was built, Xue and Palmer (2005) and Xue (2008) produced more complete and systematic research on Chinese SRL. Ding and Chang (2009) established a

[1] https://catalog.ldc.upenn.edu/LDC2005T23

[2] This Chinese dataset is available on request.

[3] https://code.google.com/p/word2vec/

word based Chinese SRL system, which is quite different from the previous parsing based ones. Sun et al. (2009) extended the work of Chen et al. (2006), performed Chinese SRL with shallow parsing, which took partial parses as inputs. Yang and Zong (2014) proposed multi-predicate SRL, which showed improvements both on English and Chinese Proposition Bank. Different from most work relying on a large number of handcrafted features, Collobert and Weston (2008) proposed a convolutional neural network for SRL. Their approach achieved competitive performance on English SRL without requiring task specific feature engineering. However, by max-pooling operation, the convolution approach only preserved the most evident features in a sentence, thus can only weakly model the dependencies. With our bidirectional LSTM RNN model, this problem can be well alleviated.

Our model is based on recurrent neural network (RNN), which uses iterative function loops to store contextual information. To remedy the problem of vanishing and exploding gradients when training the standard RNN, Hochreiter and Schmidhuber (1997) proposed long-short-term memory (LSTM), which has been shown capable of storing and accessing information over very long time spans. Bidirectional RNN (Schuster and Paliwal, 1997) and bidirectional LSTM RNN (Graves et al., 2005) are the extensions of RNN and LSTM RNN with the capability of capturing contextual information from both directions in the sequence. In recent years, RNN has shown the state-of-the-art results in many NLP problems such as language modeling (Mikolov et al., 2010) and machine translation (Sutskever et al., 2014; Bahdanau et al., 2014). Sundermeyer et al. (2014) also used bidirectional LSTM RNN model to improve strong baselines when modeling translation. More recently, Zhou and Xu (2015) proposed LSTM RNN approach for English Semantic Role Labeling, which shared similar idea with our model. However, the features used and the network architecture were different from ours. Moreover, it is delightful that our work can achieve a rather good result with a relatively simpler model architecture.

5 Conclusion

In this paper, we formulate Chinese SRL problem with the framework of bidirectional LSTM RNN model. In our approach, the bidirectional and long-range dependencies in a sentence, which are important for Chinese SRL, can be well modeled. And with the framework of deep neural network, the heavy job of feature engineering is much alleviated. Moreover, our model makes the introduction of heterogenous data, which can alleviate the problem of scalability with a single annotated corpus, more convenient. Experiments show that our approach achieves much better results than previous work, and the introduction of heterogenous resource can make further improvement on performance.

Abstract

Due to the commonality in natural language, negation focus plays a critical role in deep understanding of context. However, existing studies for negation focus identification major on supervised learning which is time-consuming and expensive due to manual preparation of annotated corpus. To address this problem, we propose an unsupervised word-topic graph model to represent and measure the focus candidates from both lexical and topic perspectives. Moreover, we propose a document-sensitive biased PageRank algorithm to optimize the ranking scores of focus candidates. Evaluation on the *SEM 2012 shared task corpus shows that our proposed method outperforms the state of the art on negation focus identification.

1 Introduction

Negation is used to reverse the polarity of part of statements that are otherwise affirmative by default (Blanco and Moldovan, 2011), which is common in natural language. *Negation focus* is defined as the special part in sentence, which is most prominently or explicitly negated by a negative expression. For example, sentence (1) could be interpreted as *He stopped, but not until he got to Jackson Hole* with a positive part *he stopped* and a negative part *until he got to Jackson Hole*.

(1) *He did**n't** stop until he got to Jackson Hole.*

Our previous work (Zou et al., 2014) showed that contextual information plays a critical role on negation focus identification. For better illustration of this conclusion, they manually analyze the evidences for 100 negation focuses. It is surprising that 77 focuses can be identified with help of contextual information. This indicates that negation focus is often related with what authors repeatedly states in context. In this paper, we thus focus on graph-based ranking methods (Mihalcea and Tarau, 2004) which first build a word graph according to word co-occurrences within document, and then use random walk algorithms (e.g., PageRank) to measure word importance.

However, for negation focus identification, the graph-based methods may suffer from the following two problems: (a) the words in graph-based methods are strongly connected by co-occurrence rather than semantic content, which do not necessarily guarantee that they are relevant to the negation focus in context; and (b) identifying a negation focus may be affected by not only the relatedness of surrounding words but also its importance in current document which is not considered in standard random walk algorithms.

To address the above problems, we propose a word-topic graph model by adding a topical layer on the original word layer to capture the semantic clues from both lexical and topic perspectives. Besides, a document-sensitive PageRank algorithm is also proposed to optimize the graph model by considering the document's major topics. Experimental results indicate that our word-topic graph model outperforms other baseline methods. Moreover, our model is unsupervised and requires only un-annotated text for training.

The rest of this paper is organized as follows. Section 2 overviews the related work. Section 3 introduces our word-topic graph model with contextual discourse information. Section 4 reports the experimental results and analysis. Finally, we conclude our work in Section 5.

2 Related Work

So far there is little work on negation focus identification, which was pioneered by Blanco and Moldovan (2011) who investigated the negation phenomenon in semantic relations and proposed a supervised learning approach to identify the focus of a negation expression. However, although Morante and Blanco (2012) proposed negation focus identification as one of the *SEM'2012 shared tasks, only one team (Rosenberg and Bergler, 2012) participated in. They identified negation focus by three heuristic rules.

Our previous work (Zou et al., 2014) demonstrates the effectiveness of contextual information for negation focus identification. On this basis, we further optimize the graph model in both the topical layer and the PageRank algorithm in this paper.

In recent years, many algorithms are widely used to incorporate word graph models and topical information within random walk. Our work is originally inspired by Liu et al. (2010). Their method runs decomposed Topical PageRank (TPR) for each topic separately, and then calculates the word scores with respect to different topics. When setting the edge weights, only word co-occurrence is considered. Different from their work, our word-topic graph model runs on a two-layers (word layer and topical layer) graph model and sets the edge weights by measuring both word similarity and topic distribution.

3 Methods

The word-topic graph model consists of word layer and topical layer, as shown in Figure 1. While the word layer is constructed according to word co-occurrence within a sliding window, which expresses the cohesion relationship between words in the context, the topical layer is to refine the graph model over the discourse contextual information.

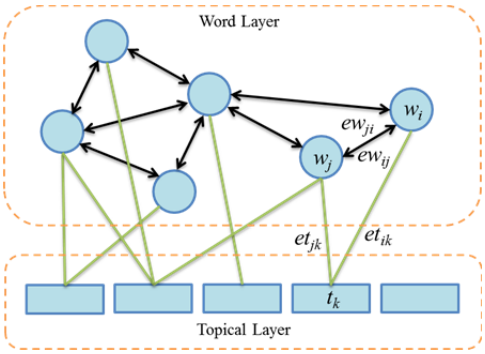

Figure 1. Word-topic graph model.

3.1 Constructing Word Layer

The word layer is constructed according to word co-occurrence within a sliding window, which expresses the cohesion relationship between words in the context. It can be denoted as $L_{word}(W, E_w)$, where vertex set $W=\{w_i\}$ represents the set of words in one document and link set $E_w=\{e_{ij}|w_i,\ w_j \in W\}$ represents the set of directed edges between these words. Note that only content words are considered. Namely, we consider nouns, verbs, adjectives, and adverbs.

The link directions are added from the first word pointing to other words within a sliding *s*-width sentence window. Directed edge ew_{ij} is weighted to represent the relatedness between word w_i and word w_j in a document with transition probability $P_w(j|i)$ from i to j, which is normalized as follows:

$$P_w(j \mid i) = \frac{sim(w_i, w_j)}{\sum_{k:w_i \to w_k} sim(w_i, w_k)}, \quad (1)$$

where the denominator represents the out-degree of vertex w_i , and $sim(w_i,w_j)$ denotes the similarity between word w_i and w_j. In this paper, both corpus-based and knowledge-based methods are evaluated to calculate the similarity between words.

- Word co-occurrence. If word w_i and word w_j occur in a *s*-width sliding sentence window, $sim(w_i,w_j)$ increases 1.
- WordNet similarity (Miller, 1995). In this paper, we adopt the *path similarity* function to measure relatedness of nouns and verbs, and adopt the *similar to* function to measure relatedness of adjectives and adverbs by using the NLTK toolkit[1] (Bird et al., 2009).

Note that $sim(w_i,w_i) = 0$ to avoid self-transition, and $sim(w_i,w_j)$ and $sim(w_j,w_i)$ may not be equal.

3.2 Preliminaries for Topical Layer

To infer the latent topic distributions of words, Latent Dirichlet Allocation (LDA) (Blei et al., 2003), a typical of topic model, is directly applied. By the set of topics which derive from a corpus, we can obtain:

- $P(t|w)$, the probability of topic t given word w, which indicates how much that word w focuses on topic t, and
- $P(t|d)$, the probability of topic t given document d, which indicates how much that document d focuses on topic t.

[1] http://www.nltk.org/

Then, the similarity between two words or between word w_i and document d can be measured by the similarity between their corresponding topic distributions. Formally, we denote a topic distribution as θ, and measure the similarity by using:

- Dot-product. We consider the topic distributions as vectors and apply the dot-product, a geometrically motivated function, to calculate the similarity:

$$Inner(\theta_{w_i}, \theta_{w_j}) = \theta_{w_i} \cdot \theta_{w_j} = \sum_{t_k \in T} P(t_k \mid w_i) \cdot P(t_k \mid w_j), \quad (2)$$

$$Inner(\theta_{w_i}, \theta_d) = \theta_{w_i} \cdot \theta_d = \sum_{t_k \in T} P(t_k \mid w_i) \cdot P(t_k \mid d). \quad (3)$$

- Kullback Leibler (KL) divergence (Lin, 1991). Considering the asymmetry (Eq.(4)), we obtain a symmetrized measure by Eq.(5).

$$D(\theta_i, \theta_j) = \sum_{t_k \in T} P_i(t_k) \log_2 \frac{P_i(t_k)}{P_j(t_k)}. \quad (4)$$

$$D_{KL}(\theta_i, \theta_j) = D(\theta_i, \theta_j) + D(\theta_j, \theta_i). \quad (5)$$

Note that $D_{KL}(\theta_i, \theta_j)$ is undefined if $P_i(t_k)=0$ or $P_j(t_k)=0$ for any $t_k \in T$. For this reason, only the topics which make both $P_i(t_k)\neq 0$ and $P_j(t_k)\neq 0$ are adopted to calculate the KL divergence between two topic distributions.

3.3 Word-Topic Graph Model

The word layer can well capture the relatedness between words, but just partially model the negation focus since it is more directly related with topic than content. Therefore, we add one more layer to refine the graph model over the topical information, as shown in Figure 1. Formally, the word-topic graph is defined as $G_{topic}(W, T, E_w, E_t)$, where vertex set $T=\{t_i\}$ represents the set of topics in all of documents in corpus and link set $E_t = \{et_{ij} | w_i \in W, t_j \in T\}$ represents the set of undirected edges between words and topics.

Considering that the topical layer can provide more contextual semantic information, we refine the relatedness between words by using a topical transition probability $P_t(j|i)$ which is calculated by two kinds of measurements:

$$P_t(j \mid i) = \frac{sim(\theta_{w_i}, \theta_{w_j})}{\sum_{k: w_i \to w_k} sim(\theta_{w_i}, \theta_{w_k})}. \quad (6)$$

Here, the similarity is measured by the dot-product or the KL divergence (using reciprocals). On this basis, the word transition probability $P_w(j|i)$ is updated as following:

$$P_w^{'}(j \mid i) = \mu \cdot P_w(j \mid i) + (1-\mu) \cdot P_t(j \mid i). \quad (7)$$

where $\mu \in [0,1]$ is the coefficient controlling the relative contributions from the lexical information and the topical information.

Moreover, the weights of word vertices are calculated by a PageRank algorithm. In standard PageRank (Page et al., 1998), words are set to be the same value, which indicates there is equal importance to all of words in a document. However, intuitively, we should allocate higher weights to those words with high relevance to the document. Therefore, we assign a document-sensitive value to word w_i:

$$R_d(w_i) = \frac{sim(\theta_{w_i}, \theta_d)}{\sum_{w_k \in W} sim(\theta_{w_k}, \theta_d)} \quad (8)$$

and calculate the weights of word vertices iteratively by using a biased PageRank algorithm:

$$Score^{(n+1)}(w_i) = \lambda \sum_{j \neq i} Score^{(n)}(w_j) P_w^{'}(j \mid i) + (1-\lambda) R_d(w_i). \quad (9)$$

All of the PageRank algorithms are terminated when the number of iterations reaches 100 or the difference of each vertex between consecutive iterations is less than 0.001.

Finally, according to the annotation guidelines (Blanco and Moldovan, 2011), the focus is always a full text of a semantic role. Thus, we select all of semantic roles in sentence as candidate focuses for ranking. The ranking score of a candidate focus f is computed by averaging the scores of all words inside the candidate:

$$score_{avg}(f) = \frac{\sum_{w_i \in f} score(w_i)}{Count(f, \bullet)}, \quad (10)$$

where $count(f,\bullet)$ denotes the number of content words within the candidate. Then the top ranked candidate is chosen as the negation focus.

4 Experimental Results

To evaluate the performance of our word-topic graph model for negation focus identification, we carry out experiments on the *SEM'2012 shared task corpus[2]. As a freely downloadable resource, the corpus is annotated on top of PropBank, which uses the WSJ section of the Penn TreeBank. In particular, negation focus annotation on this corpus is restricted to verbal negations (Blanco and Moldovan, 2011). In total, this corpus provides 3,544 instances of negation focus annotations. Although for each instance, the corpus only provides the current sentence, the previous and next sentences as its context, we sort to

[2] http://www.clips.ua.ac.be/sem2012-st-neg/

the Penn TreeBank[3] to obtain the corresponding document as its discourse context. For fair comparison, we adopt the same partition as *SEM'2012 shared task in our experiments.

We evaluate our results in terms of accuracy. To see whether an improvement is statistically significant, we conduct significance testing using the paired t-test.

For estimating the topical transition probability $P_t(j|i)$ and the document-sensitive value $R_d(w_i)$, we employ GibbsLDA++[4], an LDA model using Gibbs Sampling technique for parameter estimation and inference (Griffiths, 2002). We set the parameters $\alpha = 50/T$ and $\beta = 0.1$ as Griffiths and Steyvers (2004) suggested.

4.1 Influences of Parameters

There are two major parameters in our models that may influence the performance, including: (a) the damping factor μ of the word transition probability $P'_w(j|i)$ (Eq.(7)) and (b) the damping factor λ of the word-topic graph model (Eq.(9)).

Figure 2 shows the accuracy when varying μ from 0.1 to 0.9 with an interval of 0.1 and when varying λ from 0.05 to 1 with an interval of 0.05. We notice that the best performance is achieved when μ=0.6. It indicates that the direct lexical information contributes slightly more than the topical information. The results also show the complementarity between these two kinds of information on negation focus identification.

For λ, it has very little, if any, effect on performance, when λ is set from 0.5 to 0.85. It indicates that the contextual information (the first term in Eq.(9)) contributes more than the document information (the second term in Eq.(9)) on negation focus identification.

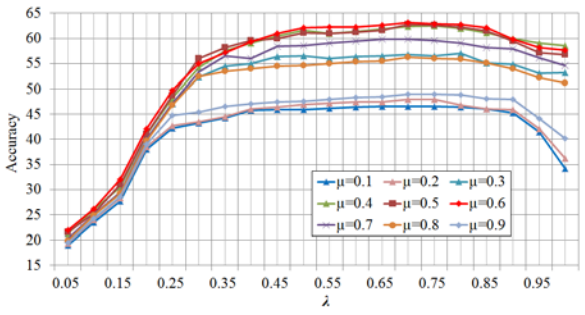

Figure 2. Influence of the damping factors μ and λ.

Moreover, the results also show that these two parameters have little impact in a certain range on performance (μ:0.4~0.6; λ:0.5~0.85), which suggests that the approach is robust to a certain extent. Therefore, we set μ=0.6 and λ=0.7 in the following experiments.

Besides, we also evaluate the other minor parameters in our model. Due to space limit, we do not report all of results here and set parameters to the following values: setting window size s=1 (the previous and next sentences) and the number of topic T=40, adopting the word co-occurrence similarity to calculate the similarity between words, and using dot-product to measure both $P_t(j|i)$ and $R_d(w_i)$.

4.2 Comparison with Other Methods

In the word-topic graph models, two primary improvements are proposed: (a) updating the word transition probability $P_w(j|i)$ by adding a topical layer ("TL"), and (b) assigning a document-sensitive value to word node ("DS").

model	Acc.
WLM	52.61
WTGM (TL)	65.74
WTGM(TL+DS)	69.39

Table 1. Performance of the word-topic graph model.

Table 1 shows that the word-topic graph model (WTGM) is significantly better (+16.78%, p<0.01) than the graph model with only word layer (WLM), which justifies the effectiveness of the topical layer. In addition, the results also indicate that the word-topic graph model not only takes the topical information into account ("TL"), but also considers the semantic relationship in current document ("DS").

We select two supervised baseline methods to compare with our word-topic graph model. One is a decision tree-based system described in Blanco and Moldovan (2011), and the other one is a SVM-based system which takes advantage of both syntactic features and contextual features (Zou et al., 2014).

system	Acc.
B&M(2011)	63.20
Zou et al.(2014)	67.14
Ours	69.39

Table 2. Comparison Results.

Table 2 shows that our word-topic graph model performs significantly better than the two others by 6.19% (p<0.01) and 2.25% (p<0.01), respectively. The results support our viewpoint that the topical information in context can help to find the negation focus, and the word-topic graph model we proposed is effective. Moreover, it is also worth noting that our method is

[3] http://www.cis.upenn.edu/~treebank/
[4] http://gibbslda.sourceforge.net/

unsupervised, which does not need the prior knowledge for training, while the other two supervised baselines employ the golden features, such as the POS tag, constituent tree, and dependency tree.

5 Conclusion

In this paper, we propose an unsupervised word-topic graph model, which represents and measures the word importance by using contextual information from both lexical and topical perspectives. And then, we propose a document-sensitive biased PageRank algorithm to calculate the ranking scores of negation focus candidates. Experimental results show that our method achieves better performance than other baselines without any annotated data.

The main shortcoming of our method is that not all of negation focus can be identified by the context. As our statistics, at least 17% of samples are hard to be determined by human beings when ignoring the information in current sentence. Therefore, in future work, we will focus on investigating an effective method to integrate the local lexical/syntactic information and the global contextual discourse information.

Reverse-engineering Language: A Study on the Semantic Compositionality of German Compounds

Corina Dima

corina.dima@uni-tuebingen.de

Abstract

In this paper we analyze the performance of different composition models on a large dataset of German compound nouns. Given a vector space model for the German language, we try to reconstruct the observed representation (the corpus-estimated vector) of a compound by composing the observed representations of its two immediate constituents. We explore the composition models proposed in the literature and also present a new, simple model that achieves the best performance on our dataset.

1 Introduction

Vector space models of language like the ones presented in (Collobert et al., 2011b; Mikolov et al., 2013; Pennington et al., 2014) create good representations for the *individual words* of a language. However, the words in a language can be combined into infinitely many distinct, well-formed *phrases* and *sentences*. Creating meaningful, reusable representations for such longer word sequences is still an open problem.

In this paper we focus on building representations for syntactic units *just above the word level*, by exploring compositional models for *compounds*. Bauer (2001) defines a compound as "a lexical unit made up of two or more elements, each of which can function as a lexeme independent of the other(s) in other contexts" (e.g. *apple tree*). The vast majority of compounds are compositional, i.e. we can understand the meaning of the compound if we know the meaning of its constituent words. We would like to equip the vector space model with a composition function able to construct a *composite* representation for *apple tree* from the representations of *apple* and *tree*. The composite representation should ideally be indistinguishable from its *observed* representation, i.e. the representation learned directly by the language model if the compound is part of the dictionary.

We situate our investigations in the context of the German language, a language where compounds represent an important fraction of the vocabulary. Baroni et al. (2002) analyzed the 28 million words German APA news corpus and discovered that compounds account for 47% of the word types but only 7% of the overall token count, with 83% of compounds having a corpus frequency of 5 or lower. The high productivity of the compounding process makes the compositional approach the most tractable way to create meaningful representations for all the compounds that have been or will be coined by the speakers of the German language.

German compounds have a strategic advantage for our study: they are generally written as a contiguous word, irrespective of how many constituents they have. Our example English compound, *apple tree*, translates into the German compound *Apfelbaum*, with the head *Baum* "tree" and the modifier *Apfel* "apple". Because the compound is written as a single word, we can directly learn the representations for the compound and for its constituents. Given a large dataset of German compounds together with their immediate constituents, and the corresponding distributed representations for each of the individual words, one can try to reverse-engineer the compounding process and learn the parameters of a function that combines the representation of the constituents into the representation of the compound. More formally, we are interested in learning a composition function f such that

$$c^{comp} = f(m^{obs}, h^{obs})$$

where $c^{comp} \in \mathbb{R}^n$ is the composite representation of the compound and $m^{obs}, h^{obs} \in \mathbb{R}^n$ are the observed representations of its modifier and its head. The function should minimize J, the mean squared error between the composite (c^{comp}) and

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1637–1642,
Lisbon, Portugal, 17-21 September 2015.

the observed (c^{obs}) representations of the $|C|$ compounds in the training set:

$$J = \sum_{i=1}^{|C|} \frac{1}{n} \sum_{j=1}^{n} (c_{ij}^{comp} - c_{ij}^{obs})^2$$

Several compositionality models have already been proposed in the literature (Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Socher et al., 2012). In this paper we evaluate several of the proposed composition functions and also present a new composition model which outperforms all previous models on a dataset of German compounds.

2 Word Representations and Compounds Dataset

We trained 4 vector space language models for German (with 50, 100, 200 and 300 dimensions respectively) using the GloVe package (Pennington et al., 2014) and a 10 billion token raw-text corpus extracted from the DECOW14AX corpus (Schäfer, 2015). We use a vocabulary of 1,029,270 (1M) words, obtained by selecting all the words with a minimum frequency of 100 (the full vocabulary had 50M unique words). We used the default GloVe training parameters, the only modifications being the use of a symmetric context when constructing the co-occurence matrix (10 words to the left and to the right of the target word) and training each model for 15 iterations. All the vector spaces were normalized to the $L2$-norm, first across features then across samples using *scikit-learn* (Pedregosa et al., 2011).

The German compounds dataset used in the experiments is a subset of the 54759 compounds available in GermaNet 9.0[1]. The compounds in the list were automatically split and manually post-corrected (Henrich and Hinrichs, 2011). Each entry in the list is a triple of the form (compound, modifier, head). We filtered the entries in the list, keeping only those where all three words have a minimum frequency of 500 in the support corpus used to create the vector space representations. The reason for the filtering step is that a "well-learned" representation (based on a sufficiently large number of contexts) should allow for a more accurate reconstruction than a representation based only on a few contexts. The filtered dataset contains 34497 entries. This dataset was randomized and partitioned into `train`, `test` and `dev` splits according to the 70-20-10 rule. The dataset contains 8580 unique modifiers and heads, and a dictionary of 41732 unique words. 1345 compounds appear as the modifier or head of another compound.

3 12 ways to Represent A Compound

We adopt a notation similar to the one introduced in (Mitchell and Lapata, 2010), where the composite representation p is the result of applying a composition function f to the vectors u and v. In this study we tested the following composition functions:

1. $p = v$, the second constituent of the compound
2. $p = u$, the first constituent of the compound
3. $p = u \odot v$, component-wise vector multiplication
4. $p = (u \cdot u)v + (\lambda - 1)(u \cdot v)u$, dilation
5. $p = 0.5u + 0.5v$, vector addition
6. $p = \lambda u + \beta v$, weighted vector addition, where the λ and β are estimated using the training set. Models 1 through 6 were introduced in (Mitchell and Lapata, 2010).
7. $p = Uv$, where $v \in \mathbb{R}^n$ is the vectorial representation of the head word (given) and $U \in \mathbb{R}^{n \times n}$ is a matrix representation for the modifier, estimated with the help of the training data. The model estimates one matrix for each word that is used as a modifier. Referred to as *alm* in (Baroni and Zamparelli, 2010) and as *Lexfunc* in (Dinu et al., 2013b).
8. $p = M_1 u + M_2 v$, where $M_1, M_2 \in \mathbb{R}^{n \times n}$ are two matrices that modify the first and the second constituent vectors, respectively. In contrast to the previous model, this model estimates just one matrix for all the modifiers and one matrix for all the head words. Refered to as EAM in (Zanzotto et al., 2010) and as *Fulladd* in (Dinu et al., 2013b).
9. $p = g(W[u; v])$, where: $[u; v] \in \mathbb{R}^{2n \times 1}$ is the concatenation of the individual word vectors; $W \in \mathbb{R}^{n \times 2n}$ is a global matrix that: (i) combines the individual dimensions of the concatenated input vector $[u; v]$; (ii) brings the composite representation back into the $\mathbb{R}^{n \times 1}$ space; g is an element-wise function, in our experiments the hyperbolic tangent *tanh*. Introduced in (Socher et al., 2010).
10. $p = g(W[Vu; Uv])$. Introduced in (Socher

et al., 2012), it is a generalization of model 7. Each word is represented using an $\mathbb{R}^{n \times n}$ matrix and a $\mathbb{R}^n$ vector. The vectors are given, while the matrices are estimated using the training data. Referred to as *Fulllex* in (Dinu et al., 2013b).

11. $p = u \odot u' + v \odot v''$, the additive mask model (*Addmask*) and
12. $p = g(W[u \odot u'; v \odot v''])$, the global matrix mask model (*Wmask*), both presented in subsection 3.1.

Models 1 through 8 were tested using the implementations available in the DISSECT toolkit (Dinu et al., 2013a). As a side note, the *Lexfunc* implementation in DISSECT does not produce a composite representation for 11.5% of the our test data, where a word does not appear as a modifier during training. Therefore, we reimplemented the *Lexfunc* model and solved the missing training material problem by initializing the matrix for all the words in the dictionary with $I + \epsilon$, the identity matrix plus a small amount of Gaussian noise. This type of initialization was proposed by (Socher et al., 2012), and allows the model to back-off to the model $p = v$ when there is no data to estimate the parameters of the modifier matrix. We also reimplemented models 9 and 10, which were used in (Socher et al., 2010; Socher et al., 2012), as the existing implementations are part of a more complex recursive architecture aimed at constructing representations for full sentences.

3.1 The *mask* models

The newly introduced mask models build upon the idea that when a word w enters a composition process, there is some variation in its meaning depending on whether it is the first or the second element of the composition. Think, for instance, of the compounds *company* ***car*** and ***car*** *factory*. In the first case, *car* has its primary denotation, that of a road vehicle. In the second case, what matters more about the *car* is its *product* aspect, the fact that it is an "artifact produced in a factory". A good representation of the word *car* should encode both aspects. Likewise, a good composition model should be able to select from the individual word representations only those aspects that are relevant for the composition process.

We want to give the composition model the possibility to deal with these slight sense variations, so we train, for each word in the dictionary, two *masks*, one for the case when it is the first word in the composition process and one for when it is the second word. The *masks* of the word w represented by $u \in \mathbb{R}^n$ are two vectors $u', u'' \in \mathbb{R}^n$. The mask vectors are initialized with a vector of all ones, $\mathbf{1}$, and estimated with the help of the training data. Each time w is the first word in the composition process, it is represented as the element-wise multiplication of the vector u and the mask u', $u \odot u'$. When w is the second word in the composition, it is represented by the element-wise multiplication of u and the mask u'', $u \odot u''$.

It is important to note that the initial vector representations remain fixed during the learning process. The learning process only affects the mask vectors. The composite representation of a compound like *car factory* is obtained by combining the masked representations, $u_{car} \odot u'_{car}$ and $v_{factory} \odot v''_{factory}$. We tried two different combination methods: (i) $p = u \odot u' + v \odot v''$, called *Addmask* (model 11), where the masked representations are combined via component-wise addition, and (ii) $p = g(W[u \odot u'; v \odot v''])$, called *Wmask* (model 12), where the combination of the masked representations is made via a global matrix $W \in \mathbb{R}^{n \times 2n}$ and a nonlinearity g (*tanh*), similar to model 10.

3.2 Implementing composition models

Models 7, 9 and 10 and the mask models were implemented using neural network architectures in the Torch7 library (Collobert et al., 2011a). We use the mean squared error as a training criterion, and optimize all models using *Adagrad* (Duchi et al., 2011) and a mini-batch of 100 samples. The hyperparameters were chosen by testing different parameter values and evaluating their performance on the `dev` set. To avoid overfitting we used early stopping (Prechelt, 1998). All the implemented models keep the input vectors fixed during the composition process.

Training the mask models entails estimating modifier and head masks for every word in the dictionary $\mathcal{D}$. The two types of masks to be learned can be formalized as two matrices $W_M, W_H \in \mathbb{R}^{n \times |\mathcal{D}|}$, where n is the size of the initial word representations. The masks of the word $w_i \in \mathcal{D}$ are the i^{th} rows in W_M and W_H. In Torch7 such representations can be learned using *lookup table layers* (Collobert et al., 2011b), which map matrix indices to the corresponding row vector.

The masked representation of the modifier is obtained by first feeding the index of the word to LT_{W_M}, the modifier lookup table, to obtain the modifier mask, and then multiplying the modifier mask with the initial representation for the modifier. The masked representation of the head is obtained in a similar manner via a lookup operation in LT_{W_H}, the head lookup table. The *Addmask* and *Wmask* models differ only in the composition method used after the masking process: the masked representations are directly added together in the case of *Addmask* and are passed through a composition matrix $W \in \mathbb{R}^{n \times 2n}$ and a nonlinearity g in the case of *Wmask*. The two matrices W_M, W_H are initialized with all ones and are modified via backpropagation during the training process.

4 Evaluation and Results

The twelve composition models presented in Section 3 were evaluated using word representations of increasing size (described in Section 2). All the models are trained on the `train` split and tested on the `test` split. We used the rank evaluation method proposed by (Baroni and Zamparelli, 2010) for a similar task: first, we generate a composite representation for each of the 6901 compounds in the test set; then, we use the cosine similarity to rank each composite representation with respect to the observed representations of the 41732 unique words in the dataset dictionary. If the observed representation is the nearest neighbour, the composition is assigned the rank 1. Similar to (Baroni and Zamparelli, 2010), we assign the rank 1000 ($\geq$1K) when the observed representation is not one of the nearest 1000 neighbours of the composite representation. We then compute the first, second and third quartiles (Q1, Q2, Q3) across all the compounds in the test set. A Q1 value of 2 means that the first 25% of the data was only assigned ranks 1 and 2. Similarly, Q2 and Q3 refer to the ranks assigned to the first 50% and 75% of data, respectively. The results of our evaluation are displayed in Table 1.

The observed representation of the head (model 1) was used as a strong baseline for the compound composition task. Two of the tested models, multiplicative (model 3) and dilation (model 4) score worse than the head baseline, while the additive models (5 and 6) score only slightly above it. The fact that the worst performing model is the multiplicative model is surprising considering its good performance in previous studies (Mitchell and Lapata, 2010). This might be either a side-effect of the normalization procedure, or a genuine incompatibility of this compositionality model with the vectorial representations produced by GloVe.

The new *Addmask* and *Wmask* models (introduced in Section 3.1) perform very well, with *Wmask* producing the best results on the test dataset across all dimensions. It is interesting to note that the linguistically motivated *Lexfunc* and *Fulllex* models, which build dedicated representations for each individual constituent, are outperformed by a simple model like *Fulladd*, that only learns two modification matrices, one for each position. The explanation is, in our opinion, that the available training material is not enough for training all the parameters of the complex *Lexfunc* and *Fulllex* models, but good enough for the more simple *Fulladd*.

The mask models are computationally cheaper than models like *Lexfunc* and *Fulllex*, as they they only train $2n$ parameters for each word in the vocabulary, and not n^2 parameters like the aforementioned models. They manage to strike a balance and learn a dedicated representation for each constituent with a small number of parameters, thus performing better than the more complex models.

We used non-parametric statistical tests to detect significant differences between the results obtained by the models. We focused our analysis on the best performing 4 models: model 9, which we will label the *Matrix* model, *Fulladd* (model 8), *Addmask* (model 11) and *Wmask* (model 12). The comparison takes into account two separate factors: (i) differences between the models using representations of the same size; (ii) differences in the performance of the same model using representations of different sizes.

A Friedman test on the ranks obtained by the 4 selected models on representations of size 300 showed that there is a significant difference between the models ($p < 0.01$). Pairwise comparisons (using the Wilcoxon signed rank test and Bonferroni corrections) showed that there is a significant difference ($p < 0.01$) between all but one pair of models, namely the *Matrix* and the *Addmask* models ($p = 0.9$). The same test confirmed that there are significant differences in the performance of the best model *Wmask* when using representations of different sizes ($p < 0.01$). Pairwise

comparisons showed that *Wmask* model significantly improves its performance ($p < 0.01$) when using word representations of increasing size (50, 100, 200 and 300 dimensions).

The twelve composition models were also compared in terms of the mean squared error (MSE) objective function, by computing the MSE between the composite and the observed representation of the compounds in the test set. The best scoring models in the rank evaluation were also the best in the MSE evaluation. However, the difference in performance between the best and the worst models was considerably smaller: the MSE of the multiplicative model is only twice as large as the MSE of the best performing *Wmask* model. This is in contrast to the rank evaluation where the multiplicative model assigned the observed representations in the test set only ranks ≥ 1000, while *Wmask* assigned ranks ≤ 25 to 75% of the test data. Additional investigations are necessary to estimate the impact of different objective functions on the performance of compositional models.

5 Comparison to related work

The experiments reported in this paper are, to the best of our knowledge, the first large scale experiments on the composition of German compounds. Other studies (Kisselew et al., 2015; Lazaridou et al., 2013) focused on morphologically complex words in German and English respectively. In terms of the size of the training and test material, our experiments are closest to the adjective-noun experiments in (Baroni and Zamparelli, 2010) and (Dinu et al., 2013b) where the lexical function model performed the best, with lowest reported median ranks (Q2) above 100.

6 Conclusions

Twelve composition models were evaluated on the task of building compositional representations for German compounds. The best results (median rank 6) were obtained by the newly introduced *Wmask* model, $p = g(W[u \odot u'; v \odot v''])$. The results show that it is possible to learn a composition function specific to compounds, an idea which we would like to further explore using existing compound datasets for English (Ó Séaghdha, 2008; Tratz and Hovy, 2010). The implementation of the newly introduced composition methods can be downloaded from the author's website.

Abstract

Events are communicated in natural language with varying degrees of certainty. For example, if you are "hoping for a raise," it may be somewhat less likely than if you are "expecting" one. To study these distinctions, we present scalable, high-quality annotation schemes for event detection and fine-grained factuality assessment. We find that non-experts, with very little training, can reliably provide judgments about what events are mentioned and the extent to which the author thinks they actually happened. We also show how such data enables the development of regression models for fine-grained scalar factuality predictions that outperform strong baselines.

1 Introduction

Interpretation of events—determining what the author claims did or did not happen—is important for many NLP applications, such as news article summarization or biomedical information extraction. However, detecting events and assessing their factuality is challenging. For example, while most non-copular verbs are events, words in general vary with use (e.g. "trade route" vs "*trade* with Iraq"). Events also have widely varying, context-dependent factuality cues, such as event interactions (e.g. "*prevent* easy *access*) and cue words (e.g. "*ordered* to" vs. "*expected* to"). As shown in Figure 1, these are common challenges that a model of event factuality must address.

In this paper, we present new data and models for these tasks, demonstrating that non-experts can provide high-quality annotations which enable fine-grained, scalar judgments of factuality. Unlike previous work, we do not use a detailed specification of exactly what events and factuality classes should be. Instead, we simply ask non-experts to find words describing things that the author claims could have happened, and rate each possibility on a scale of -3 (certainly did not happen) to 3 (certainly did). Figure 1 shows that non-expert workers—when their judgments are aggregated—consistently find a wide range of events and recognize the subtle differences in implied factuality. For example, the event *set* gets a score of 2.6, indicating that it likely but not certainly occurred, since it was *ordered*, whereas the *ordered* event, gets a score of 3.0.

We gather data for event detection and factuality, reusing sentences from the TempEval-3 corpus (Uzzaman et al., 2013). Our approach produces high-quality labels with modest costs. We also introduce simple but highly effective models for both tasks that outperform strong baselines. In

particular, our factuality regression model uses a learning objective that combines the advantages of LASSO and support vector regression, enabling it to effectively consider sparse lexical cues. By providing scalar factuality judgments for events, our models enable more fine-grained reasoning than previously considered. The corpus and learned models are available online.[1]

2 Related Work

While event definitions have been proposed in several prior studies, existing approaches vary in how they model various linguistic forms such as nominal events, stative events, generic events, and light verbs (Pustejovsky et al., 2003; Palmer et al., 2005; Meyers et al., 2004; Kim et al., 2009; Song et al., 2015). Even with a formal and precise account of events, training annotators to learn all such linguistic intricacies remains a practical challenge. Instead of *definition*-driven instructions, we propose *example*-driven instructions and show their effectiveness.

Previous studies have modeled event factuality assessment as a binary (Diab et al., 2009; Prabhakaran et al., 2010) or multi-class (Sauri and Pustejovsky, 2009) classification task, and they relied on expert annotators. A softer representation was proposed and crowdsourced by de Marneffe et al. (2012), who advocated for representing factuality from the reader's perspective as a distribution of categories, but their annotation process requires manual normalization of the text. In contrast, we model factuality from the author's perspective with scalar values, and we have an end-to-end crowdsourced annotation pipeline.

More recently, Soni et al. (2014) investigated a related problem for quoted statements on Twitter, and they also crowdsourced factuality annotations to learn regression models. While their approach is similar, we focus on predicting factuality for events that occur in every sentence. Without the restrictions of their task, we must reason about a larger variety of contextual cues.

Our method of evaluating annotator agreement (Section 3) is related to the crowdsourcing study by Snow et al. (2008), who showed that pooled non-experts can match or outperform single expert annotators. In contrast, we approximate expert judgments by independently sampling and aggregating sets of non-expert judgments.

3 Data Annotation

We use a two-stage annotation pipeline to create the labels shown in Figure 1. Event mentions are first detected, followed by factuality judgments. As motivated in Section 1, we use instructions that are easily understandable by workers with no linguistic training and improve overall quality by aggregating multiple judgments to get the final label.

Event Annotation Given a sentence, we highlight one token at a time and ask workers if it refers to an event. We use the following instructions:

> *We consider events to be things that may or may not occur either in the past, present or future (e.g., earthquake, meeting, jumping, talking, etc.). In some cases, it is not so clear whether a word is referring to an event or not. Consider these harder cases to be events.*

along with 25 example annotations that covered a large variety of cases such as nominals, statives, generic events, light verbs, and non-events. These examples include both toy sentences and sentences from the corpus to annotate. For efficiency, we did not annotate a short list of stop words, copular verbs, and auxiliaries.

Factuality Annotation For factuality, we present a sentence with one highlighted event token at a time with the following prompt:

> *On a scale from 3 to -3, rate how likely the highlighted event did or will happen according to the author of the sentence.*

along with 17 examples to calibrate the annotator's judgments, including negated, conditional, hedged, generic, and nested events. The responses -3, 0, and 3 were given explicit interpretations. 3 and -3 denote respectively that the target event certainly did or did not happen according to the author. 0 denotes that the author is neutral and expresses no bias towards the event's factuality.

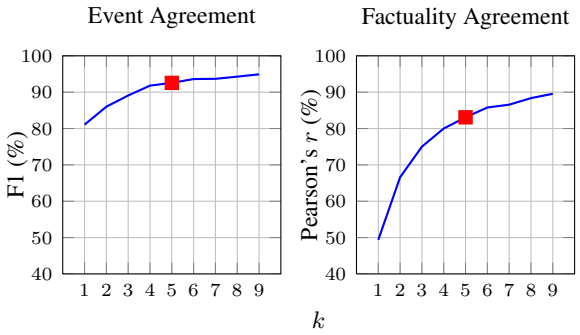

Figure 3: Agreement statistics as a function of k, the number of judgments aggregated. We choose $k = 5$ in both tasks for our experiments, as denoted by the red square.

Data collection We gathered data on CrowdFlower.[2] For quality control, annotators are randomly presented test questions with known answers. For each example, we collect and aggregate 5 judgments, as described below. For comparison, we annotated TempEval-3 (Uzzaman et al., 2013), keeping the existing test split and randomly holding out a quarter of the training examples to create a development set. Figure 2 shows data statistics. The annotation cost is 0.5¢ per judgment for detection and 2¢ per judgment for factuality.

Aggregated Agreement We introduce a simple scheme to measure agreement with aggregate data, for example when the majority class from a pool of judgments is used for the final label. Instead of comparing individuals, we want to know how often the aggregates will agree, if we were to have different groups of annotators doing the task.

Formally, we assume N samples $\{(x_i, y_i) \mid i = 1, \ldots, N\}$, where each x_i is a token within a sentence, and $y_i = \{y_i^j \mid j = 1, \ldots, M\}$ is the set of M judgments for x_i. Let $\mathcal{Y}$ be the set of possible labels, $\mathcal{Y} = \{-1, 1\}$ for detection and $\mathcal{Y} = [-3, 3]$ for factuality. Let $\text{AGG} : \mathcal{Y}^k \rightarrow \mathcal{Y}$ be an aggregation function, which maps k judgments to a single aggregate one. For event detection, we set $\text{AGG}(y^1, \ldots, y^k)$ to return the majority value from the set of judgments $\{y^1, \ldots, y^k\}$. For factuality, we set $\text{AGG}(y^1, \ldots, y^k) = \frac{1}{k} \sum_{j=1}^{k} y^j$, which computes the mean value.

To estimate the agreement between aggregates of k judgments, we collect pairs of disjoint subsets of size k from the M judgments. Given y_i, we define the set of aggregate judgment pairs: $\{(\text{AGG}(y'), \text{AGG}(y'')) \mid y', y'' \subset y_i \wedge |y'| = |y''| = k \wedge y' \cap y'' = \emptyset\}$.[3] To measure how well these aggregates agree, we treat $\text{AGG}(y')$ as a candidate hypothesis and $\text{AGG}(y'')$ as the gold label and compute the appropriate evaluation metric to measure aggregate agreement. We use the F1 score for detection and Pearson's correlation for factuality, as described in Section 5.

We experiment with $k = 1, \ldots, 9$ for 100 sentences, allowing aggregates of up to 9 judgments, as seen in Figure 3. Aggregate agreement for both tasks improve with larger k, but returns quickly diminish. Therefore, we chose $k = 5$ for the full data collection to reasonably trade off between quality and quantity. In absolute terms, the agreement at this level is strong (92.6% F1 for detection and 83.1% correlation for factuality), demonstrating that aggregate non-expert judgments can produce high-quality annotations.

		FactBank Labels								
		CT-	PR-	PS-	PS+	PR+	CT+	CTu	NA	Uu

	-2	29	2	0	0	0	0	0	0	44
	-1	16	4	1	0	0	3	0	0	58
	0	15	0	5	2	0	7	0	1	95
	1	7	0	1	30	4	27	2	0	337
	2	4	1	0	20	42	260	0	0	564
	3	2	0	0	1	10	2760	0	0	771

Figure 4: Confusion matrix between FactBank labels and our discretized factuality ratings.

Comparison to FactBank We compare our factuality ratings, rounded to the nearest integer, to FactBank annotations (author source only) for overlapping events. The confusion matrix from Figure 4 shows there is strong correlation between our ratings and FactBank labels with specified certainties and polarities. These labels are CT-, PR-, PS-, PS+, PR+, and CT+, corresponding to events that are seen as (certainly/probably/possibly) (not happening/happening).

We differ most significantly in events labeled Uu (underspecified) by FactBank, which consist largely of nested events, such as "Sandors said he'd *double* his money" or "Sandors hoped he'd *double* his money." While FactBank annotators would label both *double* events as Uu, our annotations can indicate nuances based on the author's wording (i.e., *said* vs. *hoped*). The large variation

[2] http://crowdflower.com

[3] In practice, we sample judgment pairs rather then computing all possible combinations.

in the Uu column of the confusion matrix suggests that the factuality of an event is rarely perceived as completely neutral, even when the author does not commit to a belief in the event's occurrence.

4 Approach

Learning For the detection task, we learn a linear SVM classification model. For the factuality task, we assume a dataset with N examples of labeled events $\{(x_i, y_i) \mid i = 1, \ldots, N\}$, and we learn a regression model: $y_i = w^\top \phi(x_i)$. We introduce a learning objective for regression:

$$\min_w \|w\|_1 + C \sum_{i=1}^{N} \max(0, |y_i - w^\top \phi(x_i)| - \epsilon)$$

that combines the advantages of LASSO (Tibshirani, 1996) and support vector regression (Drucker et al., 1997). It induces sparse feature weights while being insensitive to errors less than ϵ.

Features For the detection model, we include features given the input word x: (1) lemma of x, (2) part of speech of x, (3) indicator for whether x is a hyponym of the *event* synset in WordNet and the part of speech of x, (4) Brown clusters of x and its part of speech, and (5) all dependency paths from x up to length 1. For the factuality model, given the input event mention x, we include: (1) lemma of x, (2) part of speech of x, and (3) all dependency paths from x up to length 2.

For dependency paths, we include all edge labels, the target word is omitted, and each node may or may not be lexicalized; we include all possible configurations. For example in "John did not expect to *return*", the dependency path: *not*←[**neg**]—*expect*—[**xcomp**]→*return*, would produce the following features:

not←[**neg**]—*expect*—[**xcomp**]→⟨∗⟩
⟨∗⟩←[**neg**]—*expect*—[**xcomp**]→⟨∗⟩
not←[**neg**]—⟨∗⟩—[**xcomp**]→⟨∗⟩
⟨∗⟩←[**neg**]—⟨∗⟩—[**xcomp**]→⟨∗⟩

These dependency features allow for context-dependent reasoning, including many of the cases in Figure 1 where the factuality of an event depends on the identity of a neighboring verb.

5 Experimental Setup

Baselines For detection, we include a baseline reimplementation of the NAVYTIME (Chambers, 2013) classification detector, one of the top performers in the TempEval-3 event detection task.

For factuality, we include three baselines: (1) A one-vs.-rest multi-class classifier (DISCRETE) using our features (Section 4) and labels that are discretized by rounding to the nearest integer, (2) a regression model (SVR) trained with the standard SVR objective using our features, and (3) a regression model (PRABHAKARAN) trained with the standard SVR objective using features from Prabhakaran et al. (2010). These features are highly informative, but their lexical features are restricted to a small set of manually defined words.

Implementation Details The SVM models (NAVYTIME, DISCRETE, SVR, PRABHAKARAN, and our detection model) were trained with SVM-Light (Joachims, 1999). We use CPLEX[4] to solve the linear program optimizing the regression objective in Section 4. All hyperparameters were tuned on the development set.

We use the Stanford dependency parser (de Marneffe et al., 2006) for extracting dependency path and part-of-speech features. We use WordNet (Miller, 1995) to generate lemma and hyponym features. Brown clusters with 100, 320, 1000, and 3200 clusters from Turian et al. (2010) are used in the detection features.

Evaluation Metrics We use the standard F1 score for the evaluation of detection. For event factuality, we report two metrics, the mean absolute error (MAE) relative to the gold standard labels and Pearson's correlation coefficient. While MAE is an intuitive metric that evaluates the absolute fit of the model, Pearson's r better captures how well a system is able to recover the variation of the annotations. Pearson's r is also conveniently normalized such that $r = 0$ for a system that blindly chooses the best *a priori* output and $r = 1$ for a system that makes no error.

6 Results

Detection Results Figure 5 shows development and test results for detection event mentions.[5] We see a small drop in precision and large gains in recall, but a significant increase in F1, primarily

[4] http://tiny.cc/cplex

[5] We performed two-sided bootstrap resampling statistical significance tests (Graham et al., 2014). In Figures 5 and 6, asterisks indicate that the difference from the best system is statistically significant ($p < 0.05$).

due to the use of distributional features and more general dependency features.

Factuality Results Figure 6 shows development and test results for predicting the factuality of gold-labeled event mentions. Our system shows an overall improvement in performance over all baselines, demonstrating that the regression model works well for this data. It is able to make more graded judgments that correlate with the aggregate opinions of untrained annotators. As shown in Figure 8, which compares the mean average error for different buckets of factuality labels, we observe the largest gains over PRABHAKARAN in examples with low factuality, where lexical cues are especially critical.

Error Analysis We manually studied 50 development samples where our factuality model produced the largest absolute errors. Figure 7 summarizes the error types. The biggest challenge is the wide variety of sparse lexical cues. For example, the sentences "Wong Kwan will be lucky to *break* even" and "That *sale* could still fall through if financing problems develop" require modeling the influence of "lucky to" and "fall through." Even when these types of features do appear in the training data, they tend to be very rare.

We also find cases that require inference over longer distances than our model permits. Consider the sentence "Mesa had rejected a general proposal from StatesWest to *combine* the two carriers." To know that *combine* is not likely to happen, we must infer that it is conditioned on the proposal, which was rejected. Finally, we find that world knowledge and pragmatic inference is sometimes required. For example, in the sentence "There was no hint of *trouble* in the last

Error type	%
Missed lexical cue (unseen in training)	52
Missed lexical cue (seen in training)	12
Long distance inference	16
World knowledge & pragmatics	12
Annotation error	8

Figure 7: Error types for the 50 examples with the largest absolute development error.

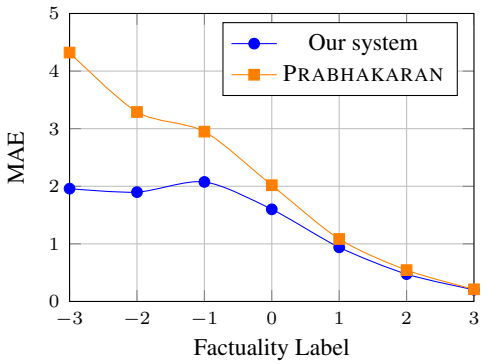

Figure 8: Mean absolute error in the development set for different labels rounded to the nearest integer. Our system's improvement is greater when predicting events with low factuality, which requires modeling sparse lexical cues.

conversation between controllers and TWA pilot Steven Snyder," the pragmatic implication that *trouble* likely happened requires common knowledge about flights.

7 Conclusion

We studied event detection and scalar factuality prediction, demonstrating that non-expert annotator can, in aggregate, provide high-quality data and introducing simple models that perform well on each task. There is significant room for future work to improve the results, including jointly modeling the factuality of multiple events and integrating factuality models into information extraction and question answering systems.

Large-Scale Acquisition of Entailment Pattern Pairs by Exploiting Transitivity

Julien Kloetzer[*] **Kentaro Torisawa**[‡] **Chikara Hashimoto**[§] **Jong-Hoon Oh**[¶]

Abstract

We propose a novel method for acquiring entailment pairs of binary patterns on a large-scale. This method exploits the transitivity of entailment and a self-training scheme to improve the performance of an already strong supervised classifier for entailment, and unlike previous methods that exploit transitivity, it works on a large-scale. With it we acquired 138.1 million pattern pairs with 70% precision with such non-trivial lexical substitution as "*use Y to distribute X*"→"*X is available on Y*" whose extraction is considered difficult. This represents 50.4 million more pattern pairs (a 57.5% increase) than what our supervised baseline extracted at the same precision.

1 Introduction

Recognizing textual entailment (Geffet and Dagan, 2005; Androutsopoulos and Malakasiotis, 2009; Zanzotto et al., 2009; Berant et al., 2011) is an important task for many NLP applications, such as relation extraction (Romano et al., 2006) or question-answering (Harabagiu and Hickl, 2006). Text L ***entails*** text R if the information written in the latter can be deduced from the information written in the former. As building blocks to recognize entailment relations between texts, numerous works have focused on recognizing entailment relations between patterns, such as "*grew up in X*"→"*lived in X*" or "*X grew up in Y*"→"*X lived in Y*" (Lin and Pantel, 2001; Weeds and Weir, 2003a; Hashimoto et al., 2009; Berant et al., 2011; Kloetzer et al., 2013b).

We propose in this paper a method for acquiring on a very large-scale, entailment pairs of such class-dependent binary patterns as "*underwent* X_{exam} *on* Y_{date}"→"X_{exam} *carried out on* Y_{date}". Our starting point is a supervised baseline trained with 83,800 manually labeled pattern pairs detailed in Kloetzer et al. (2013b). Its top 205 million output pairs have an estimated 80% precision, but this baseline's performance is saturated. Table 1 shows the baseline's average precision when varying its amount of hand-labeled training data. Since the average precision only improves slightly with additional training data, the investment in hand-labeling additional training data is difficult to justify.

Quantity of training data	Average precision
Baseline plus 5,000 training data samples	**49.0%**
Baseline: 83,800 training data samples	48.8%
Baseline minus 10,000 training data samples	48.5%
Baseline minus 20,000 training data samples	47.8%

Table 1: Average precision for baseline method with various amounts of training data

To improve our baseline further, we exploit the transitivity property of entailment to automatically generate *new features* for it. The entailment is transitive; if we detect that L entails C and C entails R, we can infer an entailment relation between L and R even if no such relation was detected beforehand. Based on this idea, we propose a self-training scheme that works in the following way. For pattern pair $\langle P,Q\rangle$, we use the baselines output to find all the chains of patterns from P to Q that are linked by entailment relations, which we call *transitivity paths*, and encode the information related to them as new features to judge the validity of pair $\langle P,Q\rangle$. Our expectation is that even if our supervised baseline fails to judge $\langle P,Q\rangle$ as an entailment pair, the existence of paths

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1649–1655,
Lisbon, Portugal, 17-21 September 2015.

from P to Q that are comprised of pairs judged as entailments by our baseline might strongly suggest that P entails Q; hence, adding our new features to the baseline should help it make better decisions based on the information encoded in the features. This self-training approach is the first that encodes the information contained in transitivity paths as features for a classifier, and as such it differs from previous state-of-the-art methods that exploit transitivity to extract new pairs using Integer Linear Programming (Berant et al., 2011) or that auto-generate training data (Kloetzer et al., 2013a).

From a corpus of 600 million web pages, we show that our proposed method extracted 217.8 million entailment pairs in Japanese with 80% precision[1], which is a 6% increase over the 205.3 million pairs output by our baseline with identical precision. It also extracted 138.1 million entailment pairs with 70% precision with non-trivial lexical substitution (generally deemed difficult to extract), which is a 50.4 million pair increase (57.5% size improvement) over the 87.7 million pairs output by our baseline with the same precision. These include such pairs as "*use X to distribute Y*"→"*Y is available on X*", "*underwent X on Y*"→"*X carried out on Y*", "*start X at Y*"→"*Y's X*" or "*attach X to Y*"→"*put X on Y*". Even though we only present results for the Japanese language, we believe that our method should be applicable to other languages as well. This is because none of the few language dependent features of our classifier are strictly needed by the baseline or our proposed method, and its performance boost is unrelated to these features.

2 Related Works

The task of recognizing entailment between texts has been proposed by Dagan et al. (2006) and intensively researched (Malakasiotis and Androutsopoulos, 2007; Szpektor et al., 2004; Androutsopoulos and Malakasiotis, 2009; Dagan et al., 2009; Hashimoto et al., 2009; Berant et al., 2011) using a various range of techniques, including Integer Linear Programming (Berant et al., 2011), machine learning with SVMs (Malakasiotis and Androutsopoulos, 2007), and probabilistic models (Wang and Manning, 2010; Shnarch et al., 2011). Entailment recognizer or entailment data sets have been used in such fields as relation extraction (Romano et al., 2006) and question-answering (Harabagiu and Hickl, 2006; Tanaka et al., 2013). In this work, we are interested into recognizing entailment between syntactic patterns, which can then be used as building blocks in a complete entailment recognition system (Shnarch et al., 2011). Recognizing entailment between patterns has generally been studied using unsupervised techniques (Szpektor et al., 2004; Hashimoto et al., 2009; Weeds and Weir, 2003b), although we showed that supervised techniques naturally obtain stronger performance (Kloetzer et al., 2013b).

The two works that are most closely related to our work are Berant et al. (2011) and Kloetzer et al. (2013a), both of which exploit transitivity to improve the result of a baseline classifier. Berant et al. (2011) proposed an entailment recognition method for binary patterns that exploits Integer Linear Programming techniques (ILP) to expand the results of an SVM classifier. This method encodes into an ILP problem an entailment graph, which is a valued graph where nodes and edges respectively represent patterns and their entailment relations, and the values equal the SVM classifiers score output. The problems variables $E_{PQ} \in \{0, 1\}$ indicate whether pattern pairs (here, $\langle P,Q \rangle$) have an entailment relation, and the goal is to maximize the sum of the scores of the pairs selected as entailment relations $\{\langle P, Q\rangle | E_{PQ} = 1\}$. In (Kloetzer et al., 2013a), we proposed a contradiction acquisition method that uses a training data expansion scheme; it automatically generates new contradictions by exploiting transitivity and adds the highest scoring contradictions based on a novel score (CDP) to the training data of the original classifier. The score is based on the assumption that if pair $\langle P,Q \rangle$, when chained by transitivity to other pairs $\langle Q,R_i \rangle$, generally leads to correct entailment pairs $\langle P,R_i \rangle$, then *all* pairs $\langle P,R_i \rangle$ should be correct entailment pairs. Although this work was designed for contradiction recognition, it is easily adapted to entailment.

3 Target Data and Baseline Classifiers

Target Pattern Pairs We extracted our binary patterns from the TSUBAKI corpus (Shinzato et al., 2008) of 600 million Japanese web pages. Binary patterns are defined as sequences of words on the path of dependency relations connecting two nouns in a sentence and have two variables. "*use Y to distribute X*" and "*X is available on Y*" are such

[1]Examples are given in English for convenience

binary patterns. Like previous works (De Saeger et al., 2009; Berant et al., 2011; Kloetzer et al., 2013a), we pose restrictions on the noun-pairs that co-occur with each pattern using word classes to disambiguate their various potential meanings: "X_{book} *by* Y_{author}" and "$X_{building}$ *by* $Y_{location}$". We used the EM-based noun clustering algorithm presented inKazama and Torisawa (2008) to classify one million nouns into 500 semantic classes. Our target set, to which we apply all of our classifiers, is set Σ of around 11 billion class-dependent pattern pairs for which both patterns share at least three co-occurring noun-pairs.

Baseline Classifier Our baseline classifier (**BASE**) is an SVM classifier trained with about 83,800 binary pattern pairs that were hand-labeled as entailment (25,436 pairs, 30.4% of the total) or non-entailment (58,361 pairs). We trained the classifier using SVMlight software[2] with a polynomial kernel of degree 2.

Following previous work (Kloetzer et al., 2013b), we used three types of features in **BASE**: **surface features** indicate clues like the presence of n-grams or measure the string overlap between two patterns; **database features** exploit existing language resources; and **distributional similarity scores** measure the patterns' semantic similarity based on the nouns that co-occur with them. See Kloetzer et al. (2013b) for more details about **BASE** s features.

4 Proposed Method

Our method consists of the following three steps:

Step 1 Chain together the entailment pairs provided by our baseline classifier **BASE** to form transitivity paths; if $P \rightarrow Q$ and $Q \rightarrow R$, then create path $P \rightarrow Q \rightarrow R$.

Step 2 Train new classifiers with features that encode the information contained in the transitivity paths obtained in Step 1.

Step 3 Combine the output of these classifiers with that of baseline classifier **BASE**.

Figure 1 shows an overview of our method, and we describe its details in the following sections.

[2]http://svmlight.joachims.org/

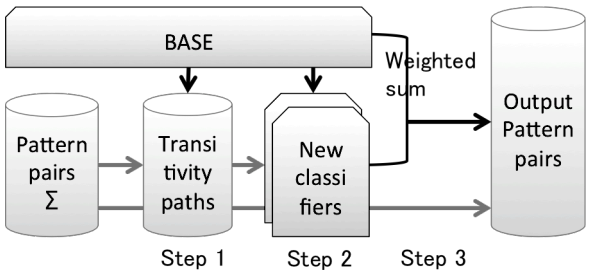

Figure 1: Overview of proposed method

4.1 Step 1: Transitivity Paths

We generate chains of entailment pairs (or transitivity paths) in the following way. First, we extract from the output of the baseline classifier **BASE** set $E(\theta)$ of the pattern pairs for which **BASE** returns a score over given threshold θ: $E(\theta) = \{\langle P, Q\rangle \in \Sigma | S_{BASE}(P, Q) \geq \theta\}$, where $S_{BASE}(P, Q)$ is the score returned by **BASE** for pattern pair $\langle P,Q\rangle$. The higher θ is, the greater the precision of the pairs in $E(\theta)$ should be. Then by chaining the entailment pairs from $E(\theta)$ together, we build sets of transitivity paths composed of two entailment pairs $Tr(\theta, 1)$ for $\theta \in \{0, -\infty\}$ and of three entailment pairs $Tr(\theta, 2)$ for $\theta = 0$. Since additional chaining is computationally expensive, we stopped at paths that consist of three pairs.

4.2 Step 2: Training New Classifiers

In this step, we train new classifiers by adding new features to **BASE**. The training data, the classifier software, and the settings are the same as for **BASE**. For given pattern pair $\langle P,R\rangle$, $Path(P, R, \theta, N)$ is the set of all the transitivity paths in $Tr(\theta, N)$ that lead to pair $\langle P,R\rangle$. We encode the information contained in these paths in three new feature sets.

Before explaining these three new feature sets, we define three scoring functions for the transitivity paths to assess their quality; the *MinScore* of a path is the minimum of scores returned by **BASE** for each pair in the path, and *ArScore* and *GeoScore* are the arithmetic and geometric averages of the scores returned by **BASE** for each pair in the path. Each of the three feature sets is computed for each of the three scoring functions, but we just mention *MinScore* in our explanations due to space limitations.

Feature set 1: scores of top-ranked paths Here we select the top ten paths of $Path(P, R, \theta, N)$ ranked by *MinScore* and use as features a new vec-

tor that consists of the following values: **(1)** the *MinScore* of each path and **(2)** the scores returned by **BASE** for each of the pairs in the ten paths. When there are fewer than ten paths, the missing features are set to 0.

Feature set 2: BASE features of the pairs in the highest ranking transitivity paths Here we select the transitivity path of $Path(P, R, \theta, N)$ with the highest *MinScore* and use the **BASE** feature values for each pair in the transitivity path as a new feature vector for pair $\langle P,R \rangle$.

Feature set 3: score distribution Given threshold α, we count the number of paths whose *MinScore* exceeds α. By varying α from lower bound low to upper bound up, we derive vector $[|\{p \in Path(P, R, \theta, N) | MinScore(p) \geq \alpha\}|]_{\alpha \in \{low, low+\beta, low+2*\beta, \ldots, up\}}$ and use it as a new feature vector for pair $\langle P,R \rangle$. We set $\beta = 0.1$ and low and up such that the score values returned by **BASE** are bounded by low and up.

4.3 Step 3: Optimization and Weighted Sum Classifier Combination

The final output of our method combines the outputs of **BASE** and two new classifiers: **(1)** a classifier with new features computed with 1-step transitivity paths ($N = 1$), and **(2)** another with new features computed with up to 2-step transitivity paths ($N \in \{1, 2\}$). We then use a weighted sum and compute score $S_{PROPOSED}(P, Q) = \sum_i n_i * S_i(P, Q)$ for each pair $\langle P,Q \rangle$. S_i represents the scores of the respective classifiers, and we set $n_0 + n_1 + n_2 = 100$ (n_i are all natural numbers).

For each potential combination of three weights n_i, we computed the average precision returned by our method on **DEV**, our development set, and selected for our final output the weight combination that gave the best average precision on **DEV**. The final classifiers weights obtained in our experiments were 62 for **BASE**, 30 for the classifier with 1-step transitivity features, and 8 for the one with the 1- and 2-step transitivity features.

Using the same method, we also performed ablation tests to remove the features that harmed the classifiers and ensured that every proposed new feature set and every scoring function were useful.

Finally, we confirmed that using a weighted sum for our proposed method returned higher average precision than Stacking (Wolpert, 1992), which is a more standard combination method, or than using the output of any of the new classifiers alone.

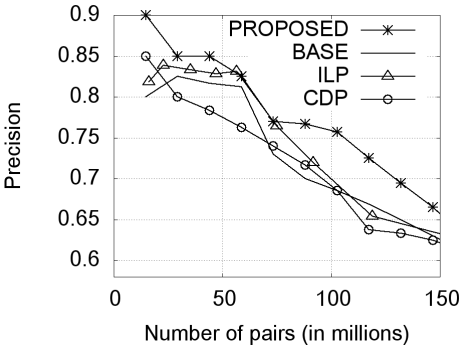

Figure 2: Precision curves for **PROPOSED** and baseline methods for *non-similar* pairs

5 Experiments

In this section, we evaluate our proposed method in a large-scale setting and compare it to **BASE** and to state-of-the-art methods based on ILP (Berant et al., 2011) and automatic training data expansion (Kloetzer et al., 2013a). We also indicate that our method shows the best performance gain for pattern pairs with non-trivial lexical substitutions, which are more difficult to acquire.

Evaluation Method For our evaluation, we prepared test set **TEST** of 15,000 pattern pairs randomly sampled from Σ (our target set of 11 billion pairs). The pairs were annotated by three humans (not the authors) who voted to settle labeling discrepancies. We also prepared development set **DEV** of $5,000$ pattern pairs from Σ for tuning our method. The Kappa score was 0.55 for the annotation of these two sets.

We measured the performance of each method by computing its *average precision* (Manning and Schütze, 1999) on the **TEST** set. We used the average precision instead of the traditional F-value because the latters value greatly varies depending on where the classification boundary is drawn, even for similar rankings. We also drew precision curves for each method using the same **TEST** set.

Proposed Methods Performance We first show the performance of **PROPOSED** (our proposed method) and **BASE** (the baseline classifier). As another baseline, we consider **BASE +DEV** where the 5,000 samples of the **DEV** set were added to the **BASE** training data. We show the average precision for each of these three classifiers and the

Classifier	Average precision	Million pairs at 80% prec.
PROPOSED	**50.64%**	**217.8**
BASE + DEV	48.96%	202.4
BASE	48.79%	205.3
ILP	N/A	205.2
CDP	48.42%	198.0

Table 2: Average precision and entailment pairs obtained (in millions) for proposed method, baseline classifiers, and state-of-the-art methods

Classifier	Av. precision (*similar*)	Av. precision (*non-similar*)
PROPOSED	**78.73%**	**39.53%**
BASE + DEV	77.72%	37.24%
BASE	77.85%	36.98%

Table 3: Average precision for *similar* and *non-similar* pairs

number of pairs obtained at 80% precision in Table 2. We also show the performance of these classifiers over *similar* pattern pairs (both patterns share a content word) and *non-similar* pairs (they do not share a content word) in Table 3.

As mentioned in the introduction, **BASE +DEV** shows that the addition of 5,000 hand-labeled samples to the training data of **BASE** (a 6% increase) only improves the average precision performance by 0.17%. Our proposed method, on the other hand, exploits the same 5,000 new annotated samples for tuning its parameters and obtains a 1.85% gain of average precision. Using **PROPOSED**, we acquired 217.8 million pattern pairs with 80% precision, an improvement of 6.0% over **BASE**.

As shown in Table 3, **BASE** s performance is much lower for *non-similar* pairs like "*use Y to distribute X*"→"*X is available on Y*", which have non-trivial lexical substitutions and are more difficult to acquire than *similar* pairs. This is also where **PROPOSED** obtains the biggest gain in performance: an average precision of 39.53 compared to 36.98 for **BASE**. We show the precision curves we obtained when ranking the *non-similar* pairs with **BASE** and **PROPOSED** in Fig. 2. **PROPOSED** acquired 138.1 million *non-similar* pairs at 70% precision, which is an increase of 50.4 million pairs (a 57.5% size improvement) compared to **BASE** with the same precision. We believe that the strong performance of **BASE** for *similar* entailment pairs helped it discover, through transitivity, the variations of *non-similar* entailment pairs it could already detect.

Comparison to State-of-the-art Methods We also compared **PROPOSED** with two state-of-the-art methods that exploit transitivity: the ILP-based method of Berant et al. (2011) (**ILP**) and the training data expansion method we proposed in Kloetzer et al. (2013a) (**CDP**). The latter, which was initially designed for acquiring contradiction pairs, was adapted to acquire entailment for comparison purposes. The results of this comparison are summarized in Table 2, and the precision curves for these two methods as well over *non-similar* pairs are shown in Fig. 2. Our proposed method is the only one that provides stable improvement in our large-scale setting; at best, the other two just slightly outperform **BASE**. We believe that our feature encoding provides more information to the classifier than the raw scores in the transitivity paths that are exploited by the other state-of-the-art methods, and as such strengthens the performance.

As for explaining the poor performance of the state-of-the-art methods, ILP is unfortunately not tractable for big problems; our ILP solver failed to solve 82% of the independent problems we fed it due to insufficient memory even on 64-Gb memory machines, making **ILP** just slightly better than **BASE**. Our pattern graph is also sparser than that in Berant et al. (2011), and as such ILP might not be completely efficient. But we assume that even if we had used the graphs whole closure, the ILP problem instances would have become even less tractable, resulting in performance that only slightly exceeds **BASE**. As for **CDP**, since our baseline classifier already has more than 80,000 hand-annotated samples as training data, the addition of automatically generated training samples is actually harmful.

6 Conclusion

In this work, we proposed a method that exploits the transitivity relation of entailment in a self-training scheme and combines classifiers with a weighted sum. In our large-scale setting, our method outperforms state-of-the-art methods that are also based on a transitivity approach, including an ILP-based method. Using our proposed method, we acquired 217.8 million Japanese entailment pairs with 80% precision and 138.1 million non-trivial pairs with 70% precision. We are considering an extrinsic evaluation for these data such as the RTE test in future research.

Abstract

We consider the problem of embedding knowledge graphs (KGs) into continuous vector spaces. Existing methods can only deal with explicit relationships within each triple, i.e., local connectivity patterns, but cannot handle implicit relationships across different triples, i.e., contextual connectivity patterns. This paper proposes context-dependent KG embedding, a two-stage scheme that takes into account both types of connectivity patterns and obtains more accurate embeddings. We evaluate our approach on the tasks of link prediction and triple classification, and achieve significant and consistent improvements over state-of-the-art methods.

1 Introduction

Knowledge Graphs (KGs) like WordNet (Miller, 1995), Freebase (Bollacker et al., 2008), and DBpedia (Lehmann et al., 2014) have become extremely useful resources for many NLP-related applications. A KG is a directed graph whose nodes correspond to entities and edges to relations. Each edge is a triple of the form (h, r, t), indicating that entities h and t are connected by relation r. Although powerful in representing complex data, the symbolic nature makes KGs hard to manipulate.

Recently, knowledge graph embedding has attracted much attention (Bordes et al., 2011; Bordes et al., 2013; Socher et al., 2013; Wang et al., 2015). It attempts to embed entities and relations in a KG into a continuous vector space, so as to simplify the manipulation while preserving the inherent structure of the original graph.

Most of the existing KG embedding methods model triples individually, ignoring the fact that entities connected to a same node are usually implicitly related to each other, even if they are not directly connected. Figure 1 gives two examples. `Shaquille_O_Neal` and `NBA` in the former example and `Nevada` and `Utah` in the latter example are implicitly related to each other, through the intermediate nodes `Phoenix_Suns` and `USA` respectively. We refer to such implicit relationships as *contextual connectivity patterns* (CCPs). Relationships explicitly represented in triples are referred to as *local connectivity patterns* (LCPs). In most of the existing methods, only LCPs are explicitly modeled.

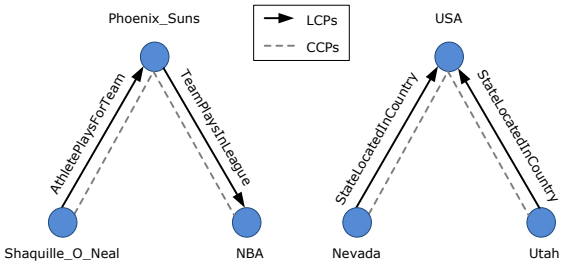

Figure 1: LCPs and CCPs.

This paper proposes a two-stage embedding scheme that explicitly takes into account both CCPs and LCPs, called *context-dependent KG embedding*. In the first stage, each CCP is formalized as a *knowledge path*, i.e., a sequence of entities and relations occurring in the pattern. A word embedding model is adopted to learn embeddings of entities and relations, by taking them as pseudo-words. The embeddings are enforced compatible within each knowledge path, and hence can capture CCPs. In the second stage, the learned embeddings are fine-tuned by an existing KG embedding technique. Since such a technique requires the embeddings to be compatible on each individual triple, LCPs are also encoded.

The advantages of our approach are three-fold. 1) It fully exploits both CCPs and LCPs, and can

*Corresponding author: Quan Wang.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1656–1661,
Lisbon, Portugal, 17-21 September 2015.

obtain more accurate embeddings. 2) It is a general scheme, applicable to a wide variety of word embedding models in the first stage and KG embedding models in the second. 3) No auxiliary data is further required in the two-stage process, except for the original graph.

We evaluate our approach on two publicly available data sets, and achieve significant and consistent improvements over state-of-the-art methods in the link prediction and triple classification tasks. The learned embeddings are not only more accurate but also more stable.

2 Context-Dependent KG Embedding

We are given a KG with nodes corresponding to entities and edges to relations. Each edge is denoted by a triple (h, r, t), where h is the head entity, t the tail entity, and r the relation between them. Entities and relations are represented as vectors, matrices, or tensors in a continuous vector space. Context-dependent KG embedding aims to automatically learn entity and relation embeddings, by using observed triples $\mathcal{O}$ in a two-stage process.

2.1 Modeling CCPs

The first stage models CCPs conveyed in the KG. Each CCP is formalized as a knowledge path, i.e., a sequence of entities and relations occurring in the pattern. For the CCPs in Figure 1, the associated knowledge paths are:

"`Shaquille_O_Neal`, `AthletePlaysForTeam`, `Phoenix_Suns`, `TeamPlaysInLeague`, `NBA`"

"`Nevada`, `StateLocatedInCountry`, `USA`, `StateLocatedInCountry`, `Utah`".

We fix the length of knowledge paths to 5. During path extraction, we ignore the directionality of edges, and treat the KG as an undirected graph.[1]

Given the extracted knowledge paths, we employ word embedding models to pre-train the embeddings of entities and relations, by taking them as pseudo-words. We use two word embedding models: CBOW and Skip-gram (Mikolov et al., 2013a; Mikolov et al., 2013b). In CBOW, words in the context are projected to their embeddings and then summed. Based on the summed embedding, log-linear classifiers are employed to predict the current word. In Skip-gram, the current word is projected to its embedding, and log-linear classifiers are further adopted to predict its context. We restrain the context of a word (i.e. entity/relation) within each knowledge path. The entity and relation embeddings pre-trained in this way are required to be compatible within each knowledge path, and thus can encode CCPs.

Perozzi et al. (2014) and Goikoetxea et al. (2015) have proposed similar ideas, i.e., to generate random walks from online social networks or from the WordNet knowledge base, and then employ word embedding techniques on these random walks. But our approach has two differences. 1) It deals with heterogeneous graphs with different types of edges. Both nodes (entities) and edges (relations) are included during knowledge path extraction. However, the previous studies focus only on nodes. 2) We devise a two-stage scheme where the embeddings learned in the first stage will be fine-tuned in the second one, while the previous studies take such embeddings as final output.

2.2 Modeling LCPs

The second stage models LCPs conveyed in the KG. We employ three state-of-the-art KG embedding models, namely SME (Bordes et al., 2014), TransE (Bordes et al., 2013), and SE (Bordes et al., 2011) to fine-tune the pre-trained embeddings. These three models work in the following way. First, entities are represented as vectors, and relations as operators in an embedding space, characterized by vectors (SME and TransE) or matrices (SE). Then, for each triple (h, r, t), an energy function $f_r(h, t)$ is defined to measure its plausibility. Plausible triples are assumed to have low energies. Finally, to obtain entity and relation embeddings, a margin-based ranking loss, i.e.,

$$\mathcal{L} = \sum_{t^+ \in \mathcal{O}} \sum_{t^- \in \mathcal{N}_{t^+}} \left[\gamma + f_r(h, t) - f_r(h', t')\right]_+ ,$$

is minimized. Here, $t^+ = (h, r, t) \in \mathcal{O}$ is an observed (positive) triple; $\mathcal{N}_{t^+}$ is the set of negative triples constructed by replacing entities in t^+, and $t^- = (h', r, t') \in \mathcal{N}_{t^+}$; γ is a margin separating positive and negative triples; $[x]_+ = \max(0, x)$. Table 1 summarizes the entity/relation embeddings and the energy functions used in SME, TansE, and SE. For other KG embedding models, please refer to (Nickel et al., 2011; Riedel et al., 2013; Wang et al., 2014; Chang et al., 2014).

We adopt stochastic gradient descent to solve the minimization problem, by taking entity and relation embeddings pre-trained in the first stage as

[1] Two entities connected to a same node are always expected to have some implicit relationships, no matter how they are connected to the intermediate node.

Method	Entity/Relation embedding	Energy function
SME (linear) (Bordes et al., 2014)	$\mathbf{h}, \mathbf{t} \in \mathbb{R}^k$, $\mathbf{r} \in \mathbb{R}^k$	$f_r(\mathbf{h}, \mathbf{t}) = (\mathbf{W}_{u1}\mathbf{r} + \mathbf{W}_{u2}\mathbf{h} + \mathbf{b}_u)^T (\mathbf{W}_{v1}\mathbf{r} + \mathbf{W}_{v2}\mathbf{t} + \mathbf{b}_v)$
SME (bilinear) (Bordes et al., 2014)	$\mathbf{h}, \mathbf{t} \in \mathbb{R}^k$, $\mathbf{r} \in \mathbb{R}^k$	$f_r(\mathbf{h}, \mathbf{t}) = ((\underline{\mathbf{W}}_u \bar{\times}_3 \mathbf{r})\,\mathbf{h} + \mathbf{b}_u)^T ((\underline{\mathbf{W}}_v \bar{\times}_3 \mathbf{r})\,\mathbf{t} + \mathbf{b}_v)$
TransE (Bordes et al., 2013)	$\mathbf{h}, \mathbf{t} \in \mathbb{R}^k$, $\mathbf{r} \in \mathbb{R}^k$	$f_r(\mathbf{h}, \mathbf{t}) = \|\mathbf{h} + \mathbf{r} - \mathbf{t}\|_{\ell_1}$
SE (Bordes et al., 2011)	$\mathbf{h}, \mathbf{t} \in \mathbb{R}^k$, $\mathbf{R}_u, \mathbf{R}_v \in \mathbb{R}^{k \times k}$	$f_r(\mathbf{h}, \mathbf{t}) = \|\mathbf{R}_u\mathbf{h} - \mathbf{R}_v\mathbf{t}\|_{\ell_1}$

NELL186	186	14,463	31,134	5,000	5,000	1,914,475

Table 2: Statistics of the data sets.

initial values.[2] The entity and relation embeddings fine-tuned in this way are required to be compatible within each triple, and thus can encode LCPs.

Socher et al. (2013) have proposed a similar idea, i.e., to use embeddings learned from an auxiliary corpus as initial values. However, linking entities recognized in an auxiliary corpus to those occurring in the KG is always a non-trivial task. Our approach requires no auxiliary data, and naturally avoids the entity linking task.

3 Experiments

We test our approach on the tasks of link prediction and triple classification. Two publicly available data sets are used. The first is WN18 released by Bordes et al. (2013)[3]. It is a subset of WordNet, consisting of 18 relations and the entities connected by them. The second is NELL186 released by Guo et al. (2015)[4], containing the most frequent 186 relations in NELL (Carlson et al., 2010) and the associated entities. Triples are split into training/validation/test sets, used for model training, parameter tuning, and evaluation respectively. Knowledge paths are extracted from training sets. Table 2 gives some statistics of the data sets.

To perform context-dependent KG embedding, we use CBOW and Skip-gram in the pre-training stage, and SME, TransE, and SE in the fine-tuning stage. We take randomly initialized SME, TransE, and SE as baselines, denoted as *-Random. We do not compare to the setting that employs only CBOW or Skip-gram, since it does not provide an energy function to calculate triple plausibility, which hinders the evaluation of both tasks.

[2]For SE, only entity vectors are initialized by pre-trained embeddings. Relation matrices are randomly initialized.

3.1 Link Prediction

Link prediction is to predict whether there is a specific relation between two entities.

Evaluation Protocol. For each test triple, the head is replaced by every entity in the KG, and the energy is calculated for each corrupted triple. Ranking the energies in ascending order, we get the rank of the correct answer. We can get another rank by corrupting the tail. We report two metrics on the test sets: Mean (averaged rank) and Hits@10 (proportion of ranks no larger than 10).

Implementation Details. To train CBOW and Skip-gram, we use the word2vec implementations[5]. 20 negative samples are drawn for each positive one. The context size is fixed to 5. To train SME, TransE, and SE, we use the implementations provided by the authors[6], with 100 mini-batches. We vary the learning rate in $\{0.01, 0.1, 1, 10\}$, the dimension k in $\{20, 50\}$, and the margin γ in $\{1, 2, 4\}$. The best model is selected by monitoring Hits@10 on the validation sets, with a total of at most 1000 iterations over the training sets.

Results. Table 3 reports the results on the test sets of WN18 and NELL186. The improvements of CBOW/Skip-gram over Random are also given. Statistically significant improvements are marked by ‡ (sign test, significance level 0.05). The results show that a pre-training stage consistently improves over the baselines for all the methods on both data sets. Almost all of the improvements are statistically significant.

3.2 Triple Classification

Triple classification aims to verify whether an unseen triple is correct or not.

Evaluation Protocol. Triples in the validation and test sets are labeled as positive instances. For each positive instance, we construct a negative instance by randomly corrupting the entities. During

classification, a triple is predicted to be positive if the energy is below a relation-specific threshold δ_r; otherwise negative. We report two metrics on the test sets: micro-averaged accuracy (per-instance average) and macro-averaged accuracy (per-relation average).

Implementation Details. We use the same parameter settings as in the link prediction task. The relation-specific threshold δ_r is determined by maximizing Micro-ACC on the validation sets.

Results. Table 4 reports the results on the test sets of WN18 and NELL186. The results again demonstrate both the superiority and the generality of our approach.

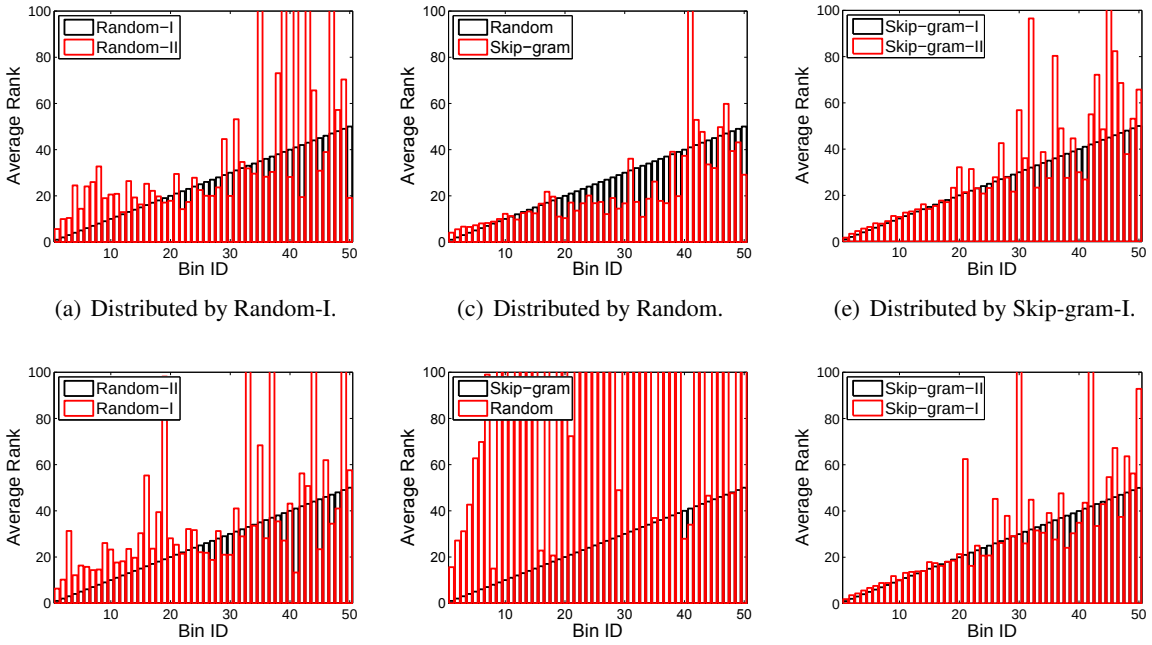
3.3 Discussions

This section is to explore why pre-training helps in KG embedding, specifically in link prediction.

We first test different random initializations in traditional KG embedding models. We run SME (linear) twice on WN18, with two different initialization settings. Both are randomly sampled from the same uniform distribution, but with different seeds, referred to as Random-I and Random-II. Each setting finally gets 10,000 ranks on the test set.[7] To better understand the difference between the two settings, we analyze the ranks individually, rather than reporting aggregated metrics (Mean and Hits@10). Specifically, we distribute the 10,000 instances into different bins according to the ranks given by one setting (e.g. Random-I). Instances assigned to the i-th bin have the same rank of i, that means, they are all ranked in the i-th position by this setting. Then, within each bin, we calculate the average rank of the instances given by the other setting (e.g. Random-II). If the average rank differs drastically from the bin ID, the instances in this bin are ranked significantly differently by the two settings. Figures 2(a) and 2(b) show the results, with the instances distributed according to Random-I and Random-II respectively. In both cases, we retain the bins with ID no larger than 50, covering about 85% of the instances. In most of the bins, the average rank (red bars in the figures) differs drastically from the bin ID (black bars in the figures), indicating that the ranks given by Random-I and Random-II are significantly different at the instance level. The results demonstrate the non-convexity of SME (linear): different initial values lead to different local minimum.

We further compare the settings of initial values 1) randomly sampled from a uniform distribution (Random) and 2) pre-trained by Skip-gram

[7] For each of the 5,000 test triples, both the head and the tail are corrupted and ranked.



(a) Distributed by Random-I. (c) Distributed by Random. (e) Distributed by Skip-gram-I.

(b) Distributed by Random-II. (d) Distributed by Skip-gram. (f) Distributed by Skip-gram-II.

Figure 2: Ranks obtained by different initialization strategies (best viewed in color).

(Skip-gram). The results are given in Figures 2(c) and 2(d). In most of the bins Skip-gram has an average rank lower than the bin ID (Figure 2(c)), while Random has an average rank much higher than the bin ID (Figure 2(d)), implying that Skip-gram performs better than Random-I at the instance level. The results indicate that pre-training might help in finding better initial values which lead to better local minimum.

Finally we test our two-stage KG embedding scheme where the skip-gram model itself is given two different initialization settings, say Skip-gram-I and Skip-gram-II. The results are given in Figures 2(e) and 2(f). In each of the first 20 bins, Skip-gram-I and Skip-gram-II get an average rank almost the same with the bin ID, implying that the two settings perform quite similarly, particularly at the highest ranking levels. The results indicate that a pre-training stage might help in obtaining more stable embeddings.

4 Conclusion

We have proposed a novel two-stage scheme for KG embedding, called context-dependent KG embedding. In the pre-training stage CCPs are encoded by a word embedding model, and in the fine-tuning stage LCPs are encoded by a traditional KG embedding model. Since both types of connectivity patterns are explicitly taken into account, our approach can obtain more accurate embeddings. Moreover, our approach is quite general, applicable to various word embedding and KG embedding models. Experimental results on link prediction and triple classification demonstrate the superiority, generality, and stability of our approach.

As future work, we plan to 1) Investigate the efficacy of longer CCPs (i.e. knowledge paths with lengths longer than 5). 2) Design a joint model that encodes LCPs and CCPs simultaneously. Moreover, our approach actually reveals the possibility of a broad idea, i.e., initializing an embedding model by another embedding model. We would also like to test the feasibility of other such strategies, e.g., initializing SME by TransE, so as to combine the benefits of both models.

Abstract

We outline a learning framework that aims at identifying useful contextual cues for knowledge-based word sense disambiguation. The usefulness of individual context words is evaluated based on diverse lexico-statistical and syntactic information, as well as simple word distance. Experiments using two different knowledge-based methods and benchmark datasets show significant improvements due to context modeling, beating the conventional window-based approach.

1 Introduction

Word sense disambiguation (WSD) is a key task of natural language processing. Unsupervised *knowledge-based* approaches to WSD (Navigli, 2009) make use of available lexical resources rather than rely on costly annotated data. Sense inference in this setting involves finding the word sense that agrees most with the specified context according to the information encoded in the knowledge base (KB). The popular Lesk (1986) method, for example, seeks to maximize word overlap between the dictionary glosses associated with the context words, and the glosses of candidate word senses. Similar methods are used in named entity disambiguation and linking to a KB (Hoffart et al., 2011).

Despite the sophistication of inference models developed, little attention has been given so far to context modeling for knowledge-based WSD. Context is represented by bag-of-words, where typically all context words are assigned equal importance (Navigli, 2009; Ling et al., 2014). However, every simple definition of context will include some unrelated or uninformative context words. Consider this usage of the word *church*: "An ancient stone church stands amid the fields , the sound of bells cascading from its tower". Known senses for 'church' according to Wordnet 3.0 (Fellbaum, 1998) correspond to a group of people, service, or a building. The latter sense is intended in this case, as one may conclude from the context words 'stone', 'stands' or 'tower'. We wish to focus on such meaningful cues and avoid the modeling of uninformative words ('ancient', 'sound').

In this work, a learning framework is proposed that is aimed at identifying contextual cues that are predictive of the target word's sense. The usefulness of a candidate context word for the disambiguation of the target word is evaluated based on syntactic and lexico-statistical information, as well as simple word distance. Indirect supervision is provided using noisy example labels induced automatically. Importantly, explicit lexical information is not encoded–the prediction model can thus be applied in settings where no sense-tagged examples are available of the target word type (see also (Szarvas et al., 2013)). Having assessed the usefulness of available context words given the learned model, we consider only the top scoring context words in performing WSD.

We believe this work to be the first to perform learning-based context selection for knowledge-based sense disambiguation. Empirical evaluation using two representative knowledge-based WSD methods and different benchmark datasets indicates on consistent improvements in performance due to context selection using the proposed approach.

2 Learned context selection models (LCS)

We first define the WSD task. Given a word mention w and available context Ctx, it is required to infer the intended sense $s^* \in S(w)$, where $S(w)$ is the set of known senses of w. Ctx may be a sentence, a paragraph, or a window over words that contain w.

Knowledge-based methods seek to maximize some measure of agreement, or *similarity*, between candidate word senses and a given context. We denote this as $Sim()$, where the sense inference procedure is defined as follows:

$$\hat{s}(w) = \arg\max_{s \in S(w)} Sim(s, Ctx) \quad (1)$$

Typically, Ctx is represented as a bag-of-words, and the similarity score $Sim(s, Ctx)$ is additive, i.e., it may be computed as a summation over the similarity scores between sense s and the individual context words $c_j \in Ctx$, using the general formula:

$$Sim(s, Ctx) = \sum_{c_j \in Ctx} weight(c_j) Sim(s, c_j) \quad (2)$$

According to this view, each context word serves as a sense disambiguation 'expert'. Context words are usually assigned uniform weight, i.e., $weight(c_j) = 1$. Alternatively, varying weights may reflect the reliability, or relevancy, of context word c_j in disambiguating target word w; ideally, unuseful context information would be down-weighted or discarded.

2.1 Learning

Our goal is to learn models that assess whether a candidate context word c_j serves as a reliable 'expert' in predicting the sense of target word w. We propose a distantly supervised learning scheme. Given sense-tagged instances of the form $\langle Ctx(w_i) \rangle$, we derive a dataset of context-target word pairs $\langle w_i, c_{ij} \rangle$, $c_{ij} \in Ctx(w_i)$. Defining whether context work c_{ij} is useful, or reliable, with respect to the disambiguation of w_i is not trivial, however. In particular, words that are perceived as relevant according to human judgment may not necessarily yield the correct prediction using the inference algorithm. We consider a context word to be reliable if it yields a correct sense prediction of the target word, as follows:

$$y(w_i, c_{ij}) = \begin{cases} 1, & \text{if } \arg\max_s Sim(s, c_{ij}) = s^*(w_i) \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

As the similarity measures $Sim()$, as well as the reference knowledge base, are imperfect, the labels assigned in this fashion are expected to be noisy.

A context and target word pair is represented as a feature vector, as described below. Importantly, we avoid the representation of explicit lexical information, so that the learned models are applicable to word pairs of arbitrary word types.

Given a new instance at test time, the learned model is used to score the individual context words. One can then assign respective non-uniform weights to the context words (Eq. 2). Here, we take a *context selection* approach–a ranking is induced over the context words based on the predicted scores, and only the top ranked context words are modelled in the disambiguation process; that is, the selected context words are assigned weight 1.0, and the weight of the remaining context words is set to zero. As discussed in Sec.3, this design choice was found to give preferable results in preliminary experiments.

2.2 Feature Types

Various aspects may be modeled as features in this framework, describing properties of the context word c_j, as well as the relationship between the target-context word pair $\langle w, c_j \rangle$. In addition to simple *word distance*, we encode the following syntactic and lexico-statistical information.

Syntactic features. Word distance is further assessed in syntactic terms, denoting the length of the shortest dependency path linking the word pair, as well as the length of the shortest connecting path in a constituency parse tree (Swanson and Gordon, 2006; Huang and Lu, 2011). It may be useful to further encode information about the edge types that comprise the connecting path, as some dependency relations indicate more salient semantic relatedness than others (Padó and Lapata, 2007; Minkov and Cohen, 2013). In this work, if the target and context words are directly connected in the dependency graph, we include a feature indicating the label of the edge. The part-of-speech tag of the context word may provide another contextual cue (Yarowsky, 1993); dedicated features indicate whether c_j is tagged as *noun*, *verb*, *adjective* or *adverb*. We used the Stanford parser (de Marneffe et al., 2006) in our experiments.

Lexico-statistical information. We use the pointwise mutual information (PMI) measure (Turney, 2001) to assess the semantic relatedness between the context–target word pair. In general, we expect context words that are topically related to the target word to be useful for its disambiguation. To compute PMI, we obtained word frequencies from the large ukWaC corpus (Ferraresi et al., 2008), considering word co-occurrences over a window of five words. It has been indicated that highly frequent words are generally less topical, where this aspect is not fully captured by PMI (Han et al., 2013). We therefore model as complimentary information the inverse document frequency (Salton and McGill, 1983) of c_j, also computed using ukWaC. Finally, a context word is often ambiguous by itself, where low polysemy is correlated with topic-specificity (Han et al., 2013). We represent the number of known senses of the context word c_j based on WordNet.

3 Experiments

We consider two WSD methods representative of prevalent knowledge-based approaches, comparing against previously published results. The popular Lesk approach (1986) mentioned before computes $Sim(s, c_j)$ in terms of word overlap between the glosses of the senses of c_j and the gloss of s. There exist multiple variants of the Lesk algorithm (Kilgarriff and Rosenzweig, 2000; Banerjee and Pedersen, 2003; Ponzetto and Navigli, 2010). We experiment with *Gloss vectors* (GV) (Patwardhan and Pedersen, 2006). This method enriches WordNet glosses with glosses of hypernyms and other related senses, as well as with co-occurring words derived from raw text. GV scores were obtained using the WordNet::Similarity package (Pedersen et al., 2004).

Graph-based methods are also commonly used for sense disambiguation (Mihalcea, 2005; Hughes and Ramage, 2007). If the KB is represented as a graph, various metrics can be applied that reflect structural similarity between word senses represented as graph nodes. We consider the Personalized PageRank (PPR) algorithm, which has been shown to yield state-of-the-art WSD performance (Agirre and Soroa, 2009). According to the *linearity theorem* (Jeh and Widom, 2003), PPR scores can be computed for each of the context words separately, and then aggregated (Eq. 2). In this case, $Sim(s, c_j)$ equals the PPR score attributed to the node denoting sense s, having the graph walk initiated at a uniform distribution over the various senses of c_j. PPR scores were generated using the UKB software (Agirre and Soroa, 2009).[1]

	Word types	Target words	Context words	Pairwise acc. (PPR/ GV)
Koeling *et al.*	41	9.6K	121K	0.32/ 0.31
Semeval'07	35	16K	390K	0.35/ 0.33

Table 1: The experimental datasets: statistics

3.1 Datasets

We experiment with two benchmark datasets. The lexical sample due to Koeling et al. (2005) includes annotated instances of 41 selected nouns. About 300 example sentences are available per noun, retrieved evenly from three sources: the domain-specific *sports* and *finance* sections of Reuters corpus, and the general British National Corpus (BNC). The second dataset consists of all noun examples from the SemEval-2007 English lexical sample task (Pradhan et al., 2007), created from another corpus–the WSJ Treebank.

The two datasets were transformed into target-context word pairs. For every word pair $\langle w, c_j \rangle$, the scores $Sim(s, c_j)$, $s \in S(w)$, were generated using GV and PPR and WordNet 3.0 as the reference knowledge base. A context-target word pair was labeled as a positive example if it yielded a correct sense prediction, or as negative otherwise (Eq. 3). Table 1 details statistics of the original and respective word pair datasets, including the ratio of context words labeled as positive examples– as shown, this 'pairwise accuracy' is low, reaching up to 0.35.

3.2 Experimental setup

We experimented with several classification paradigms using the Weka learning suite (Hall et al., 2009). Learning had to be robust to label noise. We report results using Naive Bayes, due to both its good performance and efficiency. Following preliminary experiments, we adopted a context selection approach–the learned model is used to rank the available context words, where the top ranked words, obtained by applying ratio r, are selected as context. We tune r using training examples. The reported performance uses rough values of $r = 0.5$ for the Koeling *et al.* examples, which

[1] http://ixa2.si.ehu.es/ukb/; we used the bin file wn30+gloss, and the PPR_w2w graph walk variant.

include individual sentences, and $r = 0.2$ for SemEval'07, where parahraphs of a few sentences are provided as context.

3.3 Results

Table 2 shows the results of applying context selection for each of the dataset and methods. As in previous works, performance is reported in terms of *recall*, defined as the ratio of correct sense predictions out of total number of target word mentions.[2] To avoid over fitting, we performed *cross word* evaluation, predicting contexts for all instances of each word type with a model trained using the other word types (LCS:CW). Concretely, the Koeling *et al.* dataset was split into 41 bins, according to the target word type. For each word type, we generated a model using the examples of the remaining (in this case, 40) word types. This cross word evaluation procedure was applied to both datasets. We further report the results of *cross dataset* experiments (LCS:CD), in which one dataset is used for training and the other for evaluation. As baseline, we use all of the available context words, weighting them uniformly ("uniform" in the table).

As shown, LCS yields substantial improvements over the "uniform" baseline. The improvement rate for each experiment is displayed in superscript. Recall increased at high rates on the SemEval dataset. This dataset is skewed, and much of these gains are attributed to large increase in recall for two word types, covering 27% of the examples. Improvements on the balanced dataset due to Koeling *et al.* were more modest, yet significant. Interestingly, improvement rates are higher using GV than PPR; we conjecture that PPR predictions are biased towards highly-connected graph nodes, being less sensitive to the local context defined. Remarkably, the results using cross-dataset training are comparable to or exceed the within-dataset CW results, showing generality and robustness of the proposed approach.

[2]Since predictions are generated for all examples, recall equals in this case to *precision*, and *accuracy*.

R&M'12		-	**.465**	.493

Table 4: Detailed results on the Koeling *et al.* dataset

Table 3 further shows the results of an ablation study, assessing the contribution of the various feature types by adding them incrementally. We found the contribution of the lexico-statistical features to be the largest. In particular, modeling PMI yielded the best performance when used as a standalone feature. This means that context words that are topically related to the target word are especially useful for knowledge-based WSD. Modeling IDF information led to further gains in performance. As discussed before, the two measures are complimentary, as common words are generally less topical. Representing the number of senses of the context words yielded further improvements. Overall, this combination of word features accounted for the majority of the total gains achieved. The syntactic features had a lesser impact, yet improved results further, mainly using the GV method. Finally, simple word distance was found to have little impact; similar behavior was observed elsewhere (Hoffart et al., 2011).

In another set of experiments, we evaluated and found LCS to be robust with respect to the ratio r– while performance using LCS varied, it improved over the baseline across the range $0 < r < 1$. In contrast, selecting equal-sized sets of context words using the window approach was found to

hurt performance.

Finally, we compare our results against previous works. Our approach outperforms the results obtained by unsupervised systems on the noun portion of the SemEval'07 dataset (Patwardhan et al., 2007; Mohammad et al., 2007), achieving recall of .507 vs. .497 (a higher result obtained by Mohammad *et al*). Table 4 presents LCS results separately for each of the source domains of the Koeling dataset for comparison purposes. Previous results using PPR and uniform context weighting reported by Agirre *et al.* (2009) (AL&S'09) are substantially lower than our baseline; we mainly attribute this to the different version of WordNet used.[3] Huang and Lu (2011) proposed a manually-tuned syntax-based context selection and weighting formula. They applied it in combination with the GV method, reporting improvement on BNC sentences only. Our baseline result using GV was lower (.382 vs. .390), however LCS yielded better final performance (.401 vs. .397). Compared with their work, we use learning and model richer types of evidence; with PPR and LCS, we report best results on the BNC sentences. Table 4 details also recent results obtained for the BNC and Sports portions of the dataset. Ponzetto and Navigli (2010) (P&N'10) enriched the WordNet graph with additional relations projected onto the graph from Wikipedia; the table reports their best results using a graph centrality measure (Navigli and Lapata, 2010). Raviv and Markovitch (2012) (R&M'12) reported state-of-the-art performance in the specialized domains using Wikipedia as the reference knowledge base. Each individual context word is represented in their work as a weighted vector of Wikipedia concepts, where sense inference is performed by maximizing cosine similarity between the centroid of the context vectors and a vector representation of each word sense. Our results using PPR and LCS exceed or roughly match their results without using the Wikipedia resource.

4 Conclusion

We presented a learning framework that identifies useful contextual cues for knowledge-based sense disambiguation. The generated models are non-lexicalized, and are therefore applicable to new word types. Existing approaches pay little attention to context selection, or perform simplistic context modeling, whereas the proposed approach effectively consolidates diverse types of evidence. In the future, we are interested in representing additional word relatedness measures in this framework, such as embedding-based word similarity (Wang et al., 2015). We are further interested in creating specialized models that fit different word classes, e.g., of particular part-of-speech. In general, the proposed approach may prove beneficial for additional tasks that model word meaning in context, such as lexical substitution and sense induction.

[3] They used WordNet 1.7, while we use version 3.0. Large performance gaps due to different versions of WordNet were reported elsewhere (Agirre and Soroa, 2009).

Abstract

A *prerequisite* relation describes a basic relation among concepts in cognition, education and other areas. However, as a semantic relation, it has not been well studied in computational linguistics. We investigate the problem of measuring prerequisite relations among concepts and propose a simple link-based metric, namely *reference distance* (**RefD**), that effectively models the relation by measuring how differently two concepts refer to each other. Evaluations on two datasets that include seven domains show that our single metric based method outperforms existing supervised learning based methods.

1 Introduction

What should one know/learn before starting to learn a new area such as "deep learning"? A key for answering this question is to understand what a *prerequisite* is. A prerequisite is usually a concept or requirement before one can proceed to a following one. And the prerequisite relation exists as a natural dependency among concepts in cognitive processes when people learn, organize, apply, and generate knowledge (Laurence and Margolis, 1999). While there has been serious effort in understanding prerequisite relations in learning and education (Bergan and Jeska, 1980; Ohland et al., 2004; Vuong et al., 2011), it has not been well studied as a semantic relation in computational linguistics, where researchers focus more on lexical relations among lexical items (Miller, 1995) and fine-grained entity relations in knowledge bases (Mintz et al., 2009).

Instead of treating it as a relation extraction or link prediction problem using traditional machine learning approaches (Talukdar and Cohen, 2012; Yang et al., 2015), we seek to better understand prerequisite relations from a perspective of cognitive semantics (Croft and Cruse, 2004). Partially motivated by the theory of *frame semantics* (Fillmore, 2006), or, to understand a concept, one needs to understand all the related concepts in its "frame", we propose a metric that measures prerequisite relations based on a simple observation of human learning. When learning concept A, if one needs to refer to concept B for a lot of A's related concepts but not vice versa, B would more likely be a prerequisite of A than A of B. Specifically, we model a concept in a vector space using its related concepts and measure the prerequisite relation between two concepts by computing how differently the two's related concepts refer to each other, or *reference distance* (**RefD**).

Our simple metric **RefD** successfully reflects some properties of the prerequisite relation such as asymmetry and irreflexivity; and can be properly implemented for various applications using different concept models. We present an implementation of the metric using Wikipedia by leveraging the links as reference relations among concepts; and present a scalable prerequisite dataset construction method by crawling public available university course prerequisite websites and mapping them to Wikipedia concepts. Experimental results on two datasets that include seven domains demonstrate its effectiveness and robustness on measuring prerequisites. Surprisingly, our single metric based approach significantly outperforms baselines which use more sophisticated supervised learning. All the datasets are publicly available upon request.

Our main contributions include:

- A novel metric to measure the prerequisite relation among concepts that outperforms existing supervised learning baselines.
- A new dataset containing 1336 concept pairs in Computer Science and Math.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1668–1674,
Lisbon, Portugal, 17-21 September 2015.

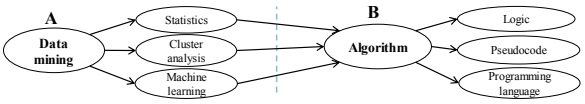

Figure 1: An example of the reference structure for two concepts ("Data mining" and "Algorithm") with a prerequisite relation.

2 Measuring Prerequisite Relations

Our goal is to design a function $f : \mathcal{C}^2 \rightarrow \mathcal{R}$ that maps a concept pair (A, B) to a real value that measures the extent to which A requires B as a prerequisite, where $\mathcal{C}$ is the concept space. How should a concept be represented in $\mathcal{C}$? According to the theory of frame semantics, one cannot understand a concept without access to all essential knowledge related to it. Such knowledge can be actually viewed as a set of related concepts. Thus, a concept could be represented by its related concepts in $\mathcal{C}$. For example, the concept "deep learning" may be represented by concepts such as "machine learning", "artificial neural network", etc.

Compared to prerequisites, a more common and observable relation among concepts is a *reference*, which widely exists in various forms such as hyperlinks, citations, notes, etc. Although a single evidence of reference does not indicate a prerequisite relation, a large number of such evidences might make a difference. For example, if most related concepts of A refer to B but few related concepts of B refer to A, then B is more likely to be a prerequisite of A, as shown in Figure 1. In order to measure prerequisite relations, we propose a *reference distance* (**RefD**), which is defined as

$$RefD(A,B) = \frac{\sum_{i=1}^{k} r(c_i,B)\cdot w(c_i,A)}{\sum_{i=1}^{k} w(c_i,A)} - \frac{\sum_{i=1}^{k} r(c_i,A)\cdot w(c_i,B)}{\sum_{i=1}^{k} w(c_i,B)} \quad (1)$$

where $\mathcal{C} = \{c_1, ..., c_k\}$ is the concept space; $w(c_i, A)$ weights the importance of c_i to A; and $r(c_i, A)$ is an indicator showing whether c_i refers to A, which could be links in Wikipedia, mentions in books, citations in papers, etc.

$RefD$ enables several useful properties for the prerequisite relation: 1) normalized: $RefD(A, B) \in [-1, 1]$; 2) asymmetric: $RefD(A, B)+RefD(B, A)=0$, which means if A is a prerequisite of B then B is not a prerequisite of A; and 3) irreflexive: $RefD(A, A)=0$, which means A is not a prerequisite of itself. To capture all three possible prerequisite relations between a concept pair, *RefD* is expected to satisfy the following constraints:

$$RefD(A,B) \in \begin{cases} (\theta, 1], & \text{if B is a prerequisite of A} \\ [-\theta, \theta], & \text{if no prerequisite relation} \\ [-1, -\theta), & \text{if A is a prerequisite of B} \end{cases}$$

where θ is a positive threshold.

Equation 1 provides a general framework to calculate *RefD*. In practice, we need to specify the concept space $\mathcal{C}$, the weight w, and the reference indicator function r.

3 Wikipedia-based RefD Implementation

We now implement *RefD* using Wikipedia. As a widely used open-access encyclopedia, Wikipedia provides relatively up-to-date and high quality knowledge and has been successfully utilized as explicit concepts (Gabrilovich and Markovitch, 2007). Moreover, the rich hyperlinks created by Wiki editors provide a natural way to calculate the reference indicator function r.

Specifically, the concept space $\mathcal{C}$ consists of all Wikipedia articles. $r(c, A)$ represents whether there is a link from Wiki article c to A. For $w(c, A)$, we experiment with two methods:

- *EQUAL*: A is represented by the concepts linked from it ($L(A)$) with equal weights.

$$w(c, A) = \begin{cases} 1 & \text{if } c \in L(A) \\ 0 & \text{if } c \notin L(A) \end{cases}$$

- *TFIDF*: A is represented by the concepts linked from it with TFIDF weights.

$$w(c, A) = \begin{cases} tf(c, A) * \log \frac{N}{df(c)} & \text{if } c \in L(A) \\ 0 & \text{if } c \notin L(A) \end{cases}$$

where $tf(c, A)$ is the number of times c being linked from A; N is the total number of Wikipedia articles; and $df(c)$ is the number of Wikipedia articles where c appears.

4 Experiments

In order to evaluate the proposed metric, we apply it to predicting prerequisite relations in Wikipedia, i.e., whether one article in Wikipedia is a prerequisite of another article. Given a pair of concepts (A,B), we predict whether B is a prerequisite of A or not. Both pairs where A is a prerequisite of

Dataset	Domain	# Pairs	# Prerequisites
CrowdComp	Meiosis	400	67
	Public-key Cryp.	200	27
	Parallel Postulate	200	25
	Newton's Laws	400	44
	Global Warming	400	43
Course	CS	678	108
	MATH	658	75

Table 1: Statistics of CrowdComp and Course Datasets

Domain	MaxEnt†	MaxEnt	EQUAL	TFIDF

Parallel Postulate	64.7	73.6	70.5	67.9
Newton's Laws	53.9	57.7	63.7	64.6
Global Warming	56.8	50.0	57.4	60.1
Average	58.7	60.4	60.0*	**61.2***

Table 2: Comparison of out-of-domain training accuracies of a MaxEnt classifier and *RefD* using EQUAL and TFIDF weighting. MaxEnt† is the number reported by Talukdar et al. (2012). MaxEnt shows the performance of our implementation. * indicates the difference between *RefD* and MaxEnt is statistically significant ($p < 0.01$).

B and pairs where no prerequisite relation exists will be viewed as negative examples.

RefD is tested on two datasets: CrowdComp dataset (Talukdar and Cohen, 2012) and a Course prerequisite dataset collected by us. We compare *RefD* with a Maximum Entropy (MaxEnt) classifier which exploits graph-based features such as PageRank scores and content-based features such as the category information, whether a title of concept is mentioned in the first sentence of the other concept, the number of times a concept is linked from the other, etc. (Talukdar and Cohen, 2012). All experiments use a Wikipedia dump of Dec 8, 2014.

4.1 Results on the CrowdComp Dataset

The CrowdComp dataset was collected using Amazon Mechanical Turk by Talukdar et al. (2012). It contains binary-labeled concept pairs from five different domains, including meiosis, public-key cryptography, the parallel postulate, Newton's laws of motion, and global warming. The label of the prerequisite relation for each pair is assigned using majority vote. Details of the dataset are shown in Table 1.

Following Talukdar et al. (2012), we evaluate

	CS				MATH			
	A	P	R	F	A	P	R	F
MaxEnt	72.8	87.6	53.2	66.1	69.0	78.1	53	63.1
EQUAL	76.4*	80.4	69.9	74.7*	**73.9***	78.4	67.3	**71.9***
TFIDF	**77.1***	82.3	69.1	**75.1***	70.3*	76.3	60.1	66.7*

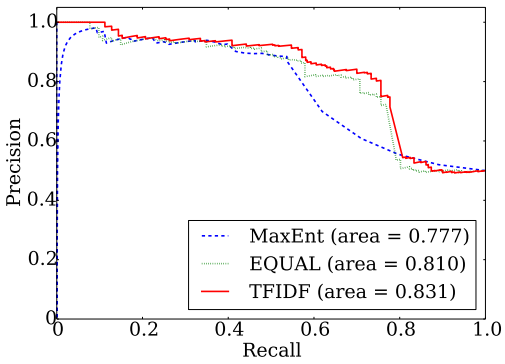
Table 3: Comparison of in-domain training accuracies, precision, recall, and F1 measure of MaxEnt and *RefD* using EQUAL and TFIDF weighting. * indicates the improvement over MaxEnt is statistically significant ($p < 0.01$).

different methods in a "leave one domain out" manner, where data from one domain is used for testing and data from other four for training. Classes in the training and testing set are balanced by oversampling the minority class. Table 2 lists the accuracies of different methods. In terms of average performance, *RefD* achieves comparable average accuracy as MaxEnt. When TFIDF is used to calculate w, *RefD* performs better than MaxEnt. Also we notice that our implementation of MaxEnt classifier achieves higher accuracy than reported in the original paper, which may be due to the difference between Wiki dumps used. In addition, we can see that there are large differences in performance across different domains, which is mainly due to two reasons. First, the coverage of Wikipedia for different domains may vary a lot. Some domains are more popular and thus edited more frequently, leading to a better quality of articles and a more complete link structure. Second, since the ground-truth labels are collected by crowdsourcing and there is no guarantee for workers' knowledge about a certain domain, the quality of labels for different domains varies.

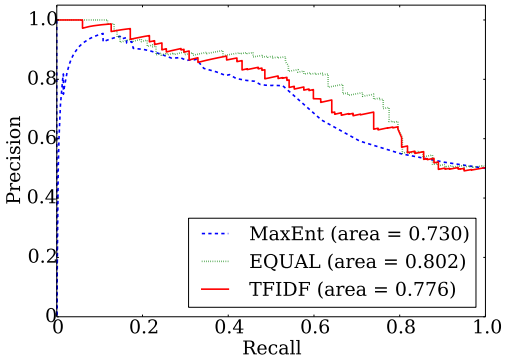
4.2 Results on the Course Dataset

We also built a Course dataset with the help of information available on a university's course website containing prerequisite relations between courses. For example, "CS 331 Data Structures and Algorithms" is a prerequisite for "CS 422 Data mining". We get the prerequisite pairs by crawling the website and linking the course to Wikipedia using simple rules such as title matching and content similarity. In order to get negative samples, we randomly sample 600 pairs using concepts appearing in the prerequisite pairs. All pairs are then checked by two domain experts by removing pairs with incorrect labels. Table 1 lists the information of the dataset.

Evaluation uses in-domain 5-fold cross-



(a) CS

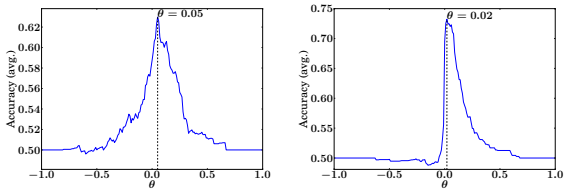


(b) MATH

Figure 2: Comparison of Precision-Recall curves of MaxEnt and *RefD* (using EQUAL and TFIDF weighting) on the Course dataset.

validation and classes are balanced by oversampling the minority class. Table 3 lists the performance comparison of different methods on accuracy, precision, recall and F1 score. We can see that *RefD* outperforms MaxEnt in terms of accuracy, recall, and F1 score on both CS and MATH domain. Because MaxEnt relies on many features but there are only limited distinct positive samples in the dataset, it is more likely to overfit the training data, which leads to high precision but low recall on test set. In order to better compare precision and recall, we plot the Precision-Recall curves of different methods, as shown in Figure 2. *RefD* shows a clear improvement in the area under the Precision-Recall curve.

Comparing two weighting methods, we find that TFIDF performs slightly better than EQUAL on CS while EQUAL has higher scores than TFIDF on MATH. Since how to compute w in *RefD* is a crucial problem, our ongoing work is to explore more sophisticated semantic representations to measure prerequisite relations. A natural extension to the two simple methods here is to represent



(a) CrowdComp (b) Course

Figure 3: Average accuracy on two datasets with a given threshold of *RefD* using TFIDF weighting.

a concept using WordNet (Miller, 1995), Explicit Semantic Analysis (Gabrilovich and Markovitch, 2007), or Word2vec embeddings (Mikolov et al., 2013). Incorporating these representations may improve the performance of *RefD*.

4.3 Parameter Analysis and Case Study

Since using *RefD* to predict prerequisites requires setting a threshold θ, we also investigate the relation between the threshold and the performance of prediction, as shown in Figure 3. We can see that a threshold of 0.05 for *RefD* using TFIDF achieves the highest average accuracy on the CrowdComp dataset while a threshold of 0.02 works the best for Course dataset. Empirically we find that a threshold between 0.02 and 0.1 yields a good performance for prerequisite prediction task.

We further explore the performance of *RefD* through a case study for the concept "deep learning" (denoted as c'). Specifically, for any concept c linked from c' we calculate *RefD*(c', c). Table 4 lists the *RefD* scores for different concepts using *EQUAL* weighting. The concepts on the left have negative *RefD* scores with high absolute values, which means that "deep learning" is a prerequisite of them. Meanwhile concepts on the right have high positive *RefD* scores, which means that "deep learning" requires knowing them first. For example, people may first need to have some knowledge of "machine learning", "artificial intelligence" and "algorithm" in order to learn "deep learning". Also we notice that concepts in the middle have *RefD* scores which are very close to 0, showing that there is no prerequisite relations between these concepts and "deep learning". However, since our *RefD* implementation is based on Wikipedia, it might not give an accurate measure for concepts if they have no Wikipedia articles or their articles are too short to provide an encyclopedic coverage, such as "discriminative model" and "feature engineering".

Concept	*RefD*	Concept	*RefD*	Concept	*RefD*
Deep belief network	-0.38	List of Nobel laureates	0.009	Machine learning	0.32
Neocognitron	-0.28	Neural development	0.009	Artificial neural network	0.31
Word embedding	-0.24	Watson (computer)	0.003	Artificial intelligence	0.15
Vanishing gradient problem	-0.22	Self-organization	8e-5	Algorithm	0.14
Feature learning	-0.17	Language model	-0.004	Statistical classification	0.13

Table 4: *RefD* scores between "deep learning" and the concepts linked from it. All scores are calculated by *RefD*('deep learning', concept).

Please note that our Wikipedia-based implementation is computationally efficient especially after precomputing weights and references and can be easily incorporated as a feature into existing supervised learning based methods.

5 Related Work

In the area of education, researchers have tried to find prerequisites based on the assessment data of students' performance (Scheines et al., 2014; Vuong et al., 2011). However, prerequisite relations have not been well studied in computer science, with only a few exceptions. Liu et al. (2011) studied learning-dependency between knowledge units using classification where a knowledge unit is a special text fragment containing concepts. We focus on more general prerequisite relations among concepts. Talukdar and Cohen (2012) applied a Maximum Entropy classifier to predict prerequisite structures in Wikipedia using various features such as a random walk with restart score and PageRank score. Instead of doing feature engineering, we propose to measure prerequisite relations using a single metric. Yang et al. (2015) proposed Concept Graph Learning to induce relations among concepts from prerequisite relations among courses, where the learned concept prerequisite relations are implicit and thus can not be evaluated. Our method is more interpretable for measuring prerequisite relations.

Our work is closely related to the study of semantic relations. One direction is automatic lexical relation extraction. Different methods have been proposed to discover hypernym-hyponym relations based on lexical patterns (Hearst, 1992; McNamee et al., 2008; Ritter et al., 2009), distributional similarity (Kotlerman et al., 2010), semantic word embeddings (Fu et al., 2014), etc. Another line is entity relation extraction, which can be performed by distant supervision (Mintz et al., 2009; Riedel et al., 2010), Open IE (Fader et al., 2011), and neural networks (Bordes et al., 2011; Lin et al., 2015).

In addition, semantic relatedness measures have been widely studied, where the key is to model the semantic representation based on a latent space, such as LSA (Deerwester et al., 1990), PLSA (Hofmann, 1999), LDA (Blei et al., 2003) and distributed word embeddings (Huang et al., 2012; Mikolov et al., 2013), or an explicit concept space, such as ESA (Gabrilovich and Markovitch, 2007), SSA (Hassan and Mihalcea, 2011), and SaSA (Wu and Giles, 2015). Our work can also be served as a basis for building concept hierarchy (Wang et al., 2015) and teaching/learning assistant tools (Liang et al., 2015).

6 Conclusions and Future Work

We studied the problem of measuring prerequisite relations among concepts and proposed *RefD*, a general, light-weight, and effective metric, to capture the relation. We presented Wikipedia-based implementations of *RefD* with two different weighting strategies. Experiments on two datasets including seven domains showed that our proposed metric outperformed existing baselines using supervised learning.

Promising future directions would be applying the framework of *RefD* to other contexts such as measuring the prerequisite relations or reading orders between papers and textbooks. In addition, *RefD* can be incorporated into existing supervised models for a more accurate measure. Also it would be meaningful to explore ranking different prerequisites of a concept. Besides the rich link structure we could take advantage of more content information from Wikipedia and other resources such as textbooks and scientific papers.

Adapting Phrase-based Machine Translation to Normalise Medical Terms in Social Media Messages

Nut Limsopatham and Nigel Collier
Department of Theoretical and Applied Linguistics
University of Cambridge
Cambridge, UK
{nl347,nhc30}@cam.ac.uk

Abstract

Previous studies have shown that health reports in social media, such as DailyStrength and Twitter, have potential for monitoring health conditions (e.g. adverse drug reactions, infectious diseases) in particular communities. However, in order for a machine to understand and make inferences on these health conditions, the ability to recognise when laymen's terms refer to a particular medical concept (i.e. text normalisation) is required. To achieve this, we propose to adapt an existing phrase-based machine translation (MT) technique and a vector representation of words to map between a social media phrase and a medical concept. We evaluate our proposed approach using a collection of phrases from tweets related to adverse drug reactions. Our experimental results show that the combination of a phrase-based MT technique and the similarity between word vector representations outperforms the baselines that apply only either of them by up to 55%.

1 Introduction

Social media, such as DailyStrength[1] and Twitter[2], is a fast growing and potentially rich source of *voice of the patient* data about experience in terms of benefits and side-effects of drugs and treatments (O'Connor et al., 2014). However, natural language understanding from social media messages is a difficult task because of the lexical and grammatical variability of the language (Baldwin et al., 2013; O'Connor et al., 2014). Indeed, language understanding by machines requires the ability to recognise when a phrase refers to a particular concept. Given a variable length phrase, an effective system should return a concept with the most similar meaning. Table 1 shows examples of mappings between Twitter phrases and medical concepts. For example, a Twitter phrase 'No way I'm gettin any sleep 2nite' might be mapped to the medical concept 'Insomnia' (SNOMED:193462001), when using the SNOMED-CT ontology (Spackman et al., 1997). The success of the mapping between social media phrases and formal medical concepts would enable an automatic integration between patient experiences and biomedical databases (Limsopatham and Collier, 2015). We refer to this mapping from social media phrases to medical concepts as *medical term normalisation*, which aims to determine the unique identifier of a medical concept that is mentioned in different forms in a free-text (Morgan et al., 2008).

Existing works, e.g. (Elkin et al., 2012; Gobbel et al., 2014; Wang et al., 2009), mostly focused on identifying medical concepts in medical documents. For example, Gobbel et al. (2014) proposed a naïve Bayesian-based technique to map phrases from clinical notes to medical concepts in the SNOMED-CT ontology. Wang et al. (2009) identified medical concepts regarding adverse drug events in electronic medical records. On the other hand, O'Connor et al. (2014) investigated the normalisation of medical terms in Twitter messages. In particular, they proposed to use the Lucene retrieval engine[3] to retrieve medical concepts that could be potentially mapped to a given Twitter phrase, when mapping between Twitter phrases and medical concepts.

In contrast, we argue that the medical text normalisation task can be achieved by using well-established phrase-based MT techniques, where we translate a text written in *a social media language* (e.g. 'No way I'm gettin any sleep 2nite') to a text written in *a formal medical language* (e.g.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1675–1680,
Lisbon, Portugal, 17-21 September 2015.

Table 1: Examples of the mappings between social media messages and medical concepts.

Social media message	Description of corresponding medical concept
No way I'm gettin any sleep 2nite	Insomnia (SNOMED ID: 193462001)
kept me up for days	Insomnia (SNOMED ID: 193462001)
can't even focus forreal	Unable to concentrate (SNOMED ID: 60032008)
I should be studying for but literally can't	Unable to concentrate (SNOMED ID: 60032008)
DRUG makes u skinny	Weight loss (SNOMED ID: 89362005)
still tired as shit	Fatigue (SNOMED ID: 84229001)
wiggin out a little bit	Fidgeting (SNOMED ID: 247910009)
I'm happiest with _DRUG_	Cheerful mood (SNOMED ID: 112080002)
DRUG made me the most chipper person	Cheerful mood (SNOMED ID: 112080002)

'Insomnia') and then calculate the similarity between the translated phrase and the description of a medical concept. Indeed, in this work we investigate an effective adaptation of phrase-based MT to map a Twitter phrase to a medical concept. Moreover, we propose to combine the adapted phrase-based MT technique and the similarity between word vector representations to effectively map a Twitter phrase to a medical concept.

The main contributions of this paper are threefold:

1. We investigate the adaptation of phrase-based MT to map a Twitter phrase to a SNOMED-CT concept.
2. We propose to combine our adaptation of phrase-based MT and the similarity between word vector representations to map Twitter phrases to formal medical concepts.
3. We thoroughly evaluate the proposed approach using phrases from our collection of tweets related to the topic of adverse drug reactions (ADRs).

2 Related Work

Phrase-based MT models, e.g. (Koehn et al., 2003; Och and Ney, 2004), have been shown to be effective in translation between languages, as they learn local term dependencies, such as collocations, reorderings, insertions and deletions. Koehn et al. (2003) showed that a phrase-based MT technique markedly outperformed traditional word-based MT techniques on several benchmarks. In this work, we adapt the phrase-based MT technique of Koehn et al. (2003) for the medical text normalisation task. In particular, we use the phrase-based MT technique to translate phrases from *Twitter language* to *formal medical language*, before mapping the translated phrases to medical concepts based on the ranked similarity of their word vector representations.

Traditional approaches for creating word vector representations treated words as atomic units (Mikolov et al., 2013b; Turian et al., 2010). For instance, the one-hot representation used a vector with a length of the size of the vocabulary, where one dimension is on, to represent a particular word (Turian et al., 2010). Recently, techniques for learning high-quality word vector representations (i.e. distributed word representations) that could capture the semantic similarity between words, such as continuous bags of words (CBOW) (Mikolov et al., 2013b) and global vectors (GloVe) (Pennington et al., 2014), have been proposed. Indeed, these distributed word representations have been effectively applied in different systems that achieve state-of-the-art performances for several NLP tasks, such as MT (Mikolov et al., 2013a) and named entity recognition (Passos et al., 2014). In this work, beside using word vector representations to measure the similarity between translated Twitter phrases and the description of medical concepts, we use the similarity between word vector representations of the original Twitter phrase and the description of a medical concept to augment the adapted phrase-based MT technique.

3 Medical Term Normalisation

We discuss our adaptation of phrase-based MT for medical text normalisation in Section 3.1. Section 3.2 introduces our proposed approach for combining similarity score of word vector representations with the adapted phrase-based MT technique.

3.1 Adapting Phrase-based MT

We aim to learn a translation between a Twitter phrase (i.e. a phrase from a Twitter message) and a formal medical phrase (i.e. the description of a medical concept). For a given Twitter phrase phr_t, we find a suitable medical phrase phr_m using *a translation score*, based on a phrase-based model, as follows:

$$score_{translation}(phr_m|phr_t) = p(phr_m|phr_t) \quad (1)$$

where $p(phr_m|phr_t)$ can be calculated using any phrase-based MT technique, e.g. (Koehn et al., 2003; Och and Ney, 2004). We then rank translated phrases phr_m based on this translation score. The top-k translated phrases are used for identifying the corresponding medical concept.

However, the translated phrase phr_m may not be exactly matched with the description of any target medical concepts. We propose two techniques to deal with this problem. For the first technique, we rank the target concepts based on the cosine similarity between the vector representation of phr_m and the vector representation of the description of each concept $desc_c$:

$$sim_{cos}(phr_m, desc_c) = \frac{V_{phr_m} \cdot V_{desc_c}}{||V_{phr_m}|| \times ||V_{desc_c}||} \quad (2)$$

where V_{phr_m} and V_{desc_c} are the vector representations of phr_m and $desc_c$, respectively. Any technique for creating word vector representations (e.g. one-hot, CBOW and GloVe) can be used. Note that if a phrase (e.g. phr_m) contains several terms, we create a vector representation by summing the value of the same dimension of the vector representation of each word (i.e. element-wise addition).

On the other hand, the second technique also incorporates the ranked position r of the translated phrase phr_m when translated from the original phrase phr_t using Equation (1). Indeed, the second technique calculates the similarity score as follows:

$$sim_{rcos}(phr_m, desc_c) = \frac{1}{r} \cdot \frac{V_{phr_m} \cdot V_{desc_c}}{||V_{phr_m}|| \times ||V_{desc_c}||} \quad (3)$$

3.2 Combining Similarity Score with Phrase-based MT

As discussed in Section 2, word vector representations (e.g. created by CBOW or GloVe) can capture semantic similarity between words by itself. Hence, we propose to map a Twitter phrase phr_t to a medical concept c, which is represented with a description $desc_c$, by linearly combining the cosine similarity, between vector representations of the Twitter phrase phr_t and the description $desc_c$, with the similarity score computed using one of the adapted phrased-based MT techniques (introduced in Section 3.1), as follows:

$$sim_{combine}(phr_t, desc_c) = \frac{V_{phr_t} \cdot V_{desc_c}}{||V_{phr_t}|| \times ||V_{desc_c}||} + MT_a(phr_t, desc_c) \quad (4)$$

where $MT_a(phr_t, desc_c)$ is calculated using one of the adapted phrase-based MT techniques described in Section 3.1.

4 Experimental Setup

4.1 Test Collection[4]

To evaluate our approach, we use a collection of 25 million tweets related to adverse drug reactions (ADRs), from cognitive enhancers (Hanson et al., 2013) and anti-depressants (Schneeweiss et al., 2010). These tweets were collected using the Twitter Streaming API[5] by filtering on the name of a particular set of drugs that can have adverse reactions to the patients. Note that terms regarding adverse drug reaction (e.g. insomnia) were not used for capturing tweets. From this collection, we use 201 ADR phrases and their corresponding SNOMED-CT concepts annotated by a PhD-level computational linguist. These phrases were anonymised by replacing numbers, user IDs, URIs, locations, email addresses, dates and drug names with appropriate tokens e.g. *_NUMBER_*.

4.2 Evaluation Approach

We conduct experiments using 10-fold cross validation, where the Twitter phrases are randomly divided into 10 separated folds. We address this task as a ranking task, where we aim to rank the medical concept with the highest similarity score, e.g. calculated using Equation (2), at the top rank. Hence, we evaluate our approach using Mean Reciprocal Rank (MRR) measure (Craswell, 2009), which is an information retrieval measure based on the user model where the user wants to see

[4]The gold-standard mapping between the Twitter phrases and the SNOMED-CT concepts are available on Zenodo.org (DOI: http://dx.doi.org/10.5281/zenodo.27354)

[5]https://dev.twitter.com/streaming/public

only one relevant concept. In particular, MRR is based on the the reciprocal of the rank at which the first relevant concept is viewed in the ranking (e.g. MRR = 0.5 if the first mapped concept is wrong but the second is correct). We limit our evaluation at top 5 of the ranking (i.e. MRR-5). In addition, we compare the significant difference between the performance achieved by our proposed approach and the baselines using the paired t-test ($p < 0.05$).

4.3 Word Vector Representation

We use three different techniques, including one-hot, CBOW and GloVe, to create word vector representations used in our approach (see Section 3). In particular, the vocabulary for creating the one-hot representation includes all terms in the Twitter phrases and the descriptions of the target SNOMED-CT concepts. Meanwhile, we create word vector representations based on CBOW and GloVe by using the word2vec[6] and GloVe[7] implementations. We learn the vector representations from the collections of tweets and medical articles, respectively, using window size of 10 words. The tweet collection (denoted *Twitter*) contains 419,702,147 English tweets, which are related to 11 drug names and 6 cities, while the medical article collection (denoted *BMC*) includes all medical articles from the BioMed Central[8]. For both CBOW and GloVe, we create vector representations with vector sizes 50 and 200, respectively.

4.4 Learning Phrase-based Model

We use the phrase-based MT technique of Koehn et al. (2003), as implemented in the Moses toolkit (Koehn et al., 2007)[9] with default settings, to learn to translate from the Twitter language to the medical language. In particular, when training the translator, we show the learner pairs of the Twitter phrases and descriptions of the corresponding SNOMED-CT concepts.

5 Experimental Results

We evaluate 6 different instantiations of the proposed approach discussed in Section 3, including:

1. *bestMT*: set $k = 1$, when finding the translated phrase phr_m for a Twitter phrase phr_t (Equation (1)), before ranking target medical concepts for the translated phrase phr_m using Equation (2).
2. *top5MT*: similar to *bestMT*, but set $k = 5$.
3. *top5MTr*: similar to *top5MT*, but also consider the rank position of the translate phrases when ranking the target medical concepts by using Equation (3).
4. *bestMT+vSim*: incorporate with the ranking generated from *bestMT*, the cosine similarity between the vector representations of the Twitter phrase phr_t and the description $desc_c$ of target medical concepts by using Equation (4).
5. *top5MT+vSim*: similar to *bestMT+vSim*, but use the ranking from *top5MT*.
6. *top5MTr+vSim*: similar to *bestMT+vSim*, but use the ranking from *top5MTr*.

Another baseline is *vSim*, where we consider only the cosine similarity between the vector representations of the Twitter phrase phr_t and the description $desc_c$ of target medical concepts.

Table 2 compares the performance of these 6 instantiations and the *vSim* baseline in terms of MRR-5. We firstly observe that for the *vSim* baseline, excepting for word vector representation with vector size 50 learned using GloVe from the Twitter collection, word vector representations learned using either CBOW or GloVe are more effective than the one-hot representation. However, the difference between the MRR-5 performance is not statistically significant ($p > 0.05$, paired t-test). In addition, word vector representations learned either using CBOW or GloVe with vector size 200 is more effective than those with vector size 50.

Next, we find that our adaptation of phrase-based MT (i.e. *bestMT*, *top5MT* and *top5MTr*) significantly ($p < 0.05$) outperforms the *vSim* baseline. For example, with the one-hot representation, *top5MT* (MRR-5 0.2491) and *top5MTr* (MRR-5 0.2458) perform significantly ($p < 0.05$) better than *vSim* (MRR-5 0.1675) by up to 49%. Meanwhile, when using word vector representations with the vector size 200 learned using GloVe from the BMC collection, *top5MT* (MRR-5 0.2638) significantly ($p < 0.05$) outperforms *vSim* with either the GloVe vector representation (MRR-5 0.1869) or the one-hot representation (MRR-5 0.1675). We observe the similar trends in performance

[9] http://www.statmt.org/moses/

Table 2: MRR-5 performance of the proposed approach and the baselines. Significant differences ($p < 0.05$) compared to the cosine similarity (*vSim*) baselines with the one-hot representation, and with the corresponding distributed word representation (e.g. CBOW or GloVe) are denoted $^{\triangle}$ and $^{\blacktriangle}$, respectively.

Approach	One-hot	BMC				Twitter			
		CBOW		GloVe		CBOW		GloVe	
		50	200	50	200	50	200	50	200
vSim	0.1675	0.1771	0.1896	0.1840	0.1869	0.1812	0.1813	0.0936	0.1807
bestMT	0.2232	0.1926	0.2070	0.1803	0.2500$^{\triangle}$	0.2014	0.2047	0.1258	0.2138
top5MT	0.2491$^{\triangle}$	**0.1994**	0.2104	0.1879	**0.2638**$^{\triangle\blacktriangle}$	**0.2037**	0.2095	**0.1322**	0.2362
top5MTr	0.2458$^{\triangle}$	0.1982	0.2109	**0.1894**	0.2617$^{\triangle}$	**0.2037**	**0.2096**	**0.1322**	0.2310
bestMT+vSim	0.2420$^{\triangle}$	0.1910	0.1953	0.1860	0.2532$^{\triangle}$	0.1891	0.1954	0.1078	0.2374
top5MT+vSim	0.2556$^{\triangle}$	0.1916	**0.2144**	0.1726	0.2600$^{\triangle}$	0.1978	0.2068	0.1079	0.2405$^{\triangle}$
top5MTr+vSim	**0.2594**$^{\triangle}$	0.1861	0.2070	0.1802	0.2590$^{\triangle}$	0.1959	0.2027	0.1129	**0.2406**$^{\triangle}$

when using vector representations learned from the Twitter collection. These results show that our adapted phrase-based MT techniques are effective for the medical term normalisation task.

In addition, we observe the effectiveness of our combined approach (i.e. *bestMT+vSim*, *top5MT+vSim* and *top5MTr+vSim*), as it further improves the performance of the adapted phrase-based MT (i.e. *bestMT*, *top5MT* and *top5MTr*, respectively), when using the one-hot representation. For example, *top5MTr+vSim* achieves the MRR-5 of 0.2594, while the MRR-5 of *top5MTr* is 0.2458. However, the performance difference is not statistically significant. Meanwhile, when using the CBOW and GloVe vectors, the achieved performance is varied based on the collection (i.e. BMC or Twitter) used for learning the vectors and the size of the vectors.

6 Conclusions

We have introduced our approach that adapts a phrase-based MT technique to normalise medical terms in Twitter messages. We evaluate our proposed approach using a collection of phrases from tweets related to ADRs. Our experimental results show that the proposed approach significantly outperforms an effective baseline by up to 55%. For future work, we aim to investigate the modelling of learned vector representation, such as CBOW and GloVe, within a phrase-based MT model when normalising medical terms.

Acknowledgements

The authors gratefully acknowledge Nestor Alvaro (Sokendai, Japan) for providing access to the Twitter/SNOMED-CT annotations which were used to derive the test collection used in these experiments. The derived dictionary and a representative sample of the word vector representations (CBOW and GloVe at 200d) are made available on Zenodo.org (DOI: http://dx.doi.org/10.5281/zenodo.27354). We wish to thank funding support from the EPSRC (grant number EP/M005089/1).

Script Induction as Language Modeling

Abstract

The *narrative cloze* is an evaluation metric commonly used for work on automatic script induction. While prior work in this area has focused on count-based methods from distributional semantics, such as pointwise mutual information, we argue that the narrative cloze can be productively reframed as a language modeling task. By training a discriminative language model for this task, we attain improvements of up to 27 percent over prior methods on standard narrative cloze metrics.

1 Introduction

Although the concept of *scripts* in artificial intelligence dates back to the 1970s (Schank and Abelson, 1977), interest in this topic has renewed with recent efforts to automatically induce scripts from text on a large scale. One particularly influential work in this area, Chambers and Jurafsky (2008), treats the problem of script induction as one of learning *narrative chains*, which they accomplish using simple textual co-occurrence statistics. For the novel task of learning narrative chains, they introduce a new evaluation metric, the *narrative cloze* test, which involves predicting a missing event from a chain of events drawn from text. Several follow-up works (Chambers and Jurafsky, 2009; Jans et al., 2012; Pichotta and Mooney, 2014; Rudinger et al., 2015) employ and extend Chambers and Jurafsky (2008)'s methods for learning narrative chains, each using the narrative cloze to evaluate their work. [1]

In this paper, we take the position that the narrative cloze test, which has been treated predominantly as a method for evaluating script knowledge, is more productively thought of simply as a language modeling task.[2] To support this claim, we demonstrate a marked improvement over previous methods on this task using a powerful discriminative language model – the Log-Bilinear model (LBL). Based on this finding, we believe one of the following conclusions must follow: either discriminative language models are a more effective technique for script induction than previous methods, or the narrative cloze test is not a suitable evaluation for this task.[3]

2 Task Definition

Following the definitions of Chambers and Jurafsky (2008), a **narrative chain** is "a partially ordered set of narrative events that share a common actor," where a **narrative event** is "a tuple of an event (most simply a verb) and its participants, represented as *typed dependencies*." (De Marneffe et al., 2006) Formally, $e := (v, d)$, where e is a narrative event, v is a verb lemma, and d is the syntactic dependency (*nsubj* or *dobj*) between v and the protagonist. As an example, consider the following narrative:

> John studied for the exam and aced it.
> His teacher congratulated him.

With John as protagonist, we have a sequence of three narrative events: $(study, nsubj)$, $(ace, nsubj)$, and $(congratulate, dobj)$.

In the **narrative cloze** test, a sequence of narrative events (like the example provided here) is extracted automatically from a document, and one

[1]A number of related works on script induction use alternative task formulations and evaluations. (Chambers, 2013; Cheung et al., 2013; Cheung and Penn, 2013; Frermann et al., 2014; Manshadi et al., 2008; Modi and Titov, 2014; Regneri et al., 2010)

[2]Manshadi et al. (2008) also take a language modeling approach to event prediction, although their experiments are not directly comparable.

[3]We note that, whether the narrative cloze was originally intended as a rigorous evaluation of script induction techniques or merely a preliminary metric, we are motivated by the observation that this evaluation has nonetheless become a standard metric for this task.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1681–1686,
Lisbon, Portugal, 17-21 September 2015.

narrative event is removed; the task is to predict the missing event.

Data Each of the models discussed in the following section are trained and tested on chains of narrative events extracted from stories in the New York Times portion of the Gigaword corpus (Graff et al., 2003) with Concrete annotations (Ferraro et al., 2014). Training is on the entirety of the 1994–2006 portion (16,688,422 chains with 58,515,838 narrative events); development is a subset of the 2007–2008 portion (10,000 chains with 35,109 events); and test is a subset of the 2009–2010 portion (5,000 chains with 17,836 events). All extracted chains are of length two or greater.

Chain Extraction To extract chains of narrative events for training and testing, we rely on the (automatically-generated) coreference chains present in Concretely Annotated Gigaword. Each narrative event in an extracted chain is derived from a single mention in the corresponding coreference chain, i.e., it consists of the verb and syntactic dependency ($nsubj$ or $dobj$) that governs the head of the mention, if such a dependency exists. Overlapping mentions within a coreference chain are collapsed to a single mention to avoid redundant extractions.

3 Models

In this section we present each of the models we train for the narrative cloze evaluation. In a single narrative cloze test, a sequence of narrative events, $(e_1, \cdots, e_L)$, with an insertion point, k, for the missing event is provided. Given a fixed vocabulary of narrative events, $\mathcal{V}$, a candidate sequence is generated for each vocabulary item by inserting that item into the sequence at index k. Each model generates a score for the candidate sequences, yielding a ranking over the vocabulary items. The rank assigned to the actual missing vocabulary item is the score the model receives on that cloze test. In this case, we set $\mathcal{V}$ to include all narrative events, e, that occur at least ten times in training, yielding a vocabulary size of 12,452. All out-of-vocabulary events are converted to (and scored as) the symbol UNK.

3.1 Count-based Methods

Unigram Baseline (UNI) A simple but strong baseline introduced by Pichotta and Mooney (2014) for this task is the unigram model: candidates are ranked by their observed frequency in training, without regard to context.

Unordered PMI (UOP) The original model for this task, proposed by Chambers and Jurafsky (2008), is based on the pointwise mutual information (PMI) between events.

$$pmi(e_1, e_2) \propto \log \frac{C(e_1, e_2)}{C(e_1, *)C(*, e_2)} \quad (1)$$

Here, $C(e_1, e_2)$ is the number of times e_1 and e_2 occur in the same narrative event sequence, i.e., the number of times they "had a coreferring entity filling the values of [their] dependencies," and the ordering of e_1 and e_2 is not considered. In our implementation, individual counts are defined as follows:

$$C(e, *) := \sum_{e' \in \mathcal{V}} C(e, e') \quad (2)$$

This model selects the best candidate event in a given cloze test according to the following score:

$$\hat{e} = \arg\max_{e \in \mathcal{V}} \sum_{i=1}^{L} pmi(e, e_i) \quad (3)$$

We tune this model with an option to apply a modified version of discounting for PMI from Pantel and Ravichandran (2004).

Ordered PMI (OP) This model is a slight variation on Unordered PMI introduced by Jans et al. (2012). The only distinction is that $C(e_1, e_2)$ is treated as an asymmetric count, sensitive to the order in which e_1 and e_2 occur within a chain.

Bigram Probability (BG) Another variant introduced by Jans et al. (2012), the "bigram probability" model uses conditional probabilities rather than PMI to compute scores. In a cloze test, this model selects the following event:

$$\hat{e} = \arg\max_{e \in \mathcal{V}} \prod_{i=1}^{k} p(e|e_i) \prod_{i=k+1}^{L} p(e_i|e) \quad (4)$$

where $p(e_2|e_1) = \frac{C(e_1, e_2)}{C(e_1, *)}$ and $C(e_1, e_2)$ is asymmetric. We tune this model with an option to perform absolute discounting. Note that this model is not a bigram model in the typical language modeling sense.

Table 1: Narrative cloze results bucketed by chain length for each model and scoring metric with best results in bold. The models are Unigram Model (UNI), Unordered PMI (UOP), Ordered PMI (OP), Bigram Probability Model (BG), Log-Bilinear Model N=2 (LBL2), Log-Bilinear Model N=4 (LBL4)

Skip N-gram We tune the previous three models (UOP, OP, and BG) with the skip n-gram counting methods introduced by Jans et al. (2012) for this task, varying the ways in which the counts, $C(e_1, e_2)$, are collected. Using skip-n counting, $C(e_1, e_2)$ is incremented every time e_1 and e_2 co-occur within a window of size n. We experiment with **skip-0** (consecutive events only), **skip-3** (window size 3), and **skip-all** (entire chain length) settings.

For each of the four narrative cloze scoring metrics we report on (average rank, mean reciprocal rank, recall at 10, and recall at 50), we tune the Unordered PMI, Ordered PMI, and Bigram Probability models over the following parameter space: $\{$**skip-0**, **skip-3**, **skip-all**$\}$ $\times$ $\{$**discount**, **no-discount**$\}$ $\times$ $\{$**T=4**, **T=10**, **T=20**$\}$, where **T** is a pairwise count threshold.

3.2 A Discriminative Method

Log-Bilinear Language Model (LBL) The Log-Bilinear language model is a language model that was introduced by Mnih and Hinton (2007). Like other language models, the LBL produces a probability distribution over the next possible word given a sequence of N previously observed words. N is a hyper-parameter that determines the size of the context used for computing the probabilities. While many variants of the LBL have been proposed since its introduction, we use the simple variant described below.

Formally, we associate one context vector $\mathbf{c}_e \in \mathbb{R}^d$, one bias parameter $b_e \in \mathbb{R}$, and one target vector $\mathbf{t}_e \in \mathbb{R}^d$ to each narrative event $e \in \mathcal{V} \cup \{$ UNK, BOS, EOS $\}$. $\mathcal{V}$ is the vocabulary of events and BOS, EOS, and UNK are the beginning-of-sequence, end-of-sequence, and out-of-vocabulary symbols, respectively. The probability of an event e that appears after a sequence $s = [s_1, s_2, \ldots, s_N]$ of context words is defined as:

$$p(e|s) = \frac{\exp(\mathbf{t}_e^\intercal \hat{\mathbf{t}}_s + b_e)}{\sum_{e' \in \mathcal{V} \cup \{ \text{ UNK, EOS } \}} \exp(\mathbf{t}_{e'}^\intercal \hat{\mathbf{t}}_s + b_{e'})}$$

$$\text{where } \hat{\mathbf{t}}_s = \sum_{j=1}^{N} \mathbf{m}_j \odot \mathbf{c}_{s_j}$$

The $\odot$ operator performs element-wise multiplication of two vectors. The parameters that are optimized during training are $\mathbf{m}_j \; \forall j \in [1, \ldots, N]$ and $\mathbf{c}_e, \mathbf{t}_e \; \forall e \in \mathcal{V} \cup \{$ UNK, BOS, EOS $\}$. To calculate the log-probability of a sequence of narrative events $E = (e_1, \ldots, e_L)$ we compute:

$$l(S) = \left(\sum_{i=1}^{n} \log(p(e_i | f_E(e_i))) \right) + \log(p(\text{EOS} | f_E(\text{EOS}))) \quad (5)$$

Here f_E is a function that returns the sequence of N words that precede the event e_i in the se-

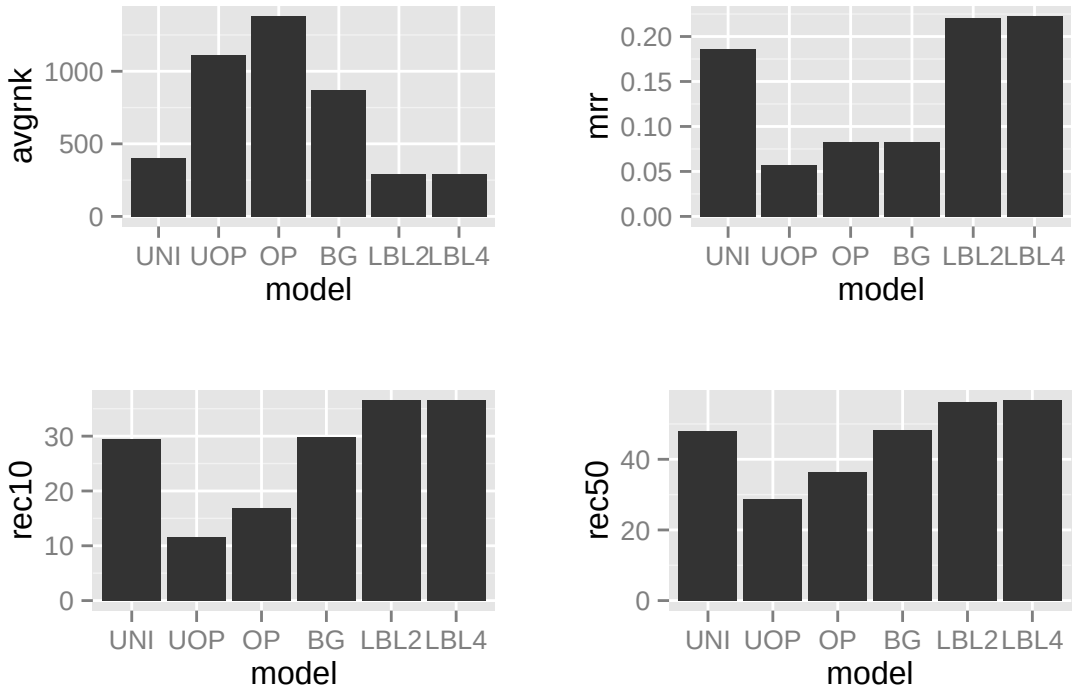

Figure 1: Narrative cloze results over all chain lengths. quence E' made by prepending N BOS tokens and appending a single EOS token to E.

The LBL models are trained by minimizing the objective described in Equation 5 for all the sequences in the training corpus. We used the OxLM toolkit (Paul et al., 2014) which internally uses Noise-Contrastive Estimation (NCE) (Gutmann and Hyvärinen, 2010) and processor parallelization for speeding up the training. For this task, we train LBL models with $N = 2$ (LBL2) and $N = 4$ (LBL4). In our experiments, increasing context size to $N = 6$ did not significantly improve (or degrade) performance.

4 Experimental Results

Table 1 shows the results of 17,836 narrative cloze tests (derived from 5,000 held-out test chains), with results bucketed by chain length. Performance is reported on four metrics: average rank, mean reciprocal rank, recall at 10, and recall at 50.

For each of the four metrics, the best overall performance is achieved by one of the two LBL models (context size 2 or 4); the LBL models also achieve the best performance on every chain length. Not only are the gains achieved by the discriminative LBL consistent across metrics and chain length, they are large. For average rank, the LBL achieves a 27.0% relative improvement over the best non-discriminative model; for mean reciprocal rank, a 19.9% improvement; for recall at 10, a 22.8% improvement; and for recall at 50, a 17.6% improvement. (See Figure 1.) Furthermore, note that both PMI models and the Bigram model have been individually tuned for each metric, while the LBL models have not. (The two LBL models are tuned only for overall perplexity on the development set.)

All models trend toward improved performance on longer chains. Because the unigram model also improves with chain length, it appears that longer chains contain more frequent events and are thus easier to predict. However, LBL performance is also likely improving on longer chains because of additional contextual information, as is evident from LBL4's slight relative gains over LBL2 on longer chains.

5 Conclusion

Pointwise mutual information and other related count-based techniques have been used widely to identify semantically similar words (Church and Hanks, 1990; Lin and Pantel, 2001; Tur-

ney and Pantel, 2010), so it is natural that these techniques have also been applied to the task of script induction. Qualitatively, PMI often identifies intuitively compelling matches; among the top 15 events to share a high PMI with $(eat, nsubj)$ under the Unordered PMI model, for example, we find events such as $(overeat, nsubj)$, $(taste, nsubj)$, $(smell, nsubj)$, $(cook, nsubj)$, and $(serve, dobj)$. When evaluated by the narrative cloze test, however, these count-based methods are overshadowed by the performance of a general-purpose discriminative language model.

Our decision to attempt this task with the Log-Bilinear model was motivated by the simple observation that the narrative cloze test is, in reality, a language modeling task. Does the LBL's success on this task mean that work in script induction should abandon traditional count-based methods for discriminative language modeling techniques? Or does it mean that an alternative evaluation metric is required to measure script knowledge? While we believe our results are sufficient to conclude that one of these alternatives is the case, we leave the task of determining which to future research.

Abstract

Word embeddings encode semantic meanings of words into low-dimension word vectors. In most word embeddings, one cannot interpret the meanings of specific dimensions of those word vectors. Non-negative matrix factorization (NMF) has been proposed to learn interpretable word embeddings via non-negative constraints. However, NMF methods suffer from scale and memory issue because they have to maintain a global matrix for learning. To alleviate this challenge, we propose online learning of interpretable word embeddings from streaming text data. Experiments show that our model consistently outperforms the state-of-the-art word embedding methods in both representation ability and interpretability. The source code of this paper can be obtained from `http://github.com/skTim/OIWE`.

1 Introduction

Word embeddings (Turian et al., 2010) aim to encode semantic meanings of words into low-dimensional dense vectors. As compared with traditional one-hot representation and distributional representation, word embeddings can better address the sparsity issue and have achieved success in many NLP applications recent years.

There are two typical approaches for word embeddings. The neural-network (NN) approach (Bengio et al., 2006) employs neural-based techniques to learn word embeddings. The matrix factorization (MF) approach (Pennington et al., 2014) builds word embeddings by factorizing word-context co-occurrence matrices. The MF approach requires a global statistical matrix, while the NN approach can flexibly perform learning from streaming text data, which is efficient in both computation and memory. For example, two recent NN methods, Skip-Gram and Continuous Bag-of-Word Model (CBOW) (Mikolov et al., 2013a; Mikolov et al., 2013b), have achieved impressive impact due to their simplicity and efficiency.

For most word embedding methods, a critical issue is that, we are unaware of what each dimension represent in word embeddings. Hence, the latent dimension for which a word has its largest value is difficult to interpret. This makes word embeddings like a black-box, and prevents them from being human-readable and further manipulation.

People have proposed non-negative matrix factorization (NMF) for word representation, denoted as non-negative sparse embedding (NNSE) (Murphy et al., 2012). NNSE realizes interpretable word embeddings by applying non-negative constraints for word embeddings. Although NNSE learns word embeddings with good interpretabilities, like other MF methods, it also requires a global matrix for learning, thus suffers from heavy memory usage and cannot well deal with streaming text data.

Inspired by the characteristics of NMF methods (Lee and Seung, 1999), we note that, non-negative constraints only allow additive combinations instead of subtractive combinations, and lead to a parts-based representation. Hence, the non-negative constraints derive interpretabilities of word embeddings. In this paper, we aim to design an online NN method to efficiently learn interpretable word embeddings. In order to achieve the goal of interpretable embeddings, we design projected gradient descent (Lin, 2007) for optimization so as to apply non-negative constraints on NN methods such as Skip-Gram. We also employ adaptive gradient descent (Sun et al., 2012) to speedup learning convergence. We name the proposed models as online interpretable word embeddings (OIWE).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1687–1692, Lisbon, Portugal, 17-21 September 2015.

For experiments, we implement OIWE based on Skip-Gram. We evaluate the representation performance of word embedding methods on the word similarity computation task. Experiment results show that, our OIWE models are significantly superior to other baselines including Skip-Gram, RNN and NNSE. We also evaluate the interpretability performance on the word intrusion detection task. The results demonstrate the effectiveness of OIWE as compared to NNSE.

2 Our Model

In this section, we first introduce Skip-Gram and then introduce the proposed online interpretable word embeddings based on Skip-Gram.

2.1 Skip-Gram

Skip-Gram (Mikolov et al., 2013b) is simple and effective to learn word embeddings. The objective of Skip-Gram is to make word vectors good at predicting its context words. More specifically, given a word sequence $\{w_1, w_2, \ldots, w_T\}$, Skip-Gram aims to maximize the average log probability

$$\frac{1}{T}\sum_{1}^{T}\Big(\sum_{-k\le j\le k, j\neq 0}\log \Pr(w_{t+j}|w_t)\Big), \quad (1)$$

where k is the context window size, and $\Pr(w_{t+j}|w_t)$ indicates the probability of seeing w_{t+j} in the context of w_t, which are measured with softmax function

$$\Pr(w_{t+j}|w_t) = \frac{\exp\big(\mathbf{w}_{t+j}\cdot\mathbf{w}_t\big)}{\sum_{w\in W}\exp\big(\mathbf{w}\cdot\mathbf{w}_t\big)}, \quad (2)$$

where $\mathbf{w}_{t+j}$ and $\mathbf{w}_t$ are word embeddings of w_{t+j} and w_t, and W is the vocabulary size. Since the computation of full softmax is time consuming, the techniques of hierarchical softmax and negative sampling (Mikolov et al., 2013b) are proposed for approximation.

Take negative sampling for example. The log probability $\Pr(w_{t+j}|w_t)$ can be approximate by

$$\log\sigma\big(\mathbf{w}_{t+j}\cdot\mathbf{w}_t\big) + \sum_{w\in N_t}\log\sigma\big(\mathbf{w}\cdot\mathbf{w}_t\big), \quad (3)$$

where $\sigma(x) = 1/(1+\exp(-x))$, and N_t is the set of negative samples as compared to the corresponding context word $\mathbf{w}_{t+j}$. The task can be regarded as to distinguish the context word $\mathbf{w}_{t+j}$ from negative samples.

For Skip-Gram with negative sampling, we can perform stochastic gradient descent for learning. The update rule for the positive/negative context words $u \in \{w_{t+j}\}\cup N_t$ is

$$\mathbf{u}^{i+1} = \mathbf{u}^i + \gamma\big[I_{w_t}(u) - \sigma(\mathbf{u}\cdot\mathbf{w}_t)\big]\mathbf{w}_t^i, \quad (4)$$

where $I_{w_t}(u) = 1$ when w is the positive context word of w_t and $I_{w_t}(u) = 0$ when w is negative, i is the iteration number, and γ is the learning rate. Correspondingly, the update rule for the input word w_t is

$$\mathbf{w}_t^{i+1} = \mathbf{w}_t^i + \gamma\sum_{u\in\{w_t\}\cup N_t}\big[I_{w_t}(u) - \sigma(\mathbf{u}\cdot\mathbf{w}_t)\big]\mathbf{u}_t^i. \quad (5)$$

We note that, the learning rate γ in Skip-Gram is shared by all word embeddings.

2.2 OIWE

In order to learn interpretable word embeddings, we have to make the word embeddings learned in Skip-Gram keep non-negative. In order to achieve this goal, we have to constrain the update rules in Equation (4) and (5) as follows:

$$\mathbf{x}_k^{i+1} = P\big[\mathbf{x}_k^i + \gamma\nabla f(\mathbf{x}_k)\big], \quad (6)$$

where x may be u or w_t, k is the corresponding dimension in word embedding $\mathbf{x}$, $\nabla f(\mathbf{x}_k)$ indicates the gradient corresponding to $\mathbf{x}_k$, and $P[\cdot]$ is defined as

$$P[x] = \begin{cases} x & \text{if } x > 0, \\ 0 & \text{if } x \le 0. \end{cases} \quad (7)$$

Motivated by the projected gradient descent methods for NMF (Lin, 2007), in this paper we propose two methods for Skip-Gram to realize the constraint in Equation (6).

Naive Projected Gradient (NPG). In NPG, we consider the most straightforward update strategy by simply setting

$$\mathbf{x}_k^{i+1} = \max\big(0, \mathbf{x}_k^i + \gamma\nabla f(\mathbf{x}_k)\big). \quad (8)$$

The method has been used for NMF (Lin, 2007) although the details are not discussed.

The NPG method only constrains the violated dimensions without taking the update consistency among dimensions of a word embedding into account. For example, if many dimensions encounter $\mathbf{x}_k^i + \gamma\nabla f(\mathbf{x}_k) < 0$ at the same time, which are set to 0 with Equation (8) with other

dimensions unchanged, the updated word embedding may heavily deviate from its semantic meaning. Hence, NPG may suffer from instable updating results. To address this issue, we propose to employ the following improved projected gradient method.

Improved Projected Gradient (IPG). In order to make the non-negative update more consistent among dimensions, we design an improved projected gradient by iteratively finding the most appropriate learning rate γ. The basic idea is that, we will find a good learning rate γ to make less dimensions violate the non-negative constraint.

More specifically, in Equation (6), for a learning rate γ, we define the *violation ratio* as

$$R(\gamma) = \frac{\left|\{k|\mathbf{x}_k^i > 0, \mathbf{x}_k^i + \gamma \nabla f(\mathbf{x}_k) < 0\}\right|}{K}, \quad (9)$$

where K is the dimension size of word embeddings. The violation ratio indicates how many dimensions violate the non-negative constraint and require to be set to 0. When the learning rate γ decreases, the violation ratio will also decrease, and the zero-setting in Equation (8) will bring less deviation to word embeddings.

We set a threshold δ for the violation ratio $R(\gamma)$ and a lower bound γ_L for the learning rate γ. Starting from an initial learning rate γ^0, we will repeatedly decrease the learning rate by

$$\gamma^{m+1} = \gamma^m \cdot \beta \quad (10)$$

with $0 < \beta < 1$ until

$$R(\gamma^{m+1}) < \delta \quad \text{or} \quad \gamma^{m+1} \leq \gamma_L, \quad (11)$$

and then update with Equation (8) using γ^{m+1}. In nature, the updating constraint of learning rate in Equation (11) play a similar role to Equation (13) in (Lin, 2007), which aims to prevent the projection operation from heavily deviating the word embeddings.

2.3 More Optimization Details

In experiments, we explore many optimization methods and find the following two strategies are important: (1) *Adaptive Gradient Descent*. Following the idea from (Sun et al., 2012), we maintain different learning rates γ_w for each word w, and the learning rates for those high-frequency words may decrease faster than those low-frequency words. This will speedup the convergence of word embedding learning. (2) *Unified Word Embedding Space*. Different from original Skip-Gram (Mikolov et al., 2013b) which learn embeddings of w_t and its context words w_{t+j} in two separate spaces, in this paper both w_t and its context words w_{t+j} share the same embedding space. Hence, a word embedding may get more opportunities for learning.

3 Experiments

In this section, we investigate the representation performance and interpretability of our OIWE models with other baselines including typical N-N and MF methods.

The representation performance is evaluated with the word similarity computation task, and the interpretability is evaluated with the word intrusion detection task. For the both tasks, we train our OIWE models using the `text8` corpus obtained from *word2vec* website[1], and the OIWE models achieve the best performance by setting the dimension number $K = 300$, $\beta = 0.6$, $\delta = 1/60$, and $\gamma_L = 2.5 \times 10^{-6}$.

3.1 Word Similarity Computation

Following the settings in (Murphy et al., 2012), we also select the following three sets for word similarity computation: (1) **WS-203**, the strict-similarity subset of 203 pairs (Agirre et al., 2009) selected from the wordsim-353 (Finkelstein et al., 2001), (2) **RG-65**, 65 concrete word pairs built by (Rubenstein and Goodenough, 1965) and (3) **MEN**, $3,000$ word pairs built by (Bruni et al., 2014). The performance is evaluated with the Spearman coefficient between human judgements and similarities calculated using word embeddings.

We select three baselines including Skip-Gram (Mikolov et al., 2013b), recurrent neural networks (RNN) (Mikolov et al., 2011) and NNSE (Murphy et al., 2012). For Skip-Gram, we report the result we learned using *word2vec* on `text8` corpus. The result of RNN is from (Faruqui and Dyer, 2014) and the one of NNSE is from (Murphy et al., 2012).

The evaluation results of word similarity computation are shown in Table 1. We can observe that: (1) The OIWE models consistently outperform other baselines. (2) IPG generally achieves better representation performance than

[1] `https://code.google.com/p/word2vec/`

Model	WS-203	RG-65	MEN
Skip-Gram	67.35	50.49	52.56
RNN	49.28	50.19	43.44
NNSE	51.06	56.48	-
OIWE-NPG	63.71	56.85	**57.60**
OIWE-IPG	**71.74**	**57.16**	56.68

Table 1: Spearman coefficient results (%) on word similarity computation.

NPG. This indicates consistent updates are important for learning of word embeddings. One can refer to `http://github.com/skTim/OIWE` for the evaluation results on more evaluation datasets.

3.2 Word Intrusion Detection

We evaluate interpretability of word embeddings with the task of word intrusion detection proposed by (Murphy et al., 2012). In this task, for each dimension we create a word set containing top-5 words in this dimension, and intruce a noisy word from the bottom half of this dimension which ranks high in other dimensions. Human editors are asked to check each word set and try to pick out the intrusion words, and the detection precision indicates the interpretability of word embedding models. Note that, for this task we do not perform normalization for word vectors.

Model	Precision
Skip-Gram	32.62
NNSE	92.00
OIWE-NPG	61.40
OIWE-IPG	**94.80**

Table 2: Experiment results (%) on word intrusion detection.

The evaluation results are shown in Table 2. We can observe that: (1) Skip-Gram performs poor in word intrusion detection without doubt since it is uninterpretable in nature. (2) The OIWE-NPG model achieves better interpretability as compared to Skip-Gram, but performs much worse than the OIWE-IPG model. The OIWE-IPG model achieves competitive interpretability with NNSE. This indicates that reducing violation rations in word embedding learning is crucial for preserving interpretability.

In Table 3, we show top-5 words for some dimensions, which clearly demonstrate semantic meanings of these dimensions. One can also refer to `http://github.com/skTim/OIWE` to find top-5 words for all dimensions.

No.	Top Words
1	type, form, way, kind, manner
2	translates, describes, combines, included, includes
3	gospel, baptism, jesus, faith, judaism
4	Franz, Johann, Wilhelm, Friedrich, von
25	prominent, famous, important, influential, popular

Table 3: Top words of some dimensions in word embeddings.

3.3 Influence of Dimension Numbers

The dimension number is an important configuration in word embeddings. In Fig. 1 we show the performance of OIWE and Skip-Gram on word similarity computation with varying dimension numbers.

From the figure, we can observe that: (1) The both models achieve their best performance under the same dimension number. This indicates that OIWE, to some extent, inherits the representation power of Skip-Gram. (2) The performance of OIWE seems to be more sensitive to dimension numbers. When the dimension number changes from 300 to 200 or 400, the performance drops much quickly than Skip-Gram. The reason may be as follows. OIWE has to concern about both representation ability of word embeddings and interpretability of each dimension. An appropriate dimension number is critical to make each dimension interpretable, just like the cluster number is important for clustering. On the contrary, Skip-Gram is much free to learn word embeddings only concerning about representation ability. (3) The performance of OIWE with various dimensions also varies on different evaluation datasets. For example, OIWE-IPG with $K = 400$ gets 68.74 on MEN, which is much better than that with $K = 300$. In future work, we will extensively investigate the characteristics of OIWE with respect to dimension numbers and other hyperparameters.

4 Conclusion and Future Work

In this paper, we present online interpretable word embeddings. The OIWE models perform project-

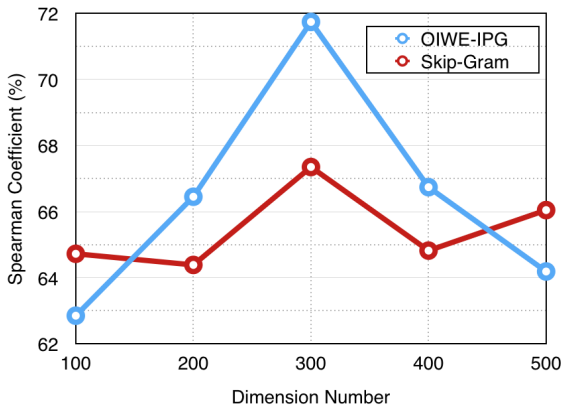

Figure 1: Influence of Dimension Number on Words Similarity

ed gradient descent to apply non-negative constraints on NN methods such as Skip-Gram. Experiment results on word similarity computation and word intrusion detection demonstrate the effectiveness and efficiency of our models in both representation ability and interpretability. We also note that, our models can be easily extended to other NN methods.

In future, we will explore the following research issues: (1) We will extensively investigate the characteristics of OIWE with respect to various hyperparameters including dimension numbers. (2) We will evaluate the performance of our OIWE models in various NLP applications. (3) We will also investigate possible extensions of our OIWE models, including multiple-prototype models for word sense embeddings (Huang et al., 2012; Chen et al., 2014), semantic compositions for phrase embeddings (Zhao et al., 2015) and knowledge representation (Bordes et al., 2013; Lin et al., 2015).

A Strong Lexical Matching Method for the Machine Comprehension Test

Ellery Smith, Nicola Greco, Matko Bošnjak, Andreas Vlachos
Department of Computer Science
University College London
{e.smith,n.greco,m.bosnjak,a.vlachos}@cs.ucl.ac.uk

Abstract

Machine comprehension of text is the overarching goal of a great deal of research in natural language processing. The Machine Comprehension Test (Richardson et al., 2013) was recently proposed to assess methods on an open-domain, extensible, and easy-to-evaluate task consisting of two datasets. In this paper we develop a lexical matching method that takes into account multiple context windows, question types and coreference resolution. We show that the proposed method outperforms the baseline of Richardson et al. (2013), and despite its relative simplicity, is comparable to recent work using machine learning. We hope that our approach will inform future work on this task. Furthermore, we argue that MC500 is harder than MC160 due to the way question answer pairs were created.

1 Introduction

Machine comprehension of text is the central goal in NLP. The academic community has proposed a variety of tasks, such as information extraction (Sarawagi, 2008), semantic parsing (Mooney, 2007) and textual entailment (Androutsopoulos and Malakasiotis, 2010). However, these tasks assess performance on each task individually, rather than on overall progress towards machine comprehension of text.

To this end, Richardson et al. (2013) proposed the Machine Comprehension Test (MCTest), a new challenge that aims at evaluating machine comprehension. It does so through an open-domain multiple-choice question answering task on fictional stories requiring the common sense reasoning typical of a 7-year-old child. It is easy to evaluate as it consists of multiple choice questions. Richardson et al. (2013) also showed how the creation of stories and questions can be crowdsourced efficiently, constructing two datasets for the task, namely MC160 and MC500. In addition, the authors presented a lexical matching baseline which is combined with the textual entailment recognition system BIUTEE (Stern and Dagan, 2011).

In this paper we develop an approach based on lexical matching which we extend by taking into account the type of the question and coreference resolution. These components improve the performance on questions that are difficult to handle with pure lexical matching. When combined with BIUTEE, we achieved 74.27% accuracy on MC160 and 65.96% on MC500, which are significantly better than those reported by Richardson et al. (2013). Despite the simplicity of our approach, these results are comparable with the recent machine learning-based approaches proposed by Narasimhan and Barzilay (2015), Wang et al. (2015) and Sachan et al. (2015).

Furthermore, we examine the types of questions and answers in the two datasets. We argue that some types are relatively simple to answer, partly due to the limited vocabulary used, which explains why simple lexical matching methods can perform well. On the other hand, some questions require understanding of higher level concepts such as those of the story and its characters, and/or require inference. This is still beyond the scope of current NLP systems. However, we believe our analysis will be useful in developing new methods and datasets for the task. To that extent, we will make our code and analysis publicly available.[1]

2 Task description

MCTest is an open-domain multiple-choice question answering task on fictional stories consisting of two datasets, MC160 and MC500. The

It was a terrible day to live in the zoo again for Pauly. It wasn't a terrible day for Zip, the monkey next to him, or Garth, the giraffe down the sidewalk, or Pat, the alligator in the pond, or for Bam the prairie dog, but it was a terrible day in the monkey cage for Pauly. Pauly didn't feel he belonged in the monkey cage because he wasn't a monkey. He was a sailor who had visited the zoo on vacation and fallen asleep on a bench right before closing time. The zoo worker saw how hairy he was and thought he was a monkey that had escaped from his cage, so they put him in a cage.

1. Where was Pauly when the zoo worker saw him?
A) Looking at the monkeys
B) Sailing on a boat
C) Asleep on a bench
D) Walking down a path

2. Why did Pauly feel he didn't belong in the monkey cage?
A) Because he wasn't a monkey
B) Because he was a zoo worker
C) Because he didn't fall asleep
D) Because he was hairy

Figure 1: An excerpt from story *mc500.train.44*

two datasets contain 160 and 500 stories respectively, with 4 questions per story, and 4 candidate answers per question (Figure 1). All stories and questions were crowd-sourced using Amazon Mechanical Turk.[2] MC160 was manually curated by Richardson et al., while MC500 was curated by crowdworkers. Both datasets are divided into training, development, and test sets. All development was conducted on the training and development sets; the test sets were used only to report the final results.

3 Scoring function

Richardson et al. (2013) proposed a sliding window algorithm that ranks the answers by forming the bag-of-words vector of each answer paired with the question text and then scoring them according to their overlap with the story text. We propose a modified version of this algorithm, which combines the scores across a range of window sizes.

More concretely, the algorithm of Richardson et al. (2013) passes a sliding window over the story, size of which is equal to the number of words in the question-answer pair. The highest overlap score between a story text window and the question-answer pair is taken as the score for the answer. Therefore, their algorithm makes a single pass over the story text per answer. In comparison, our system scores each answer by making multiple passes and summing the obtained scores. Concretely, on the first pass, we set the sliding window size to 2 tokens, and increment this size on each subsequent pass, up to a length of 30 tokens. We then combine this score with the overall number of matches of the question-answer pair across the story as a whole. This enables our algorithm to catch long-distance relations in the story. Similar to Richardson et al. (2013), we use a linear combination of this score with their distance-based scoring function, and we weigh tokens with their inverse document frequencies in each individual story.

By itself, this simple enhancement gives substantial improvements over the MSR baseline as shown in Table 1 (*Enhanced SW+D*), as it measures the overlap of the question-answer pair with multiple portions of the story text.

4 Incorporating linguistic analyses

We build upon our enhanced scoring function using stemming, rules taking into account the type of the question, and coreference. The improvements due to each of these components are presented in Table 1, and we discuss the application of coreference and the rules used in more detail in the following subsections.

	MC160	**MC500**
MSR SW+D	69.43%	63.01%
Enhanced SW+D	72.65%	63.57%
+Coreference Rules	+2.38%	+1.36%
+Negation	+0.75%	+0.36%
+Stemming	+2.04%	+0.50%
Final system	**75.77%**	**65.43%**

Table 1: Performance improvements on combined train and dev sets.

4.1 Coreference resolution

The entities mentioned in MCTest stories are frequently referred to by anaphoric expressions throughout the story and the questions, which is ignored by the described scoring function. Therefore, we substituted each mention in a coreference chain with its representative mention, applied the scoring function on the processed text

[2] http://www.mturk.com

and added the score to the original one. The chains and their represenatative mentions were obtained using the Stanford CoreNLP toolkit (Manning et al., 2014). We found that coreference improved performance on some question types, but decreased performance on others. Thus we developed a set of question rules in order to apply it selectively, which we discuss in the next section.

4.2 Rules

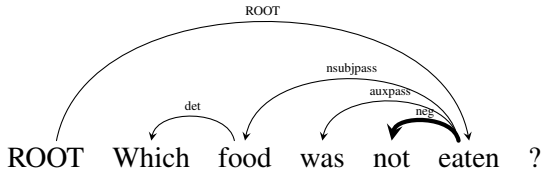

Figure 2: Dependency tree to detect negation

To account for the variety of questions in MCTest, we developed a set of rules to handle certain question types differently. To this purpose, we created rules which detect numerical, temporal, narrative and negation-based questions, and additionally partition questions by their *wh*-word.

By partitioning questions in different types, we found that *who* questions, which primarily deal with identifying a character in the story, benefit from the use of coreference chains described in the previous section. In addition, performance in questions aimed at selecting an appropriate noun, such as *which*, *where* or numerical questions, also improved with coreference. However, other question types, such as *why* questions, or questions concerning the story narrative, did not register any consistent improvement, and we opted not to use co-reference for them. This selective application of co-reference resulted in improvements on both datasets (Table 1).

We also identified negation questions as requiring special treatment. Some negation questions are trivially solvable by selecting an answer which does not appear in the text. However, our proposed function that scores answers according to the lexical overlap with the story text is unlikely to score answers not appearing in text highly. Motivated by this observation we invert the score of each word when a question with a negated root verb was detected, e.g. *"What did James not eat for dinner?"*, using Stanford Typed Dependencies (De Marneffe and Manning, 2008), as depicted in Figure 2. Due to this inversion a higher lexical overlap results in a lower score, improving accuracy on both MC160 and MC500 (+*negation* in Table 1)

In a similar fashion we detected numerical questions based on the presence of a POS tag for a cardinal number in either the question or any of the answers choices. Questions concerning the story's narrative (e.g. *"Which is the first character mentioned in the story"*) were detected using keywords (e.g. *character*, *book*, etc.). Additionally, we detected temporal questions such as *"What did Jane do before she went home?"* by the presence of a temporal modifier or temporal prepositions (e.g. *before*, *while*, etc.). Then we attempted to account for them by searching the text for the sentence indicating that she had gone home and reducing the weight for all subsequent sentences. However, since the improvements due to these rules were negligible, we did not include them in our final system. Nevertheless, these rules were helpful in analyzing problem areas in the datasets, as discussed in Section 6.

5 Results

We evaluated our system on MC160 and MC500 test sets and the results are shown in Table 2. Our proposed baseline outperforms the baseline of Richardson et al. (2013) by 4 and 3 points in accuracy on MC160 and MC500 respectively.[3] Our system is comparable to the MSR baseline with the RTE system BIUTEE (Stern and Dagan, 2011). If we linearly combine the RTE scores used in the MSR baseline with our method, we achieve 5 and 2.5 accuracy points higher than the best results achieved by Richardson et al. (2013).

Concurrently with ours, three other approaches to solving MCTest were developed and subsequently published a few months before our method. Narasimhan and Barzilay (2015) presented a discourse-level approach, which chooses an answer by utilising relations between sentences chosen as important. Despite is simplicity, our method is comparable in performance, suggesting that better lexical matching could help improve their model. Sachan et al. (2015) treated MCTest as a structured prediction problem, searching for a latent structure connecting the question, answer and the text, dubbed the answer-entailing structure. Their model performs better on MC500 (was

Final system + RTE	74.27%*	65.96%*
Narasimhan & Barzilay	73.23%	63.75%
Sachan et al.	-	67.83%
Wang et al.	75.27%	69.94%

Table 2: Performance on the MC160 and MC500 test sets, including the results of all previous work. * denotes statistically significant ($p < 0.05$) improvement using McNemar's test, with respect to the MSR baseline (SW+D)

not tested on MC160), however the strength of our model is obtaining comparable results with a much simpler model. The work of Wang et al. (2015) is the most similar to ours, in the sense that they combine a baseline feature set with more advanced linguistic analyses, namely syntax, frame semantics, coreference, and word embeddings. Instead of a rule-based approach, they combine them through a latent-variable classifier achieving the current state-of-the-art performance on MCTest.

6 Discussion

Using the question-filtering rules mentioned in Section 4.2, we obtained individual accuracy scores per question type for the final system combined with RTE (Table 3). Note that these types are in three groups: i) wh-word questions (disjoint, questions without an wh-word are in *Other*), ii) classes of questions requiring non-trivial linguistic analysis and reasoning (not disjoint, not all questions considered), and iii) questions originally classified by crowdworkers, classifying whether the question can be answered by a single or multiple sentences in the story (disjoint).

Compared to the wh-word question type results of Narasimhan and Barzilay (2015), our approach performs better primarily on *why* questions (72.97% and 80.65% vs. 59.45% and 69.35% on MC160 and MC500 respectively) and slightly better on *how*, *when* and *what* questions on MC500. Additionally, our system is more successful in questions requiring multiple sentences to be answered correctly (70.31% and 63.3%vs. 65.23% and 59.9% on MC160 and MC500 respectively).

If we remove the RTE component from our system, the performance on relatively simple question types such as *what*, *who* and *where* remains practically the same, thus confirming that our approach can handle simple questions well. On the other hand, the performance on *why* questions drops without RTE, thus stressing the need for deeper text understanding.

Category	MC160	MC500
What	76.98% (126)	68.77% (317)
Who	71.43% (28)	58.44% (77)
When	80.00% (5)	100.00% (7)
How	72.62% (21)	50.58% (43)
Which	66.67% (6)	40.00% (25)
Where	91.67% (12)	68.97% (58)
Why	72.97% (37)	80.65% (62)
Whose	-	66.67% (3)

Single	78.79% (112)	69.12% (272)
Multi	70.31% (128)	63.34% (328)

Table 3: Performance of our final system + RTE per question type on the test sets. The number of relevant questions is in parentheses.

There are several clear deficiencies in certain question types, particularly in handling negation. These errors provide a broad overview of the cases in which simple lexical techniques are not sufficient to determine the correct answer.

Many numerical questions, particularly in MC500, require the use of simple algebra over story elements, including counting characters and objects, and understanding temporal order. One question even requires calculating the probability of an event occurring, while another one calls for complex volumetric calculation. Answering questions such as these is beyond the capabilities of a lexical algorithm, and accuracies in this category are worse than on all questions. Additionally, lexical algorithms such as ours, which ignore predicate-argument structure, perform worse in the presence of quantifiers.

In MC500, the performance of our system on more abstract questions, concerning the overall narrative of the story, also demonstrates a sig-

nificant inadequacy of lexical-based algorithms. Questions such as "*What was the first character mentioned in the story?*", which relate to the overall narrative flow of the passage, or questions concerning the state of the story environment, such as "*Where is the story set?*", are difficult to solve without a system which understands the concept of a story. Typical question-answering methods would also struggle here.

Another type of challenging question are those which require an implicit temporal understanding of the text, i.e. questions concerning time without using a temporal modifier. For example, given a story which states that "*John is at the beach*", then later "*John went home*", a question such as "*What did John do at home?*" would prove itself difficult for traditional methods to answer. These questions are difficult to identify automatically by the form of the question alone, thus we cannot provide accuracies for them.

Our results confirm that it is easier to achieve better performance on MC160 with simple lexical techniques, while the MC500 has proved more resilient to the same improvements. We also observed that the MC500 registers smaller improvements in accuracy when adding components such as co-reference. This is a consequence of the design and curation process of the MC500 dataset, which stipulated that answers must not be contained directly within the story text, or if they are, that two or more misleading choices included.

Richardson et al. (2013) demonstrate that the MC160 and MC500 have similar ratings for clarity and grammar, and that humans perform equally well on both. However, in many cases MC500 appears to be designed in such a way to confuse lexical algorithms and encourage the use of more sophisticated techniques necessary to deal with phenomena such as elimination questions, negation, and common knowledge not explicitly written in the story.

7 Related work

The use of shallow methods for machine comprehension has been explored in previous work, for example Hirschman et al. (1999) used a bag-of-words to match question-answer pairs to sentences in the text, and choose the best pair with the best matching sentence. As discussed in our analysis, such systems cannot handle well questions involving negation and quantification. Numerical questions, which we found to be particularly challenging, have been the focus of recent work on algebra word problems (Kushman et al., 2014) for which dedicated systems have been developed.

MacCartney et al. (2006) demonstrated that a large set of rules can be used to recognize valid textual entailments. These consider phenomena such as polarity and quantification, similar to those we used in our analysis of the MCTest datasets. More complex methods, which attempt deeper modeling of text include Natural Logic (Angeli and Manning, 2014) and Combinatorial Categorial Grammars (Lewis and Steedman, 2013) combined with distributional models. While promising, these approaches have been developed primarily on sentence-level tasks, thus the stories in MCTest are likely to present additional challenges.

The recently proposed class of methods called Memory Network (Weston et al., 2014), uses neural networks and external memory to answer a simpler comprehension task. Though quite successful on toy tasks, those methods cannot yet be applied to MCTest as they require much larger training datasets than the ones available for this task.

A recent approach by Hermann et al. (2015) uses attention-based recurrent neural networks to attack the problem of machine comprehension. In this work, the authors show how to generate large amounts of data for machine comprehension exploiting news websites, and how to use novel architectures in deep learning to solve the task. However, due to the need for a large dataset for training, and the focus only on questions that take entities as answers, this approach has not been applied to MCTest.

8 Conclusion

In this paper we developed an approach to MCTest that combines lexical matching with simple linguistic analysis. We evaluated it on the two MCTest datasets, MC160 and MC500, and we showed that it improves upon the original baseline by 4 and 3 percentage points respectively, while being comparable to more complex approaches. In addition, our analysis highlighted the challenges involved and in particular in the MC500 dataset.

Abstract

We propose a grammar induction technique for AMR semantic parsing. While previous grammar induction techniques were designed to re-learn a new parser for each target application, the recently annotated AMR Bank provides a unique opportunity to induce a single model for understanding broad-coverage newswire text and support a wide range of applications. We present a new model that combines CCG parsing to recover compositional aspects of meaning and a factor graph to model non-compositional phenomena, such as anaphoric dependencies. Our approach achieves 66.2 Smatch F1 score on the AMR bank, significantly outperforming the previous state of the art.

1 Introduction

Semantic parsers map sentences to formal representations of their meaning (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2011). Existing learning algorithms have primarily focused on building actionable meaning representations which can, for example, directly query a database (Liang et al., 2011; Kwiatkowski et al., 2013) or instruct a robotic agent (Chen, 2012; Artzi and Zettlemoyer, 2013b). However, due to their end-to-end nature, such models must be relearned for each new target application and have only been used to parse restricted styles of text, such as questions and imperatives.

Recently, AMR (Banarescu et al., 2013) was proposed as a general-purpose meaning representation language for broad-coverage text, and work is ongoing to study its use for variety of applications such as machine translation (Jones et al., 2012) and summarization (Liu et al., 2015). The AMR meaning bank provides a large new corpus that, for the first time, enables us to study the problem of grammar induction for broad-coverage semantic parsing. However, it also presents significant challenges for existing algorithms, including much longer sentences, more complex syntactic phenomena and increased use of non-compositional semantics, such as within-sentence coreference. In this paper, we introduce a new, scalable Combinatory Categorial Grammar (CCG; Steedman, 1996, 2000) induction approach that solves these challenges with a learned joint model of both compositional and non-compositional semantics, and achieves state-of-the-art performance on AMR Bank parsing.

We map sentences to AMR structures in a two-stage process (Section 5). First, we use CCG to construct lambda-calculus representations of the compositional aspects of AMR. CCG is designed to capture a wide range of linguistic phenomena, such as coordination and long-distance dependencies, and has been used extensively for semantic parsing. To use CCG for AMR parsing we define a simple encoding for AMRs in lambda calculus, for example, as seen with the logical form z and AMR a in Figure 1 for the sentence *Pyongyang officials denied their involvement*. However, using CCG to construct such logical forms requires a new mechanism for non-compositional reasoning, for example to model the long-range anaphoric dependency introduced by *their* in Figure 1.

To represent such dependencies while maintaining a relatively compact grammar, we follow Steedman's (2011) use of generalized Skolem terms, a mechanism to allow global references in lambda calculus. We then allow the CCG derivation to mark when non-compositional reasoning is required with underspecified placeholders. For example, Figure 1 shows an underspecified logical form u that would be constructed by the grammar with the bolded placeholder ID indicating an un-

*Work done at the University of Washington.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1699–1710,
Lisbon, Portugal, 17-21 September 2015.

resolved anaphoric reference. These placeholders are resolved by a factor graph model that is defined over the output logical form and models which part of it they refer to, for example to find the referent for a pronoun. Although primarily motivated by non-compositional reasoning, we also use this mechanism to underspecify certain relations during parsing, allowing for more effective search.

Following most work in semantic parsing, we consider two learning challenges: grammar induction, which assigns meaning representations to words and phrases, and parameter estimation, where we learn a model for combining these pieces to analyze full sentences. We introduce a new CCG grammar induction algorithm which incorporates ideas from previous algorithms (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010) in a way that scales to the longer sentences and more varied syntactic constructions observed in newswire text. During lexical generation (Section 6.1), the algorithm first attempts to use a set of templates to hypothesize new lexical entries. It then attempts to combine bottom-up parsing with top-down recursive splitting to select the best entries and learn new templates for complex syntactic and semantic phenomena, which are re-used in later sentences to hypothesize new entries.

Finally, while previous algorithms (e.g., Zettlemoyer and Collins, 2005) have assumed the existence of a grammar that can parse nearly every sentence to update its parameters, this does not hold for AMR Bank. Due to sentence complexity and search errors, our model cannot produce fully correct logical forms for a significant portion of the training data. To learn from as much of the data as possible and accelerate learning, we adopt an early update strategy to generate effective updates from partially correct analyses (Section 6.2).

We evaluate performance on the publicly available AMR Bank (Banarescu et al., 2013) and demonstrate that our modeling and learning contributions are crucial for grammar induction at this scale and achieve new state-of-the-art results for AMR parsing (Section 8). In addition, we also present, for the first time, results without surface-form alignment heuristics, which demonstrates the need for future work, especially to generalize to other languages. The source code and learned models are available online.[1]

Figure 1: A sentence (x) paired with its AMR (a), underspecified logical form (u), which contains underspecified constants in bold that are mapped to AMR relations to generate the fully specified logical form (z).

2 Technical Overview

Task Let $\mathcal{X}$ be the set of all possible sentences and A the set of all AMR structures. Given a sentence $x \in \mathcal{X}$, we aim to generate an AMR $a \in A$. We define a simple, deterministic and invertible conversion process between AMRs and lambda-calculus logical forms; roughly speaking, each AMR variable gets its own lambda term, which is scoped as low as possible, and each AMR role becomes a binary predicate applied to these variables. Figure 1 shows an example, and the full details are provided in the supplementary materials. Therefore, henceforth we discuss the task of mapping a sentence $x \in \mathcal{X}$ to a logical form $z \in \mathcal{Z}$, where $\mathcal{Z}$ is the set of all logical forms. For example, in Figure 1, we would map the sentence x to the logical form z. We evaluate system performance using SMATCH (Cai and Knight, 2013).

Model Given a sentence x and lexicon Λ, we generate the set of possible derivations $\text{GEN}(x, \Lambda)$ using a two-stage process (Section 5). First, we use a weighted CCG to map x to an *underspecified logical form* u (Section 5.1), a logical form with placeholder constants for unresolved elements. For example, in the underspecified logical form u in Figure 1, the constants REL-of, REL and ID are placeholders. We then resolve

these placeholders by defining a factor graph to find their optimal mapping and generate the final logical form z. In the figure, REL-of is mapped to ARG0-of, REL to ARG2 and ID to 2.

Learning We assume access to a training set of N examples $\{(x_i, z_i) : i = 1 \dots N\}$, each containing a sentence x_i and a logical form z_i. Our goal is to learn a CCG, which constitutes learning the lexicon and estimating the parameters of both the grammar and the factor graph. We define a learning procedure (Section 6) that alternates between expanding the lexicon and updating the parameters. Learning new lexical entries relies on a two-pass process that combines learning the meaning of words and new syntactic structures, and supports learning with and without alignment heuristics (e.g., from Flanigan et al., 2014).

3 Related Work

The problem of learning semantic parsers has received significant attention. Algorithms have been developed for learning from different forms of supervision, including logical forms (Wong and Mooney, 2007; Muresan, 2011), question-answer pairs (Clarke et al., 2010; Liang et al., 2011; Cai and Yates, 2013; Kwiatkowski et al., 2013), sentences paired with demonstrations (Goldwasser and Roth, 2011; Chen and Mooney, 2011), conversational logs (Artzi and Zettlemoyer, 2011), distant supervision (Krishnamurthy and Mitchell, 2012, 2015; Reddy et al., 2014) and without explicit semantic supervision (Poon, 2013).

Although we are first to consider using CCG to build AMR representations, our work is closely related to existing methods for CCG semantic parsing. Previous CCG induction techniques have either used hand-engineered lexical templates (e.g., Zettlemoyer and Collins, 2005) or learned templates from the data directly (e.g., Kwiatkowski et al., 2010, 2012). Our two-pass reasoning for lexical generation combines ideas from both methods in a way that greatly improves scalability to long, newswire-style sentences. CCG has also been used for broad-coverage recovery of first-order logic representations (Bos, 2008; Lewis and Steedman, 2013). However, this work lacked corpora to evaluate the logical forms recovered.

AMR (Banarescu et al., 2013) is a general-purpose meaning representation and has been used in a number of applications (Pan et al., 2015; Liu et al., 2015). There is also work on recovering AMRs, including graph parsing (Flanigan et al., 2014), methods to build AMRs from dependency trees (Wang et al., 2015) and algorithms for aligning words to AMRs (Pourdamghani et al., 2014).

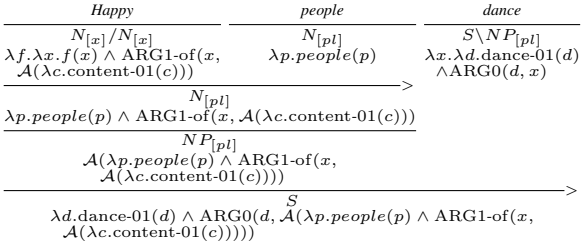

Figure 2: Example CCG tree with three lexical entries, two forward applications (>) and type-shifting of a plural noun to a noun phrase.

4 Background

Combinatory Categorial Grammar CCG is a categorial formalism that provides a transparent interface between syntax and semantics (Steedman, 1996, 2000). Section 7 details our instantiation of CCG. In CCG trees, each node is a category. Figure 2 shows a simple CCG tree. For example, $S\backslash NP_{[pl]} : \lambda x.\lambda d.\text{dance-01}(d) \wedge \text{ARG0}(d, x)$ is a category for an intransitive verb phrase. The syntactic type $S\backslash NP_{[pl]}$ indicates that an argument of type $NP_{[pl]}$ is expected and the returned syntactic type will be S. The backward slash $\backslash$ indicates the argument is expected on the left, while a forward slash $/$ indicates it is expected on the right. The syntactic attribute pl specifies that the argument must be plural. Attribute variables enforce agreement between syntactic attributes. For example, as in Figure 2, adjectives are assigned the syntax $N_{[x]}/N_{[x]}$, where x is used to indicate that the attribute of the argument will determine the attribute of the returned category. The simply-typed lambda calculus logical form in the category represents its semantic meaning. The typing system includes basic types (e.g., entity e, truth value t) and functional types (e.g., $\langle e, t \rangle$ is the type of a function from e to t). In the example category, $\lambda x.\lambda d.\text{dance-01}(d) \wedge \text{ARG0}(d, x)$ is a $\langle e, \langle e, t \rangle \rangle$-typed function expecting an ARG0 argument, and the conjunction specifies the roles of the dance-01 frame.

A CCG is defined by a lexicon and a set of combinators. The lexicon pairs words and phrases with their categorial meaning. For example, $dance \vdash \lambda x.\lambda d.\text{dance-01}(d) \wedge \text{ARG0}(d, x)$ pairs $dance$ with the category above. We adopt a factored representation of the lexicon (Kwiatkowski et al., 2011), where entries are dynamically generated by

combining *lexemes* and *templates*. For example, the above lexical entry can be generated by pairing the lexeme $\langle dance, \{\text{dance-01}\}\rangle$ with the template $\lambda v_1.[S\backslash NP : \lambda x.\lambda a.v_1(a) \wedge \text{ARG0}(a, x)]$.

Skolem Terms and IDs Generalized Skolem terms (henceforth, *Skolem terms*) for CCG were introduced by Steedman (2011) to capture complex dependencies with relatively local quantification. We define here a simplified version of the theory to represent entities and allow distant references. Let $\mathcal{A}$ be a $\langle\langle e, t\rangle, e\rangle$-typed predicate. Given a $\langle e, t\rangle$-typed logical expression C, the logical form $\mathcal{A}_n(C)$ is a Skolem term with the Skolem ID n. For example, $\mathcal{A}_2(\lambda y.\text{boy}(y))$ is a Skolem term that could represent the noun phrase *the boy*, which introduces a new entity. Skolem IDs are globally scoped, i.e., they can be referred from anywhere in the logical form without scoping constraints. To refer to Skolem terms, we define the $\langle id, e\rangle$-typed predicate $\mathcal{R}$. For example, the sentence *the boy loves himself* may be represented with $\mathcal{A}_1(\lambda x.\text{love-01}(x) \wedge \text{ARG0}(x, \mathcal{A}_2(\lambda y.\text{boy}(y))) \wedge \text{ARG1}(x, \mathcal{R}(2)))$, where $\mathcal{R}(2)$ references $\mathcal{A}_2(\lambda y.\text{boy}(y))$.

5 Mapping Sentences to Logical Form

Given a sentence x and lexicon Λ, the function $\textsc{Gen}(x, \Lambda)$ defines the set of possible derivations. Each derivation d is a tuple $\langle y, \mathcal{M}\rangle$, where y is a CCG parse tree and $\mathcal{M}$ is a mapping of constants from u, the *underspecified logical form* at the root of y, to their fully specified form.

5.1 Underspecified Logical Forms

An underspecified logical form represents multiple logical forms via a mapping function that maps its constants to sets of constants and Skolem IDs. For example, consider the underspecified logical form u at the top of Figure 3b. If, for example, REL can be mapped to manner or ARG2, then the sub-expression $\text{REL}(h, \mathcal{A}_6(\lambda o.\text{official}(o)))$ represents $\text{manner}(h, \mathcal{A}_6(\lambda o.\text{official}(o)))$ or $\text{ARG2}(h, \mathcal{A}_6(\lambda o.\text{official}(o)))$. During learning, we assume access to fully specified logical forms, which we convert to underspecified form as needed. In practice, all binary relations, except ARG0 and ARG1, and all Skolem ID references are underspecified.

Formally, let $\mathcal{C}$ be the set of all constants and $\mathcal{I}(u)$ the set of all Skolem IDs in the logical form u. Let $\mathcal{S}_u : \mathcal{C} \rightarrow 2^{\mathcal{C} \cup \mathcal{I}(u)}$ be a specification function, such that its inverse is deterministic. We call a constant c a *placeholder* if $|\mathcal{S}_u(c)| > 1$. Given an underspecified logical form u, applying $\mathcal{S}_u$ to all constants u contains, generates a set of fully specified logical forms.

We define $\mathcal{S}_u$ to be (a) $\mathcal{S}_u(\text{ID}) = \mathcal{I}(u)$, the set of Skolem IDs in u, (b) $\mathcal{S}_u(\text{REL}) = \{\text{part}, \text{ARG2}, \dots\}$, all 67 active AMR relations except ARG0 and ARG1, (c) $\mathcal{S}_u(\text{REL-of}) = \{\text{part-of}, \text{ARG0-of}, \dots\}$, all 33 passive relations, and otherwise (d) $\mathcal{S}_u(c) = c$. For example, in u in Figure 3b, the set of assignments to the ID placeholder is $\mathcal{I}(u) = \{1, 2, 3, 4, 5, 6, 7\}$.

5.2 Derivations

The first part of a derivation $d = \langle y, \mathcal{M}\rangle$ is a CCG parse tree y with an underspecified logical form u at its root. For example, Figure 3a shows such a CCG parse tree, where the logical form contains the placeholders REL, REL-of and ID.

The second part of the derivation is a function $\mathcal{M} : \textsc{Consts}(u) \rightarrow \mathcal{C} \cup \mathcal{I}(u)$, where $\textsc{Consts}(u)$ is the set of all occurrences of constants in u. For example, in Figure 3b, $\textsc{Consts}(u)$ contains, among others, three different occurrences of ARG1 and one of ID, and $\mathcal{M}$ maps REL to ARG2, REL-of to ARG0-of and ID to the Skolem ID 2. The set of potential assignments for each occurrence of constant c is $\mathcal{S}_u(c)$, and $\mathcal{M}$, which returns a single element for each constant, is a disambiguation of $\mathcal{S}_u$. Applying $\mathcal{M}$ to all constants in u results in the final logical form z.

Decomposing the derivation provides two advantages. First, we are able to defer decisions from the CCG parse to the factor graph, thereby considering fewer hypotheses during parsing and simplifying the computation. Second, we can represent distant references while avoiding the complex parse trees that would have been required to represent these dependencies with scoped variables instead of Skolem IDs.[2]

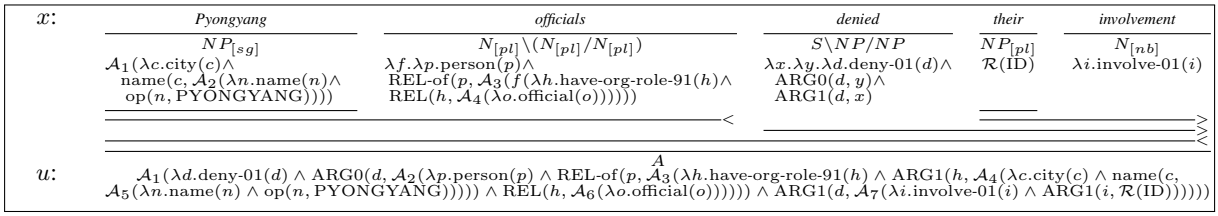
5.3 Model

Given a sentence x, we use a weighted log-linear CCG (Lafferty et al., 2001; Clark and Curran, 2007) to rank the space of possible parses under the grammar Λ. At the root of each CCG derivation is the underspecified logical form u.

To represent a probability distribution over $\mathcal{M}$, we build for each u a factor graph $G_u = \langle V, F, E\rangle$,

[2] Similar to mention clustering methods for co-reference resolution (Ng, 2010), IDs can be viewed as creating clusters.

(a) **CCG parse y:** Maps the sentence x to an underspecified logical form u (Section 5.1) with placeholders for unresolved decisions: ID for reference identifiers and the predicates REL and REL-of for unresolved relations.



(b) **Constant mapping $\mathcal{M}$:** Each constant in u, the logical form at the root of y, is mapped to a Skolem ID or a logical constant to create the fully specified logical form z, which can be converted to an AMR. Only mappings that modify constants are illustrated.

u: $\mathcal{A}_1(\lambda d.\text{deny-01}(d) \wedge \text{ARG0}(d, \mathcal{A}_2(\lambda p.\text{person}(p) \wedge \text{REL-of}(p, \mathcal{A}_3(\lambda h.\text{have-org-role-91}(h) \wedge \text{ARG1}(h, \mathcal{A}_4(\lambda c.\text{city}(c) \wedge \text{name}(c, \mathcal{A}_5(\lambda n.\text{name}(n) \wedge \text{op}(n, \text{PYONGYANG}))))) \wedge \text{REL}(h, \mathcal{A}_6(\lambda o.\text{official}(o)))))) \wedge \text{ARG1}(d, \mathcal{A}_7(\lambda i.\text{involve-01}(i) \wedge \text{ARG1}(i, \mathcal{R}(\text{ID})))))))$

z: $\mathcal{A}_1(\lambda d.\text{deny-01}(d) \wedge \text{ARG0}(d, \mathcal{A}_2(\lambda p.\text{person}(p) \wedge \text{ARG0-of}(p, \mathcal{A}_3(\lambda h.\text{have-org-role-91}(h) \wedge \text{ARG1}(h, \mathcal{A}_4(\lambda c.\text{city}(c) \wedge \text{name}(c, \mathcal{A}_5(\lambda n.\text{name}(n) \wedge \text{op}(n, \text{PYONGYANG}))))) \wedge \text{ARG2}(h, \mathcal{A}_6(\lambda o.\text{official}(o)))))) \wedge \text{ARG1}(d, \mathcal{A}_7(\lambda i.\text{involve-01}(i) \wedge \text{ARG1}(i, \mathcal{R}(2))))))$

Figure 3: A complete derivation for the sentence *Pyongyang officials denied their involvement*.

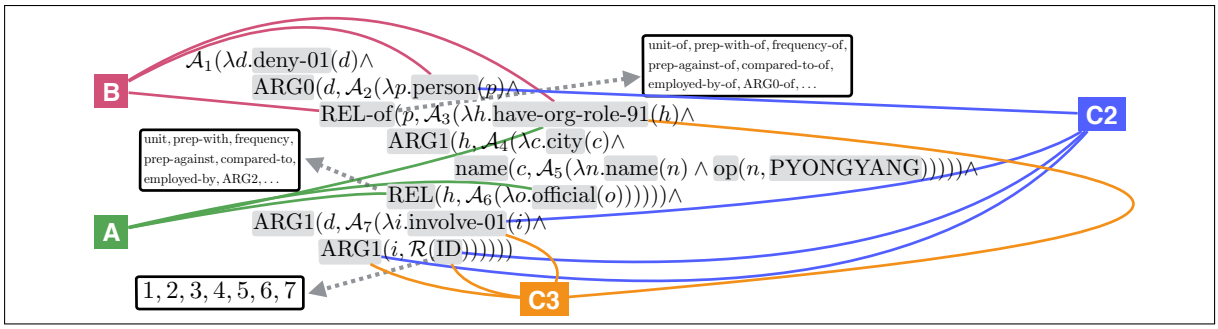


Figure 4: A visualization of the factor graph constructed for the derivation in Figure 3. Variables are marked with gray background. The set of possible assignments, marked with a dashed arrow, is only specified for placeholders (REL-of, REL and ID). Only a subset of the factors are included (A, B, C2 and C3). Solid lines represent edges. Factor A captures selectional preference between the types have-org-role-91 and official to determine the relation REL. Factor B does the same for person and have-org-role-91 to determine REF-of. Factors C2 and C3 account for selectional preferences when resolving ID. In C2, we consider the assignment 2, which will create a relation of type ARG1 between the types involve-01 and person. C3 similarly considers the assignment 3.

where $V = \textsc{Consts}(u)$ is the set of variables, F is the set of factors and E is the set of edges. Each edge is of the form (v, f) where $v \in V$ and $f \in F$. Figure 4 shows the factor graph used in generating the derivation in Figure 3, including all the variables and a subset of the factors. For each variable $v_c \in V$ such that $c \in \textsc{Consts}(u)$ the set of possible assignments is determined by $\mathcal{S}_u(c)$.

To generate the factors F and edges E we use the function $\Phi(V')$ that maps a set of variables $V' \subseteq V$ to a factor f and a set of edges, each one of the form (v, f), where $v \in V'$. Factors express various features (Section 7), such as selectional preferences and control structures. In the figure, Factor A captures the selectional preference for the assignment of the relation REL between have-org-role-91 and official. Factor B captures a similar preference, this time to resolve REL-of. Factor $C2$ captures a selectional preference triplet *involve*-01/ARG1/*person* that will be created if ID is resolved to the Skolem ID 2. Finally, $C3$ captures a similar preference for resolving ID to 3. Since the assignment of many of the variables is fixed, i.e., they are fully specified constants, in practice our factor graph representation simply conditions on them.

Derivations are scored using a log-linear model that includes both CCG parse features and those defined by the factor graph. Let $\mathcal{D}(z)$ be the subset of derivations with the final logical form z and $\theta \in \mathbb{R}^l$ be a l-dimensional parameter vector. We define the probability of the logical form z as

$$p(z|x; \theta, \Lambda) = \sum_{d \in \mathcal{D}(z)} p(d|x; \theta, \Lambda) \ ,$$

and the probability of a derivation d is defined as

$$p(d|x; \theta, \Lambda) = \frac{e^{\theta \cdot \phi(x,d)}}{\sum_{d' \in \textsc{Gen}(x,\Lambda)} e^{\theta \cdot \phi(x,d')}} \ , \qquad (1)$$

where $\phi(x, d) \in \mathbb{R}^l$ is a feature vector (Section 7).

5.4 Inference

To compute the set of derivations $\text{GEN}(x, \Lambda)$ we define a two-stage process. We first run the CCG parser to generate underspecified logical forms. Following previous work (Zettlemoyer and Collins, 2005), we use CKY parsing to enumerate the top-K underspecified logical forms.[3] During the CKY chart construction, we ignore Skolem IDs when comparing categories. This allows us to properly combine partial derivations and to fully benefit from the dynamic programming. We dynamically generate lexical entries for numbers and dates using regular expression patterns and for named-entities using a recognizer. For every underspecified logical form u, we construct a factor graph and use beam search to find the top-L configurations of the graph.[4]

During learning, we use the function $\text{GENMAX}(x, z, \theta, \Lambda)$ to get all derivations that map the sentence x to the logical form z, given parameters θ and lexicon Λ. To compute GENMAX, we follow Zettlemoyer and Collins (2005) and collect constant co-occurrence counts from z to prune from the CKY chart any category that cannot participate in a derivation leading to z. Since only constant names are changed during the second stage, setting the factor graph to get z is trivial: if the underspecified logical form is identical to z except the placeholders, we replace the placeholders with the correct final assignment, otherwise the derivation cannot result in z.

6 Learning

Learning the two-stage model requires inducing the entries of the CCG lexicon Λ and estimating the parameters θ, which score both stages of the derivation. We assume access to a training set of N examples $D = \{(x_i, z_i) : i = 1 \dots N\}$, each containing a sentence x_i and a logical form z_i. This data does not include information about the lexical entries and CCG parsing operations required to construct the correct derivations. We consider all these decisions as latent.

The main learning algorithm (Algorithm 1) starts by initializing the lexicon (line 1) and then processes the data T times (line 2), each time alternating between batch expansion of the lexicon and a sequence of mini-batch parameter updates. An iteration starts with a batch pass to expand the lexicon. The subroutine GENENTRIES, described in Section 6.1 and Algorithm 2, is called to generate a set of new entries for each sample (line 5).

Next, we update the parameters θ with mini-batch updates. Given a mini-batch size of M, we use the procedure $\text{SUB}(D, i, M)$ to get the i-th segment of the data D of size M. We process this segment (line 10) to accumulate the

Algorithm 1 The main learning algorithm.

Input: Training set $D = \{(x_i, z_i) : i = 1 \dots N\}$, number of iterations T, mini-batch size M, seed lexicon Λ_0 and learning rate μ.
Definitions: $\text{SUB}(D, i, j)$ is the set of the next j samples from D starting at i. $\text{GENMAX}(x, z, \theta, \Lambda)$ is the set of viterbi derivations from x with the final result z given parameters θ and lexicon Λ. $\text{LEX}(d)$ is the set of lexical entries used in the derivation d. $\text{COMPUTEGRAD}(x, z, \theta, \Lambda)$ computes the gradient for sentence x and logical form z, given the parameters θ and lexicon Λ, and it described in Section 6.2. $\text{ADAGRAD}(\Delta)$ applies a per-feature learning rate to the gradient Δ (Duchi et al., 2011).
Output: Lexicon Λ and model parameters θ.

1: $\Lambda \leftarrow \Lambda_0$
2: **for** $t = 1$ to T **do**
3: » Generate entries and update the lexicon.
4: **for** $i = 1$ to N **do**
5: $\lambda_{\text{new}} \leftarrow \lambda_{\text{new}} \cup \text{GENENTRIES}(x_i, z_i, \theta, \Lambda)$
6: $\Lambda \leftarrow \Lambda \cup \lambda_{\text{new}}$
7: » Compute and apply mini-batch gradient updates.
8: **for** $i = 1$ to $\lceil \frac{N}{M} \rceil$ **do**
9: $\Delta \leftarrow \vec{0}$
10: **for** (x, z) in $\text{SUB}(D, i, M)$ **do**
11: » Compute and aggregate the gradient.
12: $\Delta \leftarrow \Delta + \text{COMPUTEGRAD}(x, z, \theta, \Lambda)$
13: $\theta \leftarrow \theta + \mu \text{ADAGRAD}(\Delta)$
14: » Get all correct viterbi derivations.
15: $V \leftarrow \bigcup_{(x,z) \in D} \text{GENMAX}(x, z, \theta, \Lambda)$
16: » Retain only entries from derivations in V.
17: $\Lambda \leftarrow \bigcup_{d \in V} \text{LEX}(d)$
18: **return** Λ and θ

Algorithm 2 GENENTRIES: Procedure to generate lexical entries from one training sample. See Section 6.1 for details.

Input: Sample (x, z), model parameters θ and lexicon Λ.
Definitions: $\text{GENLEX}(x, z, \Lambda)$ and $\text{RECSPLIT}(z, z, \theta, \Lambda)$ are defined in Section 6.1.
Output: Set of lexical entries λ.

1: » Augment lexicon with sample-specific entries.
2: $\Lambda_+ \leftarrow \Lambda \cup \text{GENLEX}(x, z, \Lambda)$
3: » Get max-scoring correct derivations.
4: $\mathcal{D}_+ \leftarrow \text{GENMAX}(x, z, \Lambda_+, \theta)$
5: **if** $|\mathcal{D}_+| > 0$ **then**
6: » Return entries from max-scoring derivations.
7: **return** $\bigcup_{d \in \mathcal{D}_+} \text{LEX}(d)$
8: **else**
9: » Top-down splitting to generate new entries.
10: **return** $\text{RECSPLIT}(x, z, \theta, \Lambda_+)$

[3] See Artzi et al. (2014) for a description of this process and how to approximate the partition function in Equation 1.

[4] Experiments with loopy belief propagation showed it to be slower and less effective for our task.

mini-batch gradient Δ by calling the procedure COMPUTEGRAD(x, z, θ, Λ) (line 12), which computes the gradient for x and z given θ and Λ, as described in Section 6.2. We use AdaGrad (Duchi et al., 2011) parameter updates (line 13).

Each iteration concludes with removing all lexical entries not used in max-scoring correct derivations, to correct for overgeneration (lines 14-17).

6.1 Lexicon Expansion: GENENTRIES

Given a sentence x, a logical form z, parameters θ and a lexicon Λ, GENENTRIES(x, z, θ, Λ) (Algorithm 2) computes a set of lexical entries, such that there exists at least one derivation d using these entries from x to z. We first use GENLEX(x, z, Λ) to generate a large set of potential lexical entries from u, the underspecified form of z, by generating lexemes (Section 4) and pairing them with all templates in Λ. We then use a two-pass process to select the entries to return. The set of generated lexemes is a union of: (a) the set G_{gen} that includes all pairings of subsets of constants from z with spans in x up to length k_{gen} and (b) the set that is constructed by matching named-entity constants[5] in z with their corresponding mentions in the text to create new lexemes with potentially any other constant (for lexemes with multiple constants). Λ is augmented with the generated set of lexical entries to create Λ_+ (line 2).

First Pass Given the augmented lexicon Λ_+, we compute the set $\mathcal{D}_+ = \text{GENMAX}(x, z, \theta, \Lambda_+)$ (line 4). Following Artzi and Zettlemoyer (2013b), we constrain the set of derivations to include only those that use at most one lexeme from G_{gen}. If generating new lexemes is sufficient to derive z from x, $\mathcal{D}_+$ will contain these derivations and we return their lexical entries to be added to the lexicon Λ (lines 5-7). Otherwise, we proceed to do a second pass, where we try to generate new templates to parse the sentence.

Second Pass: RECSPLIT In this pass we try to generate max-scoring derivations in a top-down process. Starting from u, the underspecified form of z, we search for CCG parsing steps that will connect to existing partial derivations in the CKY chart to create a complete parse tree. Since the space of possible operations is extremely large, we use CCGBank (Hockenmaier and Steedman, 2007) categories to prune, as described below.

The second pass is executed by calling RECSPLIT$(x, z, \theta, \Lambda_+)$, which returns a set of lexical entries to add to the model (line 10). We recursively apply the splitting operation introduced by Kwiatkowski et al. (2010). Given a CCG category, splitting outputs all possible category pairs that could have originally generated it. For example, given the category $S\backslash NP \vdash \lambda y.\lambda d.\text{deny-01}(d) \wedge \text{ARG0}(d, y) \wedge \text{ARG1}(d, \mathcal{A}_1(\lambda i.\text{involve-01}(i) \wedge \text{ARG1}(i, \mathcal{R}(\text{ID}))))$, one of the possible splits will include the categories $S\backslash NP/NP \vdash \lambda x.\lambda y.\lambda d.\text{deny-01}(d) \wedge \text{ARG0}(d, y) \wedge \text{ARG1}(d, x)$ and $NP \vdash \mathcal{A}_1(\lambda i.\text{involve-01}(i) \wedge \text{ARG1}(i, \mathcal{R}(\text{ID})))$ which would combine with forward application ($>$). Kwiatkowski et al. (2010) present the full details.[6] The process starts from u, the underspecified form of z, and recursively applies the splitting operation while ensuring that: (1) there is at most one entry from G_{gen} or one entry where both the template and lexemes are new in the derivation, (2) each parsing step must have at least one child that may be constructed from an existing partial derivation, and (3) for each new parsing step, the syntax of a newly generated child must match the syntax of a CCGBank category for the same span. To search the space of derivations we populate a CKY chart and do a top-down beam search, where in each step we split categories for smaller spans.

6.2 Gradient Computation: COMPUTEGRAD

Given a sentence x, its labeled logical form z, parameters θ and lexicon Λ, the procedure COMPUTEGRAD(x, z, θ, Λ) computes the gradient for the sample (x, z). Let $\mathcal{D}^*(z) = \text{GENMAX}(x, z, \theta, \Lambda)$, the set of max-scoring correct derivations. The *hard* gradient update is:

$$\frac{1}{|\mathcal{D}^*(z)|} \sum_{d \in \mathcal{D}^*(z)} \phi(x_i, d) - E_{p(d, |x_i; \theta, \Lambda)}[\phi(x_i, d)] \quad , \quad (2)$$

where $\phi(x, d) \in \mathbb{R}^l$ is a l-dimensional feature vector (Section 5.3) and the positive portion of the gradient, rather than using expected features, averages over all max-scoring correct derivations.

Early updates To generate an effective update when no correct derivation is observed, we follow Collins and Roark (2004) and do an early update if $\mathcal{D}^*(z)$ is empty or if GEN(x, Λ), the set

[5] Named-entity constants are created from name instances when converting from AMR to lambda calculus. See the supplementary material for the exact procedure.

[6] Unlike Kwiatkowski et al. (2010), we also introduce syntactic attributes (e.g., pl, sg) when splitting.

of derivations for x, does not contain a derivation with the correct final logical form z. Given the partial derivations, our gradient computation is identical to Equation 2. However, in contrast to Collins and Roark (2004) our data does not include gold derivations. Therefore, we attempt to identify max-scoring partial derivations that may lead to the correct derivation. We extract sub-expressions from u,[7] the underspecified form of z, and search the CKY chart for the top-scoring non-overlapping spans that contain categories with these logical forms. We use the partial derivations leading to these cells to compute the gradient.

The benefit of early updates is two-fold. First, as expected, it leads to higher quality updates that are focused on the errors the model makes. Second, given the complexity of the data, it allows us to have updates for many examples that would be otherwise ignored. In our experiments, we observe this behavior with nearly 40% of the training set.

7 Experimental Setup

Data, Tools and Metric For evaluation, we use AMR Bank release 1.0 (LDC2014T12). We use the proxy report portion, which includes newswire articles from the English Gigaword corpus, and follow the official split for training, development and evaluation (6603/826/823 sentences). We use EasyCCG (Lewis and Steedman, 2014) trained with the re-banked CCGBank (Hockenmaier and Steedman, 2007; Honnibal et al., 2010) to generate CCGBank categories, the Illinois Named Entity Tagger (Ratinov and Roth, 2009) for NER, Stanford CoreNLP (Manning et al., 2014) for tokenization and part-of-speech tagging and UW SPF (Artzi and Zettlemoyer, 2013a) to develop our system. We use SMATCH (Cai and Knight, 2013) to evaluate logical forms converted back to AMRs.

CCG We use three syntactic attributes: singular sg, mass nouns nb and plural pl. When factoring lexical entries, we avoid extracting binary relations and references, and leave them in the template. We use backward and forward binary combinators for application, composition and crossing composition. We allow non-crossing composition up to the third order. We also add rules to handle punctuation and unary rules for type-shifting non-adjectives in adjectival positions and verb phrases in adverbial positions. We allow shifting of bare plurals, mass nouns and named entities to noun phrases. To avoid spurious ambiguity during parsing, we use normal-form constraints (Hockenmaier and Bisk, 2010). We use five basic lambda calculus types: entity e, truth value t, identifier id, quoted text txt and integer i.

Features During CCG parsing, we use indicator features for unary type shifting, crossing composition, lexemes, templates and dynamically generated lexical entries. We also use indicators for co-occurrence of part-of-speech tags and syntactic attributes, repetitions in logical conjunctions and attachments in the logical form. In the factor graph, we use indicator features for control structures, parent-relation-child selectional preferences and for mapping a relation to its final form. See the supplementary material for a detailed description.

Initialization and Parameters We created the seed lexicon from the training data by sampling and annotating 50 sentences with lexical entries, adding entries for pronouns and adding lexemes for all alignments generated by JAMR (Flanigan et al., 2014). We initialize features weights as follows: 10 for all lexeme feature for seed entries and entries generated by named-entity matching (Section 6.1), IBM Model 1 scores for all other lexemes (Kwiatkowski et al., 2011), -3 for unary type shifting and crossing composition features, 3 for features that pair singular and plural part-of-speech tags with singular and plural attributes and 0 for all other features. We set the number of iterations $T = 10$ and select the best model based on development results. We set the max number of tokens for lexical generation $k_{\text{gen}} = 2$, learning rate $\mu = 0.1$, CCG parsing beam $K = 50$, factor graph beam $L = 100$, mini batch size $M = 40$ and use a beam of 100 for GENMAX.

Two-pass Inference During testing, we perform two passes of inference for every sentence. First, we run our inference procedure (Section 5.4). If no derivations are generated, we run inference again, allowing the parser to skip words at a fixed cost and use the entries for *related* words if a word is unknown. We find related words in the lexicon using case, plurality and inflection string transformations. Finally, if necessary, we heuristically transform the logical forms at the root of the CCG parse trees to valid AMR logical forms. We set the cost of logical form transformation and word skipping to 10 and the cost of using related entries to 5.

[7] We extract all sub-expressions of type e, $\langle e, t\rangle$, $\langle e, t\rangle, \langle e, t\rangle\rangle$ or $\langle e, \langle e, t\rangle\rangle$ from u.

8 Results

Table 1 shows SMATCH test results. We compare our approach to the latest, *fixed* version of JAMR (Flanigan et al., 2014) available online,[8] the only system to report test results on the official LDC release. Our approach outperforms JAMR by 3 SMATCH F1 points, with a significant gain in recall. Given consensus inter-annotator agreement of 83 SMATCH F1 (Flanigan et al., 2014), this improvement reduces the gap between automated methods and human performance by 15%. Although not strictly comparable, Table 1 also includes results on the pre-release AMR Bank corpus, including the published JAMR results, their fixed results and the results of Wang et al. (2015).

Table 2 shows SMATCH scores for the developments set, with ablations. The supplementary material includes example output derivations and qualitative comparison to JAMR outputs. We first remove underspecifying constants, which leaves the factor graph to resolve only references. While the expressivity of the model remains the same, more decisions are considered during parsing, modestly impacting performance.

We also study the different methods for lexical generation. Skipping the second recursive splitting pass in GENENTRIES creates an interesting tradeoff. As we are unable to learn templates without splitting, we induce a significantly smaller lexicon (500K vs. 1.6M entries). Although we are unable to recover many syntactic constructions, our search problem is in general much simpler. We therefore see a relatively mild drop in overall performance (1.1 F1). Removing G_{gen} during lexical generation (Section 6.1) creates a more significant drop in performance (3.4 F1), demonstrating how considering all possible lexemes allows the system to recover entries that are not covered by heuristic alignments. We are also able for the first time to report AMR parsing results without any surface-form similarity heuristics, by removing both JAMR alignments and named-entity matching lexical generation (Section 6.1). The significant drop in performance (20 points F1) demonstrates the need for better alignment algorithm.

Finally, Figure 5 plots development SMATCH F1 with and without early updates. As expected, early updates increase the learning rate significantly and have a large impact on overall performance. Without early updates we are unable to learn from almost half of the data, and performance drops by nearly 15 points.

9 Conclusion

We described an approach for broad-coverage CCG induction for semantic parsing, including a joint representation of compositional and non-compositional semantics, a new grammar induction technique and an early update procedure. We used AMR as the target representation and present new state-of-the-art AMR parsing results.

While we focused on recovering non-compositional dependencies, other non-compositional phenomena remain to be studied. Although our technique is able to learn certain idioms as multi-word phrases, learning to recognize discontinuous idioms remains open. Similarly, resolving cross-sentence references, which are not annotated in AMR Bank, is important future work. Finally, we would like to reduce the dependency on surface-form heuristics, for example to better generalize to other languages.

Abstract

Natural language generation (NLG) is a critical component of spoken dialogue and it has a significant impact both on usability and perceived quality. Most NLG systems in common use employ rules and heuristics and tend to generate rigid and stylised responses without the natural variation of human language. They are also not easily scaled to systems covering multiple domains and languages. This paper presents a statistical language generator based on a semantically controlled Long Short-term Memory (LSTM) structure. The LSTM generator can learn from unaligned data by jointly optimising sentence planning and surface realisation using a simple cross entropy training criterion, and language variation can be easily achieved by sampling from output candidates. With fewer heuristics, an objective evaluation in two differing test domains showed the proposed method improved performance compared to previous methods. Human judges scored the LSTM system higher on informativeness and naturalness and overall preferred it to the other systems.

1 Introduction

The natural language generation (NLG) component provides much of the persona of a spoken dialogue system (SDS), and it has a significant impact on a user's impression of the system. As noted in Stent et al. (2005), a good generator usually depends on several factors: adequacy, fluency, readability, and variation. Previous approaches attacked the NLG problem in different ways. The most common and widely adopted today is the *rule-based* (or *template-based*) approach (Cheyer and Guzzoni, 2007; Mirkovic and Cavedon, 2011). Despite its robustness and adequacy, the frequent repetition of identical, rather stilted, output forms make talking to a *rule-based* generator rather tedious. Furthermore, the approach does not easily scale to large open domain systems(Young et al., 2013; Gašić et al., 2014; Henderson et al., 2014). Hence approaches to NLG are required that can be readily scaled whilst meeting the above requirements.

The *trainable generator* approach exemplified by the HALOGEN (Langkilde and Knight, 1998) and SPaRKy system (Stent et al., 2004) provides a possible way forward. These systems include specific trainable modules within the generation framework to allow the model to adapt to different domains (Walker et al., 2007), or reproduce certain style (Mairesse and Walker, 2011). However, these approaches still require a handcrafted generator to define the decision space within which statistics can be used for optimisation. The resulting utterances are therefore constrained by the predefined syntax and any domain-specific colloquial responses must be added manually.

More recently, *corpus-based* methods (Oh and Rudnicky, 2000; Mairesse and Young, 2014; Wen et al., 2015) have received attention as access to data becomes increasingly available. By defining a flexible learning structure, *corpus-based* methods aim to learn generation directly from data by adopting an over-generation and reranking paradigm (Oh and Rudnicky, 2000), in which final responses are obtained by reranking a set of candidates generated from a stochastic generator. Learning from data directly enables the system to mimic human responses more naturally, removes the dependency on predefined rules, and makes the system easier to build and extend to other domains. As detailed in Sections 2 and 3, however, these existing approaches have weaknesses in the areas of training data efficiency, accuracy and naturalness.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1711–1721,
Lisbon, Portugal, 17-21 September 2015.

This paper presents a statistical NLG based on a semantically controlled Long Short-term Memory (LSTM) recurrent network. It can learn from unaligned data by jointly optimising its sentence planning and surface realisation components using a simple cross entropy training criterion without any heuristics, and good quality language variation is obtained simply by randomly sampling the network outputs. We start in Section 3 by defining the framework of the proposed neural language generator. We introduce the semantically controlled LSTM (SC-LSTM) cell in Section 3.1, then we discuss how to extend it to a deep structure in Section 3.2. As suggested in Wen et al. (2015), a backward reranker is introduced in Section 3.3 to improve fluency. Training and decoding details are described in Section 3.4 and 3.5.

Section 4 presents an evaluation of the proposed approach in the context of an application providing information about venues in the San Francisco area. In Section 4.2, we first show that our generator outperforms several baselines using objective metrics. We experimented on two different ontologies to show not only that good performance can be achieved across domains, but how easy and quick the development lifecycle is. In order to assess the subjective performance of our system, a quality test and a pairwise preference test are presented in Section 4.3. The results show that our approach can produce high quality utterances that are considered to be more natural and are preferred to previous approaches. We conclude with a brief summary and future work in Section 5.

2 Related Work

Conventional approaches to NLG typically divide the task into sentence planning and surface realisation. Sentence planning maps input semantic symbols into an intermediary form representing the utterance, e.g. a tree-like or template structure, then surface realisation converts the intermediate structure into the final text (Walker et al., 2002; Stent et al., 2004). Although statistical sentence planning has been explored previously, for example, generating the most likely context-free derivations given a corpus (Belz, 2008) or maximising the expected reward using reinforcement learning (Rieser and Lemon, 2010), these methods still rely on a pre-existing, handcrafted generator. To minimise handcrafting, Stent and Molina (2009) proposed learning sentence planning rules directly from a corpus of utterances labelled with Rhetorical Structure Theory (RST) discourse relations (Mann and Thompson, 1988). However, the required corpus labelling is expensive and additional handcrafting is still needed to map the sentence plan to a valid syntactic form.

As noted above, *corpus-based* NLG aims at learning generation decisions from data with minimal dependence on rules and heuristics. A pioneer in this direction is the class-based n-gram language model (LM) approach proposed by Oh and Rudnicky (2000). Ratnaparkhi (2002) later addressed some of the limitations of class-based LMs in the over-generation phase by using a modified generator based on a syntactic dependency tree. Mairesse and Young (2014) proposed a phrase-based NLG system based on factored LMs that can learn from a semantically aligned corpus. Although active learning (Mairesse et al., 2010) was also proposed to allow learning online directly from users, the requirement for human annotated alignments limits the scalability of the system. Another similar approach casts NLG as a template extraction and matching problem, e.g., Angeli et al. (2010) train a set of log-linear models to make a series of generation decisions to choose the most suitable template for realisation. Kondadadi et al. (2013) later show that the outputs can be further improved by an SVM reranker making them comparable to human-authored texts. However, template matching approaches do not generalise well to unseen combinations of semantic elements.

The use of neural network-based (NN) approaches to NLG is relatively unexplored. The stock reporter system ANA by Kukich (1987) is perhaps the first NN-based generator, although generation was only done at the phrase level. Recent advances in recurrent neural network-based language models (RNNLM) (Mikolov et al., 2010; Mikolov et al., 2011a) have demonstrated the value of distributed representations and the ability to model arbitrarily long dependencies. Sutskever et al. (2011) describes a simple variant of the RNN that can generate meaningful sentences by learning from a character-level corpus. More recently, Karpathy and Fei-Fei (2014) have demonstrated that an RNNLM is capable of generating image descriptions by conditioning the network model on a pre-trained convolutional image feature representation. Zhang and Lapata (2014) also describes interesting work using RNNs to generate

Chinese poetry. A forerunner of the system presented here is described in Wen et al. (2015), in which a forward RNN generator, a CNN reranker, and a backward RNN reranker are trained jointly to generate utterances. Although the system was easy to train and extend to other domains, a heuristic gate control was needed to ensure that all of the attribute-value information in the system's response was accurately captured by the generated utterance. Furthermore, the handling of unusual slot-value pairs by the CNN reranker was rather arbitrary. In contrast, the LSTM-based system described in this paper can deal with these problems automatically by learning the control of gates and surface realisation jointly.

Training an RNN with long range dependencies is difficult because of the vanishing gradient problem (Bengio et al., 1994). Hochreiter and Schmidhuber (1997) mitigated this problem by replacing the sigmoid activation in the RNN recurrent connection with a self-recurrent memory block and a set of multiplication gates to mimic the read, write, and reset operations in digital computers. The resulting architecture is dubbed the Long Short-term Memory (LSTM) network. It has been shown to be effective in a variety of tasks, such as speech recognition (Graves et al., 2013b), handwriting recognition (Graves et al., 2009), spoken language understanding (Yao et al., 2014), and machine translation (Sutskever et al., 2014). Recent work by Graves et al. (2014) has demonstrated that an NN structure augmented with a carefully designed memory block and differentiable read/write operations can learn to mimic computer programs. Moreover, the ability to train deep networks provides a more sophisticated way of exploiting relations between labels and features, therefore making the prediction more accurate (Hinton et al., 2012). By extending an LSTM network to be both deep in space and time, Graves (2013) shows the resulting network can used to synthesise handwriting indistinguishable from that of a human.

3 The Neural Language Generator

The generation model proposed in this paper is based on a recurrent NN architecture (Mikolov et al., 2010) in which a 1-hot encoding $\mathbf{w}_t$ of a token[1] w_t is input at each time step t conditioned on a recurrent hidden layer $\mathbf{h}_t$ and outputs the probability distribution of the next token w_{t+1}. Therefore, by sampling input tokens one by one from the output distribution of the RNN until a stop sign is generated (Karpathy and Fei-Fei, 2014) or some constraint is satisfied (Zhang and Lapata, 2014), the network can produce a sequence of tokens which can be lexicalised [2] to form the required utterance.

3.1 Semantic Controlled LSTM cell

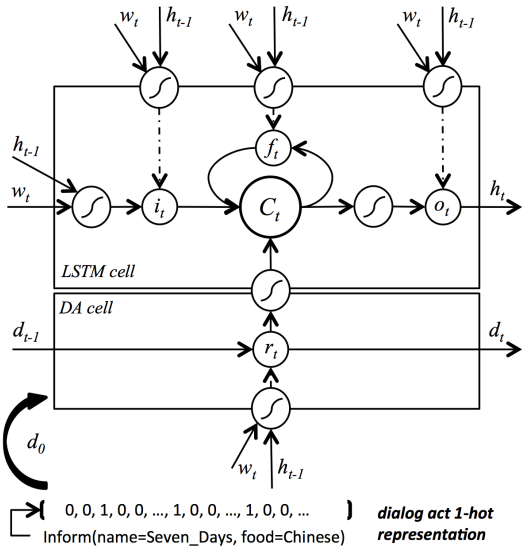

Figure 1: Semantic Controlled LSTM cell proposed in this paper. The upper part is a traditional LSTM cell in charge of surface realisation, while the lower part is a sentence planning cell based on a sigmoid control gate and a dialogue act (DA).

Long Short-term Memory (Hochreiter and Schmidhuber, 1997) is a recurrent NN architecture which uses a vector of memory cells $\mathbf{c}_t \in \mathbb{R}^n$ and a set of elementwise multiplication gates to control how information is stored, forgotten, and exploited inside the network. Of the various different connectivity designs for an LSTM cell (Graves, 2013; Zaremba et al., 2014), the architecture used in this paper is illustrated in Figure 3.1 and defined by the following equations,,

$$\mathbf{i}_t = \sigma(\mathbf{W}_{wi}\mathbf{w}_t + \mathbf{W}_{hi}\mathbf{h}_{t-1}) \quad (1)$$

$$\mathbf{f}_t = \sigma(\mathbf{W}_{wf}\mathbf{w}_t + \mathbf{W}_{hf}\mathbf{h}_{t-1}) \quad (2)$$

$$\mathbf{o}_t = \sigma(\mathbf{W}_{wo}\mathbf{w}_t + \mathbf{W}_{ho}\mathbf{h}_{t-1}) \quad (3)$$

$$\hat{\mathbf{c}}_t = tanh(\mathbf{W}_{wc}\mathbf{w}_t + \mathbf{W}_{hc}\mathbf{h}_{t-1}) \quad (4)$$

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \hat{\mathbf{c}}_t \quad (5)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot tanh(\mathbf{c}_t) \quad (6)$$

[1] We use *token* instead of *word* because our model operates on text for which slot values are replaced by its corresponding slot tokens. We call this procedure delexicalisation.

[2] The process of replacing slot token by its value.

where σ is the sigmoid function, $\mathbf{i}_t, \mathbf{f}_t, \mathbf{o}_t \in [0,1]^n$ are input, forget, and output gates respectively, and $\hat{\mathbf{c}}_t$ and $\mathbf{c}_t$ are proposed cell value and true cell value at time t. Note that each of these vectors has a dimension equal to the hidden layer $\mathbf{h}$.

In order to ensure that the generated utterance represents the intended meaning, the generator is further conditioned on a control vector $\mathbf{d}$, a 1-hot representation of the dialogue act (DA) type and its slot-value pairs. Although a related work (Karpathy and Fei-Fei, 2014) has suggested that reapplying this auxiliary information to the RNN at every time step can increase performance by mitigating the *vanishing gradient problem* (Mikolov and Zweig, 2012; Bengio et al., 1994), we have found that such a model also omits and duplicates slot information in the surface realisation. In Wen et al. (2015) simple heuristics are used to turn off slot feature values in the control vector $\mathbf{d}$ once the corresponding slot token has been generated. However, these heuristics can only handle cases where slot-value pairs can be identified by exact matching between the delexicalised surface text and the slot value pair encoded in $\mathbf{d}$. Cases such as binary slots and slots that take don't care values cannot be explicitly delexicalised in this way and these cases frequently result in generation errors.

To address this problem, an additional control cell is introduced into the LSTM to gate the DA as shown in Figure 1. This cell plays the role of *sentence planning* since it manipulates the DA features during the generation process in order to produce a surface realisation which accurately encodes the input information. We call the resulting architecture Semantically Controlled LSTM (SC-LSTM). Starting from the original DA 1-hot vector $\mathbf{d}_0$, at each time step the DA cell decides what information should be retained for future time steps and discards the others,

$$\mathbf{r}_t = \sigma(\mathbf{W}_{wr}\mathbf{w}_t + \alpha\mathbf{W}_{hr}\mathbf{h}_{t-1}) \quad (7)$$

$$\mathbf{d}_t = \mathbf{r}_t \odot \mathbf{d}_{t-1} \quad (8)$$

where $\mathbf{r}_t \in [0,1]^d$ is called the reading gate, and α is a constant. Here $\mathbf{W}_{wr}$ and $\mathbf{W}_{hr}$ act like keyword and key phrase detectors that learn to associate certain patterns of generated tokens with certain slots. Figure 3 gives an example of how these detectors work in affecting DA features inside the network. Equation 5 is then modified so that the cell value $\mathbf{c}_t$ also depends on the DA,

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \hat{\mathbf{c}}_t + tanh(\mathbf{W}_{dc}\mathbf{d}_t) \quad (9)$$

After updating Equation 6 by Equation 9, the output distribution is formed by applying a softmax function g, and the distribution is sampled to obtain the next token,

$$P(w_{t+1}|w_t, w_{t-1}, ...w_0, \mathbf{d}_t) = g(\mathbf{W}_{ho}\mathbf{h}_t) \quad (10)$$

$$w_{t+1} \sim P(w_{t+1}|w_t, w_{t-1}, ...w_0, \mathbf{d}_t). \quad (11)$$

3.2 The Deep Structure

Deep Neural Networks (DNN) enable increased discrimination by learning multiple layers of features, and represent the state-of-the-art for many applications such as speech recognition (Graves et al., 2013b) and natural language processing (Collobert and Weston, 2008). The neural language generator proposed in this paper can be easily extended to be deep in both space and time by stacking multiple LSTM cells on top of the original structure. As shown in Figure 2, *skip connections* are applied to the inputs of all hidden layers as well as between all hidden layers and the outputs (Graves, 2013). This reduces the number of processing steps between the bottom of the network and the top, and therefore mitigates the vanishing gradient problem (Bengio et al., 1994) in the vertical direction. To allow all hidden layer information to influence the reading gate, Equation 7 is changed to

$$\mathbf{r}_t = \sigma(\mathbf{W}_{wr}\mathbf{w}_t + \sum_l \alpha_l \mathbf{W}^l_{hr}\mathbf{h}^l_{t-1}) \quad (12)$$

where l is the hidden layer index and α_l is a layer-wise constant. Since the network tends to overfit when the structure becomes more complex, the dropout technique (Srivastava et al., 2014) is used to regularise the network. As suggested in (Zaremba et al., 2014), dropout was only applied to the non-recurrent connections, as shown in the Figure 2. It was not applied to word embeddings since pre-trained word vectors were used.

3.3 Backward LSTM reranking

One remaining problem in the structure described so far is that the LSTM generator selects words based only on the preceding history, whereas some sentence forms depend on the backward context. Previously, bidirectional networks (Schuster and

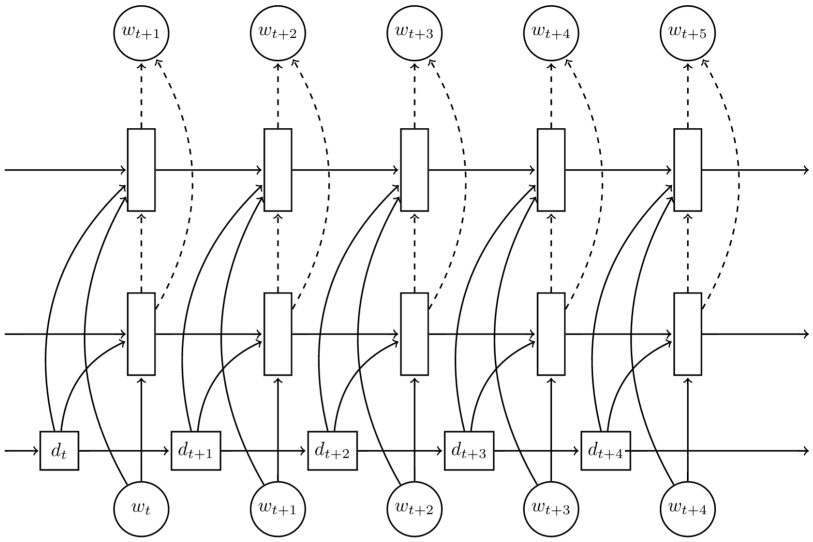

Figure 2: The Deep LSTM generator structure by stacking multiple LSTM layers on top of the DA cell. The skip connection was adopted to mitigate the vanishing gradient, while the dropout was applied on dashed connections to prevent co-adaptation and overfitting.

Paliwal, 1997) have been shown to be effective for sequential problems (Graves et al., 2013a; Sundermeyer et al., 2014). However, applying a bidirectional network directly in the SC-LSTM generator is not straightforward since the generation process is sequential in time. Hence instead of integrating the bidirectional information into one network, we trained another SC-LSTM from backward context to choose best candidates from the forward generator outputs. In our experiments, we also found that by tying the keyword detector weights $\mathbf{W}_{wr}$ (see Equations 7 and 12) of both the forward and backward networks together makes the generator less sensitive to random initialisation.

3.4 Training

The forward generator and the backward reranker were both trained by treating each sentence as a mini-batch. The objective function was the cross entropy error between the predicted word distribution $\mathbf{p}_t$ and the actual word distribution $\mathbf{y}_t$ in the training corpus. An l_2 regularisation term was added to the objective function for every 10 training examples as suggested in Mikolov et al. (2011b). However, further regularisation was required for the reading gate dynamics. This resulted in the following modified cost function for each mini-match (ignoring standard l_2),

$$F(\theta) = \sum_t \mathbf{p}_t^{\mathrm{T}} log(\mathbf{y}_t) + \|\mathbf{d}_T\| + \sum_{t=0}^{T-1} \eta \xi^{\|\mathbf{d}_{t+1} - \mathbf{d}_t\|} \quad (13)$$

where $\mathbf{d}_T$ is the DA vector at the last word index T, and η and ξ are constants set to 10^{-4} and 100, respectively. The second term is used to penalise generated utterances that failed to render all the required slots, while the third term discourages the network from turning more than one gate off in a single time step. The forward and backward networks were structured to share the same set of word embeddings, initialised with pre-trained word vectors (Pennington et al., 2014). The hidden layer size was set to be 80 for all cases, and deep networks were trained with two hidden layers and a 50% dropout rate. All costs and gradients were computed and stochastic gradient descent was used to optimise the parameters. Both networks were trained with back propagation through time (Werbos, 1990). In order to prevent overfitting, early stopping was implemented using a held-out validation set.

3.5 Decoding

The decoding procedure is split into two phases: (a) over-generation, and (b) reranking. In the over-generation phase, the forward generator conditioned on the given DA, is used to sequentially generate utterances by random sampling of the predicted next word distributions. In the reranking phase, the cost of the backward reranker $F_b(\theta)$ is computed. Together with the cost $F_f(\theta)$ from the forward generator, the reranking score R is com-

puted as:

$$R = -(F_f(\theta) + F_b(\theta) + \lambda \text{ERR}) \quad (14)$$

where λ is a tradeoff constant, and the slot error rate ERR is computed by exact matching the slot tokens in the candidate utterances,

$$\text{ERR} = \frac{p+q}{N} \quad (15)$$

where N is the total number of slots in the DA, and p, q is the number of missing and redundant slots in the given realisation. Note that the ERR reranking criteria cannot handle arbitrary slot-value pairs such as binary slots or slots that take the don't care value because they cannot be delexicalised and exactly matched. λ is set to a large value in order to severely penalise nonsensical outputs.

4 Experiments

4.1 Experimental Setup

The target application for our generation system is a spoken dialogue system providing information about certain venues in San Francisco. In order to demonstrate the scalability of the proposed method and its performance in different domains, we tested on two domains that talk about restaurants and hotels respectively. There are 8 system dialogue act types such as *inform* to present information about restaurants, *confirm* to check that a slot value has been recognised correctly, and *reject* to advise that the user's constraints cannot be met. Each domain contains 12 attributes (slots), some are common to both domains and the others are domain specific. The detailed ontologies for the two domains are provided in Table 1. To form a training corpus for each domain, dialogues collected from a previous user trial (Gašić et al., 2015) of a statistical dialogue manager were randomly sampled and shown to workers recruited via the Amazon Mechanical Turk (AMT) service. Workers were shown each dialogue turn by turn and asked to enter an appropriate system response in natural English corresponding to each system DA. For each domain around 5K system utterances were collected from about 1K randomly sampled dialogues. Each categorical value was replaced by a token representing its slot, and slots that appeared multiple times in a DA were merged into one. After processing and grouping each utterance according to its delexicalised DA, we obtained 248 distinct DAs in the restaurant domain and 164 in the hotel domain. The average number of slots per DA for each domain is 2.25 and 1.95, respectively.

	SF Restaurant	SF Hotel
act type	inform, inform_only, reject, confirm, select, request, reqmore, goodbye	
shared	name, type, *pricerange, price, phone, address, postcode, *area, *near	
specific	*food *goodformeal ***kids-allowed**	***hasinternet** ***acceptscards** ***dogs-allowed**

bold=binary slots, *=slots can take "don't care" value

Table 1: Ontologies used in the experiments.

The system was implemented using the Theano library (Bergstra et al., 2010; Bastien et al., 2012), and trained by partitioning each of the collected corpus into a training, validation, and testing set in the ratio 3:1:1. The frequency of each action type and slot-value pair differs quite markedly across the corpus, hence up-sampling was used to make the corpus more uniform. Since our generator works stochastically and the trained networks can differ depending on the initialisation, all the results shown below[3] were averaged over 5 randomly initialised networks. For each DA, we overgenerated 20 utterances and selected the top 5 realisations after reranking. The BLEU-4 metric was used for the objective evaluation (Papineni et al., 2002). Multiple references for each test DA were obtained by mapping them back to the distinct set of DAs, grouping those delexicalised surface forms that have the same DA specification, and then lexicalising those surface forms back to utterances. In addition, the slot error rate (ERR) as described in Section 3.5 was computed as an auxiliary metric alongside the BLEU score. However, for the experiments it is computed at the corpus level, by averaging slot errors over each of the top 5 realisations in the entire corpus. The trade-off weights α between keyword and key phrase detectors as mentioned in Section 3.1 and 3.2 were set to 0.5.

4.2 Objective Evaluation

We compared the single layer semantically controlled LSTM (*sc-lstm*) and a deep version with

[3]Except human evaluation, in which only one set of networks was used.

Method	SF Restaurant		SF Hotel	
	BLEU	ERR(%)	BLEU	ERR(%)
hdc	0.451	0.0	0.560	0.0
kNN	0.602	0.87	0.676	1.87
classlm	0.627	8.70	0.734	5.35
rnn w/o	0.706	4.15	0.813	3.14
lstm w/o	0.714	1.79	0.817	1.93
rnn w/	0.710	1.52	0.815	1.74
lstm w/	0.717	0.63	0.818	1.53
sc-lstm	0.711	0.62	0.802	0.78
+deep	**0.731**	**0.46**	**0.832**	**0.41**

Table 2: Objective evaluation of the top 5 realisations. Except for handcrafted (*hdc*) and k-nearest neighbour (*kNN*) baselines, all the other approaches ranked their realisations from 20 over-generated candidates.

two hidden layers (+*deep*) against several baselines: the handcrafted generator (*hdc*), k-nearest neighbour (*kNN*), class-based LMs (*classlm*) as proposed in Oh and Rudnicky (2000), the heuristic gated RNN as described in Wen et al. (2015) and a similar LSTM variant (*rnn w/* & *lstm w/*), and the same RNN/LSTM but without gates (*rnn w/o* & *lstm w/o*). The handcrafted generator was developed over a long period of time and is the standard generator used for trialling end-to-end dialogue systems (for example (Gašić et al., 2014)). The kNN was implemented by computing the similarity of the test DA 1-hot vector against all of the training DA 1-hot vectors, selecting the nearest and then lexicalising to generate the final surface form. The objective results are shown in Table 2. As can be seen, none of the baseline systems shown in the first block (*hdc*, *kNN*, & *classlm*) are comparable to the systems described in this paper (*sc-lstm* & +*deep*) if both metrics are considered. Setting aside the difficulty of scaling to large domains, the handcrafted generator's (*hdc*) use of predefined rules yields a fixed set of sentence plans, which can differ markedly from the real colloquial human responses collected from AMT, while the class LM approach suffers from inaccurate rendering of information. Although the *kNN* method provides reasonable adequacy i.e. low ERR, the BLEU is low, probably because of the errors in the collected corpus which *kNN* cannot handle but statistical approaches such as LMs can by suppressing unlikely outputs.

The last three blocks in Table 2 compares the proposed method with previous RNN approaches.

Method	**Informativeness**	**Naturalness**
+deep	2.58	**2.51**
sc-lstm	**2.59**	2.50
rnn w/	2.53	2.42^{*}
classlm	2.46^{**}	2.45

$^{*}p < 0.05$ $^{**}p < 0.005$

Pref.%	**classlm**	**rnn w/**	**sc-lstm**	**+deep**
classlm	-	46.0	40.9^{**}	37.7^{**}
rnn w/	54.0	-	43.0	35.7^{*}
sc-lstm	59.1^{*}	57	-	47.6
+deep	62.3^{**}	64.3^{**}	52.4	-

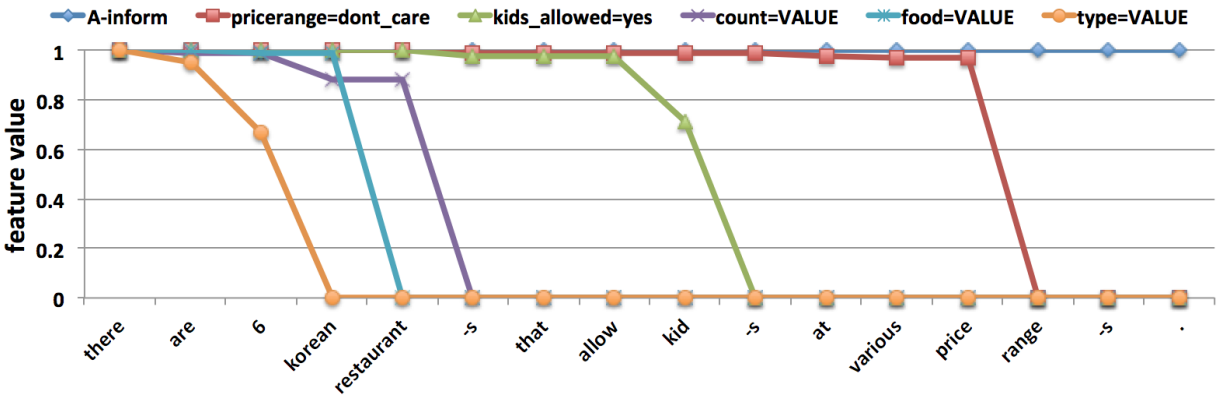
$^{*}p < 0.05$ $^{**}p < 0.005$

Table 4: Pairwise preference test among four systems. Statistical significance was computed using two-tailed binomial test.

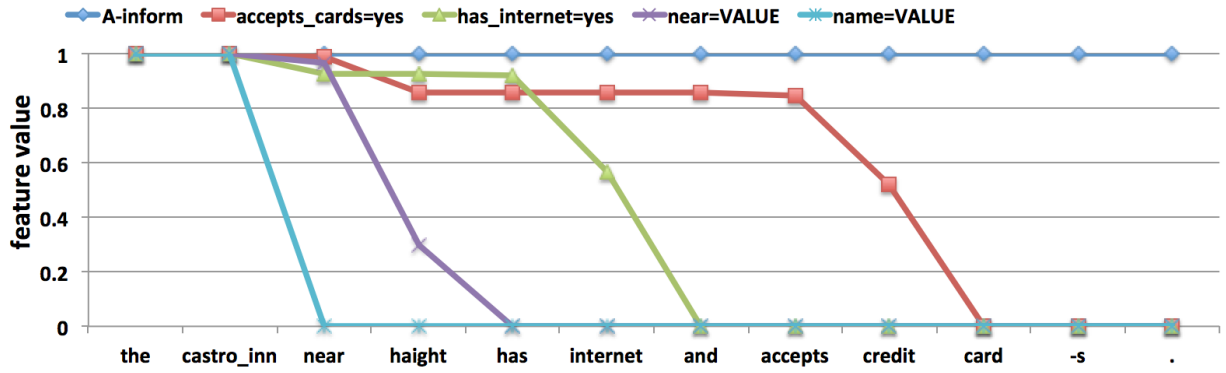
LSTM generally works better than vanilla RNN due to its ability to model long range dependencies more efficiently. We also found that by using gates, whether learned or heuristic, gave much lower slot error rates. As an aside, the ability of the SC-LSTM to learn gates is also exemplified in Figure 3. Finally, by combining the learned gate approach with the deep architecture (+*deep*), we obtained the best overall performance.

4.3 Human Evaluation

Since automatic metrics may not consistently agree with human perception (Stent et al., 2005), human testing is needed to assess subjective quality. To do this, a set of judges were recruited using AMT. For each task, two systems among the four (*classlm*, *rnn w/*, *sc-lstm*, and +*deep*) were randomly selected to generate utterances from a set of newly sampled dialogues in the restaurant domain. In order to evaluate system performance in the presence of language variation, each system generated 5 different surface realisations for each input DA and the human judges were asked to score each of them in terms of informativeness and naturalness (rating out of 3), and also asked to state a preference between the two. Here *informativeness*



(a) An example realisation from SF restaurant domain



(b) An example realisation from SF hotel domain

Figure 3: Examples showing how the SC-LSTM controls the DA features flowing into the network via its learned semantic gates. Despite errors due to sparse training data for some slots, each gate generally learned to detect words and phrases describing a particular slot-value pair.

is defined as whether the utterance contains all the information specified in the DA, and *naturalness* is defined as whether the utterance could plausibly have been produced by a human. In order to decrease the amount of information presented to the judges, utterances that appeared identically in both systems were filtered out. We tested 1000 DAs in total, and after filtering there were approximately 1300 generated utterances per system.

Table 3 shows the quality assessments which exhibit the same general trend as the objective results. The SC-LSTM systems (*sc-lstm* & *+deep*) outperform the class-based LMs (*classlm*) and the RNN with heuristic gates (*rnn w/*) in both metrics. The deep SC-LSTM system (*+deep*) is significantly better than the class LMs (*classlm*) in terms of *informativeness*, and better than the RNN with heuristic gates (*rnn w/*) in terms of *naturalness*. The preference test results are shown in Table 4. Again, the SC-LSTM systems (*sc-lstm & +deep*) were significantly preferred by the judges. Moreover, the judges recorded a strong preference for the deep approach (*+deep*) compared to the others, though the preference is not significant when comparing to its shallow counterpart (*sc-lstm*). Example dialogue acts and their top-5 realisations are shown in Table 5.

5 Conclusion and Future Work

In this paper we have proposed a neural network-based generator that is capable of generating natural linguistically varied responses based on a deep, semantically controlled LSTM architecture which we call SC-LSTM. The generator can be trained on unaligned data by jointly optimising its sentence planning and surface realisation components using a simple cross entropy criterion without any heuristics or handcrafting. We found that the SC-LSTM model achieved the best overall performance on two objective metrics across two different domains. An evaluation by human judges also confirmed that the SC-LSTM approach is strongly preferred to a variety of existing methods.

This work represents a line of research that tries

to model the NLG problem in a unified architecture, whereby the entire model is end-to-end trainable from data. We contend that this approach can produce more natural responses which are more similar to colloquial styles found in human conversations. Another key potential advantage of neural network based language processing is the implicit use of distributed representations for words and a single compact parameter encoding of the information to be conveyed. This suggests that it should be possible to further condition the generator on some dialogue features such discourse information or social cues during the conversation. Furthermore, adopting a corpus based regime enables domain scalability and multilingual NLG to be achieved with less cost and a shorter lifecycle. These latter aspects will be the focus of our future work in this area.

Abstract

Learning a distinct representation for each sense of an ambiguous word could lead to more powerful and fine-grained models of vector-space representations. Yet while 'multi-sense' methods have been proposed and tested on artificial word-similarity tasks, we don't know if they improve real natural language understanding tasks. In this paper we introduce a multi-sense embedding model based on Chinese Restaurant Processes that achieves state of the art performance on matching human word similarity judgments, and propose a pipelined architecture for incorporating multi-sense embeddings into language understanding.

We then test the performance of our model on part-of-speech tagging, named entity recognition, sentiment analysis, semantic relation identification and semantic relatedness, controlling for embedding dimensionality. We find that multi-sense embeddings do improve performance on some tasks (part-of-speech tagging, semantic relation identification, semantic relatedness) but not on others (named entity recognition, various forms of sentiment analysis). We discuss how these differences may be caused by the different role of word sense information in each of the tasks. The results highlight the importance of testing embedding models in real applications.

1 Introduction

Enriching vector models of word meaning so they can represent multiple word senses per word type seems to offer the potential to improve many language understanding tasks. Most traditional embedding models associate each word type with a single embedding (e.g., Bengio et al. (2006)). Thus the embedding for homonymous words like *bank* (with senses including 'sloping land' and 'financial institution') is forced to represent some uneasy central tendency between the various meanings. More fine-grained embeddings that represent more natural regions in semantic space could thus improve language understanding.

Early research pointed out that embeddings could model aspects of word sense (Kintsch, 2001) and recent research has proposed a number of models that represent each word type by different senses, each sense associated with a sense-specific embedding (Kintsch, 2001; Reisinger and Mooney, 2010; Neelakantan et al., 2014; Huang et al., 2012; Chen et al., 2014; Pina and Johansson, 2014; Wu and Giles, 2015; Liu et al., 2015). Such sense-specific embeddings have shown improved performance on simple artificial tasks like matching human word similarity judgments— WS353 (Rubenstein and Goodenough, 1965) or MC30 (Huang et al., 2012).

Incorporating multisense word embeddings into general NLP tasks requires a pipelined architecture that addresses three major steps:

1. **Sense-specific representation learning**: learn word sense specific embeddings from a large corpus, either unsupervised or aided by external resources like WordNet.

2. **Sense induction**: given a text unit (a phrase, sentence, document, etc.), infer word senses for its tokens and associate them with corresponding sense-specific embeddings.

3. **Representation acquisition for phrases or sentences:** learn representations for text units given sense-specific embeddings and pass them to machine learning classifiers.

Most existing work on multi-sense embeddings emphasizes the first step by learning sense spe-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1722–1732,
Lisbon, Portugal, 17-21 September 2015.

cific embeddings, but does not explore the next two steps. These are important steps, however, since it isn't clear how existing multi-sense embeddings can be incorporated into and benefit real-world NLU tasks.

We propose a pipelined architecture to address all three steps and apply it to a variety of NLP tasks: part-of-speech tagging, named entity recognition, sentiment analysis, semantic relation identification and semantic relatedness. We find:

- Multi-sense embeddings give improved performance in some tasks (e.g., semantic similarity for words and sentences, semantic relation identification part-of-speech tagging), but not others (e.g., sentiment analysis, named entity extraction). In our analysis we offer some suggested explanations for these differences.
- Some of the improvements for multi-sense embeddings are no longer visible when using more sophisticated neural models like LSTMs which have more flexibility in filtering away the informational chaff from the wheat.
- It is important to carefully compare against embeddings of the same dimensionality.
- When doing so, the most straightforward way to yield better performance on these tasks is just to increase embedding dimensionality.

After describing related work, we introduce the new unsupervised sense-learning model in section 3, give our sense-induction algorithm in section 4, and then in following sections evaluate its performance for word similarity, and then various NLP tasks.

2 Related Work

Neural embedding learning frameworks represent each token with a dense vector representation, optimized through predicting neighboring words or decomposing co-occurrence matrices (Bengio et al., 2006; Collobert and Weston, 2008; Mnih and Hinton, 2007; Mikolov et al., 2013; Mikolov et al., 2010; Pennington et al., 2014). Standard neural models represent each word with a single unique vector representation.

Recent work has begun to augment the neural paradigm to address the multi-sense problem by associating each word with a series of sense specific embeddings. The central idea is to augment standard embedding learning models like skip-grams by disambiguating word senses based on local co-occurrence— e.g., the fruit "apple" tends to co-occur with the words "cider, tree, pear" while the homophonous IT company co-occurs with words like "iphone", "Google" or "ipod".

For example Reisinger and Mooney (2010) and Huang et al. (2012) propose ways to develop multiple embeddings per word type by pre-clustering the contexts of each token to create a fixed number of senses for each word, and then relabeling each word token with the clustered sense before learning embeddings. Neelakantan et al. (2014) extend these models by relaxing the assumption that each word must have a fixed number of senses and using a non-parametric model setting a threshold to decide when a new sense cluster should be split off; Liu et al. (2015) learns sense/topic specific embeddings by combining neural frameworks with LDA topic models. Wu and Giles (2015) disambiguate sense embeddings from Wikipedia by first clustering wiki documents. Chen et al. (2014) turn to external resources and used a predefined inventory of senses, building a distinct representation for every sense defined by the Wordnet dictionary. Other relevant work includes Qiu et al. (2014) who maintains separate representations for different part-of-speech tags of the same word.

Recent work is mostly evaluated on the relatively artificial task of matching human word similarity judgments.

3 Learning Sense-Specific Embeddings

We propose to build on this previous literature, most specifically Huang et al. (2012) and Neelakantan et al. (2014), to develop an algorithm for learning multiple embeddings for each word type, each embedding corresponding to a distinct induced word sense. Such an algorithm should have the property that a word should be associated with a new sense vector just when evidence in the context (e.g., neighboring words, document-level co-occurrence statistics) suggests that it is sufficiently different from its early senses. Such a line of thinking naturally points to Chinese Restaurant Processes (CRP) (Blei et al., 2004; Teh et al., 2006) which have been applied in the related field of word sense induction. In the analogy of

CRP, the current word could either sit at one of the existing tables (belonging to one of the existing senses) or choose a new table (a new sense). The decision is made by measuring semantic relatedness (based on local context information and global document information) and the number of customers already sitting at that table (the popularity of word senses). We propose such a model and show that it improves over the state of the art on a standard word similarity task.

3.1 Chinese Restaurant Processes

We offer a brief overview of Chinese Restaurant Processes in this section; readers interested in more details can consult the original papers (Blei et al., 2004; Teh et al., 2006; Pitman, 1995). CRP can be viewed as a practical interpretation of Dirichlet Processes (Ferguson, 1973) for non-parametric clustering. In the analogy, each data point is compared to a customer in a restaurant. The restaurant has a series of tables t, each of which serves a dish d_t. This dish can be viewed as the index of a cluster or a topic. The next customer w to enter would either choose an existing table, sharing the dish (cluster) already served or choosing a new cluster based on the following probability distribution:

$$Pr(t_w = t) \propto \begin{cases} N_t P(w|d_t) & \text{if t already exists} \\ \gamma P(w|d_{new}) & \text{if t is new} \end{cases} \quad (1)$$

where N_t denotes the number of customers already sitting at table t and $P(w|d_t)$ denotes the probability of assigning the current data point to cluster d_t. γ is the hyper parameter controlling the preference for sitting at a new table.

CRPs exhibit a useful "rich get richer" property because they take into account the popularity of different word senses. They are also more flexible than a simple threshold strategy for setting up new clusters, due to the robustness introduced by adopting the relative ratio of $P(w|d_t)$ and $P(w|d_{new})$.

3.2 Incorporating CRP into Distributed Language Models

We describe how we incorporate CRP into a standard distributed language model[1].

As in the standard vector-space model, each token w is associated with a K dimensional global embedding e_w. Additionally, it is associated with a set of senses $Z_w = \{z_w^1, z_w^2, ..., z_w^{|Z_w|}\}$ where $|Z_w|$ denotes the number of senses discovered for word w. Each sense z is associated with a distinct sense-specific embedding e_w^z. When we encounter a new token w in the text, at the first stage, we maximize the probability of seeing the current token given its context as in standard language models using the global vector e_w:

$$p(e_w|e_{\text{neigh}}) = F(e_w, e_{\text{neigh}}) \quad (2)$$

F() can take different forms in different learning paradigms, e.g., $F = \prod_{w' \in neigh} p(e_w, e_{w'})$ for skip-gram or $F = p(e_w, g(e_w))$ for SENNA (Collobert and Weston, 2008) and CBOW, where $g(e_{neigh})$ denotes a function that projects the concatenation of neighboring vectors to a vector with the same dimension as e_w for SENNA and the bag-or-word averaging for CBOW (Mikolov et al., 2013).

Unlike traditional one-word-one-vector frameworks, e_{neigh} includes sense information in addition to the global vectors for neighbors. e_{neigh} can therefore be written as[2].

$$e_{\text{neigh}} = \{e_{n-k}, , ..., e_{n-1}, e_{n+1}, ..., e_{n-k}\} \quad (3)$$

Next we would use CRP to decide which sense the current occurrence corresponds to, or construct a new sense if it is a new meaning that we have not encountered before. Based on CRP, the probability that assigns the current occurrence to each of the discovered senses or a new sense is given by:

$$Pr(z_w = z) \propto \begin{cases} N_z^w P(e_w^z|\text{context}) \\ \qquad \text{if z already exists} \\ \gamma P(w|z_{new}) \quad \text{if z is new} \end{cases} \quad (4)$$

where N_z^w denotes the number of times already assigned to sense z for token w. $P(e_w^z|\text{context})$ denotes the probability that current occurrence belonging to (or generated by) sense z.

The algorithm for parameter update for the one token predicting procedure is illustrated in Figure

[1] We omit details about training standard distributed models; see Collobert and Weston (2008) and Mikolov et al. (2013).

[2] For models that predict succeeding words, sense labels for preceding words have already been decided. For models that predict words using both left and right contexts, the labels for right-context words have not been decided yet. In such cases we just use its global word vector to fill up the position.

01: **Input** : Token sequence $\{w_n, w_{\text{neigh}}\}$.
02: Update parameters involved in Equ (3)(4) based on current word prediction.
03: Sample sense label z from CRP.
04: If a new sense label z is sampled:
05: - add z to Z_{w_n}
06: - $e^z_{w_n} = \text{argmax}\, p(w_n|z_m)$
07: else: update parameters involved based on sampled sense label z.

Figure 1: Incorporating CRP into Neural Language Models.

1: Line 2 shows parameter updating through predicting the occurrence of current token. Lines 4-6 illustrate the situation when a new word sense is detected, in which case we would add the newly detected sense z into Z_{w_n}. The vector representation e^z_w for the newly detected sense would be obtained by maximizing the function $p(e^z_w|\text{context})$.

As we can see, the model performs word-sense clustering and embedding learning jointly, each one affecting the other. The prediction of the global vector of the current token (line2) is based on both the global and sense-specific embeddings of its neighbors, as will be updated through predicting the current token. Similarly, once the sense label is decided (line7), the model will adjust the embeddings for neighboring words, both global word vectors and sense-specific vectors.

Training We train embeddings using Gigaword5 + Wikipedia2014. The training approach is implemented using skip-grams (SG) (Mikolov et al., 2013). We induced senses for the top 200,000 most frequent words (and used a unified "unknown" token for other less-frequent tokens). The window size is set to 11. We iterate three times over the corpus.

4 Obtaining Word Representations for NLU tasks

Next we describe how we decide sense labels for tokens in context. The scenario is treated as a inference procedure for sense labels where all global word embeddings and sense-specific embeddings are kept fixed.

Given a document or a sentence, we have an objective function with respect to sense labels by multiplying Eq.2 over each containing token. Computing the global optimum sense labeling—in which every word gets an optimal sense label—requires searching over the space of all senses for all words, which can be expensive. We therefore chose two simplified heuristic approaches:

- **Greedy Search**: Assign each token the locally optimum sense label and represent the current token with the embedding associated with that sense.

- **Expectation**: Compute the probability of each possible sense for the current word, and represent the word with the expectation vector:

$$\vec{e}_w = \sum_{z \in Z_w} p(w|z, \text{context}) \cdot e^z_w$$

5 Word Similarity Evaluation

We evaluate our embeddings by comparing with other multi-sense embeddings on the standard artificial task for matching human word similarity judgments.

Early work used similarity datasets like WS353 (Finkelstein et al., 2001) or RG (Rubenstein and Goodenough, 1965), whose context-free nature makes them a poor evaluation. We therefore adopt Stanford's Contextual Word Similarities (SCWS) (Huang et al., 2012), in which human judgments are associated with pairs of words in context. Thus for example "bank" in the context of "river bank" would have low relatedness with "deficit" in the context "financial deficit".

We first use the Greedy or Expectation strategies to obtain word vectors for tokens given their context. These vectors are then used as input to get the value of cosine similarity between two words.

Performances are reported in Table 1. Consistent with earlier work (e.g.., Neelakantan et al. (2014)), we find that multi-sense embeddings result in better performance in the context-dependent SCWS task (SG+Greedy and SG+Expect are better than SG). As expected, performance is not as high when global level information is ignored when choosing word senses (SG+Greedy) as when it is included (SG+Expect), as neighboring words don't provide sufficient information for word sense disambiguation.

To note, the proposed CRF models work a little better than earlier baselines, which gives some evidence that it is sufficiently strong to stand in for

Model	SCWS Correlation
SkipGram	66.4
SG+Greedy	69.1
SG+Expect	69.7
Chen	68.4
Neelakantan	69.3

Table 1: Performances for different set of multi-sense embeddings (300d) evaluated on SCWS by measuring the Spearman correlation between each model's similarity and the human judgments. Baselines performances are reprinted from Neelakantan et al. (2014) and Chen et al. (2014); we report the best performance across all settings mentioned in their paper.

this class of multi-sense models and serves as a promise for being extended to NLU tasks.

Visualization Table 2 shows examples of semantically related words given the local context. Word embeddings for tokens are obtained by using the inferred sense labels from the Greedy model and are then used to search for nearest neighbors in the vector space based on cosine similarity. Like earlier models (e.g., Neelakantan et al. (2014))., the model can disambiguate different word senses (in examples like *bank, rock* and *apple*) based on their local context; although of course the model is also capable of dealing with polysemy—senses that are less distinct.

6 Experiments on NLP Tasks

Having shown that multi-sense embeddings improve word similarity tasks, we turn to ask whether they improve real-world NLU tasks: POS tagging, NER tagging, sentiment analysis at the phrase and sentence level, semantic relationship identification and sentence-level semantic relatedness. For each task, we experimented on the following sets of embeddings, which are trained using the word2vec package on the same corpus:

- Standard one-word-one-vector embeddings from skip-gram (50d).
- Sense disambiguated embeddings from Section 3 and 4 using Greedy Search and Expectation (50d)
- The concatenation of global word embeddings and sense-specific embeddings (100d).
- Standard one-word-one-vector skip-gram embeddings with dimensionality doubled (100d) (100d is the correct corresponding baseline since the concatenation above doubles the dimensionality of word vectors)
- Embeddings with very high dimensionality (300d).

As far as possible we try to perform an apple-to-apple comparison on these tasks, and our goal is an analytic one—to investigate how well semantic information can be encoded in multi-sense embeddings and how they can improve NLU performances—rather than an attempt to create state-of-the-art results. Thus for example, in tagging tasks (e.g., NER, POS), we follow the protocols in (Collobert et al., 2011) using the concatenation of neighboring embeddings as input features rather than treating embeddings as auxiliary features which are fed into a CRF model along with other manually developed features as in Pennington et al. (2014). Or for experiments on sentiment and other tasks where sentence level embeddings are required we only employ standard recurrent or recursive models for sentence embedding rather than models with sophisticated state-of-the-art methods (e.g., Tai et al. (2015; Irsoy and Cardie (2014)).

Significance testing for comparing models is done via the bootstrap test (Efron and Tibshirani, 1994). Unless otherwise noted, significant testing is performed on one-word-one-vector embedding (50d) versus multi-sense embedding using Expectation inference (50d) and one-vector embedding (100d) versus Expectation (100d).

6.1 The Tasks

Named Entity Recognition We use the CoNLL-2003 English benchmark for training, and test on the CoNLL-2003 test data. We follow the protocols in Collobert et al. (2011), using the concatenation of neighboring embeddings as input to a multi-layer neural model. We employ a five-layer neural architecture, comprised of an input layer, three convolutional layers with rectifier linear activation function and a softmax output layer. Training is done by gradient descent with minibatches where each sentence is treated as one batch. Learning rate, window size, number of hidden units of hidden layers, L2 regularizations and number of iterations are tuned on the development set.

Part-of-Speech Tagging We use Sections 0–18 of the Wall Street Journal (WSJ) data for train-

Context	Nearest Neighbors
Apple is a kind of fruit.	pear, cherry, mango, juice, peach, plum, fruit, cider, apples, tomato, orange, bean, pie

Sentence-level Sentiment Classification (Pang) The sentiment dataset of Pang et al. (2002) consists of movie reviews with a sentiment label for each sentence. We divide the original dataset into training(8101)/dev(500)/testing(2000). Word embeddings are initialized using the aforementioned types of embeddings and kept fixed in the learning procedure. Sentence level embeddings are achieved by using standard sequence recurrent neural models (Pearlmutter, 1989) (for details, please refer to Appendix section). The obtained embedding is then fed into a sigmoid classifier. Convolutional matrices at the word level are randomized from [-0.1, 0.1] and learned from sequence models. For training, we adopt AdaGrad with mini-batch. Parameters (i.e., $L2$ penalty, learning rate and mini batch size) are tuned on the development set. Due to space limitations, we omit details of recurrent models and training.

Standard (50) 0.750	Greedy (50) 0.752(+0.02)	Expectation (50) 0.750(+0.00)
Standard (100) 0.768	Global+G (100) 0.765(-0.03)	Global+E (100) 0.763(-0.05)
Standard (300) 0.774		

Table 5: Accuracy for Different Models on Sentiment Analysis (Pang et al.'s dataset). P-value 0.442 for 50d and 0.375 for 100d.

Sentiment Analysis–Stanford Treebank The Stanford Sentiment Treebank (Socher et al., 2013) contains gold-standard labels for each constituent in the parse tree (phrase level), thus allowing us to investigate a sentiment task at a finer granularity than the dataset in Pang et al. (2002) where labels are only found at the top of each sentence, The sentences in the treebank were split into a training(8544)/development(1101)/testing(2210) dataset.

Following Socher et al. (2013) we obtained embeddings for tree nodes by using a recursive neural network model, where the embedding for parent node is obtained in a bottom-up fashion based on its children. The embeddings for each parse tree constituent are output to a softmax layer; see Socher et al. (2013).

We focus on the standard version of recursive neural models. Again we fixed word embeddings to each of the different embedding settings described above[3]. Similarly, we adopted AdaGrad

[3]Note that this is different from the settings used in

with mini-batch. Parameters (i.e., $L2$ penalty, learning rate and mini batch size) are tuned on the development set. The number of iterations is treated as a variable to tune and parameters are harvested based on the best performance on the development set.

0.854		

Table 6: Accuracy for Different Models on Sentiment Analysis (binary classification on Stanford Sentiment Treebank.). P-value 0.250 for 50d and 0.401 for 100d.

Semantic Relationship Classification SemEval-2010 Task 8 (Hendrickx et al., 2009) is to find semantic relationships between pairs of nominals, e.g., in "My [apartment]$_{e1}$ has a pretty large [kitchen]$_{e2}$" classifying the relation between [apartment] and [kitchen] as *component-whole*. The dataset contains 9 ordered relationships, so the task is formalized as a 19-class classification problem, with directed relations treated as separate labels; see Hendrickx et al. (2009) for details.

We follow the recursive implementations defined in Socher et al. (2012). The path in the parse tree between the two nominals is retrieved, and the embedding is calculated based on recursive models and fed to a softmax classifier. For pure comparison purpose, we only use embeddings as features and do not explore other combination of artificial features. We adopt the same training strategy as for the sentiment task (e.g., Adagrad, mini-batches, etc).

Standard (50)	Greedy (50)	Expectation (50)
0.748	0.760 (+0.12)	0.762 (+0.14)
Standard(100)	Global+G (100)	Global+E (100)

(Socher et al., 2013) where word vectors were treated as parameters to optimize.

Sentence Semantic Relatedness We use the Sentences Involving Compositional Knowledge (SICK) dataset (Marelli et al., 2014) consisting of 9927 sentence pairs, split into training(4500)/development(500)/Testing(4927). Each sentence pair is associated with a gold-standard label ranging from 1 to 5, indicating how semantically related are the two sentences, from 1 (the two sentences are unrelated) to 5 (the two are very related).

In our setting, the similarity between two sentences is measured based on sentence-level embeddings. Let s_1 and s_2 denote two sentences and e_{s_1} and e_{s_2} denote corresponding embeddings. e_{s_1} and e_{s_2} are achieved through recurrent or recursive models (as illustrated in Appendix section). Again, word embeddings are obtained by simple table look up in one-word-one-vector settings and inferred using the Greedy or Expectation strategy in multi-sense settings. We adopt two different recurrent models for acquiring sentence-level embeddings, a standard recurrent model and an LSTM model (Hochreiter and Schmidhuber, 1997).

The similarity score is predicted using a regression model built on the structure of a three layer convolutional model, with concatenation of e_{s1} and e_{s2} as input, and a regression score from 1-5 as output. We adopted the same training strategy as described earlier. The trained model is then used to predict the relatedness score between two new sentences. Performance is measured using Pearson's r between the predicted score and gold-standard labels.

Standard(50)	Greedy (50)	Expectation (50)

6.2 Discussions

Results for different tasks are represented in Tables 3-9.

At first glance it seems that multi-sense embeddings do indeed offer superior performance, since combining global vectors with sense-specific vectors introduces a consistent performance boost

Standard(50)	Greedy(50)	Expectation(50)
0.843	0.848 (+0.05)	0.846 (+0.03)
Standard(100)	Global+G (100)	Global+E (100)
0.850	0.853 (+0.03)	0.854 (+0.04)
Standard(300)		
0.850		

Table 9: Pearson's r for Different Models on Semantic Relatedness for LSTM Models. P-value 0.145 for 50d and 0.170 for 100d.

for every task, when compared with the standard (50d) setting. But of course this is an unfair comparison; combining global vector with sense-specific vector doubles the dimensionality of vector to 100, making comparison with standard dimensionality (50d) unfair. When comparing with standard (100), the conclusions become more nuanced.

For every task, the +Expectation method has performances that often seem to be higher than the simple baseline (both for the 50d case or the 100d case). However, only some of these differences are significant.

(1) Using multi-sense embeddings is significantly helpful for tasks like semantic relatedness (Tables 7-8). This is sensible since sentence meaning here is sensitive to the semantics of one particular word, which could vary with word sense and which would directly be reflected on the relatedness score.

(2) By contrast, for sentiment analysis (Tables 5-6), much of the task depends on correctly identifying a few sentiment words like "good" or "bad", whose senses tend to have similar sentiment values, and hence for which multi-sense embeddings offer little help. Multi-sense embeddings might promise to help sentiment analysis for some cases, like disambiguating the word "sound" in "safe and sound" versus "movie sound". But we suspect that such cases are not common, explaining the non-significance of the improvement. Furthermore, the advantages of neural models in sentiment analysis tasks presumably lie in their capability to capture local composition like negation, and it's not clear how helpful multi-sense embeddings are for that aspect.

(3) Similarly, multi-sense embeddings help for POS tagging, but not for NER tagging (Table 3-4). Word senses have long been known to be related to POS tags. But the largest proportion of NER tags consists of the negative not-a-NER ("O") tag, each of which is likely correctly labelable regardless of whether senses are disambiguated or not (since presumably if a word is not a named entity, most of its senses are not named entities either).

(4) As we apply more sophisticated models like LSTM to semantic relatedness tasks (in Table 9), the advantages caused by multi-sense embeddings disappears.

(5) Doubling the number of dimensions is sufficient to increase performance as much as using the complex multi-sense algorithm. (Of course increasing vector dimensionality (to 300) boosts performance even more, although at the significant cost of exponentially increasing time complexity.) We do larger one-word-one-vector embeddings do so well? We suggest some hypotheses:

- though information about distinct senses is encoded in one-word-one-vector embeddings in a mixed and less structured way, we suspect that the compositional nature of neural models is able to separate the informational chaff from the wheat and choose what information to take up, bridging the gap between single vector and multi-sense paradigms. For models like LSTMs which are better at doing such a job by using gates to control information flow, the difference between two paradigms should thus be further narrowed, as indeed we found.

- The pipeline model proposed in the work requires sense-label inference (i.e., step 2). We proposed two strategies: GREEDY and EXPECTATION, and found that GREEDY models perform worse than EXPECTATION, as we might expect[4]. But even EXPECTATION can be viewed as another form of one-word-one-vector models, just one where different senses are entangled but weighted to emphasize the important ones. Again, this suggests another cause for the strong relative performance of larger-dimensioned one-word-one-vector models.

7 Conclusion

In this paper, we expand ongoing research into multi-sense embeddings by first proposing a new version based on Chinese restaurant processes that achieves state of the art performance on simple

[4]GREEDY models work in a more aggressive way and likely make mistakes due to the non-global-optimum nature and limited context information

word similarity matching tasks. We then introduce a pipeline system for incorporating multi-sense embeddings into NLP applications, and examine multiple NLP tasks to see whether and when multi-sense embeddings can introduce performance boosts. Our results suggest that simply increasing the dimensionality of baseline skip-gram embeddings is sometimes sufficient to achieve the same performance wins that come from using multi-sense embeddings. That is, the most straightforward way to yield better performance on these tasks is just to increase embedding dimensionality.

Our results come with some caveats. In particular, our conclusions are based on the pipelined system that we introduce, and other multi-sense embedding systems (e.g., a more advanced sense learning model or a better sense label model or a completely different pipeline system) may find stronger effects of multi-sense models. Nonetheless we do consistently find improvements for multi-sense embeddings in some tasks (part-of-speech tagging and semantic relation identification), suggesting the benefits of our multi-sense models and those of others. Perhaps the most important implication of our results may be the evidence they provide for the importance of going beyond simple human-matching tasks, and testing embedding models by using them as components in real NLP applications.

8 Appendix

In sentiment classification and sentence semantic relatedness tasks, classification models require embeddings that represent the input at a sentence or phrase level. We adopt recurrent networks (standard ones or LSTMs) and recursive networks in order to map a sequence of tokens with various length to a vector representation.

Recurrent Networks A recurrent network successively takes word w_t at step t, combines its vector representation e_t with the previously built hidden vector h_{t-1} from time $t-1$, calculates the resulting current embedding h_t, and passes it to the next step. The embedding h_t for the current time t is thus:

$$h_t = \tanh(W \cdot h_{t-1} + V \cdot e_t) \tag{5}$$

where W and V denote compositional matrices. If N_s denote the length of the sequence, h_{N_s} represents the whole sequence S.

Recursive Networks Standard recursive models work in a similar way by working on neighboring words by parse tree order rather than sequence order. They compute the representation for each parent node based on its immediate children recursively in a bottom-up fashion until reaching the root of the tree. For a given node η in the tree and its left child η_{left} (with representation e_{left}) and right child η_{right} (with representation e_{right}), the standard recursive network calculates e_η:

$$e_\eta = \tanh(W \cdot e_{\eta_{\text{left}}} + V \cdot e_{\eta_{\text{right}}}) \tag{6}$$

Long Short Term Memory (LSTM) LSTM models (Hochreiter and Schmidhuber, 1997) are defined as follows: given a sequence of inputs $X = \{x_1, x_2, ..., x_{n_X}\}$, an LSTM associates each timestep with an input, memory and output gate, respectively denoted as i_t, f_t and o_t. We notationally disambiguate e and h, where e_t denote the vector for an individual text unit (e.g., word or sentence) at time step t while h_t denotes the vector computed by the LSTM model at time t by combining e_t and h_{t-1}. σ denotes the sigmoid function. $W \in \mathbb{R}^{4K \times 2K}$. The vector representation h_t for each time-step t is given by:

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ l_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} W \cdot \begin{bmatrix} h_{t-1} \\ e_t \end{bmatrix} \tag{7}$$

$$c_t = f_t \cdot c_{t-1} + i_t \cdot l_t \tag{8}$$

$$h_t^s = o_t \cdot c_t \tag{9}$$

Abstract

Non-compositionality of multiword expressions is an intriguing problem that can be the source of error in a variety of NLP tasks such as language generation, machine translation and word sense disambiguation. We present methods of non-compositionality detection for English noun compounds using the unsupervised learning of a semantic composition function. Compounds which are not well modeled by the learned semantic composition function are considered non-compositional. We explore a range of distributional vector-space models for semantic composition, empirically evaluate these models, and propose additional methods which improve results further. We show that a complex function such as polynomial projection can learn semantic composition and identify non-compositionality in an unsupervised way, beating all other baselines ranging from simple to complex. We show that enforcing sparsity is a useful regularizer in learning complex composition functions. We show further improvements by training a decomposition function in addition to the composition function. Finally, we propose an EM algorithm over latent compositionality annotations that also improves the performance.

1 Introduction

Multiword Expressions (MWEs) are sequences of words that exhibit some kind of idiosyncrasy. This idiosyncrasy can be semantic, statistical, or syntactic[1]. *Ivory tower*, *speed limit*, and *at large* are examples of semantically, statistically and syntactically idiosyncratic MWEs respectively. Note that an MWE can be idiosyncratic at several levels. In general, semantically idiosyncratic MWEs are commonly referred to as non-compositional (Baldwin and Kim, 2010) and statistically idiosyncratic MWEs are commonly referred to as collocations (Sag et al., 2002). Non-compositional MWEs are those whose meaning can not be readily inferred from the meaning of their constituents and collocations are those MWEs whose constituents co-occur more than expected by chance. Collocations constitute the largest subset of all kinds of MWEs, however, non-compositional ones cause more problems in various NLP tasks, for example word sense disambiguation (McCarthy et al., 2003) and machine translation (Lin, 1999). It may also be more challenging to model non-compositionality than collocational weight as the former has to do with modelling the semantics and the latter can to some extent be modeled by conventional statistical measures such as mutual information. Detecting non-compositionality in an automatic fashion has been the aim of much previous research.

In this paper, we capture non-compositionality of English Noun Compounds (NCs)[2] based on the assumption that the majority of the compounds are compositional, for which a composition function can be learned. This implies that the compounds for which a composition function cannot be learned with a relatively low error are non-compositional.

In previous work on vector-space models of distributional semantics, semantic composition has been commonly assumed to be a trivial predetermined function such as addition, multiplication,

[1] MWEs can have other less significant kinds of idiosyncrasies. For instance lexical idiosyncrasy as in *ad hoc*, and pragmatic idiosyncrasy as in *good morning* (Baldwin and Kim, 2010)

[2] MWEs have various syntactic categories such as noun compounds, verb particle constructions, light verb constructions, etc., with noun compounds and verb particle constructions constituting the most prominent categories of MWEs.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1733–1742,
Lisbon, Portugal, 17-21 September 2015.

and their weighted variations (Mitchell and Lapata, 2008; Reddy et al., 2011; Salehi et al., 2015). Nevertheless there is some work that regards composition as a more complex function. For instance Widdows (2008) who propose (but doesn't empirically test) the use of Tensor and Convolution products for modelling non-compositionality, Baroni and Zamparelli (2010) who regard adjectives in adjectival-noun compositions as matrices that can be learned by linear regression, and Socher et al. (2012) who present a model that learns phrase composition by means of a recursive neural network. The two latter works show that complex composition models significantly outperform additive and multiplicative functions. In this work, we too assume that composition is arguably a complex function. We believe simplified composition functions, such as additive and multiplicative functions and their weighted variations, while having advantages such as being impervious to overfitting, can not completely capture semantic composition. Nevertheless modelling composition by means of a powerful function can be equally inadequate for our purposes. An overly powerful composition function memorizes all compositional and non-compositional compounds, resulting in overfitting and low learning error that hinders discrimination between compositional and non-compositional compounds. We examine various classes of composition functions, ranging from the least to the most powerful (in terms of learning capacity). We show that complex functions clearly do a better job in modelling semantic composition and in detecting non-compositionality compared to commonly used additive and multiplicative functions.

Compositional compounds are also decomposable; intuitively, their semantics is the union of the semantics of their components. More formally, conditioned on the vector of the compound, vectors of the component words should be *independently* predictable. This principle, together with the assumption that most of the compounds are compositional, leads to the conclusion that a model of composition should be able to be auto-reconstructive: the composition function that maps component-words' vectors to their compound vector should have an associated decomposition function that independently predicts each of the component-words' vectors from this compound vector. An auto-reconstructive model enables us to exploit more data in order to learn semantic composition and predict compositionality. We show that auto-reconstruction can improve the accuracy of composition functions and improve detecting non-compositionality.

To further improve non-compositionality detection, we propose an EM-like detection algorithm based on hidden compositionality annotations. The best composition is the one that is the best fit on all the data points except the non-compositional ones. Since we don't use annotated data at training time, we assume annotations to be hidden variables and iteratively alternate between optimizing the composition function and optimizing the hidden compositionality annotations. We show that this iterative algorithm increases the accuracy of non-compositionality detection compared to the case when training is done on all examples.

We run our experiments on the data set of Farahmand et al. (2015) who provide a set of English NCs which are annotated with non-compositionality judgments. We show that quadratic regression significantly outperforms additive and multiplicative baselines and all other models in modelling semantic composition and identifying the non-compositional NCs. In short, the contributions of our work are: to empirically evaluate various composition functions ranging from simple to overly complex in order to find the most accurate function; to propose, to the best of our knowledge for the first time, a method of identifying non-compositional phrases as phrases for which a composition function cannot be readily learned; to propose learning decomposability as another criterion to detect non-compositionality; and to examine possible ways of improving the accuracy of the models by means of EM on hidden compositionality annotations.

2 Related Work

To the best of our knowledge, attempts to extract non-compositionality in computational linguistics go back to 1998. Tapanainen et al. (1998) propose a method to identify non-compositional verb-object collocations based on the semantic asymmetry of verb-object relation. They assume that in a verb-object idiomatic expression, the object is a more interesting element in the sense that if the object appears with one (or only a few) verbs in a large corpus, it presumably has an id-

iomatic nature. Lin (1999) argues that the mutual information between the constituents of a non-compositional phrase is significantly different from that of a phrase created by substituting the constituents of that phrase with their similar words. Their evaluation reveals a low precision ($16 - 39\%$) and recall ($14 - 21\%$). In any case this method is not able to discriminate non-compositional MWEs from collocational MWEs as they share the same property of non-substitutability (their constituents cannot be replaced with their synonyms). Baldwin et al. (2003) present a method that decides about the non-compositionality of English NCs and verb particle constructions by using latent semantic analysis to calculate the similarity between a MWE and its components. They argue that a higher similarity indicates a higher degree of compositionality. McCarthy et al. (2003) devise a number of measures based on comparison of the neighbors of phrasal verbs and their corresponding simplex verbs. They evaluate these measures by calculating their correlation with human compositionality judgments on a set of phrasal verbs. They show that some of the measures have significant correlations with human judgments. Venkatapathy and Joshi (2005) present a supervised model that benefits from both collocational and contextual information and ranks the MWE candidates based on their non-compositionality. Katz and Giesbrecht (2006) use distributional semantics and LSA as a model of context similarity to test whether the local context of a MWE can distinguish its idiomatic use from literal use. They further compare the context of a MWE with the context of its components and show that this can be used to decide whether the expression is idiomatic or not. Cook et al. (2007) is a relatively different work where the authors propose a syntactic approach to identify semantic non-compositionality of verb-noun MWEs. McCarthy et al. (2007) use various models of selectional preferences for detecting non-compositional verb-object pairs.

Reddy et al. (2011) employ the additive and multiplicative composition functions presented by Mitchell and Lapata (2008)[3] and several similarity based models to measure the compositionality of MWEs. Similarity based models measure the similarity of a MWE vector and sum/product of its constituents' vectors. Their evaluation (which is carried out on a set of 90 annotated NCs) shows that there is a relatively high correlation (Spearman ρ of between 0.51 and 0.71) between their models' predictions and human judgments on non-compositionality of English NCs, with weighted additive function outperforming all the other models. Kiela and Clark (2013) present a model of detecting non-compositionality based on the hypothesis that the average distance between a phrase vector and its substituted phrase vectors is related to its compositionality. In particular compositional phrases are less similar to their neighbors in semantic space. The distributional vectors representing the semantics of words were created using the standard window method and 50,000 most frequent context words. They show that their model slightly ($+0.014$ and $+0.007$) outperforms their baselines (Venkatapathy and Joshi, 2005; McCarthy et al., 2007).

All of the models mentioned so far are based on conventional[4] or count based vector space representation of the words. More recent works however are based on representation learning of word embeddings. Baroni and Zamparelli (2010) regard adjective as matrices and nouns as real-valued vectors for Italian adjective noun composition. They learn the adjective matrices by linear regression. In this work, however, every adjective is presented by a new matrix which leads to a large number of parameters. Socher et al. (2012) suggest that composition function is a matrix that multiplies on the word vectors, and Mikolov et al. (2013b) present a model of learning non-compositional phrases by calculating a data-driven score for certain frequent phrases (up to size two) and learn them as a whole. Salehi et al. (2015) borrow the word embeddings from (Mikolov et al., 2013a) to model the semantics of words and use several composition functions from (Mitchell and Lapata, 2008; Reddy et al., 2011) to predict the non-compositionality of MWEs. They compare the performance of word embeddings with conventional distributional vector representations and discover the superiority of word embeddings in predicting non-compositionality of MWEs.

[3] Mitchell and Lapata (2008) present an analysis of vector-based additive and multiplicative semantic composition models where each words is represented by its distributional vector. They conclude that multiplicative and combined models do a better job in modelling vector-based semantic composition than other models.

[4] Conventional or count based models of distributional similarity as oppose to word embeddings (Salehi et al., 2015; Baroni et al., 2014).

3 Representation of Words and Compounds

In order to represent words and compounds we use word embeddings, which are a form of vector space models. Vector space models represent the semantics of words and phrases with real valued vectors. Word embeddings have proven to be effective models of semantic representation of words and outperform the count-based models in various NLP tasks (Baroni et al., 2014; Collobert et al., 2011; Collobert and Weston, 2008; Yazdani and Popescu-Belis, 2013; Huang et al., 2012; Mikolov et al., 2013c). They have been successfully applied to semantic composition (Mikolov et al., 2013b) and outperformed the conventional count based contextual models in predicting non-compositionality of MWEs (Salehi et al., 2015).

In this work we use word embeddings of Mikolov et al. (2013a) to represent the semantics of words and compounds. We chose an English Wikipedia dump as our corpus. After filtering HTML tags and noise we POS-tagged the corpus and extracted $\approx 70k$ compounds whose frequency of occurrence was above 50. We learn the embeddings of these compounds as single tokens using the word2vec[5] bag-of-word model. We also learn the embeddings of the compounds of the evaluation set, plus the embeddings of all the compounds' component words. Compounds' sizes are restricted to two (i.e. bigrams) for the sake of simplicity and to respect the evaluation set standards. The compounds and word embeddings are then used as supervised signals to learn a composition function.

4 Supervised Models of Composition on Word Embeddings

After the unsupervised learning of word embeddings and candidate compound embeddings (see section 3), we use these embeddings as supervised signals in order to train our composition functions. The term supervised might be misleading as the models do not have any information about the compositionality of the compounds during the training phase, and in that respect it is unsupervised. To describe the models in a formal way, throughout the paper we use the following notations: d represents the size of embeddings, $\phi(w_i)$ represents embedding of w_i, and $\tilde{\phi}(w_i{-}w_j) = f(\phi(w_i), \phi(w_j))$ represents the learned embedding of bigram $w_i{-}w_j$ by the composition function f. The training error of bigram $w_i{-}w_j$ by f is $e_{ij} = \|\tilde{\phi}(w_i{-}w_j) - \phi(w_i, w_j)\|$, and $\|\|$ is norm 2. The composition functions are described in the following sections.

Given unsupervised embeddings for both words and compounds, a composition model is trained to map the word embeddings to the compound embeddings, with norm 2 error e_{ij} defined above. Then this same error for this same task (norm 2 between predicted and unsupervised compound embeddings) is used to measure non-compositionality. In other words, we learn a composition function (with several models) and identify non-compositional expressions as those for which the error of this composition function is high.

We explore various classes of composition functions of word embeddings, ranging from simple to complex, to find the most effective one. We want a composition function that is powerful enough to learn composition for compositional compounds, but simple enough that it fails to learn composition for non-compositional compounds. To this end, we investigate linear projections, polynomial projections, and neural networks. We try these models with and without sparsity regularisation, which reduces the number of non-zero parameters while otherwise keeping the complexity of the function that can be learned.

4.1 Linear Projection

In this model we assume that the embedding of a bigram is a linear projection of its component words' embeddings.

$$f(\phi(w_i), \phi(w_j)) = [\phi(w_i), \phi(w_j)]\theta_{2d\times d}$$

To train this function we optimize the least square error, which gives us a multi-variant linear regression.

$$\min_{\theta} \|[\phi(w_i), \phi(w_j)]\theta_{2d\times d} - \phi(w_i, w_j)\|$$

As mentioned earlier, a composition function that doesn't overfit the training data and induces a more meaningful error is more suitable for our purpose. One effective way of reducing overfitting and increasing generalization is by keeping only the important parameters of the model, which is done by enforcing sparsity on model parameters.

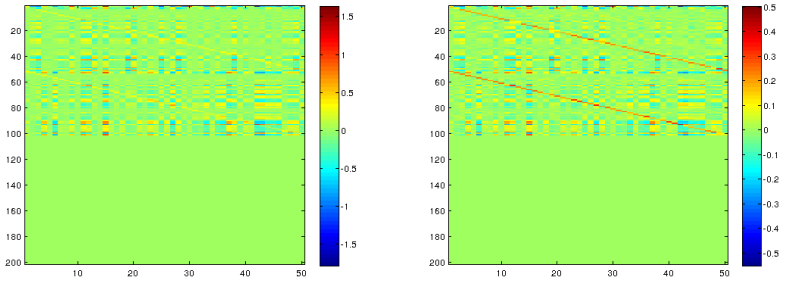
(a) Linear Projection (b) Sparse Linear Projection

Figure 1: Linear transformation matrix of compositionality for embeddings of size 50



(a) Pure Quadratic (b) Sparse Pure Quadratic

Figure 2: Pure quadratic transformation matrix of compositionality for embeddings of size 50

In case of sparse linear projections, only a few elements of the projection matrix θ are non-zero. This means that not all dimensions of the latent space has a role in all dimensions of the compound embedding.

To apply sparsity on θ, we add a norm 1 penalty on it and add that to the least square optimization. This forms a multi-variant lasso regression (Tibshirani, 2011).

$$\min_{\theta} \|[\phi(w_i), \phi(w_j)]\theta - \phi(w_i, w_j)\| + \lambda|\theta|$$

Figure 1 shows the transformation matrices of linear projection and sparse linear projection. The two diagonals of the matrices correspond to the sum of the two embeddings, which we can see are the main component of the sparse function, and play an important role in the non-sparse one. We will see that despite being an important component of these functions, sum alone is not capable of accurately modelling semantic composition.

4.2 Polynomial Projection

Polynomial projection is a non-linear projection that assumes the relation between compound embedding and the component words' embeddings should be a polynomial of degree n. This can be viewed as a form of linear regression where first a polynomial transformation is applied to the input vector and then a linear projection is fitted. If ψ shows the polynomial transformation then we have:

$$f(\phi(w_i), \phi(w_j)) = \psi([\phi(w_i), \phi(w_j)])\theta$$

We couldn't successfully apply any polynomial beyond quadratic transformation without overfitting. The case of a quadratic ψ transformation is:

$$\psi(x) = \underbrace{x_1^2, \cdots x_n^2}_{\text{Pure quadratic}}, \underbrace{x_1x_2, \cdots x_{n-1}x_n}_{\text{interaction terms}}, \underbrace{x_1, \cdots x_n}_{\text{linear terms}}$$

Similar to the linear case we can have sparse version of the polynomial regression in which we allow the presence of only a few non-zero elements in the θ matrix. The sparsity regularizer is more important in the case of polynomial regression as we have many more parameters. The quadratic model is similar to Recursive Neural Tensor compositionality model of Socher et al. (2013). But in our model the tensor is symmetric around the diagonal. Figure 2 shows the pure quadratic transformation matrices.

4.3 Neural Networks

A feed forward neural network is a universal approximator (Cybenko, 1989): feed-forward network with a single hidden layer can approximate any continuous function, provided it has enough hidden units. Therefore we use neural networks as a powerful class of learning models to learn semantic composition. The number of hidden units gives us a measure to control expressiveness of our model.

$$f(\phi(w_i), \phi(w_j)) = \sigma([\phi(w_i), \phi(w_j)]W_{ih})W_{ho}$$

Similar to the previous models, we optionally impose sparsity over weight matrices of the neural network to be able to induce more meaningful learning errors.

4.4 Experimental Results

We evaluated the above models on the data set of Farahmand et al. (2015). They provide a set of 1042 English NCs with four non-compositionality judgments. The judgments are binary decisions taken by four experts about whether or not a compound is non-compositional. We calculate a vote-based non-compositionality score for each of the data set compounds by summing over its non-compositionality judgments. The neural network models are trained using stochastic gradient descent. We use the additive and multiplicative models of modelling composition and detecting non-compositionality presented by Salehi et al. (2015) and (Reddy et al., 2011) as state of the art baselines.

The results are shown in Table 1. The second column shows the correlation between different models' predictions and the annotated data in terms of Spearman ρ. The last three columns show the performance of different models in terms of Normalized Discounted Cumulative Gain (NDCG), F_1 score and and Precision at 100 (P@100). For these three scores we consider the problem of predicting non-compositional NCs a problem with a binary solution where we assume compounds (of the evaluation set) with at least two non-compositionality votes are non-compositional. *NDCG* assigns a higher score to a ranked list of compounds if the non-compositional ones are ranked higher in the list. F_1 column represents the maximum F_1 score on the top-n elements of the ranked list returned by the corresponding model for all n in $[1 - \text{size-of-ranked-list}]$. P@100 shows the precision at the first 100 compounds ranked as non-compositional. The models are listed in the order of complexity of the composition function. The addition-based baseline which was explored in a variety of previous work does not seem to be as powerful as the other models. It is outperformed by almost all learned models. In general, we can see that more complex functions tend to learn compositionality in a more effective way.

Model	Spearman ρ	NDCG	F_1	P@100
Additive model (Salehi et al., 2015); (Reddy et al., 2011)	20.83	81.39	36.95	43
Multiplicative model (Reddy et al., 2011)	9.18	76	35.61	22

Sparse NN (H=1000)	37.08	85.04	46.35	52
NN (H=1000)	37.51	84.97	45.47	51

Table 1: Results for each model's ability to predict non-compositionality.

As mentioned earlier, overly powerful learners overfit and do not produce meaningful errors for the detection task. Sparsity seems to address this issue by reducing the number of non-zero parameters while the function can still keep the complex terms if needed. In general sparse models show improvement over their non-sparse counterparts, specifically for more powerful models.

5 Auto-reconstructive Models

In this section, we investigate the hypothesis that we can detect non-compositionality better by not only modelling a composition function, but also modelling a decomposition function. For compositional compounds, given the meaning of the compound, the meaning of the two component words should be conditionally independent. We therefore assume that the decomposition function predicts the component words' vectors independently. Let us illustrate this assumption by examining the non-compositional compound *flag stop*. Given the semantics of this compound (a point at which a vehicle in public transportation stops only

on prearrangement or signal[6]), we can not readily predict one of its component words without knowing the other. Now consider the compositional compound *hip injury*. Given the semantics of this compound it is much easier to predict each of its component words independently.

In the previous section, the training signals came from the embeddings of the candidate compounds and their component words. In this section we extend our model such that it can benefit from more training signals. To this end, we formalize the assumption that a compositional compound is also decomposable as an auto-reconsructive model. We thus add this hypothesis to the learning process: a good composition function not only builds the semantics of the compound from the semantics of its component words, but it also allows the independent prediction of the semantics of its component words from the compound semantics. In the following sections we add this assumption to both linear projection (which encompasses polynomial) and Neural Network models.

5.1 Auto-reconstructive Linear Models

Let $Y_{M\times d}$ be a matrix whose rows are the precomputed compound embeddings, and $X_{M\times 2d}$ be a matrix whose rows are the concatenation of the embeddings for the words of these compounds. Let $A_{N\times 2d}$ be another matrix where every row contains the concatenation of the embeddings for the words of a compound, but this matrix includes many compounds for which we did not precompute compound embeddings. We assume that the rows of matrix A include the rows of matrix X. In linear models the auto-reconstructive objective function is as follows:

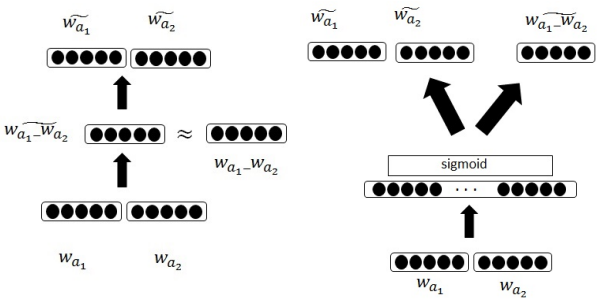
$$\min_{\theta,\theta'} \|X\theta - Y\| + \lambda\|A\theta\theta' - A\|$$

where λ is a meta-parameter for the importance of the auto-reconstruction in the objective. A schematic of this model is shown in Figure 3a.

We can look at this problem as the following weighted least square problem:

$$\min_{\theta,\theta'} \| \begin{pmatrix} X \\ A \end{pmatrix} \theta - \begin{pmatrix} Y \\ A\theta'^T(\theta'\theta'^T)^{-1} \end{pmatrix} \| \begin{pmatrix} 1 \\ \vdots \\ \lambda \end{pmatrix}$$

In the above matrix formula we transformed the auto-reconstruction part of the objective to a pseudo regressand of the least square. To solve this optimization we design an efficient alternating least squares algorithm.



(a) Linear auto-reconstructive (b) NN Auto-reconstructive

Figure 3: Auto-reconstructive linear and neural network models

First we initialize θ_0 to be the answer of the original multi-variant linear regression, $\theta_0 = X \setminus Y$ where $X \setminus = (X^T X)^{-1} X^T$ is the pseudoinverse of X. Let us assume W is the diagonal matrix with first M elements of the diagonal being 1 and the remaining N being λ. We alternate between the following formulas until the algorithm converges. First we approximate the next θ' based on the current approximation of θ, then we use this value of θ' to calculate the pseudo regressand part of the least square. In the final step we solve the weighted least square for this new regressand matrix and continue iterating these stages until the algorithm converges.

$$\theta'_t = (A\theta_t) \setminus A \tag{1}$$

$$X_2 = \begin{pmatrix} X \\ A \end{pmatrix}$$

$$Y_2 = \begin{pmatrix} Y \\ A\theta'^T_{t-1}(\theta'_{t-1}\theta'^T_{t-1})^{-1} \end{pmatrix} \tag{2}$$

$$\theta_t = (X_2^T W X_2)^{-1}(X_2)^T W Y_2 \tag{3}$$

The above algorithm can also be used in the case of polynomial regression. The only thing that needs to be done is to replace X and A by their polynomial transformations.

5.2 Auto-reconstructive Neural Networks

The auto-reconstructive neural network follows the same idea. The objective function changes to:

$$\min_{W_{ih},W_{hi},W_{oh}} \|\sigma(XW_{ih})W_{ho} - Y\| + \lambda\|\sigma(AW_{ih})W_{hi} - A\| \tag{4}$$

Table 3: Results comparing the latent annotation models' ability to predict non-compositionality.

Figure 3b shows the schematic of this model. We optimize this objective using stochastic gradient descent with early stopping. The results are shown in Table 2. We choose the first $300K$ frequent noun-noun compounds from the corpus in order to build matrix A. Each row of A created by concatenating the component words vectors. The results show that the auto-reconstructive models generally improve over their counterparts. As mentioned earlier, the improvement comes from two facts. On the one hand we increase the training signals by implementing the decomposability hypothesis. On the other hand, the auto-reconstructive model enables us to exploit more data in addition to the candidate compounds. There is almost no improvement in the case of linear model because this model does not have enough learning capacity to benefit from a higher number of training signals.

6 Non-compositionality Detection Using Latent Annotations

All the models discussed in this paper are unsupervised since they don't have any access to labels specifying compositionality of compounds. The above models simply assume that most compounds are compositional, and therefore train their composition and decomposition functions on all compounds. In this section we incorporate in the models an intrinsic uncertainty about the compositionality annotation of the training set.

The best (optimum) composition function is the one that fits well all the compositional compounds and does not fit the non-compositional ones. But we assume that we do not have training labels indicating compositionality. To overcome this uncertainty and improve the learning process, we introduce latent compositionality labels to the model. We assume each candidate compound has a latent annotation, 1 or 0, showing whether or not it is compositional. Let us assume a non-compositionality detection system that returns B non-compositional candidates that should have their own lexical unit and parameters. The objective of this composition function training is to minimize the error of compositional compounds and not the error of non-compositional ones. In order to implement this objective we use the following loss function:

$$\min_{\lambda_{ij},\theta} \sum_{ij} \lambda_{ij} e_{ij}^2$$

$$\text{s.t } \lambda_{ij} \in \{0,1\},$$

$$\sum_{ij} \lambda_{ij} = N - B$$

where λ_{ij} represents the hidden compositionality annotation and e_{ij} is again the learning error for the pair $w_i{-}w_j$. We want to find the B points such that annotating them as non-compositional results in the minimum error of this objective. The algorithm that alternates between optimizing the composition learning and the hidden annotations eventually converges to this solution.

If the errors are fixed, the B compounds with the biggest errors are the answers to the non-compositional annotation optimization of that iteration. Therefore to solve this optimization we follow an EM-like algorithm: First we set all λ_{ij} to 1 and perform the optimization on the composition function. Then we sort the compounds by their error and set the λ_{ij} of the biggest B elements to 0, and the rest to 1. In other words we assume the compounds with big error are presumably non-compositional according to what we know until that iteration. We continue alternating between training the composition function and annotating high error points until the algorithm reaches convergence. The results are shown in Table 3. Models that use latent annotations clearly outperform their counterparts, especially in terms

of precision at 100. This is expected since at training time we consider a model that returns B non-compositional compounds and therefore precision at 100 is optimized. The latent annotations do not improve the linear model since the model is simple and there is not much room to improve its learning.

7 Conclusions

We proposed a framework to detect non-compositional compounds as the compounds that stand out as outliers in the process of learning compositionality of English noun compounds. We proposed and evaluated a range of functions with a variety of complexities that model semantic composition. We showed that learners such as polynomial projection and neural networks which are distinctly more complex than commonly used additive and multiplicative functions can model semantic composition more effectively. We showed that a function as complex as quadratic projection is a better learner of compositionality than simpler models. We further showed that enforcing sparsity is an effective way of learning a complex composition function while avoiding overfitting and producing meaningful learning errors. Furthermore, we improved our models by incorporating an auto-reconstructive loss function that enables us to benefit from more training signals and cover more data. Finally, we addressed the intrinsic label uncertainty in training data by considering latent annotations, and showed that it can further improve the results.

Abstract

This paper presents a novel approach to automatically solving arithmetic word problems. This is the first algorithmic approach that can handle arithmetic problems with multiple steps and operations, without depending on additional annotations or predefined templates. We develop a theory for expression trees that can be used to represent and evaluate the target arithmetic expressions; we use it to uniquely decompose the target arithmetic problem to multiple classification problems; we then compose an expression tree, combining these with world knowledge through a constrained inference framework. Our classifiers gain from the use of *quantity schemas* that supports better extraction of features. Experimental results show that our method outperforms existing systems, achieving state of the art performance on benchmark datasets of arithmetic word problems.

1 Introduction

In recent years there is growing interest in understanding natural language text for the purpose of answering science related questions from text as well as quantitative problems of various kinds. In this context, understanding and solving arithmetic word problems is of specific interest. Word problems arise naturally when reading the financial section of a newspaper, following election coverage, or when studying elementary school arithmetic word problems. These problems pose an interesting challenge to the NLP community, due to its concise and relatively straightforward text, and seemingly simple semantics. Arithmetic word problems are usually directed towards elementary school students, and can be solved by combining the numbers mentioned in text with basic operations (addition, subtraction, multiplication, division). They are simpler than algebra word problems which require students to identify variables, and form equations with these variables to solve the problem.

Initial methods to address arithmetic word problems have mostly focussed on subsets of problems, restricting the number or the type of operations used (Roy et al., 2015; Hosseini et al., 2014) but could not deal with multi-step arithmetic problems involving all four basic operations. The template based method of (Kushman et al., 2014), on the other hand, can deal with all types of problems, but implicitly assumes that the solution is generated from a set of predefined equation templates.

In this paper, we present a novel approach which can solve a general class of arithmetic problems without predefined equation templates. In particular, it can handle multiple step arithmetic problems as shown in Example 1.

Example 1
Gwen was organizing her book case making sure each of the shelves had exactly 9 *books on it. She has* 2 *types of books - mystery books and picture books. If she had* 3 *shelves of mystery books and* 5 *shelves of picture books, how many books did she have in total?*

The solution involves understanding that the number of shelves needs to be summed up, and that the total number of shelves needs to be multiplied by the number of books each shelf can hold. In addition, one has to understand that the number "2" is not a direct part of the solution of the problem.

While a solution to these problems eventually requires composing multi-step numeric expressions from text, we believe that directly predicting this complex expression from text is not feasible.

At the heart of our technical approach is the novel notion of an *Expression Tree*. We show that the arithmetic expressions we are interested in can always be represented using an Expression Tree that has some unique decomposition properties. This allows us to decompose the problem of mapping the text to the arithmetic expression to a collection of simple prediction problems, each determining the lowest common ancestor operation between a pair of quantities mentioned in the problem. We then formulate the decision problem of composing the final expression tree as a joint inference problem, via an objective function that consists of all these decomposed prediction problems, along with legitimacy and background knowledge constraints.

Learning to generate the simpler decomposed expressions allows us to support generalization across problems types. In particular, our system could solve Example 1 even though it has never seen a problem that requires both addition and multiplication operations.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1743–1752,
Lisbon, Portugal, 17-21 September 2015.

We also introduce a second concept, that of *quantity schema*, that allows us to focus on the information relevant to each quantity mentioned in the text. We show that features extracted from quantity schemas help reasoning effectively about the solution. Moreover, quantity schemas help identify unnecessary text snippets in the problem text. For instance, in Example 2, the information that "Tom washed cars over the weekend" is irrelevant; he could have performed any activity to earn money. In order to solve the problem, we only need to know that he had $76 last week, and now he has $86.

Example 2
Last week Tom had $74. He washed cars over the weekend and now has $86. How much money did he make from the job?

We combine the classifiers' decisions using a constrained inference framework that allows for incorporating world knowledge as constraints. For example, we deliberatively incorporate the information that, if the problems asks about an "amount", the answer must be positive, and if the question starts with "how many", the answer will most likely be an integer.

Our system is evaluated on two existing datasets of arithmetic word problems, achieving state of the art performance on both. We also create a new dataset of multistep arithmetic problems, and show that our system achieves competitive performance in this challenging evaluation setting.

The next section describes the related work in the area of automated math word problem solving. We then present the theory of expression trees and our decomposition strategy that is based on it. Sec. 4 presents the overall computational approach, including the way we use quantity schemas to learn the mapping from text to expression tree components. Finally, we discuss our experimental study and conclude.

2 Related Work

Previous work in automated arithmetic problem solvers has focussed on a restricted subset of problems. The system described in (Hosseini et al., 2014) handles only addition and subtraction problems, and requires additional annotated data for verb categories. In contrast, our system does not require any additional annotations and can handle a more general category of problems. The approach in (Roy et al., 2015) supports all four basic operations, and uses a pipeline of classifiers to predict different properties of the problem. However, it makes assumptions on the number of quantities mentioned in the problem text, as well as the number of arithmetic steps required to solve the problem. In contrast, our system does not have any such restrictions, effectively handling problems mentioning multiple quantities and requiring multiple steps. Kushman's approach to automatically solving algebra word problems (Kushman et al., 2014) might be the most related to ours. It tries to map numbers from the problem text to predefined equation templates. However, they implicitly assume that similar equation forms have been seen in the training data. In contrast, our system can perform competitively, even when it has never seen similar expressions in training.

There is a recent interest in understanding text for the purpose of solving scientific and quantitative problems of various kinds. Our approach is related to work in understanding and solving elementary school standardized tests (Clark, 2015). The system described in (Berant et al., 2014) attempts to automatically answer biology questions, by extracting the structure of biological processes from text. There has also been efforts to solve geometry questions by jointly understanding diagrams and associated text (Seo et al., 2014). A recent work (Sadeghi et al., 2015) tries to answer science questions by visually verifying relations from images.

Our constrained inference module falls under the general framework of Constrained Conditional Models (CCM) (Chang et al., 2012). In particular, we use the $L + I$ scheme of CCMs, which predicts structured output by independently learning several simple components, combining them at inference time. This has been successfully used to incorporate world knowledge at inference time, as well as getting around the need for large amounts of jointly annotated data for structured prediction (Roth and Yih, 2005; Punyakanok et al., 2005; Punyakanok et al., 2008; Clarke and Lapata, 2006; Barzilay and Lapata, 2006; Roy et al., 2015).

3 Expression Tree and Problem Decomposition

We address the problem of automatically solving arithmetic word problems. The input to our system is the problem text P, which mentions n quantities $q_1, q_2, \ldots, q_n$. Our goal is to map this problem to a read-once arithmetic expression E that, when evaluated, provides the problem's solution. We define a read-once arithmetic expression as one that makes use of each quantity at most once. We say that E is a *valid* expression, if it is such a Read-Once arithmetic expression, and we only consider in this work problems that *can be* solved using valid expressions (it's possible that they can be solved also with invalid expressions).

An expression tree $\mathcal{T}$ for a valid expression E is a binary tree whose leaves represent quantities, and each internal node represents one of the four basic operations. For a non-leaf node n, we represent the operation associated with it as $\odot(n)$, and its left and right child as $lc(n)$ and $rc(n)$ respectively. The numeric value of the quantity associated with a leaf node n is denoted as $\mathrm{Q}(n)$. Each node n also has a value associated with it, represented as $\textsc{Val}(n)$, which can be computed in a

recursive way as follows:

$$\textsc{Val}(n) = \begin{cases} \mathrm{Q}(n) & \text{if } n \text{ is a leaf} \\ \textsc{Val}(lc(n)) \odot(n) \textsc{Val}(rc(n)) & \text{otherwise} \end{cases} \quad (1)$$

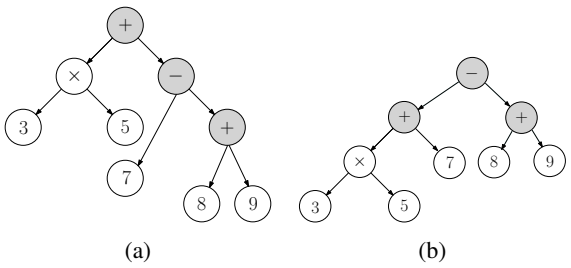
For any expression tree $\mathcal{T}$ for expression E with root node n_{root}, the value of $\textsc{Val}(n_{root})$ is exactly equal to the numeric value of the expression E. Therefore, this gives a natural representation of numeric expressions, providing a natural parenthesization of the numeric expression. Fig 1 shows an example of an arithmetic problem with solution expression and an expression tree for the solution expression.

Problem	
Gwen was organizing her book case making sure each of the shelves had exactly 9 *books on it. She has* 2 *types of books - mystery books and picture books. If she had* 3 *shelves of mystery books and* 5 *shelves of picture books, how many books did she have total?*	
Solution	Expression Tree of Solution
$(3 + 5) \times 9 = 72$	
Figure 1: An arithmetic word problem, solution expression and the corresponding expression tree

Definition An expression tree $\mathcal{T}$ for a valid expression E is called ***monotonic*** if it satisfies the following conditions:

1. If an addition node is connected to a subtraction node, then the subtraction node is the parent.
2. If a multiplication node is connected to a division node, then the division node is the parent.

Fig 2 shows two different expression trees for the same expression. Fig 2b is monotonic whereas fig 2a is not.



(a) (b)

Figure 2: Two different expression trees for the numeric expression $(3 \times 5) + 7 - 8 - 9$. The right one is monotonic, whereas the left one is not.

Our decomposition relies on the idea of monotonic expression trees. We try to predict for each pair of quantities q_i, q_j, the operation at the lowest common ancestor (LCA) node of the monotonic expression tree for the solution expression. We also predict for each quantity, whether it is relevant to the solution. Finally, an inference module combines all these predictions.

In the rest of the section, we show that for any pair of quantities q_i, q_j in the solution expression, any monotonic tree for the solution expression has the same LCA operation. Therefore, predicting the LCA operation becomes a multiclass classification problem.

The reason that we consider the monotonic representation of the expression tree is that different trees could otherwise give different LCA operation for a given pair of quantities. For example, in Fig 2, the LCA operation for quantities 5 and 8 can be $+$ or $-$, depending on which tree is considered.

Definition We define an ***addition-subtraction chain*** of an expression tree to be the maximal connected set of nodes labeled with addition or subtraction.

The nodes of an addition-subtraction (AS) chain C represent a set of terms being added or subtracted. These terms are sub-expressions created by subtrees rooted at neighboring nodes of the chain. We call these terms the ***chain terms*** of C, and the whole expression, after node operations have been applied to the chain terms, the ***chain expression*** of C. For example, in fig 2, the shaded nodes form an addition-subtraction chain. The chain expression is $(3\times5)+7-8-9$, and the chain terms are 3×5, 7, 8 and 9. We define a ***multiplication-division (MD) chain*** in a similar way.

Theorem 3.1. *Every valid expression can be represented by a monotonic expression tree.*

Proof. The proof is procedural, that is, we provide a method to convert any expression tree to a monotonic expression tree for the same expression. Consider a non-monotonic expression tree E, and without loss of generality, assume that the first condition for monotonicity is not valid. Therefore, there exists an addition node n_i and a subtraction node n_j, and n_i is the parent of n_j. Consider an addition-subtraction chain C which includes n_i, n_j. We now replace the nodes of C and its subtrees in the following way. We add a single subtraction node n_-. The left subtree of n_- has all the addition chain terms connected by addition nodes, and the right subtree of n_- has all the subtraction chain terms connected by addition nodes. Both subtrees of n_- only require addition nodes, hence monotonicity condition is satisfied. We can construct the monotonic tree in Fig 2b from the non-monotonic tree of Fig 2a using this procedure. The addition chain terms are 3×5 and 7, and the subtraction chain terms are 8 and 9. As as was described above, we introduce the root subtraction node in Fig 2b and attach the addition chain terms to the left and the subtraction chain terms to the right. The same line of reasoning can be used to handle the second condition with multiplication and division replacing addition and subtraction, respectively.

□

Theorem 3.2. *Consider two valid expression trees $\mathcal{T}_1$ and $\mathcal{T}_2$ for the same expression E. Let C_1, C_2 be the chain containing the root nodes of $\mathcal{T}_1$ and T_2 respectively. The chain type (addition-subtraction or multiplication-division) as well as the the set of chain terms of C_1 and C_2 are identical.*

Proof. We first prove that the chains containing the roots are both AS or both MD, and then show that the chain terms are also identical.

We prove by contradiction that the chain type is same. Let C_1's type be "addition-subtraction" and C_2's type be "multiplication-division" (without loss of generality). Since both C_1 and C_2 generate the same expression E, we have that E can be represented as sum (or difference) of two expressions as well as product(or division) of two expressions. Transforming a sum (or difference) of expressions to a product (or division) requires taking common terms from the expressions, which imply that the sum (or difference) had duplicate quantities. The opposite transformation adds same term to various expressions leading to multiple uses of the same quantity. Therefore, this will force at least one of C_1 and C_2 to use the same quantity more than once, violating validity.

We now need to show that individual chain terms are also identical. Without loss of generality, let us assume that both C_1 and C_2 are "addition-subtraction" chains. Suppose the chain terms of C_1 and C_2 are not identical. The chain expression for both the chains will be the same (since they are root chains, the chain expressions has to be the same as E). Let the chain expression for C_1 be $\sum_i t_i - \sum_i t'_i$, where t_i's are the addition chain terms and t'_i are the subtraction chain terms. Similarly, let the chain expression for C_2 be $\sum_i s_i - \sum_i s'_i$. We know that $\sum_i t_i - \sum_i t'_i = \sum_i s_i - \sum_i s'_i$, but the set of t_i's and t'_i's is not the same as the set of s_i and s'_i's. However it should be possible to transform one form to the other using mathematical manipulations. This transformation will involve taking common terms, or multiplying two terms, or both. Following previous explanation, this will force one of the expressions to have duplicate quantities, violating validity. Hence, the chain terms of C_1 and C_2 are identical.

□

Consider an expression tree $\mathcal{T}$ for a valid expression E. For a distinct pair of quantities q_i, q_j participating in expression E, we denote by n_i, n_j the leaves of the expression tree $\mathcal{T}$ representing q_i, q_j, respectively. Let $n_{LCA}(q_i, q_j; \mathcal{T})$ to be the lowest common ancestor node of n_i and n_j. We also define $order(q_i, q_j; \mathcal{T})$ to be true if n_i appears in the left subtree of $n_{LCA}(q_i, q_j; \mathcal{T})$ and n_j appears in the right subtree of $n_{LCA}(q_i, q_j; \mathcal{T})$ and set $order(q_i, q_j; \mathcal{T})$ to false otherwise. Finally we define $\odot_{LCA}(q_i, q_j; \mathcal{T})$ for a pair of quantities q_i, q_j as follows :

$$\odot_{LCA}(q_i, q_j, \mathcal{T}) = \begin{cases} + & \text{if } \odot(n_{LCA}(q_i, q_j; \mathcal{T})) = + \\ \times & \text{if } \odot(n_{LCA}(q_i, q_j; \mathcal{T})) = \times \\ - & \text{if } \odot(n_{LCA}(q_i, q_j; \mathcal{T})) = - \text{ and } order(q_i, q_j; \mathcal{T}) = true \\ -_{reverse} & \text{if } \odot(n_{LCA}(q_i, q_j; \mathcal{T})) = - \text{ and } order(q_i, q_j; \mathcal{T}) = false \\ \div & \text{if } \odot(n_{LCA}(q_i, q_j; \mathcal{T})) = \div \text{ and } order(q_i, q_j; \mathcal{T}) = true \\ \div_{reverse} & \text{if } \odot(n_{LCA}(q_i, q_j; \mathcal{T})) = \div \text{ and } order(q_i, q_j; \mathcal{T}) = false \end{cases} \quad (2)$$

Definition Given two expression trees $\mathcal{T}_1$ and $\mathcal{T}_2$ for the same expression E, $\mathcal{T}_1$ is *LCA-equivalent* to $\mathcal{T}_2$ if for every pair quantities q_i, q_j in the expression E, we have $\odot_{LCA}(q_i, q_j, \mathcal{T}_1) = \odot_{LCA}(q_i, q_j, \mathcal{T}_2)$.

Theorem 3.3. *All monotonic expression trees for an expression are LCA-equivalent to each other.*

Proof. We prove by induction on the number of quantities used in an expression. For all expressions E with 2 quantities, there exists only one monotonic expression tree, and hence, the statement is trivially true. This satisfies our base case.

For the inductive case, we assume that for all expressions with $k < n$ quantities, the theorem is true. Now, we need to prove that any expression with n nodes will also satisfy the property.

Consider a valid (as in all cases) expression E, with monotonic expression trees $\mathcal{T}_1$ and $\mathcal{T}_2$. From theorem 3.2, we know that the chains containing the roots of $\mathcal{T}_1$ and $\mathcal{T}_2$ have identical type and terms. Given two quantities q_i, q_j of E, the lowest common ancestor of both $\mathcal{T}_1$ and $\mathcal{T}_2$ will either both belong to the chain containing the root, or both belong to one of the chain terms. If the LCA node is part of the chain for both $\mathcal{T}_1$ and $\mathcal{T}_2$, monotonic property ensures that the LCA operation will be identical. If the LCA node is part of a chain term (which is an expression tree of size less than n), the property is satisfied by induction hypothesis.

□

The theory just presented suggests that it is possible to uniquely decompose the overall problem to simpler steps and this will be exploited in the next section.

4 Mapping Problems to Expression Trees

Given the uniqueness properties proved in Sec. 3, it is sufficient to identify the operation between any two relevant quantities in the text, in order to determine the unique valid expression. In fact, identifying the operation between *any* pair of quantities provides much needed redundancy given the uncertainty in identifying the operation from text, and we exploit it in our final joint inference.

Consequently, our overall method proceeds as follows: given the problem text P, we detect quantities $q_1, q_2, \ldots, q_n$. We then use two classifiers, one for relevance and other to predict the LCA operations for a monotonic expression tree of the solution. Our training makes use of the notion of quantity schemas, which we describe in Section 4.2. The distributional output of these classifiers is then used in a joint inference procedure that determines the final expression tree.

Our training data consists of problem text paired with a monotonic expression tree for the solution expression. Both the relevance and LCA operation classifiers are trained on gold annotations.

4.1 Global Inference for Expression Trees

In this subsection, we define the scoring functions corresponding to the decomposed problems, and show how we combine these scores to perform global inference. For a problem P with quantities $q_1, q_2, \ldots, q_n$, we define the following scoring functions:

1. $\textsc{Pair}(q_i, q_j, op)$: Scores the likelihood of $\odot_{LCA}(q_i, q_j, \mathcal{T}) = op$, where $\mathcal{T}$ is a monotone expression tree of the solution expression of P. A multiclass classifier trained to predict LCA operations (Section 4.4) can provide these scores.

2. $\textsc{Irr}(q)$: Scores the likelihood of quantity q being an irrelevant quantity in P, that is, q is not used in creating the solution. A binary classifier trained to predict whether a quantity q is relevant or not (Section 4.3), can provide these scores.

For an expression E, let $\mathcal{I}(E)$ be the set of all quantities in P which are not used in expression E. Let $\mathcal{T}$ be a monotonic expression tree for E. We define $\text{Score}(E)$ of an expression E in terms of the above scoring functions and a scaling parameter w_{IRR} as follows:

$$\text{Score}(E) = w_{\text{IRR}} \sum_{q \in \mathcal{I}(E)} \textsc{Irr}(q) + \sum_{q_i, q_j \notin \mathcal{I}(E)} \textsc{Pair}(q_i, q_j, \odot_{LCA}(q_i, q_j, \mathcal{T})) \quad (3)$$

Our final expression tree is an outcome of a constrained optimization process, following (Roth and Yih, 2004; Chang et al., 2012). Our objective function makes use of the scores returned by $\textsc{Irr}(\cdot)$ and $\textsc{Pair}(\cdot)$ to determine the expression tree and is constrained by legitimacy and background knowledge constraints, detailed below.

1. **Positive Answer**: Most arithmetic problems asking for amounts or number of objects usually have a positive number as an answer. Therefore, while searching for the best scoring expression, we reject expressions generating negative answer.

2. **Integral Answer**: Problems with questions such as 'how many" usually expect integral solutions. We only consider integral solutions as legitimate outputs for such problems.

Let $\mathcal{C}$ be the set of valid expressions that can be formed using the quantities in a problem P, and which satisfy the above constraints. The inference algorithm now becomes the following:

$$\arg\max_{E \in \mathcal{C}} \text{Score}(E) \quad (4)$$

The space of possible expressions is large, and we employ a beam search strategy to find the highest scoring constraint satisfying expression (Chang et al., 2012). We construct an expression tree using a bottom up approach, first enumerating all possible sets of irrelevant quantities, and next over all possible expressions, keeping the top k at each step. We give details below.

1. **Enumerating Irrelevant Quantities**: We generate a state for all possible sets of irrelevant quantities, ensuring that there is at least two relevant quantities in each state. We refer to each of the relevant quantities in each state as a term. Therefore, each state can be represented as a set of terms.

2. **Enumerating Expressions**: For generating a next state S' from S, we choose a pair of terms t_i and t_j in S and one of the four basic operations, and form a new term by combining terms t_i and t_j with the operation. Since we do not know which of the possible next states will lead to the optimal goal state, we enumerate all possible next states (that is, enumerate all possible pairs of terms and all possible operations); we prune the beam to keep only the top k candidates. We terminate when all the states in the beam have exactly one term.

Once we have a top k list of candidate expression trees, we choose the highest scoring tree which satisfies the constraints. However, there might not be any tree in the beam which satisfies the constraints, in which case, we choose the top candidate in the beam. We use $k = 200$ in our experiments.

In order to choose the value for the w_{IRR}, we search over the set $\{10^{-6}, 10^{-4}, 10^{-2}, 1, 10^2, 10^4, 10^6\}$, and choose the parameter setting which gives the highest accuracy on the training data.

4.2 Quantity Schema

In order to generalize across problem types as well as over simple manipulations of the text, it is necessary to train our system only with relevant information from the problem text. E.g., for the problem in example 2, we do not want to take decisions based on how Tom earned money. Therefore, there is a need to extract the relevant information from the problem text. To this end, we introduce the concept of a *quantity schema* which we extract for each quantity in the problem's text. Along with the question asked, the quantity

schemas provides all the information needed to solve most arithmetic problems.

A quantity schema for a quantity q in problem P consists of the following components.

1. **Associated Verb** For each quantity q, we detect the verb associated with it. We traverse up the dependency tree starting from the quantity mention, and choose the first verb we reach. We used the easy first dependency parser (Goldberg and Elhadad, 2010).

2. **Subject of Associated Verb** We detect the noun phrase, which acts as subject of the associated verb (if one exists).

3. **Unit** We use a shallow parser to detect the phrase p in which the quantity q is mentioned. All tokens of the phrase (other than the number itself) are considered as unit tokens. Also, if p is followed by the prepositional phrase "of" and a noun phrase (according to the shallow parser annotations), we also consider tokens from this second noun phrase as unit tokens. Finally, if no unit token can be extracted, we assign the unit of the neighboring quantities as the unit of q (following previous work (Hosseini et al., 2014)).

4. **Related Noun Phrases** We consider all noun phrases which are connected to the phrase p containing quantity q, with NP-PP-NP attachment. If only one quantity is mentioned in a sentence, we consider all noun phrases in it as related.

5. **Rate** We determine whether quantity q refers to a *rate* in the text, as well as extract two unit components defining the rate. For example, "7 kilometers per hour" has two components "kilometers" and "hour". Similarly, for sentences describing unit cost like "Each egg costs 2 dollars", "2" is a rate, with units "dollars" and "egg".

In addition to extracting the quantity schemas for each quantity, we extract the surface form text which poses the question. For example, in the question sentence, "How much will John have to pay if he wants to buy 7 oranges?", our extractor outputs "How much will John have to pay" as the question.

4.3 Relevance Classifier

We train a binary SVM classifier to determine, given problem text P and a quantity q in it, whether q is needed in the numeric expression generating the solution. We train on gold annotations and use the score of the classifier as the scoring function $\textsc{Irr}(\cdot)$.

4.3.1 Features

The features are extracted from the quantity schemas and can be broadly categorized into three groups:

1. **Unit features**: Most questions specifically mention the object whose amount needs to be computed, and hence questions provide valuable clue as to which quantities can be irrelevant. We add a feature for whether the unit of quantity q is present in the question tokens. Also, we add a feature based on whether the units of other quantities have better matches with question tokens (based on the number of tokens matched), and one based on the number of quantities which have the maximum number of matches with the question tokens.

2. **Related NP features**: Often units are not enough to differentiate between relevant and irrelevant quantities. Consider the following:

Example 3
Problem : *There are 8 apples in a pile on the desk. Each apple comes in a package of 11. 5 apples are added to the pile. How many apples are there in the pile?*
Solution : $(8 + 5) = 13$

   The relevance decision depends on the noun phrase "the pile", which is absent in the second sentence. We add a feature indicating whether a related noun phrase is present in the question. Also, we add a feature based on whether the related noun phrases of other quantities have better match with the question. Extraction of related noun phrases is described in Section 4.2.

3. **Miscellaneous Features**: When a problem mentions only two quantities, both of them are usually relevant. Hence, we also add a feature based on the number of quantities mentioned in text.

We include pairwise conjunction of the above features.

4.4 LCA Operation Classifier

In order to predict LCA operations, we train a multiclass SVM classifier. Given problem text P and a pair of quantities p_i and p_j, the classifier predicts one of the six labels described in Eq. 2. We consider the confidence scores for each label supplied by the classifier as the scoring function $\textsc{Pair}(\cdot)$.

4.4.1 Features

We use the following categories of features:

1. **Individual Quantity features**: Dependent verbs have been shown to play significant role in solving addition and subtraction problems (Hosseini et al., 2014). Hence, we add the dependent verb of the quantity as a feature. Multiplication and division problems are largely dependent on rates described in text. To capture that, we add a feature based on whether the quantity is a rate, and whether any component of rate unit is present in

the question. In addition to these quantity schema features, we add selected tokens from the neighborhood of the quantity mention. Neighborhood of quantities are often highly informative of LCA operations, for example, "He got 80 more marbles", the term "more" usually indicates addition. We add as features adverbs and comparative adjectives mentioned in a window of size 5 around the quantity mention.

2. **Quantity Pair features**: For a pair (q_i, q_j) we add features to indicate whether they have the same dependent verbs, to indicate whether both dependent verbs refer to the same verb mention, whether the units of q_i and q_j are the same and, if one of them is a rate, which component of the unit matches with the other quantity's unit. Finally, we add a feature indicating whether the value of q_i is greater than the value of q_j.

3. **Question Features**: Finally, we add a few features based on the question asked. In particular, for arithmetic problems where only one operation is needed, the question contains signals for the required operation. Specifically, we add indicator features based on whether the question mentions comparison-related tokens (e.g., "more", "less" or "than"), or whether the question asks for a rate (indicated by tokens such as "each" or "one").

We include pairwise conjunction of the above features. For both classifiers, we use the Illinois-SL package [1] under default settings.

5 Experimental Results

In this section, we evaluate the proposed method on publicly available datasets of arithmetic word problems. We evaluate separately the relevance and LCA operation classifiers, and show the contribution of various features. Lastly, we evaluate the performance of the full system, and quantify the gains achieved by the constraints.

5.1 Datasets

We evaluate our system on three datasets, each of which comprise a different category of arithmetic word problems.

1. **AI2 Dataset**: This is a collection of 395 addition and subtraction problems, released by (Hosseini et al., 2014). They performed a 3-fold cross validation, with every fold containing problems from different sources. This helped them evaluate robustness to domain diversity. We follow the same evaluation setting.

2. **IL Dataset**: This is a collection of arithmetic problems released by (Roy et al., 2015). Each of these problems can be solved by performing one operation. However, there are multiple problems having the same template. To counter this, we perform a few modifications to the dataset. First, for each problem, we replace the numbers and nouns with the part of speech tags, and then we cluster the problems based on unigrams and bigrams from this modified problem text. In particular, we cluster problems together whose unigram-bigram similarity is over 90%. We next prune each cluster to keep at most 5 problems in each cluster. Finally we create the folds ensuring all problems in a cluster are assigned to the same fold, and each fold has similar distribution of all operations. We have a final set of 562 problems, and we use a 5-fold cross validation to evaluate on this dataset.

3. **Commoncore Dataset**: In order to test our system's ability to handle multi-step problems, we create a new dataset of multi-step arithmetic problems. The problems were extracted from *www.commoncoresheets.com*. In total, there were 600 problems, 100 for each of the following types:

   (a) Addition followed by Subtraction
   (b) Subtraction followed by Addition
   (c) Addition and Multiplication
   (d) Addition and Division
   (e) Subtraction and Multiplication
   (f) Subtraction and Division

   This dataset had no irrelevant quantities. Therefore, we did not use the relevance classifier in our evaluations.

   In order to test our system's ability to generalize across problem types, we perform a 6-fold cross validation, with each fold containing all the problems from one of the aforementioned categories. This is a more challenging setting relative to the individual data sets mentioned above, since we are evaluating on multi-step problems, without ever looking at problems which require the same set of operations.

5.2 Relevance Classifier

Table 2 evaluates the performance of the relevance classifier on the AI2 and IL datasets. We report two accuracy values: Relax - fraction of quantities which the classifier got correct, and Strict - fraction of math problems, for which all quantities were correctly classified. We report accuracy using all features and then removing each feature group, one at a time.

[1] http://cogcomp.cs.illinois.edu/page/software_view/Illinois-SL

	AI2		IL		CC	
	Relax	Strict	Relax	Strict	Relax	Strict
All features	**88.7**	**85.1**	**75.7**	**75.7**	60.0	25.8
No Individual Quantity features	73.6	67.6	52.0	52.0	29.2	0.0
No Quantity Pair features	83.2	79.8	63.6	63.6	49.3	16.5
No Question features	86.8	83.9	73.3	73.3	**60.5**	**28.3**

Table 1: Performance of LCA Operation classifier on the datasets AI2, IL and CC.

	AI2		IL	
	Relax	Strict	Relax	Strict
All features	94.7	89.1	**95.4**	**93.2**
No Unit features	88.9	71.5	92.8	91.0
No NP features	**94.9**	**89.6**	95.0	91.2
No Misc. features	92.0	85.9	93.7	89.8

Table 2: Performance of Relevance classifier on the datasets AI2 and IL.

We see that features related to units of quantities play the most significant role in determining relevance of quantities. Also, the related NP features are not helpful for the AI2 dataset.

5.3 LCA Operation Classifier

Table 1 evaluates the performance of the LCA Operation classifier on the AI2, IL and CC datasets. As before, we report two accuracies - Relax - fraction of quantity pairs for which the classifier correctly predicted the LCA operation, and Strict - fraction of math problems, for which all quantity pairs were correctly classified. We report accuracy using all features and then removing each feature group, one at a time.

The strict and relaxed accuracies for IL dataset are identical, since each problem in IL dataset only requires one operation. The features related to individual quantities are most significant; in particular, the accuracy goes to 0.0 in the CC dataset, without using individual quantity features. The question features are not helpful for classification in the CC dataset. This can be attributed to the fact that all problems in CC dataset require multiple operations, and questions in multi-step problems usually do not contain information for each of the required operations.

5.4 Global Inference Module

Table 3 shows the performance of our system in correctly solving arithmetic word problems. We show the impact of various contraints, and also compare against previously best known results on the AI2 and IL datasets. We also show results using each of the two constraints separately, and using no constraints at all.

	AI2	IL	CC
All constraints	72.0	**73.9**	**45.2**
Positive constraint	**78.0**	72.5	36.5
Integral constraint	71.8	73.4	39.0
No constraint	77.7	71.9	29.6
(Hosseini et al., 2014)	77.7	-	-
(Roy et al., 2015)	-	52.7	-
(Kushman et al., 2014)	64.0	73.7	2.3

Table 3: Accuracy in correctly solving arithmetic problems. First four rows represent various configurations of our system. We achieve state of the art results in both AI2 and IL datasets.

The previously known best result in the AI2 dataset is reported in (Hosseini et al., 2014). Since we follow the exact same evaluation settings, our results are directly comparable. We achieve state of the art results, without having access to any additional annotated data, unlike (Hosseini et al., 2014), who use labeled data for verb categorization. For the IL dataset, we acquired the system of (Roy et al., 2015) from the authors, and ran it with the same fold information. We outperform their system by an absolute gain of over 20%. We believe that the improvement was mainly due to the dependence of the system of (Roy et al., 2015) on lexical and neighborhood of quantity features. In contrast, features from quantity schemas help us generalize across problem types. Finally, we also compare against the template based system of (Kushman et al., 2014). (Hosseini et al., 2014) mentions the result of running the system of (Kushman et al., 2014) on AI2 dataset, and we report their result here. For IL and CC datasets, we used the system released by (Kushman et al., 2014).

The integrality constraint is particularly helpful when division is involved, since it can lead to fractional answers. It does not help in case of the AI2 dataset, which involves only addition and subtraction problems. The role of the constraints becomes more significant in case of multi-step problems and, in particular, they contribute an absolute improvement of over 15% over the system without constraints on the CC dataset. The template based system of (Kushman et al., 2014) performs on par with our system on the IL dataset. We believe that it is due to the small number of equation templates in the IL dataset. It performs poorly on the CC dataset, since we evaluate on unseen problem types, which do not ensure that equation templates in the test data will be seen in the training data.

5.5 Discussion

The leading source of errors for the classifiers are erroneous quantity schema extraction and lack of understanding of unknown or rare verbs. For the relevance classifier on the AI2 dataset, 25% of the errors were due to mistakes in extracting the quantity schemas and 20% could be attributed to rare verbs. For the LCA operation classifier on the same dataset, 16% of the errors were due to unknown verbs and 15% were due to mistakes in extracting the schemas. The erroneous extraction of accurate quantity schemas is very significant for the IL dataset, contributing 57% of the errors for the relevance classifier and 39% of the errors for the LCA operation classifier. For the operation classifier on the CC dataset, 8% of the errors were due to verbs and 16% were due to faulty quantity schema extraction. Quantity Schema extraction is challenging due to parsing issues as well as some non-standard rate patterns, and it will be one of the future work targets. For example, in the sentence, "How many 4-dollar toys can he buy?", we fail to extract the rate component of the quantity 4.

6 Conclusion

This paper presents a novel method for understanding and solving a general class of arithmetic word problems. Our approach can solve all problems whose solution can be expressed by a read-once arithmetic expression, where each quantity from the problem text appears at most once in the expression. We develop a novel theoretical framework, centered around the notion of monotone expression trees, and showed how this representation can be used to get a unique decomposition of the problem. This theory naturally leads to a computational solution that we have shown to uniquely determine the solution - determine the arithmetic operation between any two quantities identified in the text. This theory underlies our algorithmic solution - we develop classifiers and a constrained inference approach that exploits redundancy in the information, and show that this yields strong performance on several benchmark collections. In particular, our approach achieves state of the art performance on two publicly available arithmetic problem datasets and can support natural generalizations. Specifically, our approach performs competitively on multistep problems, even when it has never observed the particular problem type before.

Although we develop and use the notion of expression trees in the context of numerical expressions, the concept is more general. In particular, if we allow leaves of expression trees to represent variables, we can express algebraic expressions and equations in this framework. Hence a similar approach can be targeted towards algebra word problems, a direction we wish to investigate in the future.

The datasets used in the paper are available for download at *http://cogcomp.cs.illinois.edu/page/resource_view/98*.

Distant Supervision for Relation Extraction via Piecewise Convolutional Neural Networks

Daojian Zeng, Kang Liu, Yubo Chen and Jun Zhao

Institute of Automation, Chinese Academy of Sciences, Beijing, 100190, China
{djzeng,kliu,yubo.chen,jzhao}@nlpr.ia.ac.cn

Abstract

Two problems arise when using distant supervision for relation extraction. First, in this method, an already existing knowledge base is heuristically aligned to texts, and the alignment results are treated as labeled data. However, the heuristic alignment can fail, resulting in wrong label problem. In addition, in previous approaches, statistical models have typically been applied to ad hoc features. The noise that originates from the feature extraction process can cause poor performance.

In this paper, we propose a novel model dubbed the Piecewise Convolutional Neural Networks (PCNNs) with multi-instance learning to address these two problems. To solve the first problem, distant supervised relation extraction is treated as a multi-instance problem in which the uncertainty of instance labels is taken into account. To address the latter problem, we avoid feature engineering and instead adopt convolutional architecture with piecewise max pooling to automatically learn relevant features. Experiments show that our method is effective and outperforms several competitive baseline methods.

1 Introduction

In relation extraction, one challenge that is faced when building a machine learning system is the generation of training examples. One common technique for coping with this difficulty is distant supervision (Mintz et al., 2009) which assumes that if two entities have a relationship in a known knowledge base, then all sentences that mention these two entities will express that relationship in some way. Figure 1 shows an example of the automatic labeling of data through distant supervision. In this example, *Apple* and *Steve Jobs* are two related entities in Freebase[1]. All sentences that contain these two entities are selected as training instances. The distant supervision strategy is an effective method of automatically labeling training data. However, it has two major shortcomings when used for relation extraction.

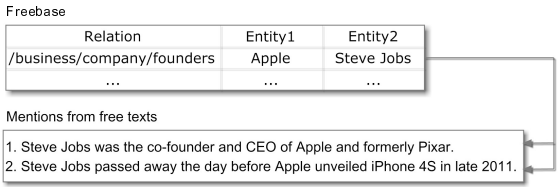

Figure 1: Training instances generated through distant supervision. Upper sentence: correct labeling; lower sentence: incorrect labeling.

First, the distant supervision assumption is too strong and causes the wrong label problem. A sentence that mentions two entities does not necessarily express their relation in a knowledge base. It is possible that these two entities may simply share the same topic. For instance, the upper sentence indeed expresses the "company/founders" relation in Figure 1. The lower sentence, however, does not express this relation but is still selected as a training instance. This will hinder the performance of a model trained on such noisy data.

Second, previous methods (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011) have typically applied supervised models to elaborately designed features when obtained the labeled data through distant supervision. These features are often derived from preexisting Natural Language Processing (NLP) tools. Since errors inevitably exist in NLP tools, the use of traditional features leads to error propagation or accumulation. Distant supervised relation extraction generally ad-

Lisbon, Portugal, 17-21 September 2015.

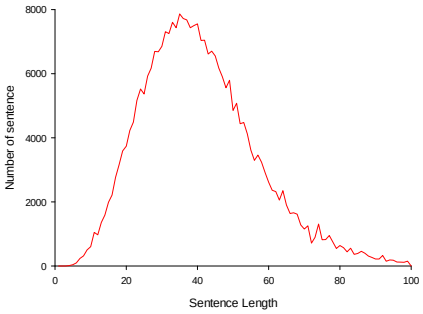

Figure 2: The sentence length distribution of Riedel's dataset.

dresses corpora from the Web, including many informal texts. Figure 2 shows the sentence length distribution of a benchmark distant supervision dataset that was developed by Riedel et al. (2010). Approximately half of the sentences are longer than 40 words. McDonald and Nivre (2007) showed that the accuracy of syntactic parsing decreases significantly with increasing sentence length. Therefore, when using traditional features, the problem of error propagation or accumulation will not only exist, it will grow more serious.

In this paper, we propose a novel model dubbed Piecewise Convolutional Neural Networks (PCNNs) with multi-instance learning to address the two problems described above. To address the first problem, distant supervised relation extraction is treated as a multi-instance problem similar to previous studies (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). In multi-instance problem, the training set consists of many bags, and each contains many instances. The labels of the bags are known; however, the labels of the instances in the bags are unknown. We design an objective function at the bag level. In the learning process, the uncertainty of instance labels can be taken into account; this alleviates the wrong label problem.

To address the second problem, we adopt convolutional architecture to automatically learn relevant features without complicated NLP preprocessing inspired by Zeng et al. (2014). Our proposal is an extension of Zeng et al. (2014), in which a single max pooling operation is utilized to determine the most significant features. Although this operation has been shown to be effective for textual feature representation (Collobert et al., 2011; Kim, 2014), it reduces the size of the hidden layers too rapidly and cannot capture the structural information between two entities (Graham, 2014). For example, to identify the relation between *Steve Jobs* and *Apple* in Figure 1, we need to specify the entities and extract the structural features between them. Several approaches have employed manually crafted features that attempt to model such structural information. These approaches usually consider both internal and external contexts. A sentence is inherently divided into three segments according to the two given entities. The internal context includes the characters inside the two entities, and the external context involves the characters around the two entities (Zhang et al., 2006). Clearly, single max pooling is not sufficient to capture such structural information. To capture structural and other latent information, we divide the convolution results into three segments based on the positions of the two given entities and devise a piecewise max pooling layer instead of the single max pooling layer. The piecewise max pooling procedure returns the maximum value in each segment instead of a single maximum value over the entire sentence. Thus, it is expected to exhibit superior performance compared with traditional methods.

The contributions of this paper can be summarized as follows.

- We explore the feasibility of performing distant supervised relation extraction without hand-designed features. PCNNS are proposed to automatically learn features without complicated NLP preprocessing.
- To address the wrong label problem, we develop innovative solutions that incorporate multi-instance learning into the PCNNS for distant supervised relation extraction.
- In the proposed network, we devise a piecewise max pooling layer, which aims to capture structural information between two entities.

2 Related Work

Relation extraction is one of the most important topics in NLP. Many approaches to relation extraction have been developed, such as bootstrapping, unsupervised relation discovery and supervised classification. Supervised approaches are the most commonly used methods for relation

extraction and yield relatively high performance (Bunescu and Mooney, 2006; Zelenko et al., 2003; Zhou et al., 2005). In the supervised paradigm, relation extraction is considered to be a multi-class classification problem and may suffer from a lack of labeled data for training. To address this problem, Mintz et al. (2009) adopted Freebase to perform distant supervision. As described in Section 1, the algorithm for training data generation is sometimes faced with the wrong label problem. To address this shortcoming, (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012) developed the relaxed distant supervision assumption for multi-instance learning. The term 'multi-instance learning was coined by (Dietterich et al., 1997) while investigating the problem of predicting drug activity. In multi-instance learning, the uncertainty of instance labels can be taken into account. The focus of multi-instance learning is to discriminate among the bags.

These methods have been shown to be effective for relation extraction. However, their performance depends strongly on the quality of the designed features. Most existing studies have concentrated on extracting features to identify the relations between two entities. Previous methods can be generally categorized into two types: feature-based methods and kernel-based methods. In feature-based methods, a diverse set of strategies is exploited to convert classification clues (e.g., sequences, parse trees) into feature vectors (Kambhatla, 2004; Suchanek et al., 2006). Feature-based methods suffer from the necessity of selecting a suitable feature set when converting structured representations into feature vectors. Kernel-based methods provide a natural alternative to exploit rich representations of input classification clues, such as syntactic parse trees. Kernel-based methods enable the use of a large set of features without needing to extract them explicitly. Several kernels have been proposed, such as the convolution tree kernel (Qian et al., 2008), the subsequence kernel (Bunescu and Mooney, 2006) and the dependency tree kernel (Bunescu and Mooney, 2005).

Nevertheless, as mentioned in Section 1, it is difficult to design high-quality features using existing NLP tools. With the recent revival of interest in neural networks, many researchers have investigated the possibility of using neural networks to automatically learn features (Socher et al., 2012; Zeng et al., 2014). Inspired by Zeng et al. (2014), we propose the use of PCNNs with multi-instance learning to automatically learn features for distant supervised relation extraction. Dietterich et al. (1997) suggested that the design of multi-instance modifications for neural networks is a particularly interesting topic. Zhang and Zhou (2006) successfully incorporated multi-instance learning into traditional Backpropagation (BP) and Radial Basis Function (RBF) networks and optimized these networks by minimizing a sum-of-squares error function. In contrast to their method, we define the objective function based on the cross-entropy principle.

3 Methodology

Distant supervised relation extraction is formulated as multi-instance problem. In this section, we present innovative solutions that incorporate multi-instance learning into a convolutional neural network to fulfill this task. PCNNs are proposed for the automatic learning of features without complicated NLP preprocessing. Figure 3 shows our neural network architecture for distant supervised relation extraction. It illustrates the procedure that handles one instance of a bag. This procedure includes four main parts: *Vector Representation*, *Convolution*, *Piecewise Max Pooling* and *Softmax Output*. We describe these parts in detail below.

3.1 Vector Representation

The inputs of our network are raw word tokens. When using neural networks, we typically transform word tokens into low-dimensional vectors. In our method, each input word token is transformed into a vector by looking up pre-trained word embeddings. Moreover, we use position features (PFs) to specify entity pairs, which are also transformed into vectors by looking up position embeddings.

3.1.1 Word Embeddings

Word embeddings are distributed representations of words that map each word in a text to a 'k'-dimensional real-valued vector. They have recently been shown to capture both semantic and syntactic information about words very well, setting performance records in several word similarity tasks (Mikolov et al., 2013; Pennington et al., 2014). Using word embeddings that have been trained a priori has become common practice for

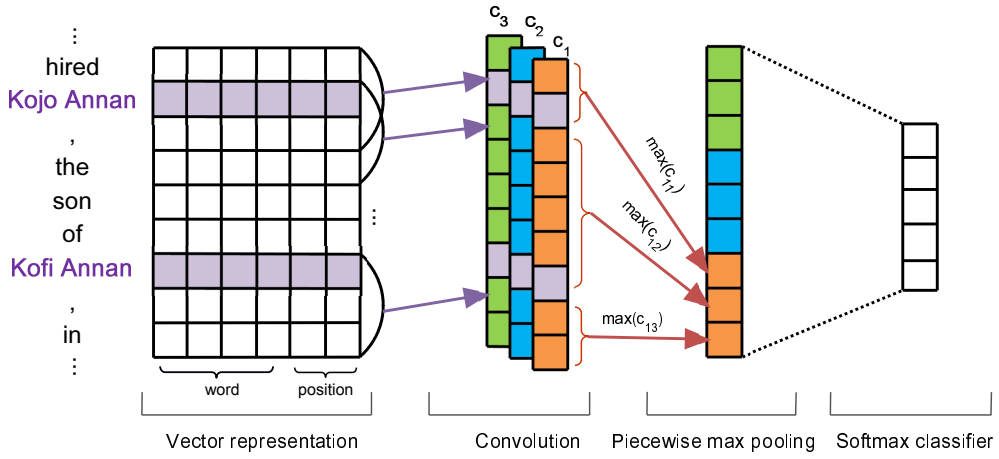

Figure 3: The architecture of PCNNs (better viewed in color) used for distant supervised relation extraction, illustrating the procedure for handling one instance of a bag and predicting the relation between *Kojo Annan* and *Kofi Annan*.

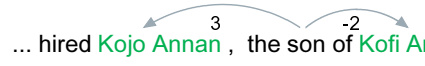
enhancing many other NLP tasks (Parikh et al., 2014; Huang et al., 2014).

A common method of training a neural network is to randomly initialize all parameters and then optimize them using an optimization algorithm. Recent research (Erhan et al., 2010) has shown that neural networks can converge to better local minima when they are initialized with word embeddings. Word embeddings are typically learned in an entirely unsupervised manner by exploiting the co-occurrence structure of words in unlabeled text. Researchers have proposed several methods of training word embeddings (Bengio et al., 2003; Collobert et al., 2011; Mikolov et al., 2013). In this paper, we use the Skip-gram model (Mikolov et al., 2013) to train word embeddings.

3.1.2 Position Embeddings

In relation extraction, we focus on assigning labels to entity pairs. Similar to Zeng et al. (2014), we use PFs to specify entity pairs. A PF is defined as the combination of the relative distances from the current word to e_1 and e_2. For instance, in the following example, the relative distances from *son* to e_1 (*Kojo Annan*) and e_2 (*Kofi Annan*) are 3 and -2, respectively.



Two position embedding matrixes ($\mathbf{PF}_1$ and $\mathbf{PF}_2$) are randomly initialized. We then transform the relative distances into real valued vectors by looking up the position embedding matrixes. In the example shown in Figure 3, it is assumed that the size of the word embedding is $d_w = 4$ and that the size of the position embedding is $d_p = 1$. In combined word embeddings and position embeddings, the vector representation part transforms an instance into a matrix $\mathbf{S} \in \mathbb{R}^{s \times d}$, where s is the sentence length and $d = d_w + d_p * 2$. The matrix $\mathbf{S}$ is subsequently fed into the convolution part.

3.2 Convolution

In relation extraction, an input sentence that is marked as containing the target entities corresponds only to a relation type; it does not predict labels for each word. Thus, it might be necessary to utilize all local features and perform this prediction globally. When using a neural network, the convolution approach is a natural means of merging all these features (Collobert et al., 2011).

Convolution is an operation between a vector of weights, $\mathbf{w}$, and a vector of inputs that is treated as a sequence $\mathbf{q}$. The weights matrix $\mathbf{w}$ is regarded as the filter for the convolution. In the example shown in Figure 3, we assume that the length of the filter is w ($w = 3$); thus, $\mathbf{w} \in \mathbb{R}^m$ ($m = w * d$). We consider $\mathbf{S}$ to be a sequence $\{\mathbf{q}_1, \mathbf{q}_2, \cdots, \mathbf{q}_s\}$, where $\mathbf{q}_i \in \mathbb{R}^d$. In general, let $\mathbf{q}_{i:j}$ refer to the concatenation of $\mathbf{q}_i$ to $\mathbf{q}_j$. The convolution operation involves taking the dot product of $\mathbf{w}$ with each w-gram in the sequence $\mathbf{q}$ to obtain another sequence $\mathbf{c} \in \mathbb{R}^{s+w-1}$:

$$c_j = \mathbf{w}\mathbf{q}_{j-w+1:j} \quad (1)$$

where the index j ranges from 1 to $s+w-1$. Out-of-range input values $\mathbf{q}_i$, where $i < 1$ or $i > s$, are

taken to be zero.

The ability to capture different features typically requires the use of multiple filters (or feature maps) in the convolution. Under the assumption that we use n filters ($\mathbf{W} = \{\mathbf{w}_1, \mathbf{w}_2, \cdots, \mathbf{w}_n\}$), the convolution operation can be expressed as follows:

$$c_{ij} = \mathbf{w}_i \mathbf{q}_{j-w+1:j} \quad 1 \leq i \leq n \tag{2}$$

The convolution result is a matrix $\mathbf{C} = \{\mathbf{c}_1, \mathbf{c}_2, \cdots, \mathbf{c}_n\} \in \mathbb{R}^{n \times (s+w-1)}$. Figure 3 shows an example in which we use 3 different filters in the convolution procedure.

3.3 Piecewise Max Pooling

The size of the convolution output matrix $\mathbf{C} \in \mathbb{R}^{n \times (s+w-1)}$ depends on the number of tokens s in the sentence that is fed into the network. To apply subsequent layers, the features that are extracted by the convolution layer must be combined such that they are independent of the sentence length. In traditional Convolution Neural Networks (CNNs), max pooling operations are often applied for this purpose (Collobert et al., 2011; Zeng et al., 2014). This type of pooling scheme naturally addresses variable sentence lengths. The idea is to capture the most significant features (with the highest values) in each feature map.

However, despite the widespread use of single max pooling, this approach is insufficient for relation extraction. As described in the first section, single max pooling reduces the size of the hidden layers too rapidly and is too coarse to capture fine-grained features for relation extraction. In addition, single max pooling is not sufficient to capture the structural information between two entities. In relation extraction, an input sentence can be divided into three segments based on the two selected entities. Therefore, we propose a piecewise max pooling procedure that returns the maximum value in each segment instead of a single maximum value. As shown in Figure 3, the output of each convolutional filter $\mathbf{c}_i$ is divided into three segments $\{\mathbf{c}_{i1}, \mathbf{c}_{i2}, \mathbf{c}_{i3}\}$ by *Kojo Annan* and *Kofi Annan*. The piecewise max pooling procedure can be expressed as follows:

$$p_{ij} = \max(\mathbf{c}_{ij}) \quad 1 \leq i \leq n, \ 1 \leq j \leq 3 \tag{3}$$

For the output of each convolutional filter, we can obtain a 3-dimensional vector $\mathbf{p}_i = \{p_{i1}, p_{i2}, p_{i3}\}$. We then concatenate all vectors $\mathbf{p}_{1:n}$ and apply a non-linear function, such as the hyperbolic tangent. Finally, the piecewise max pooling procedure outputs a vector:

$$\mathbf{g} = \tanh(\mathbf{p}_{1:n}) \tag{4}$$

where $\mathbf{g} \in \mathbb{R}^{3n}$. The size of $\mathbf{g}$ is fixed and is no longer related to the sentence length.

3.4 Softmax Output

To compute the confidence of each relation, the feature vector $\mathbf{g}$ is fed into a softmax classifier.

$$\mathbf{o} = \mathbf{W}_1 \mathbf{g} + b \tag{5}$$

$\mathbf{W_1} \in \mathbb{R}^{n_1 \times 3n}$ is the transformation matrix, and $\mathbf{o} \in \mathbb{R}^{n_1}$ is the final output of the network, where n_1 is equal to the number of possible relation types for the relation extraction system.

We employ dropout (Hinton et al., 2012) on the penultimate layer for regularization. Dropout prevents the co-adaptation of hidden units by randomly dropping out a proportion p of the hidden units during forward computing. We first apply a "masking" operation $(\mathbf{g} \circ \mathbf{r})$ on $\mathbf{g}$, where $\mathbf{r}$ is a vector of Bernoulli random variables with probability p of being 1. Eq.(5) becomes:

$$\mathbf{o} = \mathbf{W}_1(\mathbf{g} \circ \mathbf{r}) + b \tag{6}$$

Each output can then be interpreted as the confidence score of the corresponding relation. This score can be interpreted as a conditional probability by applying a softmax operation (see Section 3.5). In the test procedure, the learned weight vectors are scaled by p such that $\hat{\mathbf{W}}_1 = p\mathbf{W}_1$ and are used (without dropout) to score unseen instances.

3.5 Multi-instance Learning

In order to alleviate the wrong label problem, we use multi-instance learning for PCNNs. The PCNNs-based relation extraction can be stated as a quintuple $\theta = (\mathbf{E}, \mathbf{PF}_1, \mathbf{PF}_2, \mathbf{W}, \mathbf{W}_1)$[2]. The input to the network is a bag. Suppose that there are T bags $\{M_1, M_2, \cdots, M_T\}$ and that the i-th bag contains q_i instances $M_i = \{m_i^1, m_i^2, \cdots, m_i^{q_i}\}$. The objective of multi-instance learning is to predict the labels of the unseen bags. In this paper, all instances in a bag are considered independently. Given an input instance m_i^j, the network with the parameter θ outputs a vector $\mathbf{o}$, where the r-th component o_r corresponds to the score associated

[2] $\mathbf{E}$ represents the word embeddings.

Algorithm 1 Multi-instance learning

1: Initialize θ. Partition the bags into mini-batches of size b_s.
2: Randomly choose a mini-batch, and feed the bags into the network one by one.
3: Find the j-th instance m_i^j $(1 \leq i \leq b_s)$ in each bag according to Eq. (9).
4: Update θ based on the gradients of m_i^j $(1 \leq i \leq b_s)$ via Adadelta.
5: Repeat steps 2-4 until either convergence or the maximum number of epochs is reached.

with relation r. To obtain the conditional probability $p(r|m, \theta)$, we apply a softmax operation over all relation types:

$$p(r|m_i^j;\theta) = \frac{e^{o_r}}{\sum_{k=1}^{n_1} e^{o_k}} \quad (7)$$

The objective of multi-instance learning is to discriminate bags rather than instances. To do so, we must define the objective function on the bags. Given all (T) training bags (M_i, y_i), we can define the objective function using cross-entropy at the bag level as follows:

$$J(\theta) = \sum_{i=1}^{T} \log p(y_i|m_i^j;\theta) \quad (8)$$

where j is constrained as follows:

$$j^* = \arg\max_j p(y_i|m_i^j;\theta) \;\; 1 \leq j \leq q_i \quad (9)$$

Using this defined objective function, we maximize $J(\theta)$ through stochastic gradient descent over shuffled mini-batches with the Adadelta (Zeiler, 2012) update rule. The entire training procedure is described in Algorithm 1.

From the introduction presented above, we know that the traditional backpropagation algorithm modifies a network in accordance with all training instances, whereas backpropagation with multi-instance learning modifies a network based on bags. Thus, our method captures the nature of distant supervised relation extraction, in which some training instances will inevitably be incorrectly labeled. When a trained PCNN is used for prediction, a bag is positively labeled if and only if the output of the network on at least one of its instances is assigned a positive label.

4 Experiments

Our experiments are intended to provide evidence that supports the following hypothesis: automatically learning features using PCNNs with multi-instance learning can lead to an increase in performance. To this end, we first introduce the dataset and evaluation metrics used. Next, we test several variants via cross-validation to determine the parameters to be used in our experiments. We then compare the performance of our method to those of several traditional methods. Finally, we evaluate the effects of piecewise max pooling and multi-instance learning[3].

4.1 Dataset and Evaluation Metrics

We evaluate our method on a widely used dataset[4] that was developed by (Riedel et al., 2010) and has also been used by (Hoffmann et al., 2011; Surdeanu et al., 2012). This dataset was generated by aligning Freebase relations with the NYT corpus, with sentences from the years 2005-2006 used as the training corpus and sentences from 2007 used as the testing corpus.

Following previous work (Mintz et al., 2009), we evaluate our method in two ways: the held-out evaluation and the manual evaluation. The held-out evaluation only compares the extracted relation instances against Freebase relation data and reports the precision/recall curves of the experiments. In the manual evaluation, we manually check the newly discovered relation instances that are not in Freebase.

4.2 Experimental Settings

4.2.1 Pre-trained Word Embeddings

In this paper, we use the Skip-gram model (word2vec)[5] to train the word embeddings on the NYT corpus. Word2vec first constructs a vocabulary from the training text data and then learns vector representations of the words. To obtain the embeddings of the entities, we concatenate the tokens of a entity using the ## operator when the entity has multiple word tokens. Since a comparison of the word embeddings is beyond the scope

[3] With regard to the position feature, our experiments yield the same positive results described in Zeng et al. (2014). Because the position feature is not the main contribution of this paper, we do not present the results without the position feature.

Table 1: Parameters used in our experiments.

of this paper, our experiments directly utilize 50-dimensional vectors.

4.2.2 Parameter Settings

In this section, we experimentally study the effects of two parameters on our models: the window size, w, and the number of feature maps, n. Following (Surdeanu et al., 2012), we tune all of the models using three-fold validation on the training set. We use a grid search to determine the optimal parameters and manually specify subsets of the parameter spaces: $w \in \{1, 2, 3, \cdots, 7\}$ and $n \in \{50, 60, \cdots, 300\}$. Table 1 shows all parameters used in the experiments. Because the position dimension has little effect on the result, we heuristically choose $d_p = 5$. The batch size is fixed to 50. We use Adadelta (Zeiler, 2012) in the update procedure; it relies on two main parameters, ρ and ε, which do not significantly affect the performance (Zeiler, 2012). Following (Zeiler, 2012), we choose 0.95 and $1e^{-6}$, respectively, as the values of these parameters. In the dropout operation, we randomly set the hidden unit activities to zero with a probability of 0.5 during training.

4.3 Comparison with Traditional Approaches

4.3.1 Held-out Evaluation

The held-out evaluation provides an approximate measure of precision without requiring costly human evaluation. Half of the Freebase relations are used for testing. The relation instances discovered from the test articles are automatically compared with those in Freebase.

To evaluate the proposed method, we select the following three traditional methods for comparison. *Mintz* represents a traditional distant-supervision-based model that was proposed by (Mintz et al., 2009). *MultiR* is a multi-instance learning method that was proposed by (Hoffmann et al., 2011). *MIML* is a multi-instance multi-label model that was proposed by (Surdeanu et al., 2012). Figure 4 shows the precision-recall curves for each method, where *PCNNs+MIL* denotes our method, and demonstrates that *PCNNs+MIL* achieves higher precision over the entire range of recall. *PCNNs+MIL* enhances the recall to approximately 34% without any loss of precision. In terms of both precision and recall, *PCNNs+MIL* outperforms all other evaluated approaches. Notably, the results of the methods evaluated for comparison were obtained using manually crafted features. By contrast, our result is obtained by automatically learning features from original words. The results demonstrate that the proposed method is an effective technique for distant supervised relation extraction. Automatically learning features via PCNNs can alleviate the error propagation that occurs in traditional feature extraction. Incorporating multi-instance learning into a convolutional neural network is an effective means of addressing the wrong label problem.

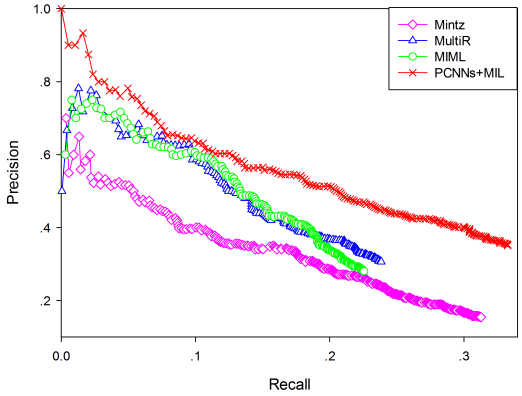

Figure 4: Performance comparison of the proposed method with traditional approaches.

Top N	Mintz	MultiR	MIML	PCNNs+MIL
Top 100	0.77	0.83	0.85	**0.86**
Top 200	0.71	0.74	0.75	**0.80**
Top 500	0.55	0.59	0.61	**0.69**
Average	0.676	0.720	0.737	**0.783**

Table 2: Precision values for the top 100, top 200, and top 500 extracted relation instances upon manual evaluation.

4.3.2 Manual Evaluation

It is worth emphasizing that there is a sharp decline in the held-out precision-recall curves of *PCNNs+MIL* at very low recall (Figure 4). A manual check of the misclassified examples that were produced with high confidence reveals that the ma-

jorities of these examples are false negatives and are actually true relation instances that were misclassified due to the incomplete nature of Freebase.

Thus, the held-out evaluation suffers from false negatives in Freebase. We perform a manual evaluation to eliminate these problems. For the manual evaluation, we choose the entity pairs for which at least one participating entity is not present in Freebase as a candidate. This means that there is no overlap between the held-out and manual candidates. Because the number of relation instances that are expressed in the test data is unknown, we cannot calculate the recall in this case. Instead, we calculate the precision of the top N extracted relation instances. Table 2 presents the manually evaluated precisions for the top 100, top 200, and top 500 extracted instances. The results show that *PCNNs+MIL* achieves the best performance; moreover, the precision is higher than in the held-out evaluation. This finding indicates that many of the false negatives that we predict are, in fact, true relational facts. The sharp decline observed in the held-out precision-recall curves is therefore reasonable.

4.4 Effect of Piecewise Max Pooling and Multi-instance Learning

In this paper, we develop a method of piecewise max pooling and incorporate multi-instance learning into convolutional neural networks for distant supervised relation extraction. To demonstrate the effects of these two techniques, we empirically study the performance of systems in which these techniques are not implemented through held-out evaluations (Figure 5). *CNNs* represents convolutional neural networks to which single max pooling is applied. Figure 5 shows that when piecewise max pooling is used (*PCNNs*), better results are produced than those achieved using *CNNs*. Moreover, compared with *CNNs+MIL*, *PCNNs* achieve slightly higher precision when the recall is greater than 0.08. Since the parameters for all the model are determined by grid search, we can observe that *CNNs* cannot achieve competitive results compared to *PCNNs* when increasing the size of the hidden layer of convolutional neural networks. It means that we cannot capture more useful information by simply increasing the network parameter. These results demonstrate that the proposed piecewise max pooling technique is beneficial and

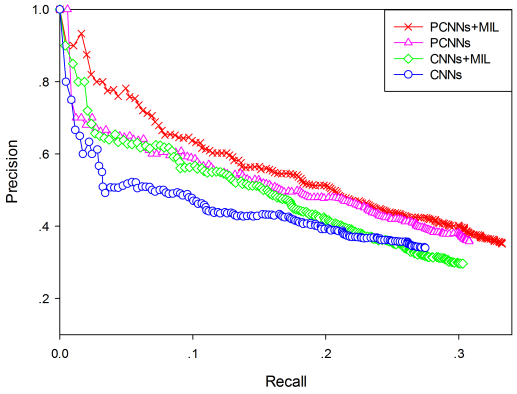

Figure 5: Effect of piecewise max pooling and multi-instance learning.

can effectively capture structural information for relation extraction. A similar phenomenon is also observed when multi-instance learning is added to the network. Both *CNNs+MIL* and *PCNNs+MIL* outperform their counterparts *CNNs* and *PCNNs*, respectively, thereby demonstrating that incorporation of multi-instance learning into our neural network was successful in solving the wrong label problem. As expected, *PCNNs+MIL* obtains the best results because the advantages of both techniques are achieved simultaneously.

5 Conclusion

In this paper, we exploit Piecewise Convolutional Neural Networks (PCNNs) with multi-instance learning for distant supervised relation extraction. In our method, features are automatically learned without complicated NLP preprocessing. We also successfully devise a piecewise max pooling layer in the proposed network to capture structural information and incorporate multi-instance learning to address the wrong label problem. Experimental results show that the proposed approach offers significant improvements over comparable methods.

Abstract

We propose CORE, a novel matrix factorization model that leverages contextual information for open relation extraction. Our model is based on factorization machines and integrates facts from various sources, such as knowledge bases or open information extractors, as well as the context in which these facts have been observed. We argue that integrating contextual information—such as metadata about extraction sources, lexical context, or type information—significantly improves prediction performance. Open information extractors, for example, may produce extractions that are unspecific or ambiguous when taken out of context. Our experimental study on a large real-world dataset indicates that CORE has significantly better prediction performance than state-of-the-art approaches when contextual information is available.

1 Introduction

Open relation extraction (open RE) is the task of extracting new facts for a potentially unbounded set of relations from various sources such as knowledge bases or natural language text. The task is closely related to *targeted information extraction* (IE), which aims to populate a knowledge base (KB) with new facts for the KB's relations, such as wasBornIn(Sepp Herberger, Mannheim). Existing methods either reason within the KB itself (Franz et al., 2009; Nickel et al., 2011; Drumond et al., 2012) or leverage large text corpora to learn patterns that are indicative of KB relations (Mintz et al., 2009; Surdeanu et al., 2012; Min et al., 2013). In both cases, targeted IE methods are inherently limited to an (often small) set of predefined relations, i.e., they are not "open". The open RE task is also related to *open information extraction* (open IE) (Banko et al., 2007; Del Corro and Gemulla, 2013), which extracts large amounts of surface relations and their arguments from natural language text; e.g., "critizices"("Dante", "Catholic Church").[1] Although open IE is a domain-independent approach, the extracted surface relations are purely syntactic and often ambiguous or noisy. Moreover, open IE methods usually do not "predict" facts that have not been explicitly observed in the input data. Open RE combines the above tasks by predicting new facts for an open set of relations. The key challenge in open RE is to reason jointly over the *universal schema* consisting of KB relations and surface relations (Riedel et al., 2013).

A number of matrix or tensor factorization models have recently been proposed in the context of relation extraction (Nickel et al., 2012; Riedel et al., 2013; Huang et al., 2014; Chang et al., 2014). These models use the available data to learn latent semantic representations of entities (or entity pairs) and relations in a domain-independent way; the latent representations are subsequently used to predict new facts. Existing models often focus on either targeted IE or open RE. Targeted models are used for within-KB reasoning; they rely on the closed-world assumption and often do not scale with the number of relations. Open RE models use the open-world assumption, which is more suitable for the open RE task because the available data is often highly incomplete. In this paper, we propose CORE, a novel open RE factorization model that incorporates and exploits contextual information to improve prediction performance.

Consider for example the sentence "Tom Peloso joined Modest Mouse to record their fifth studio album". Open IE systems may extract the *surface fact* "join"(TP, MM) from this sentence. Note

[1] We mark (non-disambiguated) mentions of entities and relations in quotation marks throughout this paper.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1763–1773,
Lisbon, Portugal, 17-21 September 2015.

that *surface relation* "join" is unspecific; in this case, it refers to becoming a member of a music band (as opposed to, say, an employee of a company). Most existing open RE systems use the extracted surface fact for further reasoning, but they ignore the context from which the fact was extracted. We argue in this paper that exploiting contextual information is beneficial for open RE. For our example, we may use standard NLP tools like a named entity recognizer to detect that TP is a person and MM an organization. These coarse-grained types give us hints about the domain and range of the "join" relation for the surface fact, although the actual meaning of "join" still remains opaque. Now imagine that the above sentence was extracted from a newspaper article published in the music section. This information can help to infer that "join" indeed refers to joining a band. Other contextual information, such as the words "record" and "album" that occur in the sentence, further strengthen this interpretation. A context-aware open RE system should leverage such information to accurately predict facts like "is band member of"(TP, MM) and "plays with"(TP, MM).

Note that the prediction of the fact "is band member of"(TP, MM) is facilitated if we make use of a KB that knows that TP is a musician and MM is a music band. If TP and/or MM are not present in the knowledge base, however, such a reasoning does not apply. In our work, we consider both linked *entities* (in-KB) and non-linked *entity mentions* (out of-KB). Since KB are often incomplete, this open approach to handle named entities allows us to extract facts for all entities, even if they do not appear in the KB.

In this paper, we propose CORE, a flexible open RE model that leverages contextual information. CORE is inspired by the combined factorization and entity model (FE) of Riedel et al. (2013). As FE, CORE associates latent semantic representations with entities, relations, and arguments. In contrast to FE, CORE uses factorization machines (Rendle, 2012) as its underlying framework, which allows us to incorporate context in a flexible way. CORE is able to leverage and integrate arbitrary contextual information associated with the input facts into its open RE factorization model. To support reasoning under the open-world assumption, we propose an efficient method for parameter estimation in factorization machines based on Bayesian personalized ranking (Rendle et al., 2009).

We conducted an experimental study on a real-world dataset using contextual information along the lines mentioned above. Our model is extensible, i.e., additional contextual information can be integrated when available. Even with limited amount of contextual information used in our experiments, our CORE model provided higher prediction performance than previous models. Our findings validate the usefulness of contextual information for the open RE task.

2 Related Work

There is a large body of related work on relation extraction; we restrict attention to methods that are most similar to our work.

Targeted IE. Targeted IE methods aim to extract from natural-language text new instances of a set of predefined relations, usually taken from a KB. Most existing methods make use of distant supervision, i.e., they start with a set of seed instances (pairs of entities) for the relations of interest, search for these seed instances in text, learn a relation extractor from the so-obtained training data, and optionally iterate (Mintz et al., 2009; Surdeanu et al., 2012; Min et al., 2013). Open RE models are more general then targeted IE methods in that they additionally reason about surface relations that do not correspond to KB relations. For this reason, Riedel et al. (2013) argued and experimentally validated that open RE models can outperform targeted IE methods.

Open IE. In contrast to targeted IE, the goal of open IE is to extract all (or most) relations expressed in natural-language text, whether or not these relations are defined in a KB (Banko et al., 2007; Fader et al., 2011; Del Corro and Gemulla, 2013). The facts obtained by open IE methods are often not disambiguated, i.e., the entities and/or the relation are not linked to a knowledge base; e.g., "criticizes"("Dante", "Catholic Church"). The goal of our work is to reason about extracted open-IE facts and their contextual information. Our method is oblivious to the actual open IE method being used.

Relation clustering. One way to reason about KB and surface relations is to cluster the relations: whenever two relations appear in the same cluster, they are treated as synonymous (Hasegawa et al., 2004; Shinyama and Sekine, 2006; Yao

et al., 2011; Takamatsu et al., 2011; Min et al., 2012; Akbik et al., 2012; de Lacalle and Lapata, 2013). For example, if "criticizes" and "hates" are clustered together, then we may predict "hates"("Dante", "Catholic Church") from the above fact (which is actually not true). The general problem with relation clustering is its "black and white" approach to relations: either two relations are the same or they are different. This assumption generally does not hold for the surface relations extracted by open IE systems (Riedel et al., 2013); examples of other types of relationships between relations include implication or mutual exclusion.

Tensor factorization. Matrix or tensor factorization approaches try to address the above problem: instead of clustering relations, they directly predict facts. Both matrix and tensor models learn and make use of semantic representations of relations and their arguments. The semantic representations ideally captures all the information present in the data; it does not, however, establish a direct relationship (such as synonymy) between different KB or surface relations.

Tensor factorization models conceptually model the input data as a subject×relation×object tensor, in which non-zero values correspond to input facts. The tensor is factored to construct a new tensor in which predicted facts take large non-zero values. Examples of such tensor factorization models are TripleRank (Franz et al., 2009), RESCAL (Nickel et al., 2011; Nickel et al., 2012), or PITF (Drumond et al., 2012). Tensor factorization models are generally well-suited to reason within a KB because they are able to predict relations between arbitrary pairs of subjects and objects. In the context of open RE, however, these methods suffer from limited scalability with the number of relations as well as from their large prediction space (Chang et al., 2014).

Matrix factorization. The key difference between matrix and tensor factorization models is that the former restrict the prediction space, i.e., these models generally cannot predict arbitrary facts. Similar to distant supervision approaches, matrix factorization models focus on predicting facts for which some direct evidence exists. In more detail, most methods restrict the prediction space to the set of facts for which the subject and the object share at least some relation in the input data. For this reason, matrix factorization models are not suited for in-KB reasoning; an individual pair of entities usually does not occur in more than one KB relation. In the open RE context, however, input relations are semantically related so that many subject-object pairs belong to multiple relations. The key advantage of matrix methods is (1) that this restriction allows them to use additional features—such as features for each subject-object pair—and (2) that they scale much better with the number of relations. Examples of such matrix factorization models include (Tresp et al., 2009; Jiang et al., 2012; Fan et al., 2014; Huang et al., 2014). Chang et al. (2014) have also shown that a combination of matrix and tensor factorization models can be fruitful. Closest to our work is the "universal schema" matrix factorization approach of Riedel et al. (2013), which combines a latent features model, a neighborhood model and an entity model but does not incorporate context. Our CORE model follows the universal schema idea, but uses a more general factorization model, which includes the information captured by the latent features and entity model (but not the neighborhood model), and incorporates contextual information.

Using contextual information. It is well known that contextual information can improve IE methods. Information such as bag-of-words, part-of-speech tags, entity types, or parse trees have been integrated into many existing systems (Mintz et al., 2009; Zhang et al., 2012; Takamatsu et al., 2011; Zhou et al., 2007; de Lacalle and Lapata, 2013; Akbik et al., 2012). Our work differs in that we integrate contextual information into an open RE system. To do so, we leverage factorization machines (Rendle et al., 2011; Rendle, 2012), which have been successfully applied to exploit contextual information in the context of recommender systems. We show how to model open RE data and context with factorization machines and provide a method for parameter estimation under the open-world assumption.

3 The CORE Model

Input data. We model the input data as a set of *observations* of the form (r, t, c), where r refer to a KB or surface relation, t refer to a subject-object pair of entities (or entity mentions) and c to contextual information. An observation obtained from the example of the introduction may be ("join", (TP, MM), { types:(person,org),

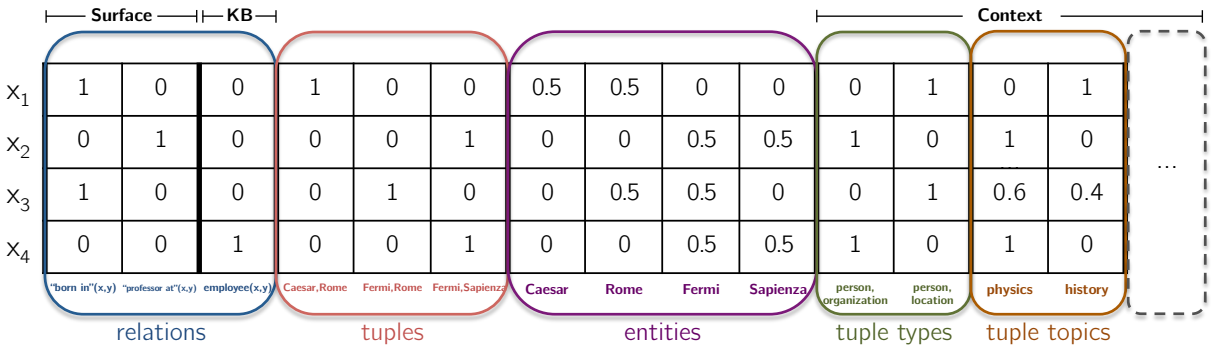

Figure 1: Example for representing a context-aware open RE problem with CORE

topic:music, word:record, word:album, ...}). Denote by R the set of all observed *relations*, by E the set of all observed *entities*, and by $T \subseteq E \times E$ the set of all observed entity pairs, which we refer to as *tuples*. A *fact* takes form $r(t)$ and is composed of a relation $r \in R$ and a tuple $t \in T$; e.g., "join"(TP, MM). Note that there may be multiple observations for a fact. Finally, denote by C the set of all *contextual variables*; each observation is associated with a set $c \subseteq C$ of context variables. In this paper we restrict attention to categorical context variables; our model can potentially handle continuous context as in (Rendle, 2012).

Problem definition. The open RE task is to produce a ranked list of tuples $T_r \subseteq T$ for each relation $r \in R$; the list is restricted to new tuples, i.e., tuples $t \in T$ for which $r(t)$ has not been observed in the input. The rank of each tuple reflects the model's prediction of the likelihood that the corresponding fact is indeed true. A good model thus ranks correct facts higher than incorrect ones.

Modeling facts. Denote by $V = R \cup T \cup E \cup C$ the set of all observed relations, tuples, entities, and contextual variables. For ease of exposition, we refer to the elements of V as *variables*. We model the input data in terms of a matrix in which each row corresponds to a fact (i.e., not an observation) and each column to a variable. We group columns according to the type of the variables; e.g, there are relation columns, tuple columns, entity columns, and a group of columns for each type of contextual information. The matrix is populated such that in each row the values of each column group sum up to unity, i.e., we normalize values within column groups. In particular, we set to 1 the values of the variable of the relation and the tuple of the corresponding fact. We set to 0.5 the variables corresponding to the two entities referred to by the fact. An example is shown in Fig. 1. Here the first row, for instance, corresponds to the fact "born in"(Caesar, Rome). Note that we model tuples and entities separately: the entity variables expose which arguments belong to the fact, the tuple variables expose their order.

Modeling context. As described above, we model the data in terms of a matrix in which rows corresponds to facts (instead of observations). The reasoning behind this approach is as follows. First, we may see a fact in multiple observations; our goal is to leverage all the available context. Second, facts but not observations are the target of our predictions. Finally, we are interested in predicting new facts, i.e., facts that we have not seen in the input data. For these facts, there is no corresponding observation so that we cannot directly obtain contextual information. To address these points, our model aggregates the context of relevant observations for each fact; this approach allows us to provide comprehensive contextual information for both observed and unobserved facts.

We group contextual information by the type of information: examples include metadata about the extraction sources (e.g., from an article on music), types of the entities of a tuple (e.g., (person, location)), or the bag-of-words in the sentence from which an extraction has been obtained. We aggregate the contextual information for each tuple $t \in T$; this tuple-level approach allows us to provide contextual information for unobserved facts. In more detail, we count in how many observations each contextual variable has been associated with the tuple, and then normalize the count values to 1 within each group of columns. The so-obtained values can be interpreted as the relative frequencies with which each contextual variable is associated with the tuple. The contextual information as-

sociated with each fact is given by the aggregated, normalized context of its tuple.

Fig. 1 shows context information arranged in two groups: tuple types and tuple topics. We capture information such as that the tuple (Caesar, Rome) has only been seen in articles on history or that tuple (Fermi, Rome) is mentioned in both physics and history articles (slightly more often in the former). Since context is associated with tuples, facts 2 and 4 on (Fermi, Sapienza) share contextual information. This form of context sharing (as well as entity sharing) allows us to propagate information about tuples across various relations.

Factorization model. CORE employs a matrix factorization model based on factorization machines and the open-world assumption to capture latent semantic information about the individual variables. In particular, we associate with each variable $v \in V$ a *bias term* $b_v \in \mathbb{R}$ and a *latent feature vector* $\boldsymbol{f}_v \in \mathbb{R}^d$, where the *dimensionality* d of the latent feature space is a hyperparameter of our model. Denote by X the set of rows in the input matrix, which we henceforth refer to as *training points*. For each training point $x \in X$, denote by x_v the value of variable $v \in V$ in the corresponding row of the matrix. Our model associates with training point $x \in X$ a *score* $s(x)$ computed as follows:

$$s(x) = \sum_{v \in V} x_v b_v + \sum_{v_1 \in V} \sum_{v_2 \in V \setminus \{v_1\}} x_{v_1} x_{v_2} \boldsymbol{f}_{v_1}^T \boldsymbol{f}_{v_2} \quad (1)$$

Here the bias terms models the contribution of each individual variable to the final score, whereas the latent feature vectors model the contribution of all pairwise interactions between variables. Note that only bias terms and feature vectors corresponding to non-zero entries in x affect the score and that x is often sparse. Since we can compute $s(x)$ in time linear to both the number of nonzero entries in x and the dimensionality d (Rendle, 2012), score computation is fast. As discussed below, we (roughly) estimate bias terms and feature vectors such that observed facts achieve high scores. We may thus think of each feature vector as a low-dimensional representation of the global information contained in the corresponding variable.

Prediction. Given estimates for bias terms and latent feature vectors, we rank unobserved facts as follows. Fix a relation $r \in R$ and a tuple $t \in T$ such that $r(t)$ has not been observed. As indicated above, our model overcomes the key problem that there is no observation, and thus no context, for $r(t)$ by context aggregation and sharing. In particular, we create an *test point* $\hat{x}$ for tuple $r(t)$ in a way similar to creating data points, i.e., we set the relation, tuple, and entity variables accordingly and add the aggregated, normalized context of t. Once test point $\hat{x}$ has been created, we can predict its score $s(\hat{x})$ using Eq. (1). We then rank each unobserved tuple by its so-obtained score, i.e., tuples with higher scores are ranked higher. The resulting ranking constitutes the list T_r of predicted facts for relation r.

Bayesian personalized ranking. The parameters of our model are given by $\Theta = \{\, b_v, \boldsymbol{f}_v \mid v \in V \,\}$. In approaches based on the closed-world assumption, Θ is estimated by minimizing the error between model predictions and target values (e.g., 1 for true facts, 0 for false facts). In our setting of open RE, all our observations are positive, i.e., we do not have negative training data. One way to handle the absence of negative training data is to associate a target value of 0 to all unobserved facts. This closed-world approach essentially assumes that all unobserved facts are false, which may not be a suitable assumption for the sparsely observed relations of open RE. Following Riedel et al. (2013), we adopt the open-world assumption instead, i.e., we treat each unobserved facts as unknown. Since factorization machines originally require explicit target values (e.g., feedback in recommender systems), we need to adapt parameter estimation to the open-world setting.

In more detail, we employ a variant of the Bayesian personalized ranking (BPR) optimization criterion (Rendle et al., 2009). We associate with each training point x a set of *negative samples* X_x^-. Each negative sample $x^- \in X_x^-$ is an unobserved fact with its associated context (constructed as described in the prediction section above). Generally, the negative samples x^- should be chosen such that they are "less likely" to be true than fact x. We maximize the following optimization criterion:

$$\frac{1}{|X|} \sum_{x \in X} \left(\sum_{x^- \in X_x^-} \frac{\ln \sigma(\delta(x, x^-))}{|X_x^-|} - \lambda \|\Theta_x\|^2 \right) \quad (2)$$

where $\sigma(x) = \frac{1}{1+e^{-x}}$ denotes the logistic function, $\delta(x, x^-) = s(x) - s(x^-)$ denotes the differ-

ence of scores, and $\Theta_x = \{ b_v, \boldsymbol{f}_v \mid x_v \neq 0 \}$ the subset of the model parameters relevant for training point x. Here we use L2 regularization controlled by a single hyperparameter λ. In essence, the BPR criterion aims to maximize the average "difference" $\ln \sigma(\delta(x, x^-))$ between the score of fact x and each of its negative samples x^-, averaged over all facts. In other words, we aim to score x higher than each x^-. (Note that under the closed-world assumption, we would instead consider x^- as being false.) For a more in-depth discussion of BPR, see (Rendle et al., 2009).

Sampling negative evidence. To make BPR effective, the set of negative samples needs to be chosen carefully. A naive approach is to take the set of all unobserved facts between each relation $r \in R$ and each tuple $t \in T$ (or $E \times E$) as the set X_x^-. The reasoning is that, after all, we expect "random" unobserved facts to be less likely to be true than observed facts. This naive approach is problematic, however, because the set of negative samples is independent of x and thus not sufficiently informative (i.e., it contains many irrelevant samples).

To overcome this problem, the negative sample set needs to be related to x in some way. Since we ultimately use our model to rank tuples for each relation individually, we consider as negative evidence for x only unobserved facts from the same relation (Riedel et al., 2013). In more detail, we (conceptually) build a negative sample set X_r^- for each relation $r \in R$. We include into X_r^- all facts $r(t)$—again, along with their context—such that $t \in T$ is an observed tuple but $r(t)$ is an unobserved fact. Thus the subject-object pair t of entities is not observed with relation r in the input data (but with some other relation). The set of negative samples associated with each training point x is defined by the relation r of the fact contained in x, that is $X_x^- = X_r^-$. Note that we do not actually construct the negative sample sets; see below.

Parameter estimation. We maximize Eq. (2) using stochastic gradient ascent. This allows us to avoid constructing the sets X_x^-, which are often infeasibly large, and worked well in our experiments. In particular, in each stochastic gradient step, we randomly sample a training point $x \in X$, and subsequently randomly sample a negative sample $x^- \in X_x^-$. This sampling procedure can be implemented very efficiently. We then perform the following ascent step with learning rate η:

$$\Theta \leftarrow \Theta + \eta \nabla_\Theta \left(\ln \sigma(d(x, x^-)) - \lambda \|\Theta_x\|^2 \right)$$

One can show that the stochastic gradient used in the formula above is an unbiased estimate of the gradient of Eq. (2). To speed up parameter estimation, we use a parallel lock-free version of stochastic gradient ascent as in Recht et al. (2011). This allows our model to handle (reasonably) large datasets.

	size	info
facts	453.9k	14.7k Freebase, 174.1k surface linked, 184.5k surface partially-linked, 80.6k surface non-linked.
relations	4.7k	94 Freebase, 4.6k surface.
tuples	178.5k	69.5k linked, 71.5k partially-linked, 37.5k non-linked.
entities	114.2k	36.8k linked, 77.4k non-linked.

Table 1: Dataset statistics.

4 Experiments

We conducted an experimental study on real-world data to compare our CORE model with other state-of-the-art approaches.[2] Our experimental study closely follows the one of Riedel et al. (2013).

4.1 Experimental Setup

Dataset. We made use of the dataset of Riedel et al. (2013), but extended it with contextual information. The dataset consisted of 2.5M surface facts extracted from the New York Times corpus (Sandhaus, 2008), as well as 16k facts from Freebase. Surface facts have been obtained by using a named-entity recognizer, which additionally labeled each named entity mention with its coarse-grained type (i.e., person, organization, location, miscellaneous). For each pair of entities found within a sentence, the shortest dependency path between these pairs was taken as surface relation. The entity mentions in each surface fact were linked to Freebase using a simple string matching

Table 2: True facts and $MAP^{100}_{\#}$ (in parentheses) in the top-100 evaluation-set tuples for Freebase relations. We consider as context the article metadata (m), the tuple types (t) and the bag-of-words (w). Best value per relation in bold (unique winner) or italic (multiple winners). Average weighs are # column values.

method. If no match was found, the entity mention was kept as is. There were around 2.2M tuples (distinct entity pairs) in this dataset, out of which 580k were fully linked to Freebase. For each of these tuples, the dataset additionally included all of the corresponding facts from Freebase. Using the metadata[3] of each New York Times article, we enriched each surface fact by the following contextual information: news desk (e.g., sports desk, foreign desk), descriptors (e.g., finances, elections), online section (e.g., sports, business), section (e.g., a, d), publication year, and bag-of-words of the sentence from which the surface fact has been extracted.

Training data. From the raw dataset described above, we filtered out all surface relations with less than 10 instances, and all tuples with less than two instances, as in Riedel et al. (2013). Tab. 1 summarizes statistics of the resulting dataset. Here we considered a fact or tuple as *linked* if both of its entities were linked to Freebase, as *partially-linked* if only one of its entities was linked, and as *non-linked* otherwise. In contrast to previous work (Riedel et al., 2013; Chang et al., 2014), we retain partially-linked and non-linked facts in our dataset.

[3]Further information can be found at `https://catalog.ldc.upenn.edu/LDC2008T19`.

Evaluation set. Open RE models produce predictions for all relations and all tuples. To keep the experimental study feasible and comparable to previous studies, we use the full training data but evaluate each model's predictions on only the subsample of 10k tuples ($\approx 6\%$ of all tuples) of Riedel et al. (2013). The subsample consisted of 20% linked, 40% partially-linked and 40% non-linked tuples. For each (surface) relation and method, we predicted the top-100 new facts (not in training) for the tuples in the subsample.

Considered methods. We compared various forms of our CORE model with PITF and the matrix factorization model NFE. Our study focused on these two factorization models because they outperformed other models (including non-factorization models) in previous studies (Riedel et al., 2013; Chang et al., 2014). All models were trained with the full training data described above.

PITF (Drumond et al., 2012). PITF is a recent tensor factorization method designed for within-KB reasoning. PITF is based on factorization machines so that we used our scalable CORE implementation for training the model.

NFE (Riedel et al., 2013). NFE is the full model proposed in the "universal schema" work of Riedel et al. (2013). It uses a linear combination of three component models: a neighborhood

Table 3: True facts and $\text{MAP}^{100}_{\#}$ (in parentheses) in the top-100 evaluation-set tuples for surface relations. We consider as context the article metadata (m), the tuple types (t) and the bag-of-words (w). Best value per relation in bold (unique winner) or italic (multiple winners). Average weighs are # column values.

model (N), a matrix factorization model (F), and an entity model (E). The F and E models together are similar (but not equal) to our CORE model without context. The NFE model outperformed tensor models (Chang et al., 2014) as well as clustering methods and distantly supervised methods in the experimental study of Riedel et al. (2013) for open RE tasks. We use the original source code of Riedel et al. (2013) for training.

CORE. We include multiple variants of our model in the experimental study, each differing by the amount of context being used. We consider as context the article metadata (m), the tuple types (t) and the bag-of-words (w). Each tuple type is a pair of subject-object types of (e.g. (person, location)). The basic CORE model uses relations, tuples and entities as variables. We additionally consider the CORE+t, CORE+w, CORE+mt, and CORE+mtw models, where the suffix indicates which contextual information has been included. The total number of variables in the resulting models varied between 300k (CORE) to 350k (CORE+mtw). We used a modified version of *libfm* for training.[4] Our version adds support for BPR and parallelizes the training algorithm.

Methodology. To evaluate the prediction performance of each method, we followed Riedel et al. (2013). We considered a collection of 19 Freebase relations (Tab. 2) and 10 surface relations (Tab. 3) and restrict predictions to tuples in the evaluation set.

Evaluation metrics. For each relation and method, we computed the top-100 evaluation set predictions and labeled them manually. We used as evaluation metrics the mean average precision defined as:

$$\text{MAP}^{100}_{\#} = \frac{\sum_{k=1}^{100} I_k \cdot P@k}{\min\{100, \#\}} \tag{3}$$

where indicator I_k takes value 1 if the k-th prediction is true and 0 otherwise, and $\#$ denotes the number of true tuples for the relation in the top-100 predictions of all models. The denominator is included to account for the fact that the evaluation set may include less than 100 true facts. $\text{MAP}^{100}_{\#}$ reflects how many true facts are found by each method as well as their ranking. If all $\#$ facts are found and ranked top, then $\text{MAP}^{100}_{\#} = 1$. Note that our definition of $\text{MAP}^{100}_{\#}$ differs slightly from Riedel et al. (2013); our metric is more robust because it is based on completely labeled evaluation data. To compare the prediction performance of each system across multiple relations, we averaged $\text{MAP}^{100}_{\#}$ values, in both an unweighted and a weighted (by $\#$) fashion.

Parameters. For all systems, we used $d = 100$ latent factors, $\lambda = 0.01$ for all variables, a constant learning rate of $\eta = 0.05$, and ran 1000 epochs of stochastic gradient ascent. These choices correspond to the ones of Riedel et al. (2013); no further tuning was performed.

4.2 Results.

Prediction performance. The results of our experimental study are summarized in Tab. 2 (Freebase relations) and Tab. 3 (surface relations). As mentioned before, all reported numbers are with respect to our evaluation set. Each entry shows the number of true facts in the top-100 predictions and, in parentheses, the $\text{MAP}^{100}_{\#}$ value. The # col-

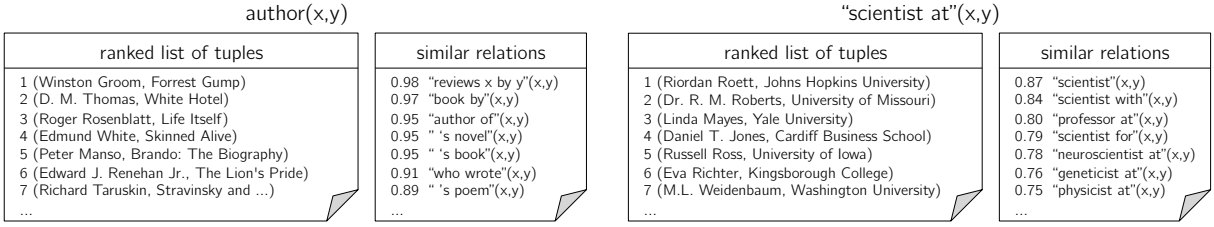

Figure 2: Some facts predicted by our model for the Freebase relation author(x,y) and the surface relation "scientist at"(x,y). Most similar relations also reported, using cosine similarity between the corresponding latent feature vectors as distance.

umn list the total number of true facts found by at least one method. The last two lines show the aggregated $\text{MAP}^{100}_{\#}$ scores.

We start our discussion with the results for Freebase relations (Tab. 2). First note that the PITF model generally did not perform well; as discussed before, tensor factorization models such as PITF suffer from a large prediction space and cannot incorporate tuple-level information. NFE and CORE, both matrix factorization models, performed better and were on par with each other. This indicates that our use of factorization machines does not affect performance in the absence of context; after all, both methods essentially make use of the same amount of information. The key advantage of our model over NFE is that we can incorporate contextual information. Our results indicate that using such information indeed improves prediction performance. The CORE+mtw model performed best overall; it increased the average $\text{MAP}^{100}_{\#}$ by four points (six points weighted) compared to the best context-unware model. Note that for some relations, including only subsets of the contextual information produced better results than using all contextual information (e.g., film/directed_by). We thus conjecture that extending our model by variable-specific regularization terms may be beneficial.

Tab. 3 summarizes our results for surface relations. In general, the relative performance of the models agreed with the one on Freebase relations. One difference is that using bag-of-word context significantly boosted prediction performance. One reason for this boost is that related surface relations often share semantically related words (e.g., "professor at" and "scientist at") and may occur in similar sentences (e.g., mentioning "university", "research", ...).

Anecdotal results. Fig. 2 shows the top test-set predictions of CORE+mtw for the author and "scientist at" relations. In both cases, we also list relations that have a similar semantic representation in our model (highest cosine similarity). Note that semantic similarity of relations is one aspect of our model; predictions incorporate other aspects such as context (i.e., two "similar" relations in different contexts are treated differently).

Training time. We used a machine with 16-cores Intel Xeon processor and 128GB of memory. Training CORE took roughly one hour, NFE roughly six hours (single core only), and training CORE+mtw took roughly 20 hours. Our implementation can handle reasonably large data, but an investigation of faster, more scalable training methods appears worthwhile.

5 Conclusion

We proposed CORE, a matrix factorization model for open RE that incorporates contextual information. Our model is based on factorization machines and the open-world assumption, integrates various forms of contextual information, and is extensible. Our experimental study suggests that exploiting context can significantly improve prediction performance.

Abstract

Compositional embedding models build a representation (or embedding) for a linguistic structure based on its component word embeddings. We propose a Feature-rich Compositional Embedding Model (FCM) for relation extraction that is expressive, generalizes to new domains, and is easy-to-implement. The key idea is to combine both (unlexicalized) hand-crafted features with learned word embeddings. The model is able to directly tackle the difficulties met by traditional compositional embeddings models, such as handling arbitrary types of sentence annotations and utilizing global information for composition. We test the proposed model on two relation extraction tasks, and demonstrate that our model outperforms both previous compositional models and traditional feature rich models on the ACE 2005 relation extraction task, and the SemEval 2010 relation classification task. The combination of our model and a log-linear classifier with hand-crafted features gives state-of-the-art results. We made our implementation available for general use[1].

1 Introduction

Two common NLP feature types are lexical properties of words and unlexicalized linguistic/structural interactions between words. Prior work on relation extraction has extensively studied how to design such features by combining *discrete* lexical properties (e.g. the identity of a word, its lemma, its morphological features) with aspects of a word's linguistic context (e.g. whether it lies between two entities or on a dependency path between them). While these help learning, they make generalization to unseen words difficult. An alternative approach to capturing lexical information relies on *continuous* word embeddings[2] as representative of words but generalizable to new words. Embedding features have improved many tasks, including NER, chunking, dependency parsing, semantic role labeling, and relation extraction (Miller et al., 2004; Turian et al., 2010; Koo et al., 2008; Roth and Woodsend, 2014; Sun et al., 2011; Plank and Moschitti, 2013; Nguyen and Grishman, 2014). Embeddings can capture lexical information, but alone they are insufficient: in state-of-the-art systems, they are used alongside features of the broader linguistic context.

In this paper, we introduce a compositional model that combines unlexicalized linguistic context and word embeddings for relation extraction, a task in which contextual feature construction plays a major role in generalizing to unseen data. Our model allows for the composition of embeddings with arbitrary linguistic structure, as expressed by hand crafted features. In the following sections, we begin with a precise construction of compositional embeddings using word embeddings in conjunction with unlexicalized features. Various feature sets used in prior work (Turian et al., 2010; Nguyen and Grishman, 2014; Hermann et al., 2014; Roth and Woodsend, 2014) are cap-

*Gormley and Yu contributed equally.
[1]https://github.com/mgormley/pacaya

[2]Such embeddings have a long history in NLP, including term-document frequency matrices and their low-dimensional counterparts obtained by linear algebra tools (LSA, PCA, CCA, NNMF), Brown clusters, random projections and vector space models. Recently, neural networks / deep learning have provided several popular methods for obtaining such embeddings.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1774–1784,
Lisbon, Portugal, 17-21 September 2015.

Class	M_1	M_2	Sentence Snippet
(1) ART(M_1,M_2)	a man	a taxicab	*A man driving what appeared to be a taxicab*
(2) PART-WHOLE(M_1,M_2)	the southern suburbs	Baghdad	*direction of the southern suburbs of Baghdad*
(3) PHYSICAL(M_2,M_1)	the united states	284 people	*in the united states , 284 people died*

Table 1: Examples from ACE 2005. In (1) the word "driving" is a strong indicator of the relation *ART*[3] between M_1 and M_2. A feature that depends on the embedding for this context word could generalize to other lexical indicators of the same relation (e.g. "operating") that don't appear with *ART* during training. But lexical information alone is insufficient; relation extraction requires the identification of lexical roles: *where* a word appears structurally in the sentence. In (2), the word "of" between "suburbs" and "Baghdad" suggests that the first entity is part of the second, yet the earlier occurrence after "direction" is of no significance to the relation. Even finer information can be expressed by a word's role on the dependency path between entities. In (3) we can distinguish the word "died" from other irrelevant words that don't appear between the entities.

tured as special cases of this construction. Adding these compositional embeddings directly to a standard log-linear model yields a special case of our full model. We then treat the word embeddings as parameters giving rise to our powerful, efficient, and easy-to-implement *log-bilinear model*. The model capitalizes on arbitrary types of linguistic annotations by better utilizing features associated with substructures of those annotations, including global information. We choose features to promote different properties and to distinguish different functions of the input words.

The full model involves three stages. First, it decomposes the annotated sentence into substructures (i.e. a word and associated annotations). Second, it extracts features for each substructure (word), and combines them with the word's embedding to form a *substructure embedding*. Third, we sum over substructure embeddings to form a composed *annotated sentence embedding*, which is used by a final softmax layer to predict the output label (relation).

The result is a state-of-the-art relation extractor for unseen domains from ACE 2005 (Walker et al., 2006) and the relation classification dataset from SemEval-2010 Task 8 (Hendrickx et al., 2010).

Contributions This paper makes several contributions, including:

1. We introduce the FCM, a new compositional embedding model for relation extraction.
2. We obtain the best reported results on ACE-2005 for coarse-grained relation extraction in the cross-domain setting, by combining FCM with a log-linear model.
3. We obtain results on on SemEval-2010 Task 8 competitive with the best reported results.

Note that other work has already been published that builds on the FCM, such as Hashimoto et al. (2015), Nguyen and Grishman (2015), dos Santos et al. (2015), Yu and Dredze (2015) and Yu et al. (2015). Additionally, we have extended FCM to incorporate a low-rank embedding of the features (Yu et al., 2015), which focuses on fine-grained relation extraction for ACE and ERE. This paper obtains better results than the low-rank extension on ACE coarse-grained relation extraction.

[3]In ACE 2005, *ART* refers to a relation between a person and an artifact; such as a user, owner, inventor, or manufacturer relationship

2 Relation Extraction

In relation extraction we are given a sentence as input with the goal of identifying, for all pairs of entity mentions, what relation exists between them, if any. For each pair of entity mentions in a sentence S, we construct an instance $(y, \mathbf{x})$, where $\mathbf{x} = (M_1, M_2, S, A)$. $S = \{w_1, w_2, ..., w_n\}$ is a sentence of length n that expresses a relation of type y between two entity mentions M_1 and M_2, where M_1 and M_2 are sequences of words in S. A is the associated annotations of sentence S, such as part-of-speech tags, a dependency parse, and named entities. We consider directed relations: for a relation type Rel, $y{=}Rel(M_1, M_2)$ and $y'{=}Rel(M_2, M_1)$ are different relations. Table 1 shows ACE 2005 relations, and has a strong label bias towards negative examples. We also consider the task of relation *classification* (SemEval), where the number of negative examples is artificially reduced.

Embedding Models Word embeddings and compositional embedding models have been successfully applied to a range of NLP tasks, however the applications of these embedding models to relation extraction are still limited. Prior work on relation classification (e.g. SemEval 2010 Task 8) has focused on short sentences with at most one relation per sentence (Socher et al., 2012; Zeng et al., 2014). For relation extraction, where negative examples abound, prior work has assumed that only the named entity boundaries and not their types were available (Plank and Moschitti, 2013; Nguyen et al., 2015). Other work has as-

sumed that the order of two entities in a relation are given while the relation type itself is unknown (Nguyen and Grishman, 2014; Nguyen and Grishman, 2015). The standard relation extraction task, as adopted by ACE 2005 (Walker et al., 2006), uses long sentences containing multiple named entities with known types[4] and unknown relation directions. We are the first to apply neural language model embeddings to this task.

Motivation and Examples Whether a word is indicative of a relation depends on multiple properties, which may relate to its context within the sentence. For example, whether the word is in-between the entities, on the dependency path between them, or to their left or right may provide additional complementary information. Illustrative examples are given in Table 1 and provide the motivation for our model. In the next section, we will show how we develop informative representations capturing both the semantic information in word embeddings and the contextual information expressing a word's role relative to the entity mentions. We are the first to incorporate all of this information at once. The closest work is that of Nguyen and Grishman (2014), who use a log-linear model for relation extraction with embeddings as features for only the entity heads. Such embedding features are insensitive to the broader contextual information and, as we show, are not sufficient to elicit the word's role in a relation.

3 A Feature-rich Compositional Embedding Model for Relations

We propose a general framework to construct an embedding of a sentence with annotations on its component words. While we focus on the relation extraction task, the framework applies to any task that benefits from both embeddings and typical hand-engineered lexical features.

3.1 Combining Features with Embeddings

We begin by describing a precise method for constructing substructure embeddings and annotated sentence embeddings from existing (usually unlexicalized) features and embeddings. Note that these embeddings can be included directly in a log-linear model as features—doing so results in a special case of our full model presented in the next subsection.

An annotated sentence is first decomposed into substructures. The type of substructures can vary by task; for relation extraction we consider one substructure per word[5]. For each substructure in the sentence we have a hand-crafted feature vector f_{w_i} and a dense embedding vector e_{w_i}. We represent each substructure as the outer product $\otimes$ between these two vectors to produce a matrix, herein called a **substructure embedding**: $h_{w_i} = f_{w_i} \otimes e_{w_i}$. The features f_{w_i} are based on the local context in S and annotations in A, which can include global information about the annotated sentence. These features allow the model to promote different properties and to distinguish different functions of the words. Feature engineering can be task specific, as relevant annotations can change with regards to each task. In this work we utilize unlexicalized binary features common in relation extraction. Figure 1 depicts the construction of a sentence's substructure embeddings.

We further sum over the substructure embeddings to form an **annotated sentence embedding**:

$$e_x = \sum_{i=1}^{n} f_{w_i} \otimes e_{w_i} \quad (1)$$

When both the hand-crafted features and word embeddings are treated as inputs, as has previously been the case in relation extraction, this annotated sentence embedding can be used directly as the features of a log-linear model. In fact, we find that the feature sets used in prior work for many other NLP tasks are special cases of this simple construction (Turian et al., 2010; Nguyen and Grishman, 2014; Hermann et al., 2014; Roth and Woodsend, 2014). This highlights an important connection: when the word embeddings are constant, our constructions of substructure and annotated sentence embeddings are just specific forms of polynomial (specifically quadratic) feature combination—hence their commonality in the literature. Our experimental results suggest that such a construction is more powerful than directly including embeddings into the model.

3.2 The Log-Bilinear Model

Our full log-bilinear model first forms the substructure and annotated sentence embeddings from

[4] Since the focus of this paper is relation extraction, we adopt the evaluation setting of prior work which uses gold named entities to better facilitate comparison.

[5] We use words as substructures for relation extraction, but use the general terminology to maintain model generality.

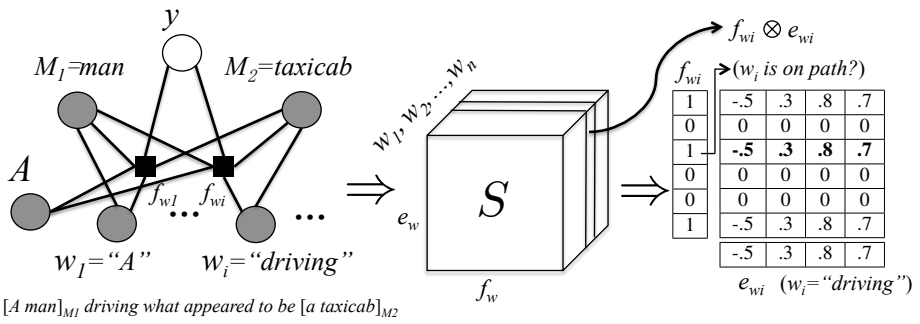

Figure 1: Example construction of substructure embeddings. Each substructure is a word w_i in S, augmented by the target entity information and related information from annotation A (e.g. a dependency tree). We show the factorization of the annotated sentence into substructures (left), the concatenation of the substructure embeddings for the sentence (middle), and a single substructure embedding from that concatenation (right). The annotated sentence embedding (not shown) would be the sum of the substructure embeddings, as opposed to their concatenation.

the previous subsection. The model uses its parameters to score the annotated sentence embedding and uses a softmax to produce an output label. We call the entire model the **Feature-rich Compositional Embedding Model (FCM)**.

Our task is to determine the label y (relation) given the instance $\mathbf{x} = (M_1, M_2, S, A)$. We formulate this as a probability.

$$P(y|\mathbf{x}; T, \mathbf{e}) = \frac{\exp\left(\sum_{i=1}^{n} T_y \odot (f_{w_i} \otimes e_{w_i})\right)}{Z(\mathbf{x})} \quad (2)$$

where $\odot$ is the 'matrix dot product' or Frobenious inner product of the two matrices. The normalizing constant which sums over all possible output labels $y' \in L$ is given by $Z(\mathbf{x}) = \sum_{y' \in L} \exp\left(\sum_{i=1}^{n} T_{y'} \odot (f_{w_i} \otimes e_{w_i})\right)$. The parameters of the model are the word embeddings $\mathbf{e}$ for each word type and a list of weight matrix $T = [T_y]_{y \in L}$ which is used to score each label y. The model is log-bilinear [6] (i.e. log-quadratic) since we recover a log-*linear* model by fixing either $\mathbf{e}$ or T. We study both the full log-bilinear and the log-linear model obtained by fixing the word embeddings.

3.3 Discussion of the Model

Substructure Embeddings Similar words (i.e. those with similar embeddings) with similar functions in the sentence (i.e. those with similar features) will have similar matrix representations. To understand our selection of the outer product, consider the example in Fig. 1. The word "driving" can indicate the *ART* relation if it appears on the dependency path between M_1 and M_2. Suppose the third feature in f_{w_i} indicates this `on-path` feature. Our model can now learn parameters which give the third row a high weight for the *ART* label. Other words with embeddings similar to "driving" that appear on the dependency path between the mentions will similarly receive high weight for the *ART* label. On the other hand, if the embedding is similar but is not on the dependency path, it will have 0 weight. Thus, our model generalizes its model parameters across words with similar embeddings only when they share similar functions in the sentence.

Smoothed Lexical Features Another intuition about the selection of outer product is that it is actually a smoothed version of traditional lexical features used in classical NLP systems. Consider a lexical feature $f = u \wedge w$, which is a conjunction (logic-and) between non-lexical property u and lexical part (word) w. If we represent w as a one-hot vector, then the outer product exactly recovers the original feature f. Then if we replace the one-hot representation with its word embedding, we get the current form of our FCM. Therefore, our model can be viewed as a smoothed version of lexical features, which keeps the expressive strength, and uses embeddings to generalize to low frequency features.

Time Complexity Inference in FCM is much faster than both CNNs (Collobert et al., 2011) and RNNs (Socher et al., 2013b; Bordes et al., 2012). FCM requires $O(snd)$ products on average with sparse features, where s is the average number of per-word non-zero feature values, n is the length of the sentence, and d is the dimension of word embedding. In contrast, CNNs and RNNs usually

[6] Other popular log-bilinear models are the log-bilinear language models (Mnih and Hinton, 2007; Mikolov et al., 2013).

have complexity $O(C \cdot nd^2)$, where C is a model dependent constant.

4 Hybrid Model

We present a hybrid model which combines the FCM with an existing log-linear model. We do so by defining a new model:

$$p_{\text{FCM+loglin}}(y|x) = \frac{1}{Z} p_{\text{FCM}}(y|x) p_{\text{loglin}}(y|x) \quad (3)$$

The log-linear model has the usual form: $p_{\text{loglin}}(y|x) \propto \exp(\boldsymbol{\theta} \cdot \boldsymbol{f}(x, y))$, where $\boldsymbol{\theta}$ are the model parameters and $\boldsymbol{f}(x, y)$ is a vector of features. The integration treats each model as a providing a score which we multiply together. The constant Z ensures a normalized distribution.

5 Training

FCM training optimizes a cross-entropy objective:

$$\ell(D; T, \mathbf{e}) = \sum_{(\mathbf{x}, y) \in D} \log P(y|\mathbf{x}; T, \mathbf{e})$$

where D is the set of all training data and $\mathbf{e}$ is the set of word embeddings. To optimize the objective, for each instance $(y, \mathbf{x})$ we perform stochastic training on the loss function $\ell = \ell(y, \mathbf{x}; T, \mathbf{e}) = \log P(y|\mathbf{x}; T, \mathbf{e})$. The gradients of the model parameters are obtained by backpropagation (i.e. repeated application of the chain rule). We define the vector $\mathbf{s} = [\sum_i T_y \odot (f_{w_i} \otimes e_{w_i})]_{1 \le y \le L}$, which yields

$$\frac{\partial \ell}{\partial \mathbf{s}} = \left[\left(I[y' = y] - P(y'|\mathbf{x}; T, \mathbf{e}) \right)_{1 \le y \le L} \right]^T,$$

where the indicator function $I[x]$ equals 1 if x is true and 0 otherwise. We have the following gradients: $\frac{\partial \ell}{\partial T} = \frac{\partial \ell}{\partial \mathbf{s}} \otimes \sum_{i=1}^{n} f_{w_i} \otimes e_{w_i}$, which is equivalent to:

$$\frac{\partial \ell}{\partial T_{y'}} = \left(I[y = y'] - P(y'|\mathbf{x}; T, \mathbf{e}) \right) \cdot \sum_{i=1}^{n} f_{w_i} \otimes e_{w_i}.$$

When we treat the word embeddings as parameters (i.e. the log-bilinear model), we also fine-tune the word embeddings with the FCM model:

$$\frac{\partial \ell}{\partial e_w} = \sum_{i=1}^{n} \left(\left(\sum_y \frac{\partial \ell}{\partial \mathbf{s}_y} T_y \right) \cdot f_i \right) \cdot I[w_i = w].$$

As is common in deep learning, we initialize these embeddings from an neural language model and then *fine-tune* them for our supervised task. The training process for the hybrid model (§ 4) is also easily done by backpropagation since each sub-model has separate parameters.

Set	Template
`HeadEmb`	$\{I[i = h_1], I[i = h_2]\}$ (w_i is head of M_1/M_2) $\times \{\phi, t_{h_1}, t_{h_2}, t_{h_1} \oplus t_{h_2}\}$
`Context`	$I[i = h_1 \pm 1]$ (left/right token of w_{h_1}) $I[i = h_2 \pm 1]$ (left/right token of w_{h_2})
`In-between`	$I[i > h_1] \& I[i < h_2]$ (in between) $\times \{\phi, t_{h_1}, t_{h_2}, t_{h_1} \oplus t_{h_2}\}$
`On-path`	$I[w_i \in P]$ (on path) $\times \{\phi, t_{h_1}, t_{h_2}, t_{h_1} \oplus t_{h_2}\}$

Table 2: Feature sets used in FCM.

6 Experimental Settings

Features Our FCM features (Table 2) use a feature vector f_{w_i} over the word w_i, the two target entities M_1, M_2, and their dependency path. Here h_1, h_2 are the indices of the two head words of M_1, M_2, $\times$ refers to the Cartesian product between two sets, t_{h_1} and t_{h_2} are entity types (named entity tags for ACE 2005 or WordNet supertags for SemEval 2010) of the head words of two entities, and ϕ stands for the empty feature. $\oplus$ refers to the conjunction of two elements. The `In-between` features indicate whether a word w_i is in between two target entities, and the `On-path` features indicate whether the word is on the dependency path, on which there is a set of words P, between the two entities.

We also use the target entity type as a feature. Combining this with the basic features results in more powerful compound features, which can help us better distinguish the functions of word embeddings for predicting certain relations. For example, if we have a person and a vehicle, we know it will be more likely that they have an *ART* relation. For the *ART* relation, we introduce a corresponding weight vector, which is closer to lexical embeddings similar to the embedding of "drive".

All linguistic annotations needed for features (POS, chunks[7], parses) are from Stanford CoreNLP (Manning et al., 2014). Since SemEval does not have gold entity types we obtained WordNet and named entity tags using Ciaramita and Altun (2006). For all experiments we use 200-d word embeddings trained on the NYT portion of the Gigaword 5.0 corpus (Parker et al., 2011), with word2vec (Mikolov et al., 2013). We use the CBOW model with negative sampling (15 negative words). We set a window size c=5, and remove types occurring less than 5 times.

Models We consider several methods. (1) FCM in isolation without fine-tuning. (2) FCM in isolation with fine-tuning (i.e. trained as a log-bilinear

[7] Obtained from the constituency parse using the CONLL 2000 chunking converter (Perl script).

model). (3) A log-linear model with a rich binary feature set from Sun et al. (2011) (Baseline)—this consists of all the baseline features of Zhou et al. (2005) plus several additional carefully-chosen features that have been highly tuned for ACE-style relation extraction over years of research. We exclude the Country gazetteer and WordNet features from Zhou et al. (2005). The two remaining methods are hybrid models that integrate FCM as a submodel within the log-linear model (§ 4). We consider two combinations. (4) The feature set of Nguyen and Grishman (2014) obtained by using the embeddings of heads of two entity mentions (+HeadOnly). (5) Our full FCM model (+FCM). All models use L2 regularization tuned on dev data.

6.1 Datasets and Evaluation

ACE 2005 We evaluate our relation extraction system on the English portion of the ACE 2005 corpus (Walker et al., 2006).[8] There are 6 domains: Newswire (`nw`), Broadcast Conversation (`bc`), Broadcast News (`bn`), Telephone Speech (`cts`), Usenet Newsgroups (`un`), and Weblogs (`wl`). Following prior work we focus on the domain adaptation setting, where we train on one set (the union of the news domains (`bn+nw`), tune hyperparameters on a dev domain (half of `bc`) and evaluate on the remainder (`cts`, `wl`, and the remainder of `bc`) (Plank and Moschitti, 2013; Nguyen and Grishman, 2014). We assume that gold entity spans *and* types are available for train and test. We use all pairs of entity mentions to yield 43,518 total relations in the training set. We report precision, recall, and F1 for relation extraction. While it is not our focus, for completeness we include results with unknown entity types following Plank and Moschitti (2013) (Appendix 1).

SemEval 2010 Task 8 We evaluate on the SemEval 2010 Task 8 dataset[9] (Hendrickx et al., 2010) to compare with other compositional models and highlight the advantages of FCM. This task is to determine the relation type (or no relation) between two entities in a sentence. We adopt the setting of Socher et al. (2012). We use 10-fold cross validation on the training data to select hyperparameters and do regularization by early stopping. The learning rates for FCM with/without fine-tuning are 5e-3 and 5e-2 respectively. We report macro-F1 and compare to previously published results.

[8] Many relation extraction systems evaluate on the ACE 2004 corpus (Mitchell et al., 2005). Unfortunately, the most common convention is to use 5-fold cross validation, treating the entirety of the dataset as both train *and* evaluation data. Rather than continuing to overfit this data by perpetuating the cross-validation convention, we instead focus on ACE 2005.

7 Results

ACE 2005 Despite FCM's (1) simple feature set, it is competitive with the log-linear baseline (3) on out-of-domain test sets (Table 3). In the typical gold entity spans and types setting, both Plank and Moschitti (2013) and Nguyen and Grishman (2014) found that they were unable to obtain improvements by adding embeddings to baseline feature sets. By contrast, we find that on all domains the combination baseline + FCM (5) obtains the highest F1 and significantly outperforms the other baselines, *yielding the best reported results for this task.* We found that fine-tuning of embeddings (2) did not yield improvements on our out-of-domain development set, in contrast to our results below for SemEval. We suspect this is because fine-tuning allows the model to overfit the training domain, which then hurts performance on the unseen ACE test domains. Accordingly, Table 3 shows only the log-linear model.

Finally, we highlight an important contrast between FCM (1) and the log-linear model (3): the latter uses over 50 feature templates based on a POS tagger, dependency parser, chunker, and constituency parser. FCM uses only a dependency parse but still obtains better results (Avg. F1).

SemEval 2010 Task 8 Table 4 shows FCM compared to the best reported results from the SemEval-2010 Task 8 shared task and several other compositional models.

For the FCM we considered two feature sets. We found that using NE tags instead of WordNet tags helps with fine-tuning but hurts without. This may be because the set of WordNet tags is larger making the model more expressive, but also introduces more parameters. When the embeddings are fixed, they can help to better distinguish different functions of embeddings. But when fine-tuning, it becomes easier to over-fit. Alleviating over-fitting is a subject for future work (§ 9).

With either WordNet or NER features, FCM achieves better performance than the RNN and MVRNN. With NER features and fine-tuning, it outperforms a CNN (Zeng et al., 2014) and also

Table 4: Comparison of FCM with previously published results for SemEval 2010 Task 8.

the combination of an embedding model and a traditional log-linear model (RNN/MVRNN + linear) (Socher et al., 2012). As with ACE, FCM uses less linguistic resources than many close competitors (Rink and Harabagiu, 2010).

We also compared to concurrent work on enhancing the compositional models with task-specific information for relation classification, including Hashimoto et al. (2015) (RelEmb), which trained task-specific word embeddings, and dos Santos et al. (2015) (CR-CNN), which proposed a task-specific ranking-based loss function. Our Hybrid methods (FCM + linear) get comparable results to theirs. Note that their base compositional model results without any task-specific enhancements, i.e. RelEmb with word2vec embeddings and CR-CNN with log-loss, are still lower than the best FCM result. We believe that FCM can be also improved with these task-specific enhancements, e.g. replacing the word embeddings to the task-specific ones from (Hashimoto et al., 2015) increases the result to 83.7% (see §7.2 for details). We leave the application of ranking-based loss to future work.

Finally, a concurrent work (Liu et al., 2015) proposes DepNN, which builds representations for the dependency path (and its attached subtrees) between two entities by applying recursive and convolutional neural networks successively. Compared to their model, our FCM achieves comparable results. Of note, our FCM and the RelEmb are also the most efficient models among all above compositional models since they have linear time complexity with respect to the dimension of embeddings.

7.1 Effects of the embedding sub-models

We next investigate the effects of different types of features on FCM using ablation tests on ACE 2005 (Table 5.) We focus on FCM alone with the feature templates of Table 2. Additionally, we show results of using *only* the head embedding features from Nguyen and Grishman (2014) (HeadOnly). Not surprisingly, the HeadOnly model performs poorly (F1 score = 14.30%), showing the importance of our rich binary feature set. Among all the features templates, removing `HeadEmb` results in the largest degradation. The second most im-

Feature Set	Prec	Rec	F1
HeadOnly	31.67	9.24	14.30
FCM	69.17	**56.73**	**62.33**
-HeadEmb	66.06	47.00	54.92

-On-path	69.23	53.97	60.66
FCM-EntityTypes	**71.33**	34.68	46.67

Table 5: Ablation test of FCM on development set.

portant feature template is In-between, while Context features have little impact. Removing all entity type features (t_{h_i}) does significantly worse than the full model, showing the value of our entity type features.

7.2 Effects of the word embeddings

Good word embeddings are critical for both FCM and other compositional models. In this section, we show the results of FCM with embeddings used to initialize other recent state-of-the-art models. Those embeddings include the 300-d baseline embeddings trained on English Wikipedia (w2v-enwiki-d300) and the 100-d task-specific embeddings (task-specific-d100)[10] from the RelEmb paper (Hashimoto et al., 2015), the 400-d embeddings from the CR-CNN paper (dos Santos et al., 2015). Moreover, we list the best result (DepNN) in Liu et al. (2015), which uses the same embeddings as ours. Table 6 shows the effects of word embeddings on FCM and provides relative comparisons between FCM and the other state-of-the-art models. We use the same hyperparameters and number of iterations in Table 4.

The results show that using different embeddings to initialize FCM can improve F1 beyond our previous results. We also find that increasing the dimension of the word embeddings does not necessarily lead to better results due to the problem of over-fitting (e.g.w2v-enwiki-d400 vs. w2v-enwiki-d300). With the same initial embeddings, FCM usually gets better results without any changes to the hyperparameters than the competing model, further confirming the advantage of FCM at the model-level as discussed under Table 4. The only exception is the DepNN model, which gets better result than FCM on the same embeddings. The task-specific embeddings from (Hashimoto et al., 2015) leads to the best performance (an improvement of 0.7%). This observation suggests that the other compositional models may also benefit from the work of Hashimoto et al. (2015).

[10]In the task-specific setting, FCM will represent entity words and context words with separate sets of embeddings.

8 Related Work

Compositional Models for Sentences In order to build a representation (embedding) for a sentence based on its component word embeddings and structural information, recent work on compositional models (stemming from the deep learning community) has designed model structures that mimic the structure of the input. For example, these models could take into account the order of the words (as in Convolutional Neural Networks (CNNs)) (Collobert et al., 2011) or build off of an input tree (as in Recursive Neural Networks (RNNs) or the Semantic Matching Energy Function) (Socher et al., 2013b; Bordes et al., 2012).

While these models work well on sentence-level representations, the nature of their designs also limits them to fixed types of substructures from the annotated sentence, such as chains for CNNs and trees for RNNs. Such models cannot capture arbitrary combinations of linguistic annotations available for a given task, such as word order, dependency tree, and named entities used for relation extraction. Moreover, these approaches ignore the differences in functions between words appearing in different roles. This does not suit more general substructure labeling tasks in NLP, e.g. these models cannot be directly applied to relation extraction since they will output the same result for any pair of entities in a same sentence.

Compositional Models with Annotation Features To tackle the problem of traditional compositional models, Socher et al. (2012) made the RNN model specific to relation extraction tasks by working on the minimal sub-tree which spans the two target entities. However, these specializations

to relation extraction does not generalize easily to other tasks in NLP. There are two ways to achieve such specialization in a more general fashion:

1. Enhancing Compositional Models with Features. A recent trend enhances compositional models with annotation features. Such an approach has been shown to significantly improve over pure compositional models. For example, Hermann et al. (2014) and Nguyen and Grishman (2014) gave different weights to words with different syntactic context types or to entity head words with different argument IDs. Zeng et al. (2014) use concatenations of embeddings as features in a CNN model, according to their positions relative to the target entity mentions. Belinkov et al. (2014) enrich embeddings with linguistic features before feeding them forward to a RNN model. Socher et al. (2013a) and Hermann and Blunsom (2013) enhanced RNN models by refining the transformation matrices with phrase types and CCG super tags.

2. Engineering of Embedding Features. A different approach to combining traditional linguistic features and embeddings is hand-engineering features with word embeddings and adding them to log-linear models. Such approaches have achieved state-of-the-art results in many tasks including NER, chunking, dependency parsing, semantic role labeling, and relation extraction (Miller et al., 2004; Turian et al., 2010; Koo et al., 2008; Roth and Woodsend, 2014; Sun et al., 2011; Plank and Moschitti, 2013). Roth and Woodsend (2014) considered features similar to ours for semantic role labeling.

However, in prior work both of above approaches are only able to utilize limited information, usually one property for each word. Yet there may be different useful properties of a word which can contribute to the performances of the task. By contrast, our FCM can easily utilize these features without changing the model structures.

In order to better utilize the dependency annotations, recently work built their models according to the dependency paths (Ma et al., 2015; Liu et al., 2015), which share similar motivations to the usage of `On-path` features in our work.

Task-Specific Enhancements for Relation Classification An orthogonal direction of improving compositional models for relation classification is to enhance the models with task-specific information. For example, Hashimoto et al. (2015) trained task-specific word embeddings, and dos Santos et al. (2015) proposed a ranking-based loss function for relation classification.

9 Conclusion

We have presented FCM, a new compositional model for deriving sentence-level and substructure embeddings from word embeddings. Compared to existing compositional models, FCM can easily handle arbitrary types of input and handle global information for composition, while remaining easy to implement. We have demonstrated that FCM alone attains near state-of-the-art performances on several relation extraction tasks, and in combination with traditional feature based log-linear models it obtains state-of-the-art results.

Our next steps in improving FCM focus on enhancements based on task-specific embeddings or loss functions as in Hashimoto et al. (2015; dos Santos et al. (2015). Moreover, as the model provides a general idea for representing both sentences and sub-structures in language, it has the potential to contribute useful components to various tasks, such as dependency parsing, SRL and paraphrasing. Also as kindly pointed out by one anonymous reviewer, our FCM can be applied to the TAC-KBP (Ji et al., 2010) tasks, by replacing the training objective to a multi-instance multi-label one (e.g. Surdeanu et al. (2012)). We plan to explore the above applications of FCM in the future.

Acknowledgments

We thank the anonymous reviewers for their comments, and Nicholas Andrews, Francis Ferraro, and Benjamin Van Durme for their input. We thank Kazuma Hashimoto, Cícero Nogueira dos Santos, Bing Xiang and Bowen Zhou for sharing their word embeddings and many helpful discussions. Abstract

Relation classification is an important research arena in the field of natural language processing (NLP). In this paper, we present SDP-LSTM, a novel neural network to classify the relation of two entities in a sentence. Our neural architecture leverages the shortest dependency path (SDP) between two entities; multichannel recurrent neural networks, with long short term memory (LSTM) units, pick up heterogeneous information along the SDP. Our proposed model has several distinct features: (1) The shortest dependency paths retain most relevant information (to relation classification), while eliminating irrelevant words in the sentence. (2) The multichannel LSTM networks allow effective information integration from heterogeneous sources over the dependency paths. (3) A customized dropout strategy regularizes the neural network to alleviate overfitting. We test our model on the SemEval 2010 relation classification task, and achieve an F_1-score of 83.7%, higher than competing methods in the literature.

1 Introduction

Relation classification is an important NLP task. It plays a key role in various scenarios, e.g., information extraction (Wu and Weld, 2010), question answering (Yao and Van Durme, 2014), medical informatics (Wang and Fan, 2014), ontology learning (Xu et al., 2014), etc. The aim of relation classification is to categorize into predefined classes the relations between pairs of marked entities in given texts. For instance, in the sentence "A trillion gallons of [water]$_{e_1}$ have been poured into an empty [region]$_{e_2}$ of outer space," the entities *water* and *region* are of relation `Entity-Destination`(e_1, e_2).

Traditional relation classification approaches rely largely on feature representation (Kambhatla, 2004), or kernel design (Zelenko et al., 2003; Bunescu and Mooney, 2005). The former method usually incorporates a large set of features; it is difficult to improve the model performance if the feature set is not very well chosen. The latter approach, on the other hand, depends largely on the designed kernel, which summarizes all data information. Deep neural networks, emerging recently, provide a way of highly automatic feature learning (Bengio et al., 2013), and have exhibited considerable potential (Zeng et al., 2014; dos Santos et al., 2015). However, human engineering—that is, incorporating human knowledge to the network's architecture—is still important and beneficial.

This paper proposes a new neural network, SDP-LSTM, for relation classification. Our model utilizes the shortest dependency path (SDP) between two entities in a sentence; we also design a long short term memory (LSTM)-based recurrent neural network for information processing. The neural architecture is mainly inspired by the following observations.

- Shortest dependency paths are informative (Fundel et al., 2007; Chen et al., 2014). To determine the two entities' relation, we find it mostly sufficient to use only the words along the SDP: they concentrate on most relevant information while diminishing less relevant noise. Figure 1 depicts the dependency parse tree of the aforementioned sentence. Words along the SDP form a trimmed phrase (*gallons of water poured into region*) of the original sentence, which conveys much information about the target relation. Other words, such as *a*, *trillion*, *outer space*, are less informative and may bring noise if not dealt with properly.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1785–1794,
Lisbon, Portugal, 17-21 September 2015.

- Direction matters. Dependency trees are a kind of directed graph. The dependency relation between *into* and *region* is `PREP`; such relation hardly makes any sense if the directed edge is reversed. Moreover, the entities' relation distinguishes its directionality, that is, $r(a, b)$ differs from $r(b, a)$, for a same given relation r and two entities a, b. Therefore, we think it necessary to let the neural model process information in a direction-sensitive manner. Out of this consideration, we separate an SDP into two sub-paths, each from an entity to the common ancestor node. The extracted features along the two sub-paths are concatenated to make final classification.

- Linguistic information helps. For example, with prior knowledge of hyponymy, we know "water is a kind of substance." This is a hint that the entities, *water* and *region*, are more of `Entity-Destination` relation than, say, `Communication-Topic`. To gather heterogeneous information along SDP, we design a multichannel recurrent neural network. It makes use of information from various sources, including words themselves, POS tags, WordNet hypernyms, and the grammatical relations between governing words and their children.

For effective information propagation and integration, our model leverages LSTM units during recurrent propagation. We also customize a new dropout strategy for our SDP-LSTM network to alleviate the problem of overfitting. To the best of our knowledge, we are the first to use LSTM-based recurrent neural networks for the relation classification task.

We evaluate our proposed method on the SemEval 2010 relation classification task, and achieve an F_1-score of 83.7%, higher than competing methods in the literature.

In the rest of this paper, we review related work in Section 2. In Section 3, we describe our SDP-LSTM model in detail. Section 4 presents quantitative experimental results. Finally, we have our conclusion in Section 5.

2 Related Work

Relation classification is a widely studied task in the NLP community. Various existing methods mainly fall into three classes: feature-based, kernel-based, and neural network-based.

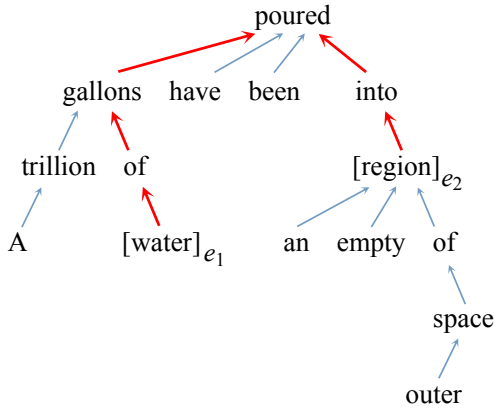

Figure 1: The dependency parse tree corresponding to the sentence "A trillion gallons of water have been poured into an empty region of outer space." Red lines indicate the shortest dependency path between entities *water* and *region*. An edge $a \rightarrow b$ refers to a being governed by b. Dependency types are labeled by the parser, but not presented in the figure for clarity.

In feature-based approaches, different sets of features are extracted and fed to a chosen classifier (e.g., logistic regression). Generally, three types of features are often used. Lexical features concentrate on the entities of interest, e.g., entities *per se*, entity POS, entity neighboring information. Syntactic features include chunking, parse trees, etc. Semantic features are exemplified by the concept hierarchy, entity class, entity mention. Kambhatla (2004) uses a maximum entropy model to combine these features for relation classification. However, different sets of handcrafted features are largely complementary to each other (e.g., hypernyms versus named-entity tags), and thus it is hard to improve performance in this way (GuoDong et al., 2005).

Kernel-based approaches specify some measure of similarity between two data samples, without explicit feature representation. Zelenko et al. (2003) compute the similarity of two trees by utilizing their common subtrees. Bunescu and Mooney (2005) propose a shortest path dependency kernel for relation classification. Its main idea is that the relation strongly relies on the dependency path between two given entities. Wang (2008) provides a systematic analysis of several kernels and show that relation extraction can bene-

fit from combining convolution kernel and syntactic features. Plank and Moschitti (2013) introduce semantic information into kernel methods in addition to considering structural information only. One potential difficulty of kernel methods is that all data information is completely summarized by the kernel function (similarity measure), and thus designing an effective kernel becomes crucial.

Deep neural networks, emerging recently, can learn underlying features automatically, and have attracted growing interest in the literature. Socher et al. (2011) propose a recursive neural network (RNN) along sentences' parse trees for sentiment analysis; such model can also be used to classify relations (Socher et al., 2012). Hashimoto et al. (2013) explicitly weight phrases' importance in RNNs to improve performance. Ebrahimi and Dou (2015) rebuild an RNN on the dependency path between two marked entities. Zeng et al. (2014) explore convolutional neural networks, by which they utilize sequential information of sentences. dos Santos et al. (2015) also use the convolutional network; besides, they propose a ranking loss function with data cleaning, and achieve the state-of-the-art result in SemEval-2010 Task 8.

In addition to the above studies, which mainly focus on relation classification approaches and models, other related research trends include information extraction from Web documents in a semi-supervised manner (Bunescu and Mooney, 2007; Banko et al., 2007), dealing with small datasets without enough labels by distant supervision techniques (Mintz et al., 2009), etc.

3 The Proposed SDP-LSTM Model

In this section, we describe our SDP-LSTM model in detail. Subsection 3.1 delineates the overall architecture of our model. Subsection 3.2 presents the rationale of using SDPs. Four different information channels along the SDP are explained in Subsection 3.3. Subsection 3.4 introduces the recurrent neural network with long short term memory, which is built upon the dependency path. Subsection 3.5 customizes a dropout strategy for our network to alleviate overfitting. We finally present our training objective in Subsection 3.6.

3.1 Overview

Figure 2 depicts the overall architecture of our SDP-LSTM network.

First, a sentence is parsed to a dependency tree by the Stanford parser;[1] the shortest dependency path (SDP) is extracted as the input of our network. Along the SDP, four different types of information—referred to as *channels*—are used, including the words, POS tags, grammatical relations, and WordNet hypernyms. (See Figure 2a.) In each channel, discrete inputs, e.g., words, are mapped to real-valued vectors, called *embeddings*, which capture the underlying meanings of the inputs.

Two recurrent neural networks (Figure 2b) pick up information along the left and right sub-paths of the SDP, respecitvely. (The path is separated by the common ancestor node of two entities.) Long short term memory (LSTM) units are used in the recurrent networks for effective information propagation. A max pooling layer thereafter gathers information from LSTM nodes in each path.

The pooling layers from different channels are concatenated, and then connected to a hidden layer. Finally, we have a $\mathrm{softmax}$ output layer for classification. (See again Figure 2a.)

3.2 The Shortest Dependency Path

The dependency parse tree is naturally suitable for relation classification because it focuses on the action and agents in a sentence (Socher et al., 2014). Moreover, the shortest path between entities, as discussed in Section 1, condenses most illuminating information for entities' relation.

We also observe that the sub-paths, separated by the common ancestor node of two entities, provide strong hints for the relation's directionality. Take Figure 1 as an example. Two entities *water* and *region* have their common ancestor node, *poured*, which separates the SDP into two parts:

$$[\text{water}]_{e_1} \rightarrow \text{of} \rightarrow \text{gallons} \rightarrow \text{poured}$$

and

$$\text{poured} \leftarrow \text{into} \leftarrow [\text{region}]_{e_2}$$

The first sub-path captures information of e_1, whereas the second sub-path is mainly about e_2. By examining the two sub-paths separately, we know e_1 and e_2 are of relation $\texttt{Entity-Destination}(e_1, e_2)$, rather than $\texttt{Entity-Destination}(e_2, e_1)$.

Following the above intuition, we design two recurrent neural networks, which propagate

[1] http://nlp.stanford.edu/software/lex-parser.shtml

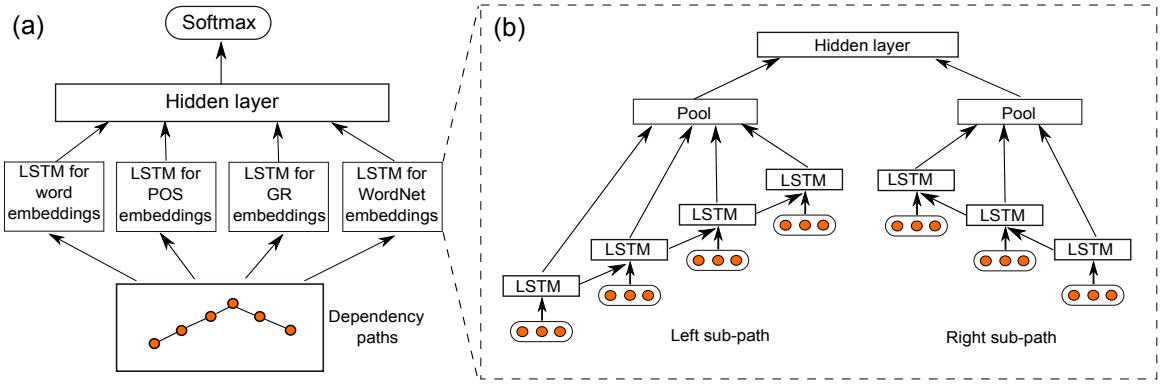

Figure 2: (a) The overall architecture of SDP-LSTM. (b) One channel of the recurrent neural networks built upon the shortest dependency path. The channels are words, part-of-speech (POS) tags, grammatical relations (abbreviated as *GR* in the figure), and WordNet hypernyms.

bottom-up from the entities to their common ancestor. In this way, our model is direction-sensitive.

3.3 Channels

We make use of four types of information along the SDP for relation classification. We call them *channels* as these information sources do not interact during recurrent propagation. Detailed channel descriptions are as follows.

- **Word representations**. Each word in a given sentence is mapped to a real-valued vector by looking up in a word embedding table. Unsupervisedly trained on a large corpus, word embeddings are thought to be able to well capture words' syntactic and semantic information (Mikolov et al., 2013b).

- **Part-of-speech tags**. Since word embeddings are obtained on a generic corpus of a large scale, the information they contain may not agree with a specific sentence. We deal with this problem by allying each input word with its POS tag, e.g., `noun`, `verb`, etc. In our experiment, we only take into use a coarse-grained POS category, containing 15 different tags.

- **Grammatical relations**. The dependency relations between a governing word and its children makes a difference in meaning. A same word pair may have different dependency relation types. For example, "*beats* $\xrightarrow{\text{nsubj}}$ *it*" is distinct from "*beats* $\xrightarrow{\text{dobj}}$ *it*." Thus, it is necessary to capture such grammatical relations in SDPs. In our experiment, grammatical relations are grouped into 19 classes, mainly based on a coarse-grained classification (De Marneffe et al., 2006).

- **WordNet hypernyms**. As illustrated in Section 1, hyponymy information is also useful for relation classification. (Details are not repeated here.) To leverage WordNet hypernyms, we use a tool developed by Ciaramita and Altun (2006).[2] The tool assigns a hypernym to each word, from 41 predefined concepts in WordNet, e.g., `noun.food`, `verb.motion`, etc. Given its hypernym, each word gains a more abstract concept, which helps to build a linkage between different but conceptual similar words.

As we can see, POS tags, grammatical relations, and WordNet hypernyms are also discrete (like words *per se*). However, no prevailing embedding learning method exists for POS tags, say. Hence, we randomly initialize their embeddings, and tune them in a supervised fashion during training. We notice that these information sources contain much fewer symbols, 15, 19, and 41, than the vocabulary size (greater than 25,000). Hence, we believe our strategy of random initialization is feasible, because they can be adequately tuned during supervised training.

3.4 Recurrent Neural Network with Long Short Term Memory Units

The recurrent neural network is suitable for modeling sequential data by nature, as it keeps a hid-

[2] http://sourceforge.net/projects/supersensetag

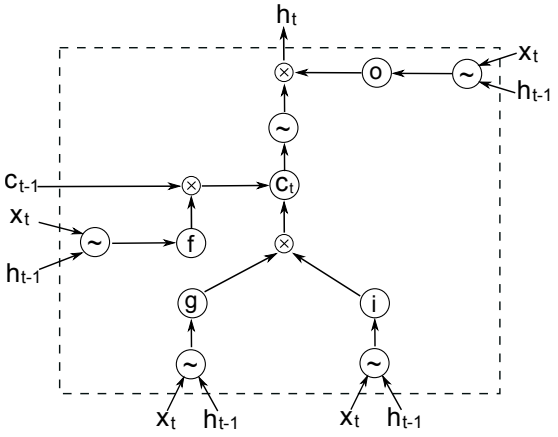

Figure 3: A long short term memory unit. h: hidden unit. c: memory cell. i: input gate. f: forget gate. o: output gate. g: candidate cell. $\otimes$: element-wise multiplication. $\sim$: activation function.

den state vector $\boldsymbol{h}$, which changes with input data at each step accordingly. We use the recurrent network to gather information along each sub-path in the SDP (Figure 2b).

The hidden state $\boldsymbol{h}_t$, for the t-th word in the sub-path, is a function of its previous state $\boldsymbol{h}_{t-1}$ and the current word $\boldsymbol{x}_t$. Traditional recurrent networks have a basic interaction, that is, the input is linearly transformed by a weight matrix and nonlinearly squashed by an activation function. Formally, we have

$$\boldsymbol{h}_t = f(W_{in}\boldsymbol{x}_t + W_{rec}\boldsymbol{h}_{t-1} + \boldsymbol{b}_h)$$

where W_{in} and W_{rec} are weight matrices for the input and recurrent connections, respectively. $\boldsymbol{b}_h$ is a bias term for the hidden state vector, and f_h a non-linear activation function (e.g., $\tanh$).

One problem of the above model is known as *gradient vanishing or exploding*. The training of neural networks requires gradient back-propagation. If the propagation sequence (path) is too long, the gradient may probably either grow, or decay, exponentially, depending on the magnitude of W_{rec}. This leads to the difficulty of training.

Long short term memory (LSTM) units are proposed in Hochreiter (1998) to overcome this problem. The main idea is to introduce an adaptive gating mechanism, which decides the degree to which LSTM units keep the previous state and memorize the extracted features of the current data input. Many LSTM variants have been proposed in the literature. We adopt in our method a variant introduced by Zaremba and Sutskever (2014), also used in Zhu et al. (2015).

Concretely, the LSTM-based recurrent neural network comprises four components: an input gate $\boldsymbol{i}_t$, a forget gate $\boldsymbol{f}_t$, an output gate $\boldsymbol{o}_t$, and a memory cell $\boldsymbol{c}_t$ (depicted in Figure 3 and formalized through Equations 1–6 as bellow).

The three adaptive gates $\boldsymbol{i}_t$, $\boldsymbol{f}_t$, and $\boldsymbol{o}_t$ depend on the previous state $\boldsymbol{h}_{t-1}$ and the current input $\boldsymbol{x}_t$ (Equations 1–3). An extracted feature vector $\boldsymbol{g}_t$ is also computed, by Equation 4, serving as the candidate memory cell.

$$\boldsymbol{i}_t = \sigma(W_i{\cdot}\boldsymbol{x}_t + U_i{\cdot}\boldsymbol{h}_{t-1} + \boldsymbol{b}_i) \quad (1)$$
$$\boldsymbol{f}_t = \sigma(W_f{\cdot}\boldsymbol{x}_t + U_f{\cdot}\boldsymbol{h}_{t-1} + \boldsymbol{b}_f) \quad (2)$$
$$\boldsymbol{o}_t = \sigma(W_o{\cdot}\boldsymbol{x}_t + U_o{\cdot}\boldsymbol{h}_{t-1} + \boldsymbol{b}_o) \quad (3)$$
$$\boldsymbol{g}_t = \tanh(W_g{\cdot}\boldsymbol{x}_t + U_g{\cdot}\boldsymbol{h}_{t-1} + \boldsymbol{b}_g) \quad (4)$$

The current memory cell $\boldsymbol{c}_t$ is a combination of the previous cell content $\boldsymbol{c}_{t-1}$ and the candidate content $\boldsymbol{g}_t$, weighted by the input gate $\boldsymbol{i}_t$ and forget gate $\boldsymbol{f}_t$, respectively. (See Equation 5 below.)

$$\boldsymbol{c}_t = \boldsymbol{i}_t \otimes \boldsymbol{g}_t + \boldsymbol{f}_t \otimes \boldsymbol{c}_{t-1} \quad (5)$$

The output of LSTM units is the the recurrent network's hidden state, which is computed by Equation 6 as follows.

$$\boldsymbol{h}_t = \boldsymbol{o}_t \otimes \tanh(\boldsymbol{c}_t) \quad (6)$$

In the above equations, σ denotes a $\mathrm{sigmoid}$ function; $\otimes$ denotes element-wise multiplication.

3.5 Dropout Strategies

A good regularization approach is needed to alleviate overfitting. Dropout, proposed recently by Hinton et al. (2012), has been very successful on feed-forward networks. By randomly omitting feature detectors from the network during training, it can obtain less interdependent network units and achieve better performance. However, the conventional dropout does not work well with recurrent neural networks with LSTM units, since dropout may hurt the valuable memorization ability of memory units.

As there is no consensus on how to drop out LSTM units in the literature, we try several dropout strategies for our SDP-LSTM network:

- Dropout embeddings;
- Dropout inner cells in memory units, including i_t, g_t, o_t, c_t, and h_t; and

- Dropout the penultimate layer.

As we shall see in Section 4.2, dropping out LSTM units turns out to be inimical to our model, whereas the other two strategies boost in performance.

The following equations formalize the dropout operations on the embedding layers, where D denotes the dropout operator. Each dimension in the embedding vector, $\boldsymbol{x}_t$, is set to zero with a predefined dropout rate.

$$\boldsymbol{i}_t = \sigma(W_i \cdot D(\boldsymbol{x}_t) + U_i \cdot \boldsymbol{h}_{t-1} + \boldsymbol{b}_i) \quad (7)$$

$$\boldsymbol{f}_t = \sigma(W_f \cdot D(\boldsymbol{x}_t) + U_f \cdot \boldsymbol{h}_{t-1} + \boldsymbol{b}_f) \quad (8)$$

$$\boldsymbol{o}_t = \sigma(W_o \cdot D(\boldsymbol{x}_t) + U_o \cdot \boldsymbol{h}_{t-1} + \boldsymbol{b}_o) \quad (9)$$

$$\boldsymbol{g}_t = \tanh\Big(W_g \cdot D(\boldsymbol{x}_t) + U_g \cdot \boldsymbol{h}_{t-1} + \boldsymbol{b}_g\Big) \quad (10)$$

3.6 Training Objective

The SDP-LSTM described above propagates information along a sub-path from an entity to the common ancestor node (of the two entities). A max pooling layer packs, for each sub-path, the recurrent network's states, $\boldsymbol{h}$'s, to a fixed vector by taking the maximum value in each dimension.

Such architecture applies to all channels, namely, words, POS tags, grammatical relations, and WordNet hypernyms. The pooling vectors in these channels are concatenated, and fed to a fully connected hidden layer. Finally, we add a $\mathrm{softmax}$ output layer for classification. The training objective is the penalized cross-entropy error, given by

$$J = -\sum_{i=1}^{n_c} t_i \log y_i + \lambda \left(\sum_{i=1}^{\omega} \|W_i\|_F^2 + \sum_{i=1}^{\upsilon} \|U_i\|_F^2 \right)$$

where $\boldsymbol{t} \in \mathbb{R}^{n_c}$ is the one-hot represented ground truth and $\boldsymbol{y} \in \mathbb{R}^{n_c}$ is the estimated probability for each class by $\mathrm{softmax}$. (n_c is the number of target classes.) $\|\cdot\|_F$ denotes the Frobenius norm of a matrix; ω and υ are the numbers of weight matrices (for W's and U's, respectively). λ is a hyperparameter that specifies the magnitude of penalty on weights. Note that we do not add ℓ_2 penalty to biase parameters.

We pretrained word embeddings by `word2vec` (Mikolov et al., 2013a) on the English Wikipedia corpus; other parameters are initialized randomly. We apply stochastic gradient descent (with mini-batch 10) for optimization; gradients are computed by standard back-propagation. Training details are further introduced in Section 4.2.

4 Experiments

In this section, we present our experiments in detail. Our implementation is built upon Mou et al. (2015). Section 4.1 introduces the dataset; Section 4.2 describes hyperparameter settings. In Section 4.3, we compare SDP-LSTM's performance with other methods in the literature. We also analyze the effect of different channels in Section 4.4.

4.1 Dataset

The SemEval-2010 Task 8 dataset is a widely used benchmark for relation classification (Hendrickx et al., 2009). The dataset contains 8,000 sentences for training, and 2,717 for testing. We split 1/10 samples out of the training set for validation.

The target contains 19 labels: 9 directed relations, and an undirected `Other` class. The directed relations are list as below.

- `Cause-Effect`
- `Component-Whole`
- `Content-Container`
- `Entity-Destination`
- `Entity-Origin`
- `Message-Topic`
- `Member-Collection`
- `Instrument-Agency`
- `Product-Producer`

In the following are illustrated two sample sentences with directed relations.

> [People]$_{e_1}$ have been moving back into [downtown]$_{e_2}$.

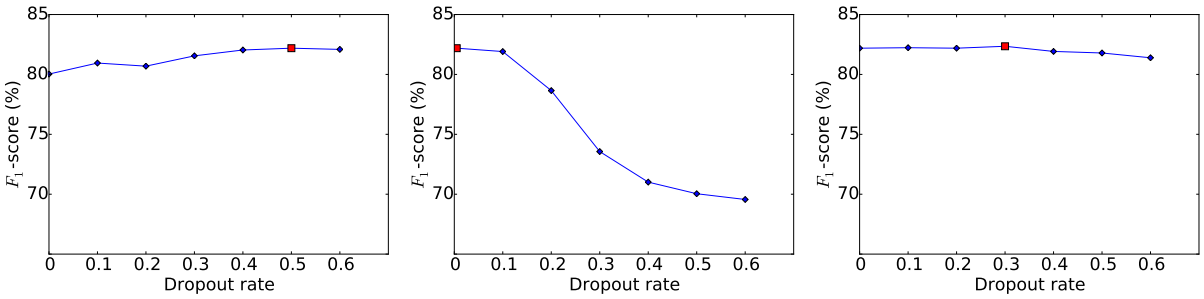
> Financial [stress]$_{e_1}$ is one of the main causes of [divorce]$_{e_2}$.

The target labels are `Entity-Destination` (e_1, e_2), and `Cause-Effect`(e_1, e_2), respectively.

The dataset also contains an undirected `Other` class. Hence, there are 19 target labels in total. The undirected `Other` class takes in entities that do not fit into the above categories, illustrated by the following example.

> A misty [ridge]$_{e_1}$ uprises from the [surge]$_{e_2}$.

We use the official macro-averaged F_1-score to evaluate model performance. This official measurement excludes the `Other` relation. Nonetheless, we have no special treatment of `Other` class in our experiments, which is typical in other studies.



(a) Dropout word embeddings (b) Dropout inner cells of memory units (c) Dropout the penultimate layer

Figure 4: F_1-scores versus dropout rates. We first evaluate the effect of dropout embeddings (a). Then the dropout of the inner cells (b) and the penultimate layer (c) is tested with word embeddings being dropped out by 0.5.

4.2 Hyperparameters and Training Details

This subsection presents hyperparameter tuning for our model. We set word-embeddings to be 200-dimensional; POS, WordNet hyponymy, and grammatical relation embeddings are 50-dimensional. Each channel of the LSTM network contains the same number of units as its source embeddings (either 200 or 50). The penultimate hidden layer is 100-dimensional. As it is not feasible to perform full grid search for all hyperparameters, the above values are chosen empirically.

We add ℓ_2 penalty for weights with coefficient 10^{-5}, which was chosen by validation from the set $\{10^{-2}, 10^{-3}, \cdots, 10^{-7}\}$.

We thereafter validate the proposed dropout strategies in Section 3.5. Since network units in different channels do not interact with each other during information propagation, we herein take one channel of LSTM networks to assess the efficacy. Taking the word channel as an example, we first drop out word embeddings. Then with a fixed dropout rate of word embeddings, we test the effect of dropping out LSTM inner cells and the penultimate units, respectively.

We find that, dropout of LSTM units hurts the model, even if the dropout rate is small, 0.1, say (Figure 4b). Dropout of embeddings improves model performance by 2.16% (Figure 4a); dropout of the penultimate layer further improves by 0.16% (Figure 4c). This analysis also provides, for other studies, some clues for dropout in LSTM networks.

4.3 Results

Table 4 compares our SDT-LSTM with other state-of-the-art methods. The first entry in the table presents the highest performance achieved by traditional feature engineering. Hendrickx et al. (2009) leverage a variety of handcrafted features, and use SVM for classification; they achieve an F_1-score of 82.2%.

Neural networks are first used in this task in Socher et al. (2012). They build a recursive neural network (RNN) along a constituency tree for relation classification. They extend the basic RNN with matrix-vector interaction and achieve an F_1-score of 82.4%.

Zeng et al. (2014) treat a sentence as sequential data and exploit the convolutional neural network (CNN); they also integrate word position information into their model. dos Santos et al. (2015) design a model called CR-CNN; they propose a ranking-based cost function and elaborately diminish the impact of the `Other` class, which is not counted in the official F_1-measure. In this way, they achieve the state-of-the-art result with the F_1-score of 84.1%. Without such special treatment, their F_1-score is 82.7%.

Yu et al. (2014) propose a Feature-rich Compositional Embedding Model (FCM) for relation classification, which combines unlexicalized linguistic contexts and word embeddings. They achieve an F_1-score of 83.0%.

Our proposed SDT-LSTM model yields an F_1-score of 83.7%. It outperforms existing competing approaches, in a fair condition of softmax with cross-entropy error.

It is worth to note that we have also conducted two controlled experiments: (1) Traditional RNN without LSTM units, achieving an F_1-score of 82.8%; (2) LSTM network over the entire dependency path (instead of two sub-paths), achieving an F_1-score of 82.2%. These results demonstrate

Classifier	Feature set	F_1
SVM	POS, WordNet, prefixes and other morphological features, depdency parse, Levin classes, PropBank, FanmeNet, NomLex-Plus, Google n-gram, paraphrases, TextRunner	82.2
RNN	Word embeddings	74.8
	Word embeddings, POS, NER, WordNet	77.6
MVRNN	Word embeddings	79.1
	Word embeddings, POS, NER, WordNet	82.4
CNN	Word embeddings	69.7
	Word embeddings, word position embeddings, WordNet	82.7
Chain CNN	Word embeddings, POS, NER, WordNet	82.7
FCM	Word embeddings	80.6
	Word embeddings, depedency parsing, NER	83.0

the effectiveness of LSTM and directionality in relation classification.

4.4 Effect of Different Channels

This subsection analyzes how different channels affect our model. We first used word embeddings only as a baseline; then we added POS tags, grammatical relations, and WordNet hypernyms, respectively; we also combined all these channels into our models. Note that we did not try the latter three channels alone, because each single of them (e.g., POS) does not carry much information.

We see from Table 2 that word embeddings alone in SDP-LSTM yield a remarkable performance of 82.35%, compared with CNNs 69.7%, RNNs 74.9–79.1%, and FCM 80.6%.

Adding either grammatical relations or WordNet hypernyms outperforms other existing methods (data cleaning not considered here). POS tagging is comparatively less informative, but still boosts the F_1-score by 0.63%.

We notice that, the boosts are not simply added when channels are combined. This suggests that these information sources are complementary to each other in some linguistic aspects. Nonetheless, incorporating all four channels further pushes the F_1-score to 83.70%.

Channels	F_1
Word embeddings	82.35
+ POS embeddings (only)	82.98
+ GR embeddings (only)	83.21
+ WordNet embeddings (only)	83.03
+ POS + GR + WordNet embeddings	83.70

Table 2: Effect of different channels.

5 Conclusion

In this paper, we propose a novel neural network model, named SDP-LSTM, for relation classification. It learns features for relation classification iteratively along the shortest dependency path. Several types of information (word themselves, POS tags, grammatical relations and WordNet hypernyms) along the path are used. Meanwhile, we leverage LSTM units for long-range information propagation and integration. We demonstrate the effectiveness of SDP-LSTM by evaluating the model on SemEval-2010 relation classification task, outperforming existing state-of-art methods (in a fair condition without data cleaning). Our result sheds some light in the relation classification task as follows.

- The shortest dependency path can be a valuable resource for relation classification, covering mostly sufficient information of target

relations.

- Classifying relation is a challenging task due to the inherent ambiguity of natural languages and the diversity of sentence expression. Thus, integrating heterogeneous linguistic knowledge is beneficial to the task.
- Treating the shortest dependency path as two sub-paths, mapping two different neural networks, helps to capture the directionality of relations.
- LSTM units are effective in feature detection and propagation along the shortest dependency path.

A Computational Cognitive Model of Novel Word Generalization

Aida Nematzadeh, Erin Grant, and Suzanne Stevenson
Department of Computer Science
University of Toronto
{aida,eringrant,suzanne}@cs.toronto.edu

Abstract

A key challenge in vocabulary acquisition is learning which of the many possible meanings is appropriate for a word. The word generalization problem refers to how children associate a word such as *dog* with a meaning at the appropriate category level in a taxonomy of objects, such as Dalmatians, dogs, or animals. We present the first computational study of word generalization integrated within a word-learning model. The model simulates child and adult patterns of word generalization in a word-learning task. These patterns arise due to the interaction of type and token frequencies in the input data, an influence often observed in people's generalization of linguistic categories.

1 Introduction

Learning word meanings is a challenging early step in child language acquisition. Imagine a child hears the word *dax* for the first time while observing a white rabbit jumping around – *dax* might mean WHITE RABBIT, RABBIT, ANIMAL, CUTE, LOOK, etc. (Quine, 1960). How does the child learn the correct meaning of a word from a large pool of potential meanings? A possible explanation is that children infer a word's meaning by identifying the commonalities across the situations in which the word occurs (Pinker, 1989). One mechanism for achieving this is *cross-situational learning* (*e.g.*, Siskind, 1996; Frank et al., 2007; Fazly et al., 2010; Kachergis et al., 2012). Recent word learning experiments confirm that both adults and children infer the correct word-meaning mappings by keeping track of cross-situational statistics across individually ambiguous learning trials (Yu and Smith, 2007; Smith and Yu, 2008; Yurovsky et al., 2014).

Although cross-situational learning is a general mechanism for narrowing down the meaning of a word, it does not explain how children overcome an interesting challenge in word learning: determining the correct level of a hierarchical taxonomy that a word refers to. For example, children learn that the word *dog* refers to all kinds of dogs, and not to a specific breed, such as Dalmatians, or to a more general category, such as animals – even though some of these choices (*e.g.*, animals) are compatible with all the cross-situational evidence available for *dog* (because all dogs are also animals). We use the term "word generalization" to refer to this problem of associating a word with the meaning at an appropriate category level, given some sample of experiences with the word.

Previous research has argued that children use a specific bias or constraint – the *basic-level assumption* – to focus their word generalizations appropriately (Markman, 1991; Golinkoff et al., 1994). According to this bias, children prefer to associate a word to a set of objects that form a *basic-level* category, such as dogs or trucks, and that share a significant number of attributes. It is less preferred to associate a new word to much more specific *subordinate* categories, such as Dalmatians or bulldozers, or to more general *superordinate* ones, like animals or vehicles, whose members share fewer attributes (Rosch, 1973; Rosch et al., 1976). It remains an important open question of whether a word learner requires such a bias to acquire appropriate mappings.

Xu and Tenenbaum (2007) (X&T henceforth) studied the word generalization problem in a set of experiments in which children and adults were asked to determine which level of a taxonomy a novel word referred to. X&T further examined this behavioral data through computational modelling. They proposed a Bayesian model that, given a few exemplars of a novel word, matches human behaviour in how it maps the word to its

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1795–1804,
Lisbon, Portugal, 17-21 September 2015.

meanings in a taxonomic category.

The Bayesian model of X&T is important in providing insight into how people might reason about samples of data that exemplify categories. However, it relies on having complete, built-in knowledge about the taxonomic hierarchy, including both the detailed composition of categories and the values for between-object similarities, drawn from adult similarity judgments. Furthermore, the X&T model does not address the issue of word generalization in the broader context of word learning: While their model reasons over samples of data associated with a word label, it does not develop a meaning representation of the word over time, as a child must do. It is important to understand how word generalization occurs when embedded in the natural process of learning a word meaning and in the context of more limited category knowledge.

We address these issues by providing a unified account of word learning and word generalization within a computational model of cross-situational learning. Unlike the X&T model, our model is an incremental learner that gradually acquires the meaning of words, and uses these developing meanings in determining the appropriate extension of a word to elements of a taxonomy. Our model has general knowledge of category structure without having an elaborated taxonomy encoding known object similarities. Moreover, in the absence of any bias toward generalization to particular kinds of categories, the model exhibits the observed "basic-level bias" due to general mechanisms of productivity that have been proposed to apply to many aspects of linguistic knowledge (*e.g.*, Bybee, 1985; Croft and Cruse, 2004).[1]

In what follows, we first describe the human experiments of X&T, and then present our computational model and the experiments that simulate the X&T data.

2 Novel Word Generalization in People

X&T perform a set of empirical studies to investigate how children and adults generalize novel words learned from a few examples to the appropriate level of meaning in a taxonomy. In each training trial of an experiment, participants hear a novel word (such as *fep*) and observe one or more instances exemplifying the word (in the form of pictures for adults and toy objects for children). The conditions vary in that the make-up of the set of training instances is representative of different levels of a taxonomy (*e.g.*, all Dalmatians vs. various kinds of dogs vs. various kinds of animals). In the testing phase, participants are asked to select all objects that they think are *feps* from a set of test items. Both children and adults make various inferences about what a *fep* is depending on the levels of the taxonomy from which the training instances are drawn.

Specifically, X&T use a taxonomy with animals, vehicles, and vegetables, from which instances are drawn to produce the training conditions in Fig. 1(a). For example, in one training condition, participants are shown a Dalmatian, a poodle, and a beagle in three consecutive trials, hearing the word *fep* to refer to each object. After training, participants are asked to select all *feps* from the set of test objects, which includes items from all 3 superordinate categories. As illustrated in Fig. 1(b), each test object is assessed as one of the following types of match to the training data:

- a **subordinate match**: an object of the same subordinate category as a training object (*e.g.*, Dalmatians in Fig. 1)
- a **basic-level match**: an object of the same basic-level category as a training object (*e.g.*, a dog, but not the same breed as one in training [which would be a subordinate match])
- a **superordinate match**: an object of the same superordinate category as the training objects (*e.g.*, another kind of animal, but not one seen in training [which would be a subordinate or basic-level match])

X&T report the percentage of test objects of each type of match that are selected by participants within each training condition; see Fig. 2. (For example, the reported value for "super. match" would be 75% if participants on average chose 3 of the 4 superordinate matches in the test set.)

Consider first the data from adults. After seeing a single object (1-example condition – *e.g.*, a Dalmatian), adults show a strong basic-level bias – i.e., they tend to generalize the word *fep* to refer to *both* Dalmatians (subordinate matches) and to

[1] Computational cognitive models are often categorized with respect to Marr's levels of analysis, *i.e.*, their degree of abstraction (Marr, 1982). The model of X&T is at the computational level, providing a Bayesian framework for the problem of word generalization. In contrast, our model investigates more detailed mechanisms and thus lies between the algorithmic and computational levels of analysis.

Training condition:	Example Trials: Trial 1	Trial 2	Trial 3
1 example	Dalmatian	∅	∅
3 subord.	Dalmatian	Dalmatian	Dalmatian
3 basic	Dalmatian	poodle	beagle
3 super.	Dalmatian	penguin	sheep

(a) An example of the training conditions.

Example test object selected:	Type of test match:
Dalmatian	subordinate match
bulldog	basic match
cat	superordinate match

(b) An example of the test responses.

other dogs (basic-level matches), but not to other animals (superordinate matches). But with 3 instances of a Dalmatian (3-subordinate condition), this behaviour is attenuated – the number of basic-level matches is much lower. For the 3-basic-level and 3-superordinate conditions, the adults show generalization up to categories consistent with the evidence – i.e., at the basic and superordinate levels, respectively.

Interestingly, children also show a basic-level bias, but differ from adults in that it is less pronounced – e.g., they are less likely than adults to select basic-level matches (other dogs) having seen a single Dalmatian or having seen 3 Dalmatians. In the other conditions, children's behaviour is similar to adults, but shows somewhat less generalization to unseen types of objects (*e.g.*, other kinds of dogs/animals than those in training).

3 The Word Learning Framework

Our computational model is based on the cross-situational word learner of Fazly et al. (2010) (henceforth, FAS), which accounts for a range of observed patterns in child and adult vocabulary acquisition. Here we give an overview of the FAS model; the next section explains extensions to handle the novel word generalization task.

A naturalistic language learning scenario consists of both linguistic data (what a child a hears) and non-linguistic data (what a child perceives). This input is modeled as a sequence of utterance–scene (U–S) pairs, where an utterance is a group of words and a scene is a set of semantic features representing the meaning of those words:

U: { *look*, *a*, *fep*, ... }
S: { PERCEPTION, LOOK, ..., DALMATIAN, DOG, ... }

Given such input, for each word w, the model of FAS learns a probability distribution over all semantic features, $P_t(.|w)$, which represents the word's meaning at time t. Initially, at time $t = 0$, $P_0(.|w)$ is a uniform distribution. The word meanings are incrementally learned using an algorithm that implements cross-situational learning: for each pair of a word w and a semantic feature f, the model learns $P_t(f|w)$ from co-occurrences of w and f across all the utterance–scene pairs seen up to time t, as follows.

Given an utterance–scene pair U–S at time t, and drawing on its learned knowledge of word meanings up to time $t-1$, the model of FAS calculates an *alignment* probability for each w_j–f_i pair. This probability reflects how strongly the feature f_i is associated with w_j compared to its association with other words in U:

$$P_t(a_{ij}|U, f_i) = \frac{P_{t-1}(f_i|w_j)}{\sum_{w' \in U} P_{t-1}(f_i|w')} \qquad (1)$$

where a_{ij} indicates the mapping between the word w_j and the semantic feature f_i.

These probabilities are incrementally accumulated for each w_j–f_i pair, capturing the overall strength of association of w_j and f_i at time t:

$$\begin{aligned} \text{assoc}_t(f_i, w_j) = \text{assoc}_{t-1}(f_i, w_j) \\ + P_t(a_{ij}|U, f_i) \end{aligned} \qquad (2)$$

The (normalized) association scores then serve as the basis for the incremental adjustment of the meaning probabilities of all features f_i for each word w_j seen in the input at time t:

$$P_t(f_i|w_j) = \frac{\text{assoc}_t(f_i, w_j) + \gamma}{\sum_{f_m \in \mathcal{M}} \text{assoc}_t(f_m, w_j) + k\,\gamma} \quad (3)$$

Here $\mathcal{M}$ is the group of all features that the model has observed, k is the expected number of such features, and γ is a small smoothing parameter, which determines the prior probability of observing a new feature.

Smoothing entails that features previously unseen with a word (all f_i such that $\text{assoc}_t(f_i, w_j) = 0$) have a small but non-zero probability. That is, when f_i is unseen with w_j, Eqn. (3) reduces to:

$$P^u_t(f_i|w_j) = \frac{\gamma}{\sum_{f_m \in \mathcal{M}} \text{assoc}_t(f_m, w_j) + k\,\gamma} \quad (4)$$

This unseen probability, P^u_t, reflects the learner's "openness" to the word being associated with new features (Nematzadeh et al., 2011): a higher or lower $P^u_t(f_i|w_j)$ will affect how strongly a previously unseen f_i can be associated with w_j in the alignment process (Eqn. (1)). We return to this property of the model below, as it relates to the behaviour of our model in making generalizations.

4 Extensions to the Model

We assume that the representation of meaning can be abstracted to features that correspond to different levels of categorization. For example, a Dalmatian in an input scene is represented as {DALMATIAN, DOG, ANIMAL} and a Bulldog as {BULLDOG, DOG, ANIMAL}, where we use FEATURENAME to refer to all the features that are specific to that level of object category. (Note that we could replace each of these features with the appropriate "true" set of features, but use the more compact representation for simplicity.) To acquire the meaning of the word *Dalmatian*, the model must learn a probability distribution in which $P(f|$*Dalmatian*$)$ is relatively high for the features DALMATIAN, DOG, and ANIMAL, and low for features such as BULLDOG, CAT, and VEGETABLE.

Introducing Feature Groups. In the FAS model, all the features for a word are dependent: increasing the probability of any feature results in decreasing the probability of others. However, this interaction is not always desirable, as many features regularly co-occur in the world. This is especially an issue for features from a category hierarchy, where features of a subordinate category should not compete with features of the parent. That is, while a higher probability of DALMATIAN features (*e.g.*, black spotted coat) may lessen the likelihood of BULLDOG features (*e.g.*, wrinkles), it should *not* decrease the probability of DOG features (*e.g.*, having 4 legs).

To address this, we extend the model by using *feature groups* that collect together sets of features that sensibly compete. Each feature group is comprised of all features at the same level of specificity in the category hierarchy, which are therefore mutually exclusive, such as DOG, CAT, and BIRD (*i.e.*, different kinds of animals). Instead of learning a single probability distribution over all features as the meaning of a word, the extended model learns *a set of* probability distributions for a word, one for each feature group (*i.e.*, one per level of the hierarchy). Features within a group thereby compete for the probability mass associated with a word, but those from across groups (*e.g.*, DALMATIAN and DOG) can freely co-occur without competing.

The model does not know a priori all the features in a group, but when presented with a newly observed feature, it can identify the appropriate group for it. In taking this approach, we assume the learner can distinguish the level of specificity of features perceived in the scene. For example, in the scene representations {DALMATIAN, DOG, ANIMAL} and {SIAMESE, CAT, ANIMAL}, the learner can recognize that DOG and CAT are at the same level of the hierarchy (kinds of animals) and that DALMATIAN and SIAMESE are at the same, *more specific* level in the hierarchy (finer-grained breeds of animals). Our assumption is that children (at this stage in their development) can identify a degree of similarity among concepts that enables them to recognize that Dalmatians and Siamese are distinguished by similar properties (such as fur color), which differ from more distinguishing properties at higher taxonomic levels (such as number of legs). The model has no other prior knowledge of the category structure. For example, it is not built into the model that DALMATIAN is a type of DOG, only that it is more specific than DOG; any association between them would be learned from their pattern of co-occurrence with a word over time.

Note that, in contrast to the model of X&T, our model does not start with a full taxonomy (it does not know, for example, that Dalmatians and poodles are hyponyms of dogs) and it does not have built-in knowledge of similarities among concepts. Still, it encodes some taxonomic knowledge in the feature groups, and an important future direction will be to show that this knowledge is learnable from the input.

Calculating Feature Group Probabilities. To appropriately split the probability mass within a feature group $\mathcal{G}$ (but not across feature groups), we use a new formulation of Eqn. (3) to update the meaning probabilities for $f_i \in \mathcal{G}$ as follows:

$$P_t(f_i|w_j) = \frac{\text{assoc}_t(f_i, w_j) + \gamma_{\mathcal{G}}}{\sum_{f_m \in \mathcal{G}} \text{assoc}_t(f_m, w_j) + k_{\mathcal{G}}\gamma_{\mathcal{G}}} \quad (5)$$

where $k_{\mathcal{G}}$ is the expected number of features in $\mathcal{G}$, and the smoothing factor $\gamma_{\mathcal{G}}$ reflects the prior belief in observing a feature f in $\mathcal{G}$.[2]

With this new formulation, the probability of a feature f_i previously unseen with word w_j now reduces to (cf. Eqn. (4)):

$$P^u_t(f_i|w_j) = \frac{\gamma_{\mathcal{G}}}{\sum_{f_m \in \mathcal{G}} \text{assoc}_t(f_m, w_j) + k_{\mathcal{G}}\gamma_{\mathcal{G}}} \quad (6)$$

for $f_i \in \mathcal{G}$. Note that the smoothing factor $\gamma_{\mathcal{G}}$ depends on $\mathcal{G}$, and thus the openness of the word to be associated with new (previously unseen) features can vary depending on the feature group.

This unseen probability is very important to the model's generalization behaviour. Generalization involves the model accepting that a learned word can refer to objects not seen with it before: e.g., in the experiments here, we would expect that the learned meaning for *fep* after seeing three animals such as a dog, a penguin, and a sheep could also accommodate the meaning of a different animal such as a cat. This ability of the model to associate new meaning features with a word depends precisely on the unseen probability formulation: the higher the unseen probability for a feature and a word, the more the feature will be acceptable as a generalization of the word.

Type-Token Effects on Generalization. The unseen probability is sensitive to how many instances of features from a group have already been seen with a word w_j: As the model observes more instances (tokens) of features from $\mathcal{G}$ with w_j, the corresponding $assoc_t$ score(s) increase, thereby increasing the denominator in Eqn. (6) and decreasing P^u_t. Thus the tendency to generalize w_j to more features in $\mathcal{G}$ – i.e., to accept additional features as part of the meaning of w_j – will decrease as the model has more evidence of (observed) features in that group occurring with w_j.

Generalization of a category to include new kinds of items is typically a function of both token *and* type frequency (*e.g.*, Bybee, 1985; Croft and Cruse, 2004): a category with more diverse types is more easily extended to new cases. While the evolving association scores capture the effect of observing more feature *tokens*, our model as given does not distinguish the number of different *types* of features seen within a group (*e.g.*, two DOGs vs. one DOG and one CAT).

We address this issue by having $\gamma_{\mathcal{G}}$ depend on the number of observed types of features in the group:

$$\gamma^t_{\mathcal{G}} = \gamma^0_{\mathcal{G}} \times \text{type}(\mathcal{G}, t)^2 \quad (7)$$

where $\text{type}(\mathcal{G}, t)$ is the number of different kinds of features seen in that group (e.g., DOG and CAT are two different feature types from the same group) up through time t. In this way, the P^u_t of a feature that occurs in a group with more observed feature types is higher than the P^u_t in a group with fewer observed types.

Thus both the type frequency of features in $\mathcal{G}$ and their token frequency of co-occurrence with word w_j will influence – the first positively and the second negatively – how readily w_j can refer to objects with previously unseen features from $\mathcal{G}$.

5 Experimental Set-up

We model X&T's behavioural experiments with our computational word learner as extended above.[3] Following X&T, we use a three-tiered category hierarchy, and the four training conditions and assessment of three types of test matches as described in Figure 1.

Training the model. In each condition, the model processes a sequence of 3 utterance-scene pairs, and updates $P_t(f_i|w_j)$ after each pair using Eqns. (5) and (6). The utterance-scene pair in each trial consists of the novel word coupled with the scene representation of a training object from the

[2] Each feature group forms a Categorical distribution with $k_{\mathcal{G}}$ categories ($\text{Cat}(\theta_1, ..., \theta_{k_{\mathcal{G}}})$), where the θ_i are drawn from a prior Dirichlet distribution $\text{Dir}(\gamma_1, ..., \gamma_{k_{\mathcal{G}}})$ at time $t = 0$, and the θ_i are updated at time t to be the expected value of the posterior Dirichlet distribution, given in Eqn. (5) or Eqn. (6).

[3] Link to our code/data: `github.com/eringrant/word_learning/tree/hypothesis-space`.

category hierarchy. The object's scene representation is given as a set of four features, each taken from one of four feature groups: one feature corresponding to each of the subordinate, basic, and superordinate levels of the hierarchy, and a unique "instance" feature, as shown in Table 1. (The "instance" feature is added to simulate the variations in the different objects of the same subordinate category in the X&T experiments.)

1	**U:**	{ *fep* }
	S:	{ INSTANCE$_1$, DALMATIAN, DOG, ANIMAL }
2	**U:**	{ *fep* }
	S:	{ INSTANCE$_2$, TABBY, CAT, ANIMAL }
3	**U:**	{ *fep* }
	S:	{ INSTANCE$_3$, POLAR BEAR, BEAR, ANIMAL }

Table 1: An example of a sequence of utterance-scene pair trials in the 3-super. condition.

Testing the model. After training on a novel word, in order to assess its level of generalization within the category hierarchy, we compare the model's learned meaning of the word to test objects that constitute various types of matches to the training conditions: *i.e.*, subordinate matches, basic-level matches, and superordinate matches. Table 2 gives an example of each type of match:

subord.:	{ INSTANCE$_4$, DALMATIAN, DOG, ANIMAL }
basic:	{ INSTANCE$_5$, POODLE, DOG, ANIMAL }
super.:	{ INSTANCE$_6$, TOUCAN, BIRD, ANIMAL }

Table 2: An example of each level match from the test objects, given the training condition in Table 1.

To assess whether the model generalizes the learned meaning of a word w to the various types of test matches, we first consider the probability of a test object Y at time t given the learned meaning of w:

$$P_t(Y|w) = \prod_{y_i \in Y} P_t(y_i|w) \qquad (8)$$

where y_i are the features in Y, and $P_t(y_i|w)$ is calculated using Eqn. (5) for features y_i observed with w during training, and using Eqn. (6) for y_i not observed with w. (Recall that Eqn. (5) reduces to Eqn. (6) when a feature has not been seen with the word.) From $P_t(Y|w)$, we subtract the predictive probability of the test object before the model has observed any data, $P_0(Y|w)$, which gives us its increase in preference attributable to the word learning trials.[4]

Calculating $P_t(Y|w) - P_0(Y|w)$ is informative about one test object, but we need to measure generalization of the learned word to all the objects of a certain type of match – *i.e.*, subordinate, basic-level, or superordinate. We formulate the probability of generalization to a type of test match as the relative average increase in preference for test items of that type of match, using the Shepard-Luce choice rule (Shepard, 1958; Luce, 1959):

$$P_{gen}(m|w) = \frac{\text{avg}_{Y \in m}\,[P_t(Y|w)\text{-}P_0(Y|w)]}{\sum_{m'} \text{avg}_{Y' \in m'}\,[P_t(Y'|w)\text{-}P_0(Y'|w)]}$$

where m is the set of test objects at a certain level of match, and m' ranges over subordinate matches, basic-level matches, and superordinate matches.

Using $P_{gen}(m|w)$ to communicate our models results has the advantage of using the learned word meanings in a very direct way to assess the preference for the various types of test matches in the X&T experiments. However, the disadvantage is that this measure is not directly comparable to the reported figures from the human data, which are the percentage of test objects selected of a particular type of match. Hence, in presenting our results below, we focus on the general patterns of preferences indicated by the different measures.

Parameters. To model children, whom we assume to have no bias towards generalization to specific category levels, we equate all parameters $k_{\mathcal{G}}$ and $\gamma_{\mathcal{G}}$ across all feature groups, reflecting that all category levels are treated equivalently. Here we use values of $k_{\mathcal{G}} = 100$ and initial values of $\gamma_{\mathcal{G}} = 0.5$ for all $\mathcal{G}$ as the "child" parameter settings.[5] In contrast, we assume that adults, through word learning experience, have accumulated biases that reflect observed differences in feature groups. More specifically, we assume that the probability of observing a new feature for a group $\mathcal{G}$ depends on the degree of specificity of that group: That is, over time, it is less likely to observe a completely new kind of animal, e.g., than a new breed of dog. We simulate these biases by us-

[4] $P_0(Y|w) = \prod_{\mathcal{G}} \frac{1}{k_{\mathcal{G}}}$ is the prior probability of any object instance, given parameters drawn from the Dirichlet prior, because Eqn. (6) yields the value $\frac{1}{k_{\mathcal{G}}}$ when all assoc_t scores are 0 – *i.e.*, no features from $\mathcal{G}$ have been observed with the word.

[5] To determine the parameters for the "child" learner, we examined a number of settings with equal parameter values for all the feature groups, and observed similar results in these settings. (We did not perform an exhaustive search over the parameter space.)

ing various values for the parameter $\gamma_{\mathcal{G}}$, which determines the prior probability of a word being observed with new (previously unseen) features in $\mathcal{G}$ (cf. Eqn. (6)). We assume that the expected number of features ($k_{\mathcal{G}}$) is the same across groups. We perform a non-exhaustive search on the parameter space of $\gamma_{\mathcal{G}}$ to select a set of values that yield the patterns of X&T's adult experiments. The "adult" parameter values are given in Table 3:[6]

$\gamma_{\text{inst}} = 1.2$	$\gamma_{\text{subord}} = 1.0$	$\gamma_{\text{basic}} = 0.5$	$\gamma_{\text{super}} = 0.2$
$k_{\text{inst}} = 100$	$k_{\text{subord}} = 100$	$k_{\text{basic}} = 100$	$k_{\text{super}} = 100$

Table 3: "Adult" parameter settings.

6 Experimental Results

We present results of the model using both child settings (Figure 3b) and adult settings (Figure 3a). Recall that these values do not correspond to the percentages reported in the human data; to evaluate the patterns of generalization, we look at the relative preference for the various types of test match. Note also that since the generalization probabilities sum to 1.0 within each of the 4 training conditions, we can only compare the *pattern* of generalization across conditions (and not the actual value of the probabilities).

We discuss each of the child and adult sets of results in detail below.

6.1 The Child Learner

Recall that in the simulations of a child, we use equal values across all feature groups for the $k_{\mathcal{G}}$ and initial $\gamma_{\mathcal{G}}$ parameter settings, to reflect that the learner has no bias towards generalization to specific category levels.

Looking at the results in Figure 3b, we can see that the child learner generally replicates the patterns of results observed in X&T's experiment on children (cf. Figure 2b). Given multiple training items (the 3-subord., 3-basic, and 3-super. conditions), the model, like children, generalizes to the lowest level category in the hierarchy that is consistent with the training items, roughly equally preferring items from that category or lower, with slight preference for the lower categories. In contrast, after seeing a single training example (the

[6]For a certain range of such parameter settings – i.e., with gradually decreasing $\gamma_{\mathcal{G}}$, which determines the prior probability of a word being observed with new (previously unseen) features in $\mathcal{G}$ (cf. Eqn. (6)). for feature groups at successively higher levels in the hierarchy — the model produces similar results to the presented adult learner.

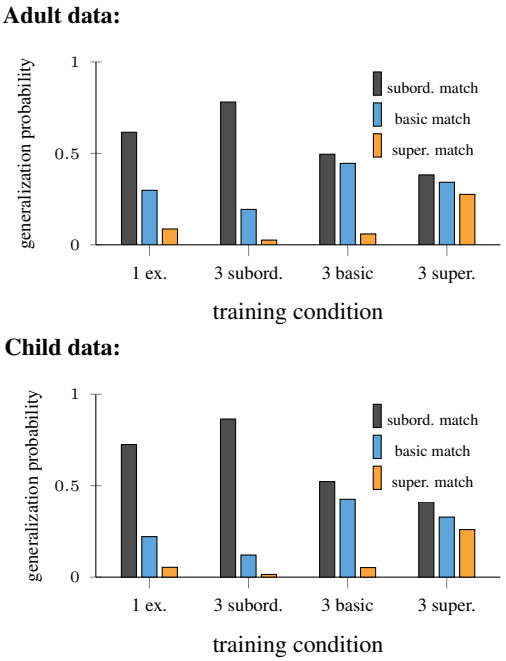

Figure 3: Our model data for (a) adults and (b) children. Each bar is the probability of a type of test match: *i.e.*, subord(inate), basic(-level), or super(ordinate).

1-ex. condition), the model shows some tendency to generalize to the basic-level, demonstrating a small but notable basic-level bias — e.g., the tendency to consider the word as referring to any dogs (but less so to other animals) after seeing just a single example of a particular kind of dog. As in children, the difference in the model between the preference for subordinate vs. basic-level matches is much smaller when trained on 1 instance as opposed to 3 subordinates. (In Figure 3b, compare the difference between the 1st bar [subord. match] and 2nd bar [basic match] of the 1-ex. training condition to that of the 3-subord. training condition.)

Interestingly, our child learner exhibits the observed basic-level bias in the absence of any difference in the model in how it treats different category levels. The observed pattern arises from a type/token frequency interaction of the kind often noted to influence generalization of linguistic categories (*e.g.*, Bybee, 1985; Croft and Cruse, 2004): here, the interaction between the token frequency of word–feature pairs in the input and the type frequency of different features within a group of dependent features. For example, having seen 3 types of animals ("3 super." condition), the model can readily accommodate that *fep* refers to another kind of animal, in contrast to the "3 basic" condition, where it has seen the same number of tokens but only a single feature type from the feature

group at that level (3 dogs). We can also clearly see the inverse impact of token frequencies on generalization: the more examples of a single subordinate type are seen, the less the model accepts that *fep* refers to a different kind of subordinate (the "3-subord." vs. "1-ex." conditions). That is, with only 1 token of DALMATIAN, the model can generalize to other types of dogs more readily than when it has seen 3 tokens of DALMATIAN.

In general, interactions between the type and token frequencies of the different feature groups interact to yield the observed patterns in the model. These results indicate that properties of the input data coupled with the model's handling of feature groups can account for children's word generalization behaviour, without the need for an explicit basic-level bias.

6.2 The Adult Learner

Adult participants in X&T exhibited a stronger tendency than children to generalize to the basic-level category, especially after seeing a single exemplar. We explore whether the model can simulate an adult learner as well. As discussed in Section 5, by varying the parameters $\gamma_{\mathcal{G}}$, we can incorporate biases towards different category levels that we assume an adult has learned. More specifically, we set $\gamma_{\mathcal{G}}$ to successively larger values for more specific feature groups $\mathcal{G}$, to ensure successively greater generalization in lower levels of the hierarchy (see Table 3). As shown in Figure 3a, our model (using such settings of the parameters) replicates the patterns of X&T's adult experiments (cf. Figure 2a), including a stronger basic-level bias than that shown by children. That is, in the 1-ex. and 3-subord. conditions, the difference between the 1st bar [subord. match] and 2nd bar [basic match] is smaller for the adult settings of the model (Figure 3a) than for the child settings (Figure 3b), mimicking the stronger basic-level bias found in adults.

6.3 Variations in Basic-level Generalization

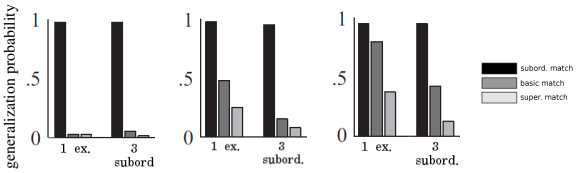
Research shows that people's degree of basic-level generalization depends on the overall category of the objects. Specifically, Abbott et al. (2012) perform the same set of experiments as X&T on adults, exploring three additional superordinate categories (clothing, containers, and seats). Their results are shown in Figure 4; for space reasons, we focus here on the training conditions with 1-example or 3-subordinates, which are the locus of the basic-level effect. The results show that people exhibit no basic-level generalization for containers, moderate generalization for clothing, and strong generalization for seats (compare Figures 4a, 4b and 4c).

Interestingly, the computational experiments of Abbott et al. (2012) also reveal that the Bayesian model of X&T mimics varying levels of basic-level generalization in the 1-example cases, but does not capture the differences that people exhibit across the categories in the 3-subordinate condition (compare "3 subord." in Figures 4 and 5): unlike people, here the X&T model does not exhibit basic-level generalization for any of the categories.

Abbott et al. (2012) note that a domain like containers may not follow a "natural taxonomy" in having a clear basic-level category. This suggestion is compatible with our view that a basic-level bias arises in response to the particular pattern of co-occurrence of features across the category hierarchy. We looked more closely at the training stimuli of their experiment, and observe that the examples of the category "containers" (with the least basic-level generalization) vary greatly, while those of "clothing" and "seats" are less differentiated. Examples from "containers" include a cigar box, trash can, and mailbox, whereas "seats" are restricted to different types of chair (such as a dining chair and an armchair; see Table 1 in Abbott et al. (2012)).

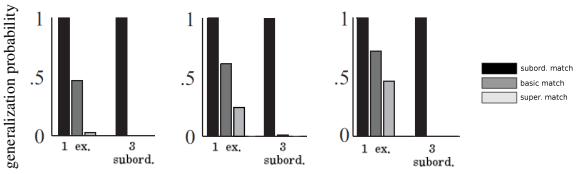
Based on this observation, we hypothesize that people generalize less to a basic-level category when their mental representations for that category's instances have more distinguishing features. Specifically, we assume that people differentiate the given instances of the category "containers" more than those for "clothing" and "seats". We model this difference in the granularity of representations by varying the number of feature groups used in representing an object. Recall that in our earlier experiments, each object was represented as a set of features drawn from 4 different feature groups. We take this representation as the least fine-grained representation and use it for the category "seats". We assume that the objects from the categories "clothing" and "containers" (that exhibit less basic-level generalization) are represented with more feature groups (8 and 12, respectively).

Figure 6 shows the results of running our model



(a) Containers (b) Clothing (c) Seats

Figure 4: Abbott et al. (2012) subject response data.



(a) Containers (b) Clothing (c) Seats

Figure 5: Abbott et al. (2012) model data.

on these three categories using the "adult" parameter settings. As expected, the generalization to the basic-level category is high for the least distinguished category "seats", moderate for the category "clothing", and low for the most distinguished category "containers".[7]

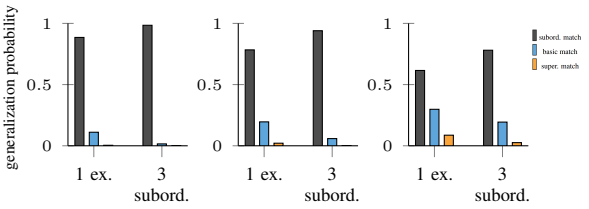
Our results suggest that the observed variation across categories in basic-level generalization could arise from differences in the granularity of representations of categories. This is particularly interesting since the model of X&T, despite encoding an elaborated taxonomy, does not capture the observed behaviour across all training conditions.

7 Conclusions

A key challenge faced by children in vocabulary acquisition is learning which of many possible meanings is appropriate for a word, based largely on ambiguous situational evidence. One aspect of this is what we term the "word generalization" problem, which refers to how children associate a word such as *dog* with a meaning at the appropriate category level in a taxonomy of objects, such as Dalmatians, dogs, or animals.

We present extensions to a cross-situational learner that enable the first computational study of word generalization that is integrated within a word learning model. The model mimics child behavior found by Xu and Tenenbaum (2007): it shows a "basic-level" bias – a preference for word meanings that refer to basic-level objects (like dogs), in contrast to higher-level (animals) or lower-level (Dalmatians) categories – and does so

[7]Similar results obtain using "child" parameter settings, but (as expected) the basic-level generalization is lower.



(a) Containers (b) Clothing (c) Seats

Figure 6: Data from our model.

under parameter settings that treat all levels of category the same in the model (*i.e.*, with no built-in basic-level bias). Other (unequal) parameter settings, which could reflect learned knowledge leading to differential treatment of categories, yield behavior that mimics that of adults, who show a stronger basic-level bias. Moreover, similarly to people (Abbott et al., 2012), our model exhibits variations in generalization to the basic level for different types of objects, a behavior that the model of Xu and Tenenbaum (2007) does not fully replicate.

Overall, the results of our model arise from the interaction of type and token frequencies of features in the input data, which impact the model's evolving word representations. This mechanism in the model captures the type-token influence often observed to underlie people's generalization of linguistic categories – *i.e.*, their linguistic productivity (*e.g.*, Bybee, 1985; Croft and Cruse, 2004).

One shortcoming of the current model is its built-in ability to "detect" in the input that DOG and CAT features are more specific than ANIMAL features. The next step is to consider how the model might learn these relationships from its evolving knowledge of co-occurring features.

Finally, a similar problem to that of word generalization in humans arises in computational linguistics: how to appropriately generalize a set of concepts to an overarching concept that subsumes the set. For example, this problem underlies one way to determine the selectional preferences of a verb: extract the set of nouns that occur as objects of the verb, map them to the concept nodes in a hierarchy such as WordNet, and then determine the best overarching WordNet category for capturing the salient properties of the object nouns overall (*e.g.*, Li and Abe, 1998; Clark and Weir, 2001). An interesting future direction is to explore how an extension of our work can be applied to such problems in computational linguistics.

Abstract

This study focuses on personality prediction of protagonists in novels based on the Five-Factor Model of personality. We present and publish a novel collaboratively built dataset of fictional character personality and design our task as a text classification problem. We incorporate a range of semantic features, including WordNet and VerbNet sense-level information and word vector representations. We evaluate three machine learning models based on the speech, actions and predicatives of the main characters, and show that especially the lexical-semantic features significantly outperform the baselines. The most predictive features correspond to reported findings in personality psychology.

1 Introduction

Recent progress in NLP has given rise to the field of personality profiling - automated classification of personality traits based on written, verbal and multimodal behavior of an individual. This research builds upon findings from classical personality psychology and has applications in a wide range of areas from medicine (suicide prevention) across security (forensics, paedophile detection, cyberbullying) to marketing and sales (recommendation systems, target group profiles). The gold standard labels for an objective evaluation of personality are mostly obtained by means of personality tests of the Five Factor Model (FFM) (McCrae and Costa, 1987; Goldberg, 1990), which is well-known and widely accepted in psychology and other research fields. The FFM defines personality along five bipolar scales: Extraversion (sociable vs. reserved), Emotional stability (secure vs. neurotic), Agreeableness (friendly vs. unsympathic), Conscientiousness (organized vs. careless) and Openness to experience (insightful vs. unimaginative). Psychologists have shown that these five personality traits are stable across individual lifespan, demographical and cultural differences (John and Srivastava, 1999) and affect many life aspects. (Terracciano et al., 2008; Rentfrow et al., 2011).

It has been shown that the personality traits of readers impact their literature preferences (Tirre and Dixit, 1995; Mar et al., 2009). Psychology researchers also found that perceived similarity is predictive of interpersonal attraction (Montoya et al., 2008; Byrne, 1961; Chartrand and Bargh, 1999). More explicitly, recent research (Kaufman and Libby, 2012) shows that readers of a narrative develop more favorable attitudes and less stereotype application towards a character, if his difference (e.g. racial) is revealed only later in the story. We therefore hypothesize that readers might have a preference for reading novels depicting fictional characters that are similar to themselves. Finding a direct link between reader's and protagonist's personality traits would advance the development of content-based recommendation systems. As a first step to explore this hypothesis further, it needs to be determined if we are able to construct a personality profile of a fictional character in a similar way as it is done for humans, and which aspects of personality profiling can be exploited to automatize such procedure.

In this paper, we open this research topic by presenting a novel collaboratively built dataset of fictional character personality in Section 3, which we make available on our website.[1] Framing the personality prediction as a text classification task, we incorporate features of both lexical-

Lisbon, Portugal, 17-21 September 2015.

resource-based and vector space semantics, including WordNet and VerbNet sense-level information and vectorial word representations. We evaluate three machine learning models based on the speech (Section 4), actions (Section 5) and predicatives (Section 6) of the protagonists, and show that especially on the direct speech and action data the lexical-semantic features significantly outperform the baselines. Qualitative analysis reveals that the most predictive features correspond to reported findings in psychology and NLP.

2 Related work

Research in the the area of content-based recommendation systems have shown that incorporating semantic information is valuable for the user and leads to measurable improvements (Passant, 2010; Di Noia et al., 2012; Heitmann and Hayes, 2010). De Clercq et al. (2014) incorporated semantic frames from FrameNet into the recommendation system for books. They represent the plot of each book with a sequence of ca. 200 semantic frames and has shown that the frame information (such as Killing - Revenge - Death) outperforms the bag-of-words approach.Recent NLP experiments begin to reveal the importance of entity-centric models in a variety of tasks. Chambers (2013) show improvement in event schema induction by learning entity-centric rules (e.g., a victim is likely to be a person). Bamman et al. (2014) and Smith et al. (2013) present latent variable models for unsupervised learning of latent character types in movie plot summaries and in English novels, taking authorial style into account. However, even the state-of-the-art NLP work rather describes personas of fictional characters by their role in the story - e.g., action hero, valley girl, best friend, villain etc. - or by their relations to other characters, such as mother or daughter (Elson et al., 2010; Kokkinakis and Malm, 2011), rather than by their inner preferences and motivations. It is important to note here that determining a personality of a character is a very different task from determining its role in the story. Psychological understanding of personality, in contrast to role attribution requires a certain detached objectivity - even outright villains may have traits considered desirable in real life. For example, the devil has in many tales a very high aspiration level, appearing highly conscientious and agreeable. We hypothesize that these deeper personality aspects are those which drive reader's affiliation to the character, thus deserve to be examined closer.

Also literary scholars formulate ad hoc personality descriptions for their experiments, for example to test hypotheses from evolutionary psychology (Johnson et al., 2011) or examine fictional portrayals of physicists (Dotson, 2009). These descriptions are usually adjusted to the experiment focus (e.g. emotions, relationships, ambitions). As McCrae et al. () point out, *a standard set of personality traits, that encompass the full range of characteristics found in all characters in literature* (p.77), is needed for a better comparison.

Hence we base our present study primarily on the previous NLP research on personality prediction of human individuals. Correlations between lexical and stylistic aspects of text and the five FFM personality traits of the author have been found in numerous experiments, with extraversion receiving the most attention (Pennebaker and King, 1999; Dewaele and Furnham, 1999; Gill and Oberlander, 2002; Mehl et al., 2006; Aran and Gatica-Perez, 2013; Lepri et al., 2010). The LIWC lexicon (Pennebaker et al., 2001) established its position as a powerful mean of such analysis.

The first machine learning experiments in this area were conducted by Argamon et al. (2005), Oberlander and Nowson (2006) and Mairesse et al. (2007). Researchers predicted the five personality traits of the authors of stream-of-conscientiousness essays, blog posts and recorded conversation snippets. Given balanced data sets, Mairesse et al. (2007) report binary classification accuracy of 50-56% on extraversion in text and 47-57% in speech, using word ngrams, LIWC, MRC psycholinguistic database (Coltheart, 1981) and prosodic features. Additional improvement is reported when the extraversion was labeled by external judges rather than by self-testing. Extended studies on larger datasets achieve accuracies around 55% (Nowson, 2007; Estival et al., 2007). More recent work in this area focuses on the personality prediction in social networks (Kosinski et al., 2013; Kosinski et al., 2014) and multimodal personality prediction (Biel and Gatica-Perez, 2013; Aran and Gatica-Perez, 2013). These trends emphasized the correlation of network features and audiovisual features with extraversion, giving rise to the Workshop on Computational Personality Recognition (for an overview see (Celli et al., 2013; Celli et al., 2014).

3 Data set construction

Traditionally, the gold standard for this supervised classification task is obtained by the means of personality questionnaires, used for the Five-Factor Model, taken by each of the individuals assessed. This poses a challenge for fictional characters. However, strong correlations have been found between the self-reported and perceived personality traits (Mehl et al., 2006). Our gold standard benefits from the fact that readers enjoy discussing the personality of their favourite book character online. A popular layman instrument for personality classification is the Myers-Brigggs Type Indicator (Myers et al., 1985), shortly MBTI, which sorts personal preferences into four opposite pairs, or dichotomies, such as Thinking vs. Feeling or Judging vs. Perceiving. While the MBTI validity has been questioned by the research community (Pittenger, 2005), the Extraversion scale is showing rather strong validity and correlation to similar trait in the Five-Factor Model (McCrae and Costa, 1989; MacDonald et al., 1994). Our study hence focuses on the Extraversion scale.

Our data was collected from the collaboratively constructed Personality Databank[2] where the readers can vote if a book character is, among other aspects, introverted or extraverted. While the readers used codes based on the MBTI typology, they did not apply the MBTI assessment strategies. There was no explicit annotation guideline and the interpretation was left to readers' intuition and knowledge.[3] This approach of gold standard collection has several obvious drawbacks. First, the question is posed as dichotomic, while in reality the extraversion is a normally distributed trait in human population (Goldberg, 1990). Second, users can view the vote of previous participants, which may influence their decision. While we address both of these issues in our ongoing data collection project based on the Five-Factor Model, we consider them acceptable for this study due to the exploratory character of our pilot research.

We have collected extraversion ratings for 298 book characters, of which 129 (43%) are rather extraverted and 166 (56%) rather introverted. Rated characters come from a wide range of novels that the online users are familiar with, often covering classical literature which is part of the high school syllabus, as well as the most popular modern fiction, such as the Harry Potter series, Twilight, Star Wars or A Game of Thrones. A sample of the most rated introverts and extraverts is given in table 1. The rating distribution in our data is strongly U-shaped. The percentage agreement of voters in our data is 84.9%, calculated as:

$$P = \frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{k}\frac{n_{ij}(n_{ij}-1)}{n(n-1)}$$

where $k = 2$ (introvert, extravert), N is the number of book characters and n the number of votes per character. Voters on the website were anonymous and cannot be uniquely identified for additional corrections. There is no correlation between the extraversion and the gender of the character.

Character	Book	E	I
Tyrion Lannister	Game of Thrones	52	1
Cersei Lannister	Game of Thrones	48	7
Joffrey Baratheon	Game of Thrones	41	1
Ron Weasley	Harry Potter series	37	4
Jamie Lannister	Game of Thrones	38	9
Draco Malfoy	Harry Potter series	33	4
Anakin Skywalker	Star Wars series	30	6
Robert Baratheon	Game of Thrones	28	2
Gimli	Lord of the Rings	19	2
Jar Jar Binks	Star Wars series	12	2
Harry Potter	Harry Potter series	1	71
Severus Snape	Harry Potter series	1	65
Gandalf	Lord of the Rings	1	59
Yoda	Star Wars series	0	58
Jon Snow	Game of Thrones	1	47
Albus Dumbledore	Harry Potter series	4	46
Ned Stark	Game of Thrones	0	41
Aragorn	Lord of the Rings	1	41
Frodo	Lord of the Rings	1	40
Bran Stark	Game of Thrones	1	36

Table 1: Extraverts (E) and introverts (I) with the highest number of user votes.

Our set of English e-books covered 220 of the characters from our gold standard. We have built three systems to assess the following:

1. **Direct speech**: Does the style and content of character's utterances predict his extraversion in a similar way as it was shown for living individuals?
2. **Actions**: Is the behavior, of which a character is an agent, predictive for extraversion?
3. **Predicatives and adverbs**: Are the explicit (*John was an **exhibitionist***) or implicit (*John shouted **abruptly***) descriptions of the character in the book predictive for extraversion?

[2] http://www.mbti-databank.com/

[3] MBTI defines extraversion as "getting energy from active involvement in events, having a lot of different activities, enjoying being around people." In the NEO Five-Factor Inventory (Costa and McCrae, 1992), underlying facets of extraversion are warmth, gregariousness, assertiveness, activity, excitement seeking and positive emotion.

In the next three sections we present the experimental settings and results for each of the systems.

4 Direct speech of fictional characters

The system for the direct speech resembles the most to the previous systems developed for author personality profiling, e.g. on stream of consciousness essays (Mairesse et al., 2007) or social media posts (Celli et al., 2013) and therefore provides the best opportunity for comparison between human individuals and fictional characters. On top of the comparison to previous research, we exploit the sense links between WordNet and VerbNet to extract additional features - an approach which is novel for this type of task.

4.1 Extraction and assignment of speech

We process the book text using freely available components of the DKPro framework (Gurevych et al., 2007). The most challenging task in building the direct speech data set is assigning to the direct speech utterance the correct speaker. We benefit from the `epub` format of the e-books which defines a paragraph structure in such a way, that only the indirect speech chunk immediately surrounding the direct speech can be considered:

```
<p> John turned to Harry.
 "Let's go," he said.</p>
```

Given the large amount of text available in the books we focus on precision and discard all utterances with no explicit speaker (i.e., 30-70% of the utterances, dependent on the book), as the performance of current systems on such utterance types is still fairly low (O'Keefe et al., 2012; He et al., 2013; Iosif and Mishra, 2014). Similarly, conventional coreference resolution systems did not perform well on this type of data and were therefore not used in the final setup. We adapt the Stanford Named Entity Recognizer(Finkel et al., 2005) to consider titles (Mr., Mrs., Sir...) as a part of the name and to treat the first person I as a named entity. However, identifying only the named entity PERSON in this way is not sufficient. On our evaluation sample consisting of *A Game of Thrones* and *Pride and Prejudice* books (the former annotated by us, the latter by He et al. (2013)), 20% of utterances with explicit named speaker were not recognized. Of those correctly identified as a Person in the adjacent indirect speech, 17% were not the speakers. Therefore we implemented a custom heuristics (Algorithm 1), which additionally benefits from the WordNet semantic classes of verbs, enriching the speaker detection by grabbing the nouns . With this method we retrieve 89% of known speakers, of which 92% is assigned correctly. Retrieved names are grouped based on string overlap (e.g. *Ser Jaime* and *Jaime Lannister*), excluding the match on last name, and corrected for non-obvious groupings (such as *Margaret* and *Peggy*).

Algorithm 1 Assign speaker

1: *nsubj* ← subjects in adjacent indirect speech
2: **if** $count(nsubj(i) = \text{PERSON}) = 1$ **then** $speaker \leftarrow nsubj$
3: **else if** $count(nsubj(i) = \text{PERSON}) \geq 1$ **then** $speaker \leftarrow$ the nearest one to $directSpeech$
4: **else if** $directSpeech$ preceded by VERB.COMMUNICATION **then** $speaker \leftarrow$ the preceding noun(s)
5: **else if** $directSpeech$ followed by VERB.COMMUNICATION **then** $speaker \leftarrow$ the following noun(s)
6: **else if** $directSpeech$ followed by gap & VERB.COMMUNICATION **then** $speaker \leftarrow$ the noun(s) in gap
7: **else if** $directSpeech$ preceded by gap & VERB.COMMUNICATION **then** $speaker \leftarrow$ the noun(s) in gap
return $speaker$

Our experimental data consists of usable direct speech sets of 175 characters - 80 extraverts (E) and 95 introverts (I) - containing 289 274 words in 21 857 utterances (on average 111 utterances for E and 136 for I, as I are often central in books).[4]

4.2 Classification approach for direct speech

All speech utterances of one book character are represented as one instance in our system. We use the leave-one-out classification setup due to the relatively small dataset size, using the support vector machines (SVM-SMO) classifier, which performs well on comparable tasks (Celli et al., 2013). The classification is performed through the DKPro TC Framework (Daxenberger et al., 2014).

Lexical features As a bottom-up approach we use the 1000 most frequent word uni-, bi- and trigrams, 1000 dependency word pairs, 1000 character trigrams and 500 most frequent verbs, adverbs, adjectives and interjections as binary features.

Semantic features Since the top-down approach, i.e. not focusing on individual words, has

[4]The data set size is comparable to ongoing personality profiling challenges - see `http://pan.webis.de`

been found more suitable for the personality profiling task on smaller data sets (Celli et al., 2013), we aim on capturing additional phenomena on a higher level of abstraction. The main part of our features is extracted on sense level. We use the most frequent sense of WordNet (Miller, 1995) to annotate all verbs in the direct speech (a simple but well performing approach for books). We then label the disambiguated verbs with their semantic field given in WordNet (WordNet defines 14 semantic classes of verbs which group verbs by their semantic field) and we measure frequency and occurence of each of these classes (e.g. cognition, communication, motion, perception)[5]. Additionally, we use the lexical-semantic resource UBY (Gurevych et al., 2012) to access the WordNet and VerbNet information, and to exploit the VerbNet sense-level links which connects WordNet senses with the corresponding 273 main VerbNet classes (Kipper-Schuler, 2005). These are more fine-grained (e.g. pay, conspire, neglect, discover) than the WordNet semantic fields. WordNet covered 90% and VerbNet 86% of all the verb occurences.

On word level, we extract 81 additional features using the Linguistic Inquiry and Word Count (LIWC) tools (Pennebaker et al., 2001), which consists of lexicons related to psychological processes (cognitive, perceptual, social, biological, affective) and personal concerns (achievement, religion, death...) and other categories such as fillers, disfluencies or swear words[6]. Additionally, since emotion detection has been found predictive in previous personality work (Mohammad and Kiritchenko, 2013), we measure overall positive and negative sentiment expressed per character, using SentiWordNet (Esuli and Sebastiani, 2006) and NRC Emotion Lexicon (Mohammad and Turney, 2010) for the word lookup, inverting sentiment scores for negated dependency sub-tree given by the Stanford Parser.

Stylistic features Features of this group capture the syntactic and stylistic properties of the utterances of a character, disregarding the content. Starting from the surfacial properties, we measure the sentence, utterance and word length, including the proportion of words shorter than 4 or longer than 6 letters, frequency of each punctuation mark, and endings of each adjective as per Corney et al. (2002). On the syntax level we measure the frequency of each part of speech as well as the 500 most frequent part-of-speech bi-, tri- and quadrigrams, and the frequency of each dependency obtained from the Stanford Parser. We additionally capture the frequency of superlatives, comparatives and modal verbs, the proportion of verbs in present, past and future tense, and the formality of the language as per the part-of-speech-based formality coefficient (Heylighen and Dewaele, 2002), and measure the average depth of the parse trees.

Word embeddings as features Since vector space semantics has been beneficial for predicting author's personality in previous work (Neuman and Cohen, 2014), we use a pre-trained word vector model created by the GloVe algorithm (Pennington et al., 2014) on English Wikipedia. GloVe employs a global log-bilinear regression model that combines the advantages of the global matrix factorization and local context window methods. We assign the resulting 300-dimensional vectors to the words in character's direct speech, excluding stopwords, and calculate an average vector for each character. We calculate for each test character the cosine similarity to the mean vector of extravert, resp. introvert, in the training data, and to each character in the training set individually using the DL4J NLP package[7]. We consider both the final scalar outcome and the difference of each of the individual vector dimensions as features.

4.3 Classification results on direct speech

Table 2 shows the precision, recall, F_1-score and accuracy for extraversion and introversion as a weighted average of the two class values.

ID	Feature set	P	R	F	A
1	- (baseline)	.295	.543	.382	.543
2	Ngrams	.519	.514	.515	.514
3	LIWC	.555	.560	**.552**	.560
4	WordNet	.527	.548	.528	.548
5	VerbNet	.649	.617	**.572**	.617
6	Style	.560	.581	**.558**	.581
7	Sentiment	.524	.543	.419	.543
8	Vectors	.295	.543	.382	.543
9	All	.550	632.	**.588**	.632
Percentage human agreement:					.849

Table 2: Weighted precision (P), recall (R), F-score (F) and accuracy (A) for a direct speech system, in each line using only the given group of features. WordNet stands for WordNet semantic labels, VerbNet setup uses the WordNet-VerbNet links to retrieve VerbNet labels. Highlighted F-scores differ from the majority baseline significantly ($p < 0.05$), using an approximate randomization test.

VerbNet	get, talk, substance emission	.18-.15
Style	pronoun We, whadjp, type-token ratio., interjections	.20-.14

Table 3: The most predictive features for each group for speaker's extraversion and introversion. Correlation merit, as per the correlation feature selection in WEKA, evaluates Pearson's correlation between the feature and the class

Similarly to previous research (Mairesse et al., 2007; Celli et al., 2013), the bottom-up word based approach is outperformed by top-down semantic approaches which employ a more abstract feature representation. As in previous work, LIWC features exhibit good performance. However, the highest performance is achieved employing the VerbNet verb classes with WordNet word-sense disambiguation. Also stylistic features contribute substantially to the classification despite the mixture of genres in our book corpus - especially frequencies of modal verbs and part-of-speech ratios were particularly informative. The most predictive features from each group are listed in Table 3 together with their correlation merit (Hall, 1999), and compared with previous work in Table 4.

Feature	**I/E**	**Ref**	**Feature**	**I/E**	**Ref**

[1]		Pennebaker and King (1999)			
[2]		Dewaele and Furnham (1999)			
[3]		Mairesse et al. (2007)			

Table 4: Comparison of our results to previously reported predictive features for speaker's extraversion (E), resp. introversion (I). We list publications where these features were, to our knowledge, reported as novel.

In accordance with the experiments of Pennebaker and King (1999), we observe more frequent exclusions (e.g. *without, but*), hedging and negation expressed by introverts, and inclusion (e.g. *with, and*) by extraverts. Extraverts talk more in first person plural, use more back-channels and interjections, and talk more about aspects related to their body. Introverts show more rationalization through insight words and more factual speech using less pronouns.

Additionally, the semantic features in Table 3 confirm the broad psychological characteristics of both types in general, i.e., for introverts the rationalization, uncertainty and preference for individual or rather static activities, and for extraverts their spontaneity, talkativeness and preference for motion. Furthermore, we observe certain directness in extraverts' speech - note the predictive words *fat* and *dirty* and frequent descriptions of body functions.

Discussion Exploiting the links between lexical-semantic resources (performing WordNet word-sense disambiguation and using VerbNet verb classes linked to the disambiguated senses) was particularly beneficial for this task. WordNet semantic fields for verbs alone are too coarse-grained to capture the nuances in direct speech, and experiments with fine-grained VerbNet classes without WSD resulted in noisy labels. We did not confirm the previously reported findings on emotional polarity - we observe that the genre of the books (e.g. love romance vs horror story) have blurred the subtle differences between individual characters, unfortunately the dataset size did not allow for genre distinctions. Furthermore, a perceived extravert in our case can be a pure villain (Draco Malfoy, Joffrey Baratheon...) as well as a friendly companion (Gimli, Ron Weasley...), while the evil extravert types are possibly rarer in the experiments on human writing, or are more likely to fit under the MBTI definition of extraversion than FFM facets. Another potential cause, based on the error analysis, is the different target of the same sentiment for extraverts and introverts. For example, the ngram "I fear" is highly predictive for an introvert in our data while extraverts would rather use formulations to imply that others should fear. Similarly to Nowson et al. (2005), we did not find any difference in the formality measure of Heylighen and Dewaele (2002). Neither we did in the complexity of sentences as per the parse tree depth

and sentence length. It is probable that these aspects were also impacted by our broad variety of author style (F. Dostoyevsky vs J. K. Rowling). Our basic vector-based features carried no useful information in our case, in contrast to the personality research of Neuman and Cohen (2014). We observed that the factual content of the stories contributed to the character similarity measure more than the subtle personality differences.

5 Actions of fictional characters

While psycholinguists and consequenlty NLP researchers analyzed the relation between speech, resp. writing, and personality of an individual, psychologists often evaluate extraversion through behavioral personality questionnaries (Costa and McCrae, 1992; Goldberg et al., 2006). We hypothesize that similar behavior shall be predictive for extraversion of fictional characters as perceived by the readers.

5.1 Action extraction

For our purpose we define actions as the subject, verb and context of a sentence, where the subject is a named entity Person and the context is either a direct object in relation *dobj* to the verb or a first child of the adjacent verb phrase in a parse tree. After grouping the actions per character, the subject name is removed. For example, a sample of actions of the character Eddard Stark of Game of Thrones would be: *X paused a moment, X studied his face, X changed his mind, X unrolled the paper, X said* etc., visualized in Figure 1. We obtained 22 030 actions for 205 characters (102 E, 116 I), with on average 100 actions for E and 101 for I. Note that also actions for those characters who do not talk enough in the books (often first-person perspectives) could be used.

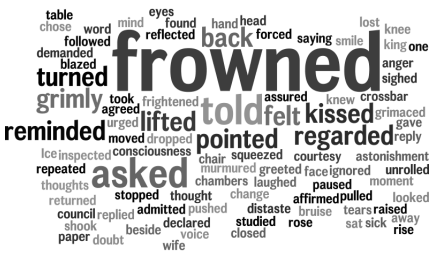

Figure 1: A revealing word cloud of the most frequent words from the actions of which Eddard Stark (Game of Thrones) is a subject. Size is proportional to the frequency of a word.

5.2 Action classification setup

In the system based on actions we use only a subset of the features described in 4.2. From the lexical features we focus on the 500 most frequent verbs and dependency word pairs. Semantic features are used the same way as in 4.2, profiting from LIWC, WordNet, Verbnet and the sentiment lexicons. Word embedding vectors for book characters are in this case computed by taking only the verbs into account rather than all content words. From the stylistic features we use the part-of-speech bigrams and trigrams, verb modality and verb tense.

5.3 Classification results on actions

Table 5 shows the performance of the classification models based on the protagonists' actions, using different feature groups. The overall performance is higher than for the direct speech model.

ID	Feature set	P	R	F	A
1	- (baseline)	.267	.517	.352	.517
2	Ngrams	.539	.506	.505	.507
3	LIWC	.600	.577	**.567**	.577
4	WordNet	.517	.518	.517	.518
5	VerbNet	.599	.583	**.578**	.583
6	Style	.573	.601	**.553**	.601
7	Sentiment	.357	.453	.382	.453
8	Vectors	.504	.497	.451	.497
9	All	.600	.623	**.598**	.623
Percentage human agreement:					.849

Table 5: Weighted precision (P), recall (R), F-score (F) and accuracy (A) for actions - in each line for a system using only the given group of features. WordNet stands for WordNet semantic labels, VerbNet setup uses the WordNet-VerbNet links. Highlighted F-scores differ from the majority baseline significantly ($p < 0.05$), using an approx. randomization test.

Due to the lack of previous NLP experiments on this task, we compare our features to the actions measured in the International Personality Item Pool (Goldberg et al., 2006), frequently used personality assesment questionnaire (Table 6).

The most predictive features of this model capture the activity and excitement seeking facets of extraversion. Stylistic features reflect the complexity difference of the verb phrases (*John jumped vs. John thought about it*), extraverts being characterized by plain verbs. Semantic features exhibit higher precision than stylistic ones. Sense-linked semantic classes of VerbNet demonstrate the preference of extraverts for being active and expressing themselves - they *jump*, *fight, shout, run* in and run out, *eat* and *drink*, *see* and *hear* and get easily *bored*. Extraverts in books also

Extravert International Personality Item Pool:
likes to party, feels comfortable around people, starts conversations, talks to many people, enjoys being a center of attention, makes friends easily, takes charge, captivates people, feels at ease with a company, is skilled in handling social situations
Our experiment:
bring (VN), consume (VN), contiguous location(VN), holding (VN), social (WN), motion (WN), emotion (WN) Leisure (LIWC), Home (LIWC), Family (LIWC), fight, march, care, take, jump, shriek, clear throat, bore, get to, come in, agree, hold, hear, inform, sell, come forward
Introvert International Personality Item Pool:
Doesn't talk much, stays in the background, has little to say, does not draw attention, has difficulties to approach others, is quiet around strangers, feels uncomfortable around others,does not show feelings, is a private person, waits to be lead
Our experiment:
snooze (VN), conceal (VN), wish (VN), stative (WN), creation (WN), walk, sleep, lay, know, maintain, expect, hope, find out, might, help, explain

Table 6: Characteristic actions for extraverts and introverts as assessed in the IPIP personality questionaire, compared to our most informative features

often *bring* or *hold* something. Introverts, on the other hand, seem to favor slow movements - while they are *thinking, reflecting, creating*, looking for *explanations* and *find out* solutions, they tend to *lie down, sit* or *walk*, eventually even *sleep* or *snooze*. The uncertainty typical for introverts is also notable in their actions, as they often *hope* or *wish* for something they *might* like to do. Additionally, semantic classes Social and Family, reported as correlated to extraversion by Pennebaker and King (1999) and not confirmed in our first model, became predictive in protaonists' actions.

5.4 Discussion

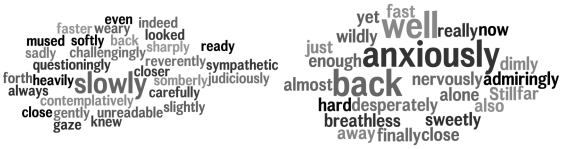
Also in this task, the VerbNet classes brought significant improvement in performance. The classification model based on actions outperforms not only the direct speech model, but also the state-of-the-art systems predicting authors' extraversion from the stream-of-consciousness essays (Mairesse et al., 2007; Celli et al., 2013; Neuman and Cohen, 2014). While surely not directly comparable, this result hints to the fact that the personality is easier to detect from behavior than from person's verbal expression. This would correspond to the findings of Mairesse et al. (2007), Biel and Gatica-Perez (2013) and Aran and Gatica-Perez (2013) on multimodal data sets.

6 Predicatives of fictional characters

Our third extraversion prediction system is subordinate to how fictional characters are described and to the manners in which they behave. We are not aware of a previous NLP work predicting extraversion using descriptive adjectives of the persons in question. We thus juxtapose the most predictive features of our system to the adjectival extraversion markers developed by Goldberg (1992).

6.1 Extraction of descriptive properties

In this setup we extract predicatives of the named entities PERSON in the books - relations *amod* (***angry*** *John*) and *cop* (*John was* ***smart***). As these explicit statements are very sparse in modern novels, we additionally include adverbial modifiers (*advmod*) related to person's actions (*John said* ***angrily***). We extract data for 205 characters, with on average 43 words per character.



(a) Master Yoda (Star Wars)

(b) Sansa Stark (Game of Thrones)

Figure 2: Frequency word clouds for character descriptions

6.2 Classification setup

This system uses similar set of lexical, semantic and vectorial features similarly as in 5.2, this time with the focus on adjectives, nouns and adverbs instead of verbs. Stylistic and VerbNet features are hence not included, word vectors are as in 4.2.

6.3 Classification results on descriptions

Table 7 reports on the performance of individual feature groups. With only few words per character semantic lexicons are less powerful than ngrams.

ID	Feature set	P	R	F	A
1	- (baseline)	.267	.517	.352	.517
2	Ngrams	.686	.657	**.648**	.657
3	LIWC	.645	.601	**.586**	.601
4	WordNet	.518	.545	.528	.545
5	Sentiment	.375	.463	.384	.463
6	Vectors	.267	.517	.352	.517
7	All	.692	.698	**.693**	.698
Percentage human agreement:					.849

Table 7: Weighted precision, recall, F-score and accuracy. Highlighted F-scores differ from the majority baseline significantly ($p < 0.05$).

Table 8 displays the most predictive features in our system contrasted to the adjectival markers.

Extravert Goldberg (1992) :
adventurous,mischievous, playful, rambunctious, dominant, forceful, demonstrative, exhibitionistic, flamboyant, brave, courageous, daring, assured,...
Our experiment :
excited, restlessly, stubbornly, restless, beloved, eager, abruptly, defiantly, darkly, eagerly, loudly, reluctant, stubborn, unwise, ruthless, quickly, abruptly, right, change (WN), social (WN)
Introvert Goldberg (1992) :
bashful, shy, timid, inhibited, restrained unadventurous, unaggressive, uncompetitive bitter, joyless, melancholic, moody, morose,...
Our experiment :
anxious, patiently, hesitantly, backward, softly, warily, coldly, helplessly, respectfully, slowly, politely, thoughtfully, nervously, silent, carefully, gratefully, dryly, sheepishly, politely, weary, calm, gently, sadly, sideways, stative (WN)

Table 8: Characteristic adjectives for extraverts and introverts as reported by L. Goldberg, compared to our most informative features as per the correlation merit

6.4 Discussion on errors

All our systems had issues with characters rated by less than five readers and with protagonists with low agreement. Other challenges arise from authorial style, age of the novel and speech individuality of characters (e.g. *Yoda*). Varied length of information for different characters poses issues in measuring normally distributed features (e.g. ratio of jumping verbs), being in shorter texts less reliable. Ongoing and future work on this task addresses the limitations of these initial experiments, especially the data set size and the gold standard quality. Extending the data will also enable us to examine different book genres as variables for the personality distribution and feature impact. It will be worth examining the relations between characters, since we observed certain patterns in our data, such as the main introvert character supported by his best friend extravert. Additionally, we want to verify if the system in Section 6 is overly optimistic due to the data size.

7 Conclusion and future work

Automated personality profiling of fictional characters, based on rigorous models from personality psychology, has a potential to impact numerous domains. We framed it as a text classification problem and presented a novel collaboratively built dataset of fictional personality. We incorporate features of both lexical resource-based and vectorial semantics, including WordNet and VerbNet sense-level information and vectorial word representations. In models based on the speech and actions of the protagonists, we demonstrated that the sense-linked lexical-semantic features significantly outperform the baselines. The most predictive features correspond to the reported findings in personality psychology and NLP experiments on human personality. Our systems based on actions and appearance of characters demonstrate higher performance than systems based on direct speech, which is in accordance with recent research on personality in social networks (Kosinski et al., 2014; Biel and Gatica-Perez, 2013), revealing the importance of the metadata. We have shown that exploiting the links between lexical resources to leverage more accurate semantic information can be beneficial for this type of tasks, oriented to actions performed by the entity. However, the human annotator agreement in our task stays high above the performance achieved. Considering that most of the sucessful novels were produced as movies, we cannot exclude that our annotators based their decision on the multimodal representation of the protagonists. In the future we aim on collecting a more detail and rigorous gold standard through gamification and expanding our work on all five personality traits from the Five-Factor Model and their facets, and ultimately extend our system to a semi-supervised model dealing with notably larger amount of data. We also plan to examine closer the differences between perceived human and fictional personality, and the relationship between the personality of the reader and the characters.

Acknowledgments

This work has been supported by the Volkswagen Foundation as part of the Lichtenberg Professorship Program under grant No. I/82806 and by the German Research Foundation under grant No. GU 798/14-1. Additional support was provided by the German Federal Ministry of Education and Research (BMBF) as a part of the Software Campus program under the promotional reference 01-S12054 and by the German Institute for Educational Research (DIPF). Abstract

Expectation-maximization algorithms, such as those implemented in GIZA++ pervade the field of unsupervised word alignment. However, these algorithms have a problem of over-fitting, leading to "garbage collector effects," where rare words tend to be erroneously aligned to untranslated words. This paper proposes a leave-one-out expectation-maximization algorithm for unsupervised word alignment to address this problem. The proposed method excludes information derived from the alignment of a sentence pair from the alignment models used to align it. This prevents erroneous alignments within a sentence pair from supporting themselves. Experimental results on Chinese-English and Japanese-English corpora show that the F_1, precision and recall of alignment were consistently increased by 5.0% – 17.2%, and BLEU scores of end-to-end translation were raised by 0.03 – 1.30. The proposed method also outperformed l_0-normalized GIZA++ and Kneser-Ney smoothed GIZA++.

1 Introduction

Unsupervised word alignment (WA) on bilingual sentence pairs serves as an essential foundation for building most statistical machine translation (SMT) systems. A lot of methods have been proposed to raise the accuracy of WA in an effort to improve end-to-end translation quality. This paper contributes to this effort through refining the widely used expectation-maximization (EM) algorithm for WA (Dempster et al., 1977; Brown et al., 1993b; Och and Ney, 2000).

The EM algorithm for WA has a great influence in SMT. Many well-known toolkits including GIZA++ (Och and Ney, 2003), the Berkeley Aligner (Liang et al., 2006; DeNero and Klein, 2007), Fast Align (Dyer et al., 2013) and SyMGIZA++ (Junczys-Dowmunt and Sza, 2012), all employ this algorithm. GIZA++ in particular is frequently used in systems participating in many shared tasks (Goto et al., 2011; Cettolo et al., 2013; Bojar et al., 2013).

However, the EM algorithm for WA is well-known for introducing "garbage collector effects." Rare words have a tendency to collect garbage, that is they have a tendency to be erroneously aligned to untranslated words (Brown et al., 1993a; Moore, 2004; Ganchev et al., 2008; V Graça et al., 2010). Figure 1(a) shows a real sentence pair, denoted $\mathbf{s}$, from the GALE Chinese-English Word Alignment and Tagging Training corpus (GALE WA corpus)[1] with it's human-annotated word alignment. The Chinese word "HE ZHANG," denoted w_r, which means river custodian, only occurs once in the whole corpus. We performed EM training using GIZA++ on this corpus concatenated with 442,967 training sentence pairs from the NIST Open Machine Translation (OpenMT) 2006 evaluation[2]. The resulting alignment is shown in Figure 1(b). It can be seen that w_r is erroneously aligned to multiple English words.

To find the cause of this, we checked the alignments in each iteration i of $\mathbf{s}$, denoted $\mathbf{a_s^i}$. We found that in $\mathbf{a_s^1}$, w_r together with the other source-side words were aligned with uniform probability to all the target-side words since the alignment models provided no prior information. However, in $\mathbf{a_s^2}$, w_r became erroneously aligned,

* The author now is affiliated with Google, Japan.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1817–1827,
Lisbon, Portugal, 17-21 September 2015.

because the alignment distribution[3] of w_r was only learned from $\mathbf{a_s^1}$, thus consisted of non-zero values only for generating the target-side words in $\mathbf{s}$. Therefore, the alignment probabilities from the rare word w_r to the unaligned words in $\mathbf{s}$ were extraordinarily high, since almost all of the probability mass was distributed among them. In other words, the story behind these garbage collector effects is that erroneous alignments are able to provide support for themselves; the probability distribution learned only from $\mathbf{s}$ is re-applied to $\mathbf{s}$. In this way, these "garbage collector effects" are a form of over-fitting.

Motivated by this observation, we propose a leave-one-out EM algorithm for WA in this paper. Recently this technique has been applied to avoid over-fitting in kernel density estimation (Roux and Bach, 2011); instead of performing maximum likelihood estimation, maximum leave-one-out likelihood estimation is performed. Figure 1(c) shows the effect of using our technique on the example. The garbage collection has not occurred, and the alignment of the word "HE ZHANG" is identical to the human annotation.

2 Related Work

The most related work to this paper is training phrase translation models with leave-one-out forced alignment (Wuebker et al., 2010; Wuebker et al., 2012). The differences are that their work operates at the phrase level, and their aim is to improve translation models; while our work operates at the word level, and our aim is to provide better word alignment. As word alignment is a foundation of most MT systems, our method have a wider application.

Recently, better estimation methods during the maximization step of EM have been proposed to avoid the over-fitting in WA, such as using Kneser-Ney Smoothing to back-off the expected counts (Zhang and Chiang, 2014) or integrating the smoothed l_0 prior to the estimation of probability (Vaswani et al., 2012). Our work differs from theirs by addressing the over-fitting directly in the EM algorithm by adopting a leave-one-out approach.

Bayesian methods (Gilks et al., 1996; Andrieu et al., 2003; DeNero et al., 2008; Neubig et al., 2011), also attempt to address the issue of over-fitting, however EM algorithms related to the proposed method have been shown to be more efficient (Wang et al., 2014).

[3]The probability distribution of generating target language words from w_r. The description here is only based on IBM model1 for simplicity, and the other alignment models are similar.

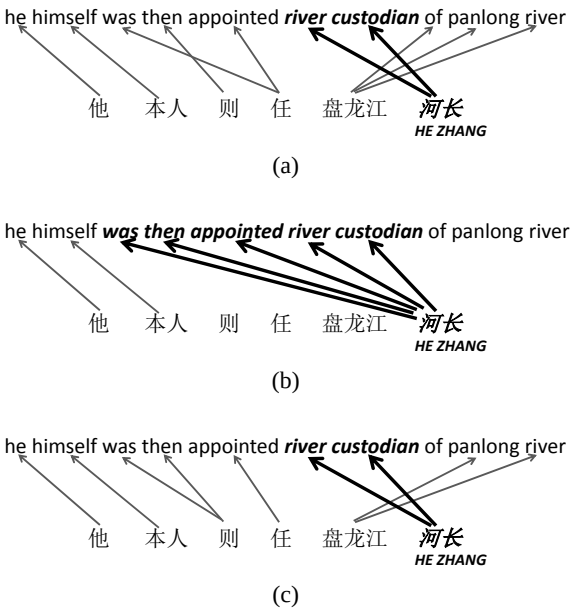

Figure 1: Examples of supervised word alignment. (a) gold alignment; (b) standard EM (GIZA++); (c) Leave-one-out alignment (proposed).

3 Methodology

This section first formulates the standard EM for WA, then presents the leave-one-out EM for WA, and finally briefly discusses handling singletons and effecient implementation. The main notation used in this section is shown in Table 1.

3.1 Standard EM for IBM Models 1, 2 and HMM Model

To perform WA through EM, the parallel corpus is taken as observed data, the alignments are taken as latent data. In order to maximize the likelihood of the alignment model θ given the data $\mathbf{S}$, the following two steps are conducted iteratively (Brown et al., 1993b; Och and Ney, 2000; Och and Ney, 2003),

Expectation Step (E step): calculating the conditional probability of alignments for each sentence pair,

$$P(\mathbf{a}|\mathbf{s},\theta) \quad = \prod_{j=1}^{J} \theta_{\text{ali}}(a_j|a_{j-1},I)\theta_{\text{lex}}(f_j|e_{a_j}) \quad (1)$$

where $\theta_{\text{ali}}(i|i',I)$ is the alignment probability and $\theta_{\text{lex}}(f|e)$ is the translation probability. Note that

$\mathbf{f}$	a foreign sentence $(f_1, \ldots, f_J)$
$\mathbf{e}$	an English sentence $(e_1, \ldots, e_I)$
$\mathbf{s}$	a sentence pair $(\mathbf{f}, \mathbf{e})$
$\mathbf{a}$	an alignment $(a_1, \ldots, a_J)$ where f_j is aligned to e_{a_j}
B_i	a list of the indexes of the foreign words which are aligned to e_i
$B_{i,k}$	the index of the k-th foreign word which is aligned to e_i
$\overline{B_i}$	is the average of all elements in B_i
ρ_i	the largest index of an English word $s.t.\ \rho_i < i$ and $\lvert B_{\rho_i}\rvert > 0$
ϕ_i	the fertility of e_i
E_i	the word class of e_i
$\theta_\cdot$	an probabilistic model
$\theta_\cdot^{\bar{\mathbf{s}}}$	a leave-one-out probabilistic model for $\mathbf{s}$
$n_x(\mathbf{s}, \mathbf{a})$	the number of times that an event x happens in $(\mathbf{s}, \mathbf{a})$
$N_x(\mathbf{s})$	the marginal number of times that an event x happens in $\mathbf{s}$

Table 1: Main Notation. Note that $N_x(\mathbf{s}) = \sum_{\mathbf{a}} n_x(\mathbf{s}, \mathbf{a}) P(\mathbf{a}|\mathbf{s})$. In practical calculation, for IBM models 1, 2 and HMM model, this summation is performed by dynamic programming; for IBM model 4, it is performed approximately using the best alignment and its neighbors.

(1) is a general form for IBM model 1, model 2 and the HMM model.

Maximization step (M step): re-estimating the probability models,

$$\theta_{\text{ali}}(i|i', I) \leftarrow \frac{\sum_{\mathbf{s}} N_{i|i',I}(\mathbf{s})}{\sum_{\mathbf{s}} N_{i',I}(\mathbf{s})} \quad (2)$$

$$\theta_{\text{lex}}(f|e) \leftarrow \frac{\sum_{\mathbf{s}} N_{f|e}(\mathbf{s})}{\sum_{\mathbf{s}} n_e(\mathbf{s})} \quad (3)$$

where $N_{i',I}(\mathbf{s})$ is the marginal number of times $e_{i'}$ is aligned to some foreign word if the length of $\mathbf{e}$ is I, or 0 otherwise; $N_{i|i',I}(\mathbf{s})$ is the marginal number of times the next alignment position after i' is i in $\mathbf{a}$ if the length of $\mathbf{e}$ is I, or 0 otherwise; $n_e(\mathbf{s})$ is the count of e in $\mathbf{e}$; $N_{f|e}(\mathbf{s}, \mathbf{a})$ is the marginal number of times e is aligned to f.

3.2 Leave-one-out EM for IBM Models 1, 2 and HMM Model

Leave-one-out EM for WA differs from standard EM in the way the alignment and translation probabilities are calculated. Each sentence pair will have its own alignment and translation probability models calculated by excluding the sentence pair itself. More formally, leave-one-out EM for WA are formulated as follows,

Leave-one-out E step: employing leave-one-out models for each $\mathbf{s}$ to calculate the conditional probability of alignments

$$P(\mathbf{a}|\mathbf{s}, \theta_{\bar{\mathbf{s}}}) = \prod_{j=1}^{J} \theta_{\text{ali}}^{\bar{\mathbf{s}}}(a_j|a_{j-1}, I) \theta_{\text{lex}}^{\bar{\mathbf{s}}}(f_j|e_{a_j}) \quad (4)$$

where $\theta_{\text{ali}}^{\bar{\mathbf{s}}}(i|i', I)$ and $\theta_{\text{lex}}^{\bar{\mathbf{s}}}(f_j|e_{a_j})$ are the leave-one-out alignment probability and translation probability, respectively.

Leave-one-out M step: re-estimating leave-one-out probability models,

$$\theta_{\text{ali}}^{\bar{\mathbf{s}}}(i|i', I) \leftarrow \frac{\sum_{\mathbf{s}' \neq \mathbf{s}} N_{i|i',I}(\mathbf{s}')}{\sum_{\mathbf{s}' \neq \mathbf{s}} N_{i',I}(\mathbf{s}')} \quad (5)$$

$$\theta_{\text{lex}}^{\bar{\mathbf{s}}}(f|e) \leftarrow \frac{\sum_{\mathbf{s}' \neq \mathbf{s}} N_{f|e}(\mathbf{s}')}{\sum_{\mathbf{s}' \neq \mathbf{s}} n_e(\mathbf{s}')}. \quad (6)$$

3.3 Standard EM for IBM Model 4

The framework of the standard EM for IBM Model 4 is similar with the one for IBM Models 1, 2 and HMM Model, but the calculation of alignment probability is more complicated.

E step: calculating the conditional probability through the reverted alignment (Och and Ney, 2003),

$$P(\mathbf{a}|\mathbf{s}, \theta) = P(B_0|B_1, \ldots, B_I) \cdot \prod_{i=1}^{I} P(B_i|B_{i-1}, e_i) \cdot \prod_{i=1}^{I} \prod_{j \in B_i} \theta_{\text{lex}}(f_j|e_i), \quad (7)$$

where B_0 means the set of foreign words aligned with the empty word; $P(B_0|B_1, \ldots, B_I)$ is assumed to be a binomial distribution for the size of B_0 (Brown et al., 1993b) or an modified distribution to relieve deficiency (Och and Ney, 2003).

The distribution $P(B_i|B_{i-1}, e_i)$ is decomposed as

$$P(B_i|B_{i-1}, e_i) = \theta_{\text{fer}}(\phi_i|e_i) \cdot \theta_{\text{hea}}(B_{i,1} - \overline{B_{\rho_i}}|E_{\rho_i}) \cdot \prod_{k=2}^{\phi_i} \theta_{\text{oth}}(B_{i,k} - B_{i,k-1}), \quad (8)$$

where θ_{fer} is a fertility model; θ_{hea} is a probability model for the head (first) aligned foreign word; θ_{oth} is a probability model for the other aligned foreign words. θ_{hea} is assumed to be conditioned

on the word class E_{ρ_i}, following the paper of (Och and Ney, 2003) and the implementation of GIZA++ and CICADA.

M step: re-estimating the probability models,

$$\theta_{\text{fer}}(\phi|e) \leftarrow \frac{\sum_{\mathbf{s}} N_{\phi|e}(\mathbf{s})}{\sum_{\mathbf{s}} \sum_{\phi'} N_{\phi'|e}(\mathbf{s})} \quad (9)$$

$$\theta_{\text{hea}}(\Delta i|E) \leftarrow \frac{\sum_{\mathbf{s}} N^{\text{hea}}_{\Delta i|E}(\mathbf{s})}{\sum_{\mathbf{s}} \sum_{\Delta i'} N^{\text{hea}}_{\Delta i'|E}(\mathbf{s})} \quad (10)$$

$$\theta_{\text{oth}}(\Delta i) \leftarrow \frac{\sum_{\mathbf{s}} N^{\text{oth}}_{\Delta i}(\mathbf{s})}{\sum_{\mathbf{s}} \sum_{\Delta i'} N^{\text{oth}}_{\Delta i'}(\mathbf{s})}, \quad (11)$$

where Δi is a difference of the indexes of two foreign words.

3.4 Leave-one-out EM for IBM Model 4

The leave-one-out treatment were applied to the three component probability models θ_{fer}, θ_{hea} and θ_{oth} of IBM model 4.

Leave-one-out E step: calculating the conditional probability through leave-one-out probability models

$$P(\mathbf{a}|\mathbf{s}, \theta^{\bar{\mathbf{s}}}) = P(B_0|B_1, \ldots, B_I) \cdot \prod_{i=1}^{I} P^{\bar{\mathbf{s}}}(B_i|B_{i-1}, e_i) \cdot \prod_{i=1}^{I} \prod_{j \in B_i} \theta^{\bar{\mathbf{s}}}_{\text{lex}}(f_j|e_i), \quad (12)$$

$$P^{\bar{\mathbf{s}}}(B_i|B_{i-1}, e_i) = \theta^{\bar{\mathbf{s}}}_{\text{fer}}(\phi_i|e_i) \cdot \theta^{\bar{\mathbf{s}}}_{\text{hea}}(B_{i,1} - \overline{B_{\rho_i}}|E_{\rho_i}) \cdot \prod_{k=2}^{\phi_i} \theta^{\bar{\mathbf{s}}}_{\text{oth}}(B_{i,k} - B_{i,k-1}). \quad (13)$$

Leave-one-out M step: re-estimating the leave-one-out probability models,

$$\theta^{\bar{\mathbf{s}}}_{\text{fer}}(\phi|e) \leftarrow \frac{\sum_{\mathbf{s}' \neq \mathbf{s}} N_{\phi|e}(\mathbf{s}')}{\sum_{\mathbf{s}' \neq \mathbf{s}} \sum_{\phi'} N_{\phi'|e}(\mathbf{s}')} \quad (14)$$

$$\theta^{\bar{\mathbf{s}}}_{\text{hea}}(\Delta i|E) \leftarrow \frac{\sum_{\mathbf{s}' \neq \mathbf{s}} N^{\text{hea}}_{\Delta i|E}(\mathbf{s}')}{\sum_{\mathbf{s}' \neq \mathbf{s}} \sum_{\Delta i'} N^{\text{hea}}_{\Delta i'|E}(\mathbf{s}')} \quad (15)$$

$$\theta^{\bar{\mathbf{s}}}_{\text{oth}}(\Delta i) \leftarrow \frac{\sum_{\mathbf{s}' \neq \mathbf{s}} N^{\text{oth}}_{\Delta i}(\mathbf{s}')}{\sum_{\mathbf{s}' \neq \mathbf{s}} \sum_{\Delta i'} N^{\text{oth}}_{\Delta i'}(\mathbf{s}')}. \quad (16)$$

3.5 Handling Singletons

Singletons are the words that occur only once in corpora. Singletons cause problems when applying leave-one-out to lexicalized models such as the translation model $\theta^{\bar{\mathbf{s}}}_{\text{lex}}$ and the fertility model $\theta^{\bar{\mathbf{s}}}_{\text{fer}}$. When calculating (6) and (14) for singletons, the denominators become zero, thus the probabilities are undefined.

For singletons, there is no prior information to guide their alignment, so we back off to uniform distributions. In that case, the alignments are primarily determined by the rest of the sentence.

In addition, singletons can be in the target side of the translation model $\theta^{\bar{\mathbf{s}}}_{\text{lex}}$. In that case, the probabilities become zero. This is handled by setting a minimum probability value of 1.0×10^{-12}, which was decided by pilot experiments.

3.6 Implementation Details

To alleviate memory requirements and increase speed, our implementation did not build or store the local alignment models explicitly for each sentence pair. The following formula was used to efficiently calculate (5), (6) and (14–16) to build temporary probability models,

$$\sum_{\mathbf{s}' \neq \mathbf{s}} N_x(\mathbf{s}') = (\sum_{\mathbf{s}'} N_x(\mathbf{s}')) - N_x(\mathbf{s}), \quad (17)$$

where x is a alignment event. Our implementation maintained global counts of all alignment events $\sum_{\mathbf{s}'} N_x(\mathbf{s}')$, and (considerably smaller) local counts $N_x(\mathbf{s})$ from each sentence pair $\mathbf{s}$.

Take the translation model $\theta^{\bar{\mathbf{s}}}_{\text{lex}}$ for example. For a sentence pair $\mathbf{s} = (f_1 \ldots f_J, e_1 \ldots e_I)$, it is caculated as,

$$\theta^{\bar{\mathbf{s}}}_{\text{lex}}(f_j|e_i) = \frac{(\sum_{\mathbf{s}'} N_{(f_j|e_i)}(\mathbf{s}')) - N_{(f_j|e_i)}(\mathbf{s})}{(\sum_{\mathbf{s}'} n_{e_i}(\mathbf{s}')) - n_{e_i}(\mathbf{s})}. \quad (18)$$

The global counts to be maintained are $\sum_{\mathbf{s}'} N_{(f_j|e_i)}(\mathbf{s}')$ and $n_{e_i}(\mathbf{s}')$, and the local counts are $\sum_{\mathbf{s}} N_{(f_j|e_i)}(\mathbf{s})$ and $n_{e_i}(\mathbf{s})$. Therefore the memory cost is,

$$|\mathcal{E}| \cdot (|\mathcal{F}| + 1) + \sum_{\mathbf{s}} I_{\mathbf{s}}(J_{\mathbf{s}} + 1), \quad (19)$$

where $|\mathcal{E}|$ is the size of English vocabulary, $|\mathcal{F}|$ is the size of foreign language vocabulary, $I_{\mathbf{s}}$ is the length of the English sentence of $\mathbf{s}$, and $J_{\mathbf{s}}$ is the length of the foreign sentence of $\mathbf{s}$.

The calculation of the leave-one-out translation model is performed for each English word and foreign word in $\mathbf{s}$. Therefore, the time cost is,

$$\sum_{\mathbf{s}} I_{\mathbf{s}}(J_{\mathbf{s}} + 1). \quad (20)$$

In addition, because the local counts $N_{(f_j|e_i)}(\mathbf{s})$ and $n_{e_i}(\mathbf{s})$ are read in order, storing them in a external memory such as a hard disk will not slow down the running speed much. This will reduce the memory cost to

$$|\mathcal{E}| \cdot (|\mathcal{F}| + 1). \quad (21)$$

This cost is independent to the number of sentence pairs[4].

The speed of the proposed method can be boosted through parallelism. These calculations on each sentence pair can be performed independently. We found empirically that when our implementation of the proposed method is run on a 16-core computer, it finishes the task earlier than GIZA++[5].

4 Experiments

The proposed WA method was tested on two language pairs: Chinese-English and Japanese-English (Table 2). Performance was measured both directly using the agreement with reference to manual WA annotations, and indirectly using the BLEU score in end-to-end machine translation tasks. GIZA++ and our own implementation of standard EM were used as baselines.

4.1 Experimental Settings

The Chinese-English experimental data consisted of the GALE WA corpus and the OpenMT corpus. They are from the same domain, both contain newswire texts and web blogs. The OpenMT evaluation 2005 was used as a development set for MERT tuning (Och, 2003), and the OpenMT evaluation 2006 was used as a test set. The Japanese-English experimental data was the Kyoto Free Translation Task (Neubig, 2011)[6]. The corpus contains a set of 1,235 sentence pairs that are manually word aligned.

The corpora were processed using a standard procedure for machine translation. The English texts were tokenized with the tokenization script released with Europarl corpus (Koehn, 2005) and converted to lowercase; the Chinese texts were segmented into words using the Stanford Word Segmenter (Xue et al., 2002)[7]; the Japanese texts were segmented into words using the Kyoto Text Analysis Toolkit (KyTea[8]). Sentences longer than 100 words or those with foreign/English word length ratios between larger than 9 were filtered out.

GIZA++ was run with the default Moses settings (Koehn et al., 2007). The IBM model 1, HMM model, IBM model 3 and IBM model 4 were run with 5, 5, 3 and 3 iterations. We implemented the proposed leave-one-out EM and standard EM in IBM model 1, HMM model and IBM model 4. In the original work (Och and Ney, 2003) this combination of models achieved comparable performance to the default Moses settings. They were run with 5, 5 and 6 iterations.

The standard EM was re-implemented as a baseline to provide a solid basis for comparison, because GIZA++ contains many undocumented details. Our implementation is based on the toolkit of CICADA (Watanabe and Sumita, 2011; Watanabe, 2012; Tamura et al., 2013)[9]. We named the implemented aligner AGRIPPA, to support our in-house decoders OCTAVIAN and AUGUSTUS.

In all experiments, WA was performed independently in two directions: from foreign languages to English, and from English to foreign languages. Then the grow-diag-final-and heuristic was used to combine the two alignments from both directions to yield the final alignments for evaluation (Och and Ney, 2000; Och and Ney, 2003).

4.2 Word Alignment Accuracy

Word alignment accuracy of the baseline and the proposed method is shown in Table 3 in terms of precision, recall and F_1 (Och and Ney, 2003). The proposed method gave rise to higher quality alignments in all our experiments. The improvement in F_1, precision and recall based on IBM Model 4 is in the range 8.3% to 9.1% compared with the GIZA++ baseline, and in the range 5.0% to 17.2% compared with our own baseline.

The most meaningful result comes from the comparison of the models trained using standard EM log-likelihood training, and the proposed EM leave-one-out log-likelihood training. These models are identical except for way in which the model likelihood is calculated. In all our experiments the proposed method gave rise to higher quality alignments. The standard EM implementation achieved

[4] We found the memory of our server is large enough, so we did not implement it

alignment performance approximately comparable to GIZA++, whereas the proposed method exceeded the performance of both implementations.

4.3 End-to-end Translation Quality

BLEU scores achieved by the phrase-based and hierachical SMT systems[10] which were trained from different alignment results, are shown in Table 4. Each experiment was conducted three times to mitigate the variance in the results due to MERT. The results show that the proposed alignment method achieved the highest BLEU score in all experiments. The improvement over the baseline is in range 0.03 to 1.03 for phrase-based systems, and ranged from 0.43 to 1.30 for hierarchical systems.

Hierarchical systems benifit more from the proposed method than phrase-based systems. We think this is because that hierarchical systems are more sensitive to word alignment quality than phrase-based systems. Phrase-based systems only

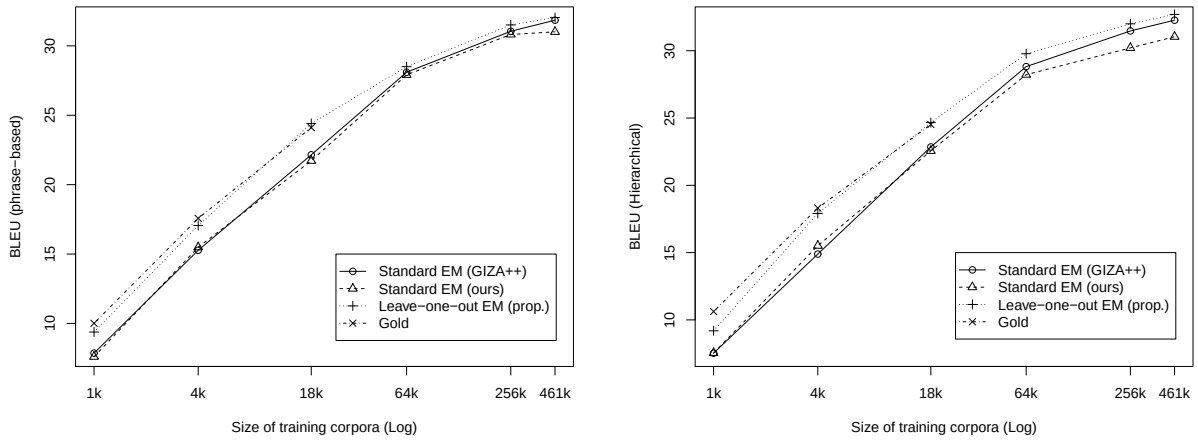
take contiguous parallel phrase pairs as translation rules, while hierarchical systems also use patterns made by subtracting (inner) short parallel phrases from (outer) longer parallel phrases. Both the outer and inner phrases typically need to be noise-free in order to produce high quality rules. This puts a high demand on the alignment quality.

4.4 Effect of Training Corpus Size

Training corpora of different sizes were employed to perform unsupervised WA experiments and MT experiments (see Tables 5 and 6).

The training corpora were randomly sampled from the Chinese-English manual WA corpora and the parallel training corpus. The manual WA corpus has a priority for being sampled so that the gold WA annotation is available for MT experi-



(a) (b)

Figure 3: Curves of translation quality (BLEU) under training corpora of different sizes. (a) Phrase-based MT; (b) Hierarchical MT.

ments.

The settings of the unsupervised WA experiments and the MT experiments are the same with the previous experiments. In the WA experiments, GIZA++, our implemented standard EM and the proposed leave-one-out EM are applied to training corpora with the same parameter settings as the previous. In the MT experiments, the WA results of different methods and the gold WA (if available) are employed to extract translation rules; the rest settings including language models, development and test corpus, and parameters are the same as the previous.

On word alignment accuracy, the proposed method achieved improvements of F_1 from 0.041 to 0.090 under the different training corpora (Table 5. The maximum improvement compared with GIZA++ is 0.069 when the training corpus has 4,000 sentence pairs. The maximum improvement compared with our own implement is 0.090 when the training corpus has 64,000 sentence pairs.

Figure 2 shows that the extent of improvements slightly changes under different training corpora, but they are all quite stable and obvious.

On translation quality, the proposed method achieved improvements of BLEU under the different training corpora. The improvements ranged from 0.19 to 1.72 for phrase-based MT and ranged from 0.25 to 3.02 (see Table 5). The improvements are larger under smaller training corpora (see Figure 3).

In addition, the BLEUs achieved by the proposed method is close to the ones achieved by gold WA annotations. The proposed method slightly outperforms the gold WA annotations when using the full manual WA corpus of 18,057 sentence pairs.

4.5 Comparison to l_0-Normalization and Kneser-Ney Smoothing Methods

The proposed leave-one-word word alignment method was empirically compared to l_0-normalized GIZA++ (Vaswani et al., 2012)[11] and Kneser-Ney smoothed GIZA++ (Zhang and Chiang, 2014)[12]. l_0-normalization and Kneser-Ney smoothing methods are established methods to overcome the sparse problem. This enables the probability distributions on rare words to be estimated more effectively. In this way, these two GIZA++ variants are related to the proposed method.

l_0-normalized GIZA++ and Kneser-Ney smoothed GIZA++ were run with the same settings as GIZA++, which came from the default settings of MOSES. For the settings of l_0-normalized GIZA++ that are not in common with GIZA++ were the default settings. As for Kneser-Ney smoothed GIZA++, the smooth switches of IBM models 1 – 4 and HMM model

Table 7: Empirical Comparision with l_0-Normalized and Kneser-Ney Smoothed GIZA++'s

were turned on.

The experimental results are presented in Table 7. The experiments were run on the Chinese-English language pair. The word alignment quality was evaluated separately for all words and for various levels of rare words. The leave-one-out method outperformed related methods in terms of precision, recall and F_1 when evaluated on all words.

Rare words were categorized based on the number of occurences in the source-language text of the training data. The evaluations were carried out on the subset of alignment links that had a rare word on the source side. Table 7 presents the results for thresholds 1, 2, 5 and 10. The proposed method achieved much higher precision on rare words than the other methods, but performed poorly on recall. The Kneser-Ney Smoothed GIZA++ had higher recall. The explanation might be that the leave-one-out method punishes rare words more than the Kneser-Ney smoothing method, by totally removing the derived expected counts of current sentence pair from the alignment models. This leads to rare words being passively aligned. In other words, the leave-one-out method would align rare words unless the confidence is high. Therefore, we plan to seek a method to integrate Kneser-Ney smoothing into the proposed leave-one-out method in the future work.

The BLEU scores achieved by phrase-based SMT and hierarchical SMT for different alignment methods are presented in Table 7. The proposed method outperforms the other methods. The Kneser-Ney Smoothed GIZA++ performed the second best. We tried to further analyze the relation between word alignment and BLEU, but found the analysis was obscured by the many processing stages. These stages include parallel phrase extraction (or translation rule extraction from hierarchical SMT), log-linear model, MERT tuning and practical decoding where a lot of pruning happened.

5 Conclusion

This paper proposes a leave-one-out EM algorithm for WA to overcome the over-fitting problem that occurs when using standard EM for WA. The experimental results on Chinese-English and Japanese-English corpora show that both the WA accuracy and the end-to-end translation are improved.

In addition, we have a interesting finding about the effect of manual WA annotations on training MT systems. In a Chinese-English parallel training corpus of 18,057 sentence pairs, the manual WA annotation outperformed the unsupervised WA results produced by standard EM algorithms. However, the unsupervised WA results produced by proposed leave-one-out EM algorithm outperformed the manual WA annotation.

Our future work will focus on increasing the gains in end-to-end translation quality through the proposed leave-one-out aligner. It is a interesting question why GIZA++ achieved competitive BLEU scores though its alignment accuracy measured by F_1 was substantially lower. The answer to this question which may reveal essence of good word alignment for MT and eventually help to improve MT. In addition, we plan to improve the proposed method by integrating Kneser-Ney smoothing.

Abstract

While agreement-based joint training has proven to deliver state-of-the-art alignment accuracy, the produced word alignments are usually restricted to one-to-one mappings because of the hard constraint on agreement. We propose a general framework to allow for arbitrary loss functions that measure the disagreement between asymmetric alignments. The loss functions can not only be defined between asymmetric alignments but also between alignments and other latent structures such as phrase segmentations. We use a Viterbi EM algorithm to train the joint model since the inference is intractable. Experiments on Chinese-English translation show that joint training with generalized agreement achieves significant improvements over two state-of-the-art alignment methods.

1 Introduction

Word alignment is a natural language processing task that aims to specify the correspondence between words in two languages (Brown et al., 1993). It plays an important role in statistical machine translation (SMT) as word-aligned bilingual corpora serve as the input of translation rule extraction (Koehn et al., 2003; Chiang, 2007; Galley et al., 2006; Liu et al., 2006).

Although state-of-the-art generative alignment models (Brown et al., 1993; Vogel et al., 1996) have been widely used in practical SMT systems, they fail to model the symmetry of word alignment. While word alignments in real-world bilingual data usually exhibit complicated mappings (i.e., mixed with one-to-one, one-to-many, many-to-one, and many-to-many links), these models assume that each target word is aligned to exactly one source word. To alleviate this problem, heuristic methods (e.g., grow-diag-final) have been proposed to combine two asymmetric alignments (source-to-target and target-to-source) to generate symmetric bidirectional alignments (Och and Ney, 2003; Koehn and Hoang, 2007).

Instead of using heuristic symmetrization, Liang et al. (2006) introduce a principled approach that encourages the agreement between asymmetric alignments in two directions. The basic idea is to favor links on which both unidirectional models agree. They associate two models via the agreement constraint and show that agreement-based joint training improves alignment accuracy significantly.

However, enforcing agreement in joint training faces a major problem: the two models are restricted to one-to-one alignments (Liang et al., 2006). This significantly limits the translation accuracy, especially for distantly-related language pairs such as Chinese-English (see Section 5). Although posterior decoding can potentially address this problem, Liang et al. (2006) find that many-to-many alignments occur infrequently because posteriors are sharply peaked around the Viterbi alignments. We believe that this happens because their model imposes a *hard* constraint on agreement: the two models must share the same alignment when estimating the parameters by calculating the products of alignment posteriors (see Section 2).

In this work, we propose a general framework for imposing agreement constraints in joint training of unidirectional models. The central idea is to use the expectation of a loss function, which measures the disagreement between two models, to replace the original probability of agreement. This allows for many possible ways to quantify agreement. Experiments on Chinese-English translation show that our approach outperforms two state-of-the-art baselines significantly.

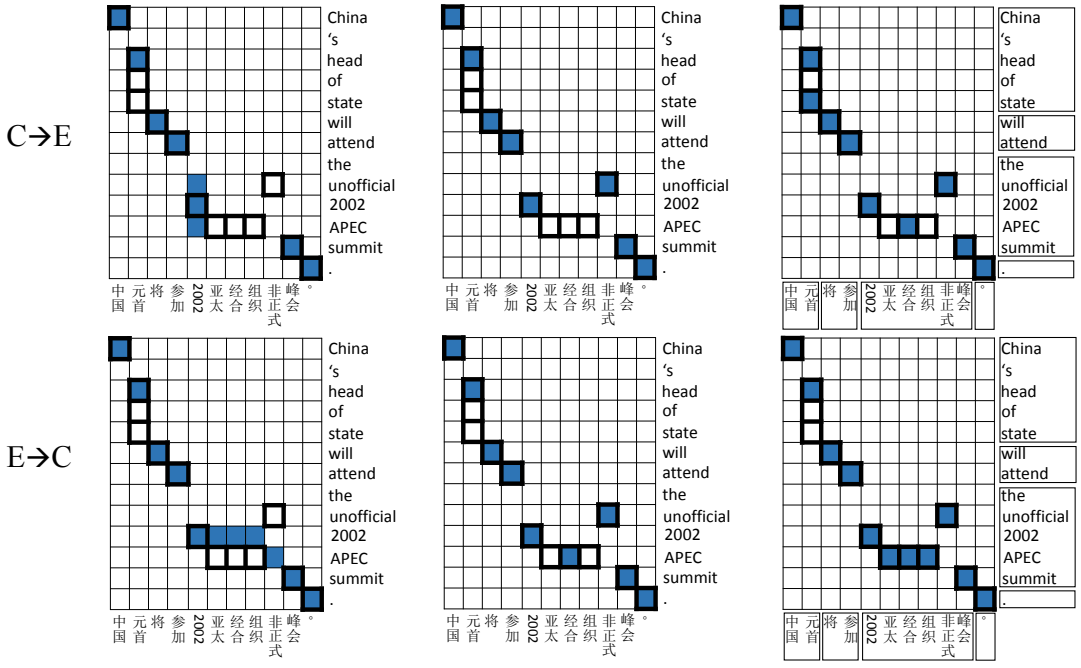

Figure 1: Comparison of (a) independent training without agreement, (b) joint training with agreement, and (c) joint training with generalized agreement. Bold squares are gold-standard links and solid squares are model predictions. The Chinese and English sentences are segmented into phrases in (c). Joint training with agreement achieves a high precision but generally only produces one-to-one alignments. We propose generalized agreement to account for not only the consensus between asymmetric alignments, but also the conformity of alignments to other latent structures such as phrase segmentations.

2 Background

2.1 Asymmetric Alignment Models

Given a source-language sentence $\mathbf{e} \equiv e_1^I = e_1, \ldots, e_I$ and a target-language sentence $\mathbf{f} \equiv f_1^J = f_1, \ldots, f_J$, a source-to-target translation model (Brown et al., 1993; Vogel et al., 1996) can be defined as

$$P(\mathbf{f}|\mathbf{e};\boldsymbol{\theta}_1) = \sum_{\mathbf{a}_1} P(\mathbf{f}, \mathbf{a}_1|\mathbf{e};\boldsymbol{\theta}_1) \quad (1)$$

where $\mathbf{a}_1$ denotes the source-to-target alignment and $\boldsymbol{\theta}_1$ is the set of source-to-target translation model parameters.

Likewise, the target-to-source translation model is given by

$$P(\mathbf{e}|\mathbf{f};\boldsymbol{\theta}_2) = \sum_{\mathbf{a}_2} P(\mathbf{e}, \mathbf{a}_2|\mathbf{f};\boldsymbol{\theta}_2) \quad (2)$$

where $\mathbf{a}_2$ denotes the target-to-source alignment and $\boldsymbol{\theta}_2$ is the set of target-to-source translation model parameters.

Given a training set $D = \{\langle \mathbf{f}^{(s)}, \mathbf{e}^{(s)} \rangle\}_{s=1}^S$, the two models are trained independently to maximize the log-likelihood of the training data for each direction, respectively:

$$\mathcal{L}(\boldsymbol{\theta}_1) = \sum_{s=1}^{S} \log P(\mathbf{f}^{(s)}|\mathbf{e}^{(s)};\boldsymbol{\theta}_1) \quad (3)$$

$$\mathcal{L}(\boldsymbol{\theta}_2) = \sum_{s=1}^{S} \log P(\mathbf{e}^{(s)}|\mathbf{f}^{(s)};\boldsymbol{\theta}_2) \quad (4)$$

One key limitation of these generative models is that they are **asymmetric**: each target word is restricted to be aligned to exactly one source word (including the empty cept) in the source-to-target direction and vice versa. This is undesirable because most real-world word alignments are **symmetric**, in which one-to-one, one-to-many, many-to-one, and many-to-many links are usually mixed. See Figure 1(a) for example. Therefore, a number of heuristic symmetrization methods such as intersection, union, and grow-diag-final have been proposed to combine asym-

metric alignments (Och and Ney, 2003; Koehn and Hoang, 2007).

2.2 Alignment by Agreement

Rather than using heuristic symmetrization methods, Liang et al. (2006) propose a principled approach to jointly training of the two models via enforcing **agreement**:

$$\begin{aligned} & J(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2) \\ = & \sum_{s=1}^{S} \log P(\mathbf{f}^{(s)}|\mathbf{e}^{(s)}; \boldsymbol{\theta}_1) + \\ & \log P(\mathbf{e}^{(s)}|\mathbf{f}^{(s)}; \boldsymbol{\theta}_2) + \\ & \log \sum_{\mathbf{a}} P(\mathbf{a}|\mathbf{f}^{(s)}, \mathbf{e}^{(s)}; \boldsymbol{\theta}_1) \times \\ & P(\mathbf{a}|\mathbf{e}^{(s)}, \mathbf{f}^{(s)}; \boldsymbol{\theta}_2) \end{aligned} \quad (5)$$

Note that the last term in Eq. (5) encourages the two models to agree on asymmetric alignments. While this strategy significantly improves alignment accuracy, the joint model is prone to generate one-to-one alignments because it imposes a *hard* constraint on agreement: the two models must share the same alignment when estimating the parameters by calculating the products of alignment posteriors. In Figure 1(b), the two one-to-one alignments are almost identical except for one link. This makes the posteriors to be sharply peaked around the Viterbi alignments (Liang et al., 2006). As a result, the lack of many-to-many alignments limits the benefits of joint training to end-to-end machine translation.

3 Generalized Agreement for Bidirectional Alignment

Our intuition is that the agreement between two alignments can be defined as a loss function, which enables us to consider various ways of quantification (Section 3.1) and even to incorporate the dependency between alignments and other latent structures such as phrase segmentations (Section 3.2).

3.1 Agreement between Word Alignments

The key idea of generalizing agreement is to leverage *loss functions* that measure the difference between two unidirectional alignments. For example, the last term in Eq. (5) can be re-written as

$$\begin{aligned} & \sum_{\mathbf{a}} P(\mathbf{a}|\mathbf{f}^{(s)}, \mathbf{e}^{(s)}; \boldsymbol{\theta}_1) P(\mathbf{a}|\mathbf{e}^{(s)}, \mathbf{f}^{(s)}; \boldsymbol{\theta}_2) \\ = & \sum_{\mathbf{a}_1} \sum_{\mathbf{a}_2} P(\mathbf{a}_1|\mathbf{f}^{(s)}, \mathbf{e}^{(s)}; \boldsymbol{\theta}_1) \times \\ & P(\mathbf{a}_2|\mathbf{e}^{(s)}, \mathbf{f}^{(s)}; \boldsymbol{\theta}_2) \times \\ & \delta(\mathbf{a}_1, \mathbf{a}_2) \end{aligned} \quad (6)$$

Note that the last term in Eq. (6) is actually the expected value of agreement:

$$\mathbb{E}_{\mathbf{a}_1|\mathbf{f}^{(s)}, \mathbf{e}^{(s)}; \boldsymbol{\theta}_1} \left[\mathbb{E}_{\mathbf{a}_2|\mathbf{e}^{(s)}, \mathbf{f}^{(s)}; \boldsymbol{\theta}_2} \left[\delta(\mathbf{a}_1, \mathbf{a}_2) \right] \right] \quad (7)$$

Our idea is to replace $\delta(\mathbf{a}_1, \mathbf{a}_2)$ in Eq. (6) with an arbitrary loss function $\Delta(\mathbf{a}_1, \mathbf{a}_2)$ that measures the difference between $\mathbf{a}_1$ and $\mathbf{a}_2$. This gives the new joint training objective with generalized agreement:

$$\begin{aligned} & J(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2) \\ = & \sum_{s=1}^{S} \log P(\mathbf{f}^{(s)}|\mathbf{e}^{(s)}; \boldsymbol{\theta}_1) + \\ & \log P(\mathbf{e}^{(s)}|\mathbf{f}^{(s)}; \boldsymbol{\theta}_2) - \\ & \log \sum_{\mathbf{a}_1} \sum_{\mathbf{a}_2} P(\mathbf{a}_1|\mathbf{f}^{(s)}, \mathbf{e}^{(s)}; \boldsymbol{\theta}_1) \times \\ & P(\mathbf{a}_2|\mathbf{e}^{(s)}, \mathbf{f}^{(s)}; \boldsymbol{\theta}_2) \times \\ & \Delta(\mathbf{a}_1, \mathbf{a}_2) \end{aligned} \quad (8)$$

Obviously, Liang et al. (2006)'s training objective is a special case of our framework. We refer to its loss function as **hard matching**:

$$\Delta_{\text{HM}}(\mathbf{a}_1, \mathbf{a}_2) = 1 - \delta(\mathbf{a}_1, \mathbf{a}_2) \quad (9)$$

We are interested in developing a soft version of the hard matching loss function because this will help to produce many-to-many symmetric alignments. For example, in Figure 1(c), the two alignments share most links but still allow for disagreed links to capture one-to-many and many-to-one links. Note that the union of the two asymmetric alignments is almost the same with the gold-standard alignment in this example.

While there are many possible ways to define a **soft matching** loss function, we choose the difference between disagreed and agreed link counts because it is easy and efficient to calculate during search:

$$\Delta_{\text{SM}}(\mathbf{a}_1, \mathbf{a}_2) = |\mathbf{a}_1 \cup \mathbf{a}_2| - 2|\mathbf{a}_1 \cap \mathbf{a}_2| \quad (10)$$

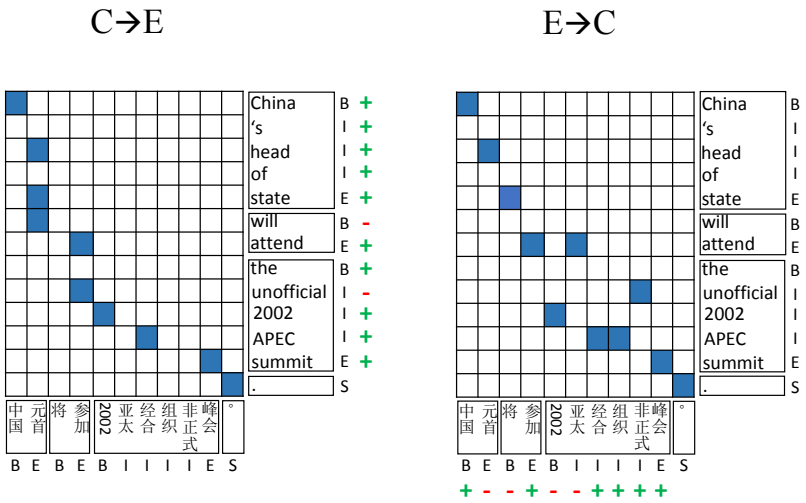

Figure 2: Generalized agreement between word alignments and phrase segmentations. The Chinese and English sentences are segmented into phrases using B (beginning), I (internal), E (ending), S (single) labels. We expect that word alignment does not violate the phrase segmentation. The word "unofficial" in the C → E alignment is labeled with "-" because "unofficial" and "2002" belong to the same English phrase but their counterparts are separated in two Chinese phrases. Words that do not violate the phrase alignment are labeled with "+". See Section 3.2 for details.

3.2 Agreement between Word Alignments and Phrase Segmentations

Our framework is very general and can be extended to include the agreement between word alignment and other latent structures such as phrase segmentations.

The words in a Chinese sentence often constitute phrases that are translated as units in English and vice versa. Inspired by the alignment consistency constraint widely used in translation rule extraction (Koehn et al., 2003), we make the following assumption to impose a structural agreement constraint between word alignment and phrase segmentation: *source words in one source phrase should be aligned to target words belonging to the same target phrase and vice versa.*

For example, consider the C → E alignment in Figure 2. We segment Chinese and English sentences into phrases, which are sequences of consecutive words. Since "2002" and "APEC" belong to the same English phrase, their counterparts on the Chinese side should also belong to one phrase.

While this assumption can potentially improve the correlation between word alignment and phrase-based translation, a question naturally arises: how to segment sentences into phrases? Instead of leveraging chunking, we treat phrase segmentation as a latent variable and train the joint alignment and segmentation model from unlabeled data in an unsupervised way.

Formally, given a target-language sentence $\mathbf{f} \equiv f_1^J = f_1, \ldots, f_J$, we introduce a latent variable $\mathbf{b} \equiv b_1^J = b_1, \ldots, b_J$ to denote a *phrase segmentation*. Each label $b_j \in \{B, I, E, S\}$, where B denotes the beginning word of a phrase, I denotes the internal word, E denotes the ending word, and S denotes the one-word phrase. Figure 2 shows the label sequences for the sentence pair.

We use a first-order HMM to model phrase segmentation of a target sentence:

$$P(\mathbf{f}; \boldsymbol{\lambda}_1) = \sum_{\mathbf{b}_1} P(\mathbf{f}, \mathbf{b}_1; \boldsymbol{\lambda}_1) \quad (11)$$

Similarly, the hidden Markov model for the phrase segmentation of the source sentence can be defined as

$$P(\mathbf{e}; \boldsymbol{\lambda}_2) = \sum_{\mathbf{b}_2} P(\mathbf{e}, \mathbf{b}_2; \boldsymbol{\lambda}_2) \quad (12)$$

Then, we can combine word alignment and phrase segmentation and define the joint training objective as

$$\begin{aligned} & J(\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \boldsymbol{\lambda}_1, \boldsymbol{\lambda}_2) \\ = & \sum_{s=1}^{S} \log P(\mathbf{f}^{(s)} | \mathbf{e}^{(s)}; \boldsymbol{\theta}_1) + \end{aligned}$$

1: **procedure** VITERBIEM(D)
2: Initialize $\boldsymbol{\Theta}^{(0)}$
3: **for all** $k = 1, \ldots, K$ **do**
4: $\hat{\mathbf{H}}^{(k)} \leftarrow$ SEARCH($D, \boldsymbol{\Theta}^{(k-1)}$)
5: $\boldsymbol{\Theta}^{(k)} \leftarrow$ UPDATE($D, \hat{\mathbf{H}}^{(k)}$)
6: **end for**
7: **return** $\hat{\mathbf{H}}^{(K)}, \boldsymbol{\Theta}^{(K)}$
8: **end procedure**

Algorithm 1: A Viterbi EM algorithm for learning the joint word alignment and phrase segmentation model from bilingual corpus. D is a bilingual corpus, $\boldsymbol{\Theta}^{(k)}$ is the set of model parameters at the k-th iteration, $\mathbf{H}^{(k)}$ is the set of Viterbi latent variables at the k-th iteration.

$$\begin{aligned} &\log P(\mathbf{e}^{(s)}|\mathbf{f}^{(s)}; \boldsymbol{\theta}_2) + \\ &\log P(\mathbf{f}^{(s)}; \boldsymbol{\lambda}_1) + \\ &\log P(\mathbf{e}^{(s)}; \boldsymbol{\lambda}_2) - \\ &\log \mathcal{E}(\mathbf{f}^{(s)}, \mathbf{e}^{(s)}, \boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \boldsymbol{\lambda}_1, \boldsymbol{\lambda}_2) \end{aligned} \quad (13)$$

where the expected loss is given by

$$\begin{aligned} &\mathcal{E}(\mathbf{f}^{(s)}, \mathbf{e}^{(s)}, \boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \boldsymbol{\lambda}_1, \boldsymbol{\lambda}_2) \\ = &\sum_{\mathbf{a}_1} \sum_{\mathbf{a}_2} \sum_{\mathbf{b}_1} \sum_{\mathbf{b}_2} P(\mathbf{a}_1|\mathbf{f}^{(s)}, \mathbf{e}^{(s)}; \boldsymbol{\theta}_1) \times \\ &\quad P(\mathbf{a}_2|\mathbf{e}^{(s)}, \mathbf{f}^{(s)}; \boldsymbol{\theta}_2) \times \\ &\quad P(\mathbf{b}_1|\mathbf{f}^{(s)}; \boldsymbol{\lambda}_1) \times \\ &\quad P(\mathbf{b}_2|\mathbf{e}^{(s)}; \boldsymbol{\lambda}_2) \times \\ &\quad \Delta(\mathbf{a}_1, \mathbf{a}_2, \mathbf{b}_1, \mathbf{b}_2) \end{aligned} \quad (14)$$

We define a new loss function **segmentation violation** to measure the degree that an alignment violates phrase segmentations.

$$\begin{aligned} &\Delta_{\text{SV}}(\mathbf{a}_1, \mathbf{a}_2, \mathbf{b}_1, \mathbf{b}_2) \\ = &\sum_{j=1}^{J-1} \beta(\mathbf{a}_1, j, \mathbf{b}_1, \mathbf{b}_2) + \sum_{i=1}^{I-1} \beta(\mathbf{a}_2, i, \mathbf{b}_2, \mathbf{b}_1) \end{aligned} \quad (15)$$

where $\beta(\mathbf{a}_1, j, \mathbf{b}_1, \mathbf{b}_2)$ evaluates whether two links $l_1 = (j, a_j)$ and $l_2 = (j+1, a_{j+1})$ violate the phrase segmentation:

1. $\mathbf{f}_j$ and $\mathbf{f}_{j+1}$ belong to one phrase but $\mathbf{e}_{a_j}$ and $\mathbf{e}_{a_{j+1}}$ belong to two phrases, or
2. $\mathbf{f}_j$ and $\mathbf{f}_{j+1}$ belong to two phrases but $\mathbf{e}_{a_j}$ and $\mathbf{e}_{a_{j+1}}$ belong to one phrase.

The β function returns 1 if there is violation and 0 otherwise.

1: **procedure** SEARCH(D, $\boldsymbol{\Theta}$)
2: $\hat{\mathbf{H}} \leftarrow \emptyset$
3: **for all** $s \in \{1, \ldots, S\}$ **do**
4: $\hat{\mathbf{a}}_1 \leftarrow$ ALIGN($\mathbf{f}^{(s)}, \mathbf{e}^{(s)}, \boldsymbol{\theta}_1$)
5: $\hat{\mathbf{a}}_2 \leftarrow$ ALIGN($\mathbf{e}^{(s)}, \mathbf{f}^{(s)}, \boldsymbol{\theta}_2$)
6: $\hat{\mathbf{b}}_1 \leftarrow$ SEGMENT($\mathbf{f}^{(s)}, \boldsymbol{\lambda}_1$)
7: $\hat{\mathbf{b}}_2 \leftarrow$ SEGMENT($\mathbf{e}^{(s)}, \boldsymbol{\lambda}_2$)
8: $\mathbf{h}_0 \leftarrow \langle \hat{\mathbf{a}}_1, \hat{\mathbf{a}}_2, \hat{\mathbf{b}}_1, \hat{\mathbf{b}}_2 \rangle$
9: $\hat{\mathbf{h}} \leftarrow$HILLCLIMB($\mathbf{f}^{(s)}, \mathbf{e}^{(s)}, \mathbf{h}_0, \boldsymbol{\Theta}$)
10: $\hat{\mathbf{H}} \leftarrow \hat{\mathbf{H}} \cup \{\hat{\mathbf{h}}\}$
11: **end for**
12: **return** $\hat{\mathbf{H}}$
13: **end procedure**

Algorithm 2: A search algorithm for finding the Viterbi latent variables. $\hat{\mathbf{a}}_1$ and $\hat{\mathbf{a}}_2$ denote Viterbi alignments, $\hat{\mathbf{b}}_1$ and $\hat{\mathbf{b}}_2$ denote Viterbi segmentations. They form a starting point $\mathbf{h}_0$ for the hill climbing algorithm, which keeps changing alignments and segmentations until the model score does not increase. $\hat{\mathbf{h}}$ is the final set of Viterbi latent variables for one sentence.

In Figure 2, we use "+" to label words that do not violate the phrase segmentations and "-" to label violations.

In practice, we combine the two loss functions to enable word alignment and phrase segmentation to benefit each other in a joint search space:

$$\begin{aligned} &\Delta_{\text{SM+SV}}(\mathbf{a}_1, \mathbf{a}_2, \mathbf{b}_1, \mathbf{b}_2) \\ = &\Delta_{\text{SM}}(\mathbf{a}_1, \mathbf{a}_2) + \Delta_{\text{SV}}(\mathbf{a}_1, \mathbf{a}_2, \mathbf{b}_1, \mathbf{b}_2) \end{aligned} \quad (16)$$

4 Training

Liang et al. (2006) indicate that it is intractable to train the joint model. For simplicity and efficiency, they exploit a simple heuristic procedure that leverages the product of posterior marginal probabilities. The intuition behind the heuristic is that links on which two models disagree should be discounted because the products of the marginals are small (Liang et al., 2006).

Unfortunately, it is hard to develop a similar heuristic for our model that allows for arbitrary loss functions. Alternatively, we resort to a Viterbi EM algorithm, as shown in Algorithm 1. The algorithm takes the training data $D = \{\langle \mathbf{f}^{(s)}, \mathbf{e}^{(s)} \rangle\}_{s=1}^{S}$ as input (line 1). We use $\boldsymbol{\Theta}^{(k)} = \langle \boldsymbol{\theta}_1^{(k)}, \boldsymbol{\theta}_2^{(k)}, \boldsymbol{\lambda}_1^{(k)}, \boldsymbol{\lambda}_2^{(k)} \rangle$ to denote the set of model parameters at the k-th iteration. After initializing the model parameters (line 2), the algorithm alternates between searching for the Viterbi alignments

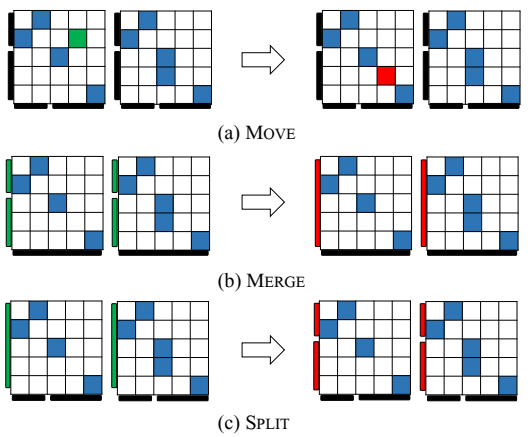

Figure 3: Operators used in the HILLCLIMB procedure.

and segmentations $\hat{\mathbf{H}}^{(k)}$ using the SEARCH procedure (line 4) and updating model parameters using the UPDATE procedure (line 5). The algorithm terminates after running for K iterations.

It is challenging to search for the Viterbi alignments and segmentations because of complicated structural dependencies. As shown in Algorithm 2, our strategy is first to find Viterbi alignments and segmentations independently using the ALIGN and SEGMENT procedures (lines 4-7), which then serve as a starting point for the HILLCLIMB procedure (lines 8-9).

Figure 3 shows three operators we use in the HILLCLIMB procedure. The MOVE operator moves a link in an alignment, the MERGE operator merges two phrases into one phrase, and the SPLIT operator splits one phrase into two smaller phrases. Note that each operator can be further divided into two variants: one for the source side and another for the target side.

5 Experiments

5.1 Setup

We evaluate our approach on Chinese-English alignment and translation tasks.

The training corpus consists of 1.2M sentence pairs with 32M Chinese words and 35.4M English words. We used the SRILM toolkit (Stolcke, 2002) to train a 4-gram language model on the Xinhua portion of the English GIGAWORD corpus, which contains 398.6M words. For alignment evaluation, we used the Tsinghua Chinese-English word alignment evaluation data set.[1] The evaluation metric is alignment error rate (AER) (Och and Ney, 2003). For translation evaluation, we used the NIST 2006 dataset as the development set and the NIST 2002, 2003, 2004, 2005, and 2008 datasets as the test sets. The evaluation metric is case-insensitive BLEU (Papineni et al., 2002).

We used both phrase-based (Koehn et al., 2003) and hierarchical phrase-based (Chiang, 2007) translation systems to evaluate whether our approach improves translation performance. For the phrase-based model, we used the open-source toolkit Moses (Koehn and Hoang, 2007). For the hierarchical phrase-based model, we used an in-house re-implementation on par with state-of-the-art open-source decoders.

We compared our approach with two state-of-the-art generative alignment models:

1. GIZA++ (Och and Ney, 2003): unsupervised training of IBM models (Brown et al., 1993) and the HMM model (Vogel et al., 1996) using EM,

2. BERKELEY (Liang et al., 2006): unsupervised training of joint HMMs using EM.

For GIZA++, we trained IBM Model 4 in two directions with the default setting and used the grow-diag-final heuristic to generate symmetric alignments. For BERKELEY, we trained joint HMMs using the default setting. The hyper-parameter of posterior decoding was optimized on the development set.

We used first-order HMMs for both word alignment and phrase segmentation. Our joint alignment and segmentation model were trained using the Viterbi EM algorithm for five iterations. Note that the Chinese-to-English and English-to-Chinese alignments are generally non-identical but share many links (see Figure 1(c)). Then, we used the grow-diag-final heuristic to generate symmetric alignments.

5.2 Comparison with GIZA++ and BERKELEY

Table 1 shows the comparison of our approach with GIZA++ and BERKELEY in terms of AER and BLEU. GIZA++ trains two asymmetric models independently and uses the grow-diag-final (i.e., GDF) for symmetrization. BERKELEY

[1] http://nlp.csai.tsinghua.edu.cn/~ly/systems/TsinghuaAligner/TsinghuaAligner.html

system	training	agreement	loss	sym.	AER	BLEU
GIZA++	indep.	N/A	N/A	GDF	21.35	24.46
BERKELEY	joint	word-word	HM	PD	20.52	24.54
this work	joint	word-word	SM	GDF	22.19	25.11
		word-word, word-phrase	SM+SV		22.01	25.78

Table 1: Comparison with GIZA++ and BERKELEY. "word-word" denotes the agreement between Chinese-to-English and English-to-Chinese word alignments. "word-phrase" denotes the agreement between word alignments and phrase segmentations. "HM" denotes the hard matching loss function, "SM" denotes soft matching, and "SV" denotes segmentation violation. "GDF" denotes grow-diag-final. "PD" denotes posterior decoding. The BLEU scores are evaluated on NIST08 test set.

alignment	loss	translation	NIST06	NIST02	NIST03	NIST04	NIST05	NIST08

Table 2: Results on (hierarchical) phrase-based translation. The evaluation metric is case-insensitive BLEU. "HM" denotes the hard matching loss function, "SM" denotes soft matching, and "SV" denotes segmentation violation. "*": significantly better than GIZA++ ($p < 0.05$). "**": significantly better than GIZA++ ($p < 0.01$). "+": significantly better than BERKELEY ($p < 0.05$). "++": significantly better than BERKELEY ($p < 0.01$).

trains two models jointly with the hard-matching (i.e., HM) loss function and uses posterior decoding for symmetrization.

For our approach, we distinguish between two variants:

1. Imposing agreement between word alignments (i.e., word-word) that uses the soft matching loss function (i.e., SM) (see Section 3.1);

2. Imposing agreement between word alignments and phrase segmentations (i.e., word-word, word-phrase) that uses both the soft matching and segmentation violation loss functions (i.e., SM+SV) (see Section 3.2).

We used the grow-diag-final heuristic for symmetrization.

For the alignment evaluation, we find that our approach achieves higher AER scores than the two baseline systems. One possible reason is that links in the intersection of two symmetric alignments or two symmetric models agree usually correspond to sure links in the gold-standard annotation. Our approach loosens the hard constraint on agreement and makes the posteriors less peaked around the Viterbi alignments.

For the translation evaluation, we used the phrase-based system Moses to report BLEU scores on the NIST 2008 test set. We find that both the two variants of our approach significantly outperforms the two baselines ($p < 0.01$).

5.3 Results on (Hierarchical) Phrase-based Translation

Table 2 shows the results on phrase-based and hierarchical phrase-based translation systems. We find that our approach systematically outperforms GIZA++ and BERKELEY on all NIST datasets.

In particular, generalizing the agreement to model the discrepancy between word alignment and phrase segmentation is consistently beneficial for improving translation quality, suggesting that it is important to introduce structural constraints into word alignment to increase the correlation between alignment and translation.

While "SM+SV" improves over "SM" significantly on phrase-based translation, the margins on the hierarchical phrase-based system are relatively smaller. One possible reason is that the "SV"

system	loss	$\|\mathcal{A}_{C\to E}\|$	$\|\mathcal{A}_{E\to C}\|$	$\|\mathcal{A}_{C\to E} \cap \mathcal{A}_{E\to C}\|$	F1
GIZA++	N/A	29.39M	27.64M	17.07M	59.86
BERKELEY	HM	29.12M	28.09M	21.30M	74.46
this work	SM	29.84M	29.31M	20.24M	68.42
	SM+SV	30.04M	29.50M	20.54M	69.00

Table 3: Agreement evaluation of GIZA++, BERKELEY and our approach. The F1 score reflects how well two asymmetric alignments agree with each other.

loss function can better account for phrase-based rather than hierarchical phrase-based translation. It is possible to design new loss functions tailored to hierarchical phrase-based translation.

We also find that the BLEU scores of BERKELEY on hierarchical phrase-based translation are much lower than those on phrase-based translation. This might result from the fact that BERKELEY is prone to produce one-to-one alignments, which are not optimal for hierarchical phrase-based translation.

5.4 Agreement Evaluation

Table 3 compares how well two asymmetric models agree with each other among GIZA++, BERKELEY and our approach. We use F1 score to measure the degree of agreement:

$$\frac{2|\mathcal{A}_{C\to E} \cap \mathcal{A}_{E\to C}|}{|\mathcal{A}_{C\to E}| + |\mathcal{A}_{E\to C}|} \quad (17)$$

where $\mathcal{A}_{C\to E}$ is the set of Chinese-to-English alignments on the training data and $\mathcal{A}_{E\to C}$ is the set of English-to-Chinese alignments.

It is clear that independent training leads to low agreement and joint training results in high agreement. BERKELEY achieves the highest value of agreement because of the hard constraint.

6 Related Work

This work is inspired by two lines of research: (1) agreement-based learning and (2) joint modeling of multiple NLP tasks.

6.1 Agreement-based Learning

The key idea of agreement-based learning is to train a set of models jointly by encouraging them to agree on the hidden variables (Liang et al., 2006; Liang et al., 2008). This can also be seen as a particular form of posterior constraint or posterior regularization (Graça et al., 2007; Ganchev et al., 2010). The agreement is prior knowledge and indirect supervision, which helps to train a more reasonable model with biased guidance.

While agreement-based learning provides a principled approach to training a generative model, it constrains that the sub-models must share the same output space. Our work extends (Liang et al., 2006) to introduce arbitrary loss functions that can encode prior knowledge. As a result, Liang et al. (2006)'s model is a special case of our framework. Another difference is that our framework allows for including the agreement between word alignment and other structures such as phrase segmentations and parse trees.

6.2 Joint Modeling of Multiple NLP Tasks

It is well accepted that different NLP tasks can help each other by providing additional information for resolving ambiguities. As a result, joint modeling of multiple NLP tasks has received intensive attention in recent years, including phrase segmentation and alignment (Zhang et al., 2003), alignment and parsing (Burkett et al., 2010), tokenization and translation (Xiao et al., 2010), parsing and translation (Liu and Liu, 2010), alignment and named entity recognition (Chen et al., 2010; Wang et al., 2013).

Among them, Zhang et al. (2003)'s integrated search algorithm for phrase segmentation and alignment is most close to our work. They use Point-wise Mutual Information to identify possible phrase pairs. The major difference is we train models jointly instead of integrated decoding.

7 Conclusion

We have presented generalized agreement for bidirectional word alignment. The loss functions can be defined both between asymmetric alignments and between alignments and other latent structures such as phrase segmentations. We develop a Viterbi EM algorithm to train the joint model. Experiments on Chinese-English translation show that joint training with generalized agreement achieves

significant improvements over two baselines for (hierarchical) phrase-based MT systems. In the future, we plan to investigate more loss functions to account for syntactic constraints.

Abstract

We propose a transition-based model for joint word segmentation, POS tagging and text normalization. Different from previous methods, the model can be trained on standard text corpora, overcoming the lack of annotated microblog corpora. To evaluate our model, we develop an annotated corpus based on microblogs. Experimental results show that our joint model can help improve the performance of word segmentation on microblogs, giving an error reduction in segmentation accuracy of 12.02%, compared to the traditional approach.

1 Introduction

Microblogs, such as Twitter, SMS and Weibo, has become an important research topic in NLP. Previous work has shown that off-the-shelf NLP tools can perform poorly on microblogs (Foster et al., 2011; Gimpel et al., 2011; Han and Baldwin, 2011). One of the major challenges for microblog processing is the issue of informal words. For example, "tmrw" has been frequently used in tweets for "tomorrow", causing OOV problems.

Text normalization has been introduced as a pre-processing step for microblog processing, which transforms informal words into their standard forms. Most work in the literature focuses on English microblog normalization, treating it as a noisy channel problem (Pennell and Liu, 2014; Cook and Stevenson, 2009; Yang and Eisenstein, 2013) or a translation problem (Aw et al., 2006; Contractor et al., 2010; Li and Liu, 2012; Zhang et al., 2014c), and training models based on words.

Lack of annotated corpora, text normalization is more challenging for Chinese. Unlike English, Chinese informal words are more difficult to mechanically normalize for two main reasons. First, Chinese does not have word delimiters. Second, Chinese informal words manifest diversity, such as abbreviations, neologisms, unconventional spellings and phonetic substitutions. Intuitively, there is mutual dependency between Chinese word segmentation and normalization, and therefore two tasks should be solved jointly.

Wang and Kan (2013) proposed a joint model to process word segmentation and informal word detection. However, text normalization was not included in the joint model. Kaji et al (2014) proposed a joint model for word segmentation, POS tagging and normalization for Japanese Microblogs, which was trained on a partially annotated microblog corpus. Their method requires special annotation for text normalization, which can be expensive.

In this paper, we propose a joint model for Chinese text normalization, word-segmentation and POS tagging, which can be trained using standard segmentation and POS tagging annotation, overcoming the lack of an annotated corpus on Chinese microblogs. Our model is based on Zhang and Clark (2010), with an extended set of transition actions to handle joint normalization. In our model, word segmentation and POS tagging are based on normalized text transformed from informal text. Assuming that the majority of informal words can be normalized into formal equivalents (Han et al., 2012; Li and Yarowsky, 2008), we seek standard forms of informal words from an automatically constructed normalization dictionary.

To evaluate our model, we developed an annotated corpus of microblog texts. Results show that our model achieves the best performances on three tasks compared with several baseline systems.

2 Text Normalization

Text normalization is a relatively new research topic. There are no precise definitions of a text

normalization task that are widely accepted by researchers. The task is generally divided into three categories: lexical-level, sentence-level and discourse-level normalization. In this paper we focus on lexical-level normalization, which aims to transform informal words into their standard forms.

Lexical normalization can be regarded as a spelling correction problem. However, researches on spelling correction focus on typographic and cognitive/orthographic errors (Kukich, 1992), while text normalization focuses on lexical variants, such as phonetic substitutions, abbreviation and paraphrases.

Unlike English, for which informal words are detected according to whether they are out of vocabulary, Chinese informal words manifest diversity. Wang et al. (2013) divided informal words into three types: phonetic substitutions, abbreviations and neologisms. Li and Yarowsky (2008) classified them into four types: homophone, abbreviation, transliteration and others. Due to variant characteristics, they normalise informal words by training a model per type, leading to increased system complexity.

Research reveals that most lexical variants have an unambiguous standard form (Han et al., 2012; Li and Yarowsky, 2008). The validity of this assumption is also empirically assessed on our corpus annotation in Section 6.1. Based on this assumption, we seek standard forms of informal words from a constructed normalization dictionary, avoiding diversity on informal words.

3 Joint Segmentation and Normalization

3.1 Transition-based Segmentation

We adapt the segmenter of Zhang and Clark (2007) as our baseline segmenter. Given an input sentence x, the baseline segmenter finds a segmentation by maximizing:

$$F(x) = \underset{y \epsilon Gen(x)}{\operatorname{argmax}} Score(y) \quad (1)$$

where $Gen(x)$ denotes the set of all possible segmentations for an input sentence.

Zhang and Clark (2007) proposed a graph-based scoring model, with features based on complete words and word sequences. We adapt their method slightly, under a transition-based framework (Zhang and Clark, 2011), which gives us a consistent way of defining all models in this paper.

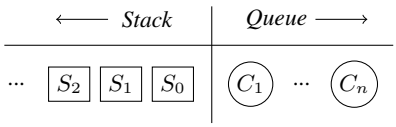

Figure 1: A state of transition-based model.

Here a transition model is defined as a quadruple $M = (C, T, W, C_t)$, where C is a state space, T is a set of transitions, each of which is a function: $C \rightarrow C$, W is an input sentence $c_1 ... \ c_n$, C_t is a set of terminal states. A model scores the output by scoring the corresponding transition sequence.

As shown in Figure 1, a state is a tuple $ST = (S, Q)$, where S contains partially segmented sequences, and $Q = (c_i, c_{i+1}, ..., c_n)$ is the sequence of input characters that have not been processed. When the character c_i is processing, the transition system would operate one of two actions that are defined as follows:

(1) APP(c_i), removing c_i from Q, and appending it to the last (partial) word in S.

(2) SEP(c_i), removing c_i from Q, making the last word in S as completed, and adding c_i as a new partial word.

Given the sentence "工作压力大啊！(How great work pressure is!)", the sequences of action "SEP(工), APP(作), SEP(压), APP(力), SEP(大), SEP(啊), SEP(!)" can be used to analyze its structure.

3.2 Joint Segmentation and Normalization

Our SN model extends the transition-based segmentation model. In addition to the actions APP and SEP, the transition system also contains a SEPS action, which substitutes an in formal word on the top of S if it exists in the normalization dictionary. Figure 2 gives a normalization transition process for the sentence "工作鸭梨大啊！(How great work pressure is!)". During processing the character "大(big)", the following actions can be applied.

(1) APP("大(big)"), appending "大(big)" to the last word "鸭梨(yālí, pear)" in the informal labeled sequence.

(2) SEP("大(big)"), making the last word "鸭梨(yālí, pear)" in the informal labeled sequence as a completed word, and adding "大(big)" as a new partial word.

(3) SEPS("大(big)", "压力(yālì, pressure)"), operating the action SEP("大(big)"), and using

Sentence: 工作鸭梨大啊! (How great work pressure is!)

State	Action	Stack	Queue	Dictionary
S_i	.....	Org: 工作 鸭梨 work pear Nor: 工作 work	大啊! big ah!	鸭梨- 压力 pear - pressure 孩纸- 孩子 child paper - child 围脖- 微博 neckerchief - microblog 盆友- 朋友 basin friend - friend .....
S_{i+1}	APP("大")	Org: 工作 鸭梨大 work pear big Nor: 工作 work	啊! (ah!)	
	SEP("大")	Org: 工作 鸭梨 大 work pear big Nor: 工作 work		
	SEPS("大", "压力")	Org: 工作 鸭梨 大 work pear big Nor: 工作 压力 work pressure		

Figure 2: Transition actions for joint segmentation and normalization.

Algorithm 1: Decoder

Input: sent, Dictionary // sent: informal sentence
Output:Best normalization sentence
1. *agenda* ←*NULL*
2. **for** *idx* ***in*** *[*0..LEN*(sent)]:*
3. **for** *state* ***in*** *agenda:*
4. *new* ←APP*(state, sent[idx])*
5. ADDITEM*(agenda, new)*
6. *new* ←SEP*(state, sent[idx])*
7. ADDITEM*(agenda, new)*
8. *norWords*←GETNWORD*(state.lastWord)*
9. **for** *word* ***in*** *norWords*
10. *new* ←SEPS*(state,sent[idx],word)*
12. ADDITEM*(agenda, new)*
13. *agenda* ←N-BEST*(agenda)*
14. **return** BEST*(agenda)*

the standard form "压力(yālì, pressure)" for the informal word " 鸭梨(yālí, pear)".

Given the sentence "工作鸭梨大啊！(How great work pressure is!)", the sequences of action "SEP(工), APP(作), SEP(鸭), APP(梨), SEPS(大, 压力), SEP(啊), SEP(!)" can be used to analyze its structure.

Lexical substitution is based on a normalization dictionary whose entries consist of <lexical variant, standard form> pairs. The output is a pair of labeled sequences, containing the informal labeled sequence and the corresponding formal labeled sequence. To rank the candidates, both labeled sequences can be scored. However, lacking annotated corpora on informal texts, we only use the score of formal labeled sequence in our model. The advantage is that we can train our model by using standard corpus only, overcoming the lack of annotated corpora on informal texts.

3.3 Training and Decoding

We apply the global training and beam-search decoding framework of Zhang and Clark (2011). An agenda is used by the decoder to keep the N-best states during the incremental process. Before decoding starts, the agenda is initialized with the initial state. When a character is processed, existing states are removed from the agenda and extended with all possible actions, and the N-best newly generated states are put back onto the agenda. After all states have been terminal, the highest-scored state from the agenda is taken as the output.

Algorithm 1 shows pseudocode for the decoder. ADDITEM adds a new item into the agenda, N-BEST returns the N highest-scored items from the agenda, and BEST returns the highest-scored item from the agenda. GETNWORD returns a possible standard form set of last word, seeking from normalization dictionary. APP appends a character to the last word in a state, SEP joins a character as the start of a new word in a state, SEPS operates SEP and replaces the last word by a possible standard form.

3.4 Features

In the experiments, we use the segmentation feature templates of Zhang and Clark (2011). These features are effective for segmentation on formal text. However, for text normalization, these features contain insufficient information. Our experiments show that by using Zhang and Clark's features, the F-Score on normalization is only 0.4207.

Prior work has shown that the language statistic information is important for text normalization (Wang et al., 2013; Li and Yarowsky, 2008; Kaji and Kitsuregawa, 2014). As a result, we extract language model features by using word-based language model learned from a large quantity of standard texts. In particular, 1-gram, 2-gram, 3-gram features are extracted. Every type of n-gram is divided into ten probability ranges. For example, if the probability of the word bigram: " 压力- 大" (high pressure) is in the 2_{nd} range, the feature is represented as "word-2-gram=2".

In our experiments, language models are trained on the Gigaword corpus[1] with SRILM tools[2]. To train a word-based language model, we segmented the corpus using our re-implementation of Zhang and Clark (2010). Results show that language model information not only improves the perfor-

[1]https://catalog.ldc.upenn.edu/LDC2003T05
[2]http://www.speech.sri.com/projects/srilm/

mance of text normalization, but also increases the performance of word-segmentation.

4 Extension for Joint Segmentation, Normalization and POS tagging

4.1 Joint Segmentation and POS Tagging

In order to reduce the error propagation of word segmentation, joint models have been applied to some NLP tasks, such as POS tagging (Zhang and Clark, 2010; Kruengkrai et al., 2009) and Parsing (Zhang et al., 2014a; Qian and Liu, 2012; Zhang et al., 2014b).

We take the joint word segmentation and POS tagging model of Zhang and Clark (2010) as the joint baseline. It extends from transition-based segmenter, adding POS arguments to the original actions. In Figure 1, when the current character c_i is processing, the transition system for ST would operate as follows :

(1) APP(c_i), removing c_i from Q, and appending it to the last (partial) word in S with the same POS tag, .

(2) SEP(c_i, pos), removing c_i from Q, making the last word in S as completed, and adding c_i as a new partial word with a POS tag "pos".

Given the sentence "工作压力大啊！(How great work pressure is!)", the sequences of action "SEP(工, NN), APP(作), SEP(压, NN), APP(力), SEP(大, VA), SEP(啊, SP), SEP(!, PU)" can be used to analyze its structure.

4.2 Joint Segmentation, Normalization and POS Tagging

Our joint model extends the model of Zhang and Clark (2010) by adding a SEPS action, which substitutes formal word for last word in S if exists in the dictionary. On the other hand, it can also be regarded as an extension of the joint segmentation and normalization model, adding POS arguments to the original actions.

Using the same example shown in Figure 2, the following three actions can be applied for the character " 大（big)":

(1) APP("大(big)"), appending "大(big)" to the last word "鸭梨(yālí, pear)" in the informal labeled sequence, which remain with the same POS tag "NN".

(2) SEP("大(big)", VA), making the last word "鸭 梨(yālí, pear)" in the informal labeled sequence as a completed word and adding "大(big)" as a new partial word with a POS tag "VA".

Text	Relation
海归也称海龟。(Overseas returnees is also referred to as turtles.)	(海归, 海龟) (overseas returnee, turtle)
一棵树，有点高，上面挂了好多人。恩，这棵树叫高数（高等数学）。(A tree, seemingly a little high, fails a lot of people. Well, this tree is called high number (advanced mathematics))	(高等数学, 高数) (advanced mathematics, high number)

Table 1: Relation patterns in microblogs.

(3) SEPS("大(big)", VA, "压 力(yālì, pressure)"), operating the action SEP("大(big)", VA), and using the standard form "压力(yālì, pressure)" for the informal word "鸭梨(yālí, pear)".

Given the sentence "工 作 鸭 梨 大 啊 ！ (How great work pressure is!)", the sequences of action "SEP(工, NN), APP(作), SEP(鸭, NN), APP(梨), SEPS(大, VA, 压 力), SEP(啊, SP), SEP(!, PU)" can be used to analyze its structure.

We use the same training and decoding framework as our joint segmentation, normalization and POS tagging model, as described in section 3.3.

5 Construction of Normalization Dictionary

Although large-scale normalization dictionaries are difficult to obtain, informal/formal relations could be extracted from large-scale web corpora (Li and Yarowsky, 2008), and informal words are mainly derived using fixed word-formation patterns. In this paper, we adopt two methods to construct a normalization dictionary.

The first method is to extract informal/formal pairs from large-scale text. In general, many informal and formal words co-occur in the same texts or similar contexts. We can find their relations with text patterns. As shown in Table 1, the first example follows the "formal也称informal" ("也称" means "is also referred to as") definition pattern, while the second example follows the pattern "informal(formal)". This gives us a reliable way to seed and bootstrap a list of informal/formal pairs.

We use a bootstrapping algorithm to extract informal/formal pairs from large-scale microblogs. First, a small set of example relations are collected manually. Second, using these relations as a seed set, we extract the text patterns, with which we identify more new relations from the data and aug-

informal也是formal的意思, formal也称informal, informal(formal), 为什么要把formal称为informal, formal其实叫informal,informal:...对formal的称谓, informal谐音自formal, “formal”缘何变“informal”, 用“informal”取代“formal”, informal就是formal的意思, informal有新的意义formal, formal的缩写是informal, 把formal说成informal, 网络...formal叫informal, 称...formal为informal, informal是formal的谐音, “formal”咋就成了“informal”, 当formal变成informal, informal可看作是formal的简称, 将formal写成informal, 网络...infromal的意思是formal.

Table 2: Examples of text patterns.

ment them into the seed set. Table 2 shows the initial text patterns extracted form the examples. The procedure iterates until it cannot identify new relations. There is much noise in the extracted informal/formal pairs. We re-rank them using a similarity-based classifier with weak supervision, with the positive pairs being inserted into dictionary.

The second method is to generate new informal/formal pairs using word-formation patterns extracted from informal/formal pairs. Although Chinese informal words manifest diversity, informal words are mainly derived using fixing word-formation methods, such as compounds, phonetic substitutions, abbreviations, acronym, reduplication. We can learn the pattern of informal word-formation from informal/formal pairs. For example, in informal/formal pair “ 妹纸(mèizhǐ, sister paper)/妹子(mèizǐ, sister)”, informal word “妹纸(mèizhǐ, sister paper)” is builded from formal word “妹子(mèizǐ, sister)” by the pattern “子→纸”. Using this pattern, we can generate many new informal/formal pairs, such as “汉纸(hànzhǐ, man paper)/汉子(hànzǐ, man)”, “男纸(nánzhǐ, man paper)/男子(nánzǐ, man)”, “孙纸(sūnzhǐ, grandson paper)/ 孙子(sūnzǐ, grandson)”, in which the formal words contain character “子”.

In the experiments, we constructed the normalization dictionary consisting of 32,787 informal/formal word pairs in total. The dictionary is used to tamper the formal training data for the joint segmentation and normalization systems with 25% of the formal words in the dictionary being replaced with their informal equivalents.

	Num	Ratio	Agree
Phonetic Substitutions	572	0.870	0.95
Abbreviation	69	0.105	0.97
Paraphrases	17	0.025	0.90
Total	658	1	0.95

Table 3: Frequency distribution and annotation agreement on various types of informal words.

6 Experiments

6.1 Microblog Corpus Annotation

To evaluate our model, we develop a microblog corpus. Our annotated corpus is collected from Sina Weibo[3], which is the largest microblogging platform in China. More than 1,000,000 Chinese posts are crawled using Sina Weibo API. Among these, 4,000 posts were randomly selected. We follow Wang et al. (2012) and apply rules to preprocess the corpus'URLs, emoticons, “@usernames” and Hashtags as pre-segmented words. As a result, we obtain 2,000 sentences as a source of the corpus.

Two human participants annotated the 2,000 sentences by using the tools we developed. The tools can simultaneously annotate word boundaries, POS and text normalization. We used the CTB scheme for word segmentation and POS tagging. We divided informal words into three types: Phonetic Substitutions, Abbreviation, Paraphrases. In total, we annotated 1,129 informal word-pairs in the 2,000 sentences, which contained 658 different informal words.

Table 3 shows the frequency distribution and annotation agreement over three types of informal words in corpus. The Cohen's kappa is 0.95 for informal words annotation, which shows that it is easy for humans to distinguish informal words, and validates our assumption that informal word generally has one formal word equivalent.

6.2 Settings and Measures

Our model is trained on the Chinese Treebank (CTB) 7[4], which is a large, word segmented, POS tagged and fully bracketed Chinese news corpus. The annotated microblog corpus is randomly divided into two parts: 1,000 sentences for development and 1,000 sentences for test.

The standard F-measure is used to measure the

S;N+lm	0.9143	0.4229	0.9025
SN+lm	**0.9149**	**0.7752**	**0.9109**

Table 5: Formal and informal word accuracies on the development test. N-R denotes the recall rate of formal words, I-R denotes the recall rate of informal words, ALL-R denotes the recall rate of all words.

accuracies of word segmentation, POS tagging and text normalization, where the accuracy is *F = 2PR/(P+R)*. In addition, we use recall rates to evaluate the identification accuracies of formal, informal and all words. The recall rate of formal words *N-R* is defined as the percentage of gold standard output formal words that are correctly segmented, the recall rate of informal words *I-R* is defined as the percentage of gold-standard output informal words that are correctly segmented and the recall rate of all words *ALL-R* is defined as the percentage of gold standard output words that are correctly segmented.

6.3 Joint Segmentation and Normalization

Our development set is used to decide the beam size and the number of training iterations. The best performances on the development set are obtained when the beam size is set to 16 and the number of iterations is set to 32.

Comparison with pipeline We investigate the influence of the language model and analyze the result compared to the baseline. Table 4 shows the results on the development and test sets, where SN model is joint model and S;N is pipeline model. Our SN model performs better on segmentation than pipeline S;N model, demonstrating the effectiveness of normalization.

Table 5 shows the accuracies (i.e., recall rate) of formal and informal word identification on the development set. After normalization, the accuracy of informal word identification has a large improvement, and the accuracy of formal word identification also increases. This shows that formal words can be better recognized when informal words are identified correctly. It demonstrates that text normalization is effective for both informal words and formal words.

The effect of language model From Table 4, we observe that the performances increase when using language model features. Particularly, the normalization accuracy improves more significantly. It indicates that statistical language model knowledge play an important role on text normalization. Using language model features, our SN model improves more in the segmentation F-Score compared with the baseline system.

Furthermore, we also find that the language model features are helpful to identifying the formal words, as shown in Table 5. The identification accuracy of informal words increases on the SN model, while the accuracy decreases on the S;N model. Due to the relatively low frequency of informal words, they score lower on informal text by using the language model information, resulting in incorrect word segmentations. This illustrates that our joint model is more suitable for microblogs than the pipeline method.

6.4 Joint Segmentation, Normalization and POS tagging

We compare the following models on word segmentation, text normalization and POS tagging.

ST Our re-implementation of Zhang and Clark(2010). We investigate how the joint model contributes to improving accuracy of word segmentation and POS tagging in microblog domain.

S;N;T It is a pipe-line method for segmentation, normalization and POS tagging. The segmentation model does not use the features of POS. The normalization model uses segmentation information, but not features of POS. The POS tagging model does not need to segmentation.

SN;T It is another pipe-line method that first performs segmentation and normalization, then performs POS tagging. The SN model does not use the features of POS, and the POS tagging model does not need to segmentation.

SNT Our joint segmentation, normalization, and POS tagging model.

6.4.1 Results

Table 6 shows the final results on the test set. Previous work has shown that the systems trained on news data give poor accuracies of word segmentation and POS tagging in the microblog domain. As shown in Table 6,the F-Score of segmentation and POS tagging is 0.902 and 0.8163 respectively by using the Stanford segmenter and POS tagger.

Comparing ST and SNT, we find that text normalization can enhance word segmentation and POS tagging in the microblog. SNT achieved larger improvements over the baseline with language features, reducing segmentation errors by 12.02% and POS errors by 3.63%.

Another goal of the experiment is to illustrate whether the three tasks benefit from each other. Comparing SN;T to S;N;T shows that the performance increases by join segmentation and normalization. It indicates that segmentation and text normalization benefit from each other. On other hand, our SNT model yields better performance than SN;T. It indicates that POS features are effective for segmentation and text normalization, and hence three tasks benefit from each other.

The effect of the normalization dictionary The dictionary plays an important role in our model, which reduces the number of OOV words. Intuitively, the performance is higher when the coverage of dictionary is larger. In the experiments, the coverage of our dictionary on the development and tests are 45.8%,48.2% respectively.

To investigate the effect of the dictionary on our model, we manually construct ten dictionaries from our development data, with coverage between 10% and 100%. Figure 3 shows the F-score curves of test set on segmentation and POS-tagging for both SNT+lm and ST+lm model by different dictionaries. With the coverage of the dictionaries increasing from 10% to 100%, the F-score generally increases. When the coverage is greater than about 20%, the F-score for joint model is higher than for the baseline model.

6.4.2 Error Analysis

We found two major categories of errors. Abbreviation is sometimes incorrectly normalised, especially an informal word mapping to more than one formal word. For example, informal word “美偶” mapped to “美国偶像” (American idol), which consists of two words: “美国” (American) and “偶像” (idol). However, our model cannot normalise the word “美偶” in the experiment.

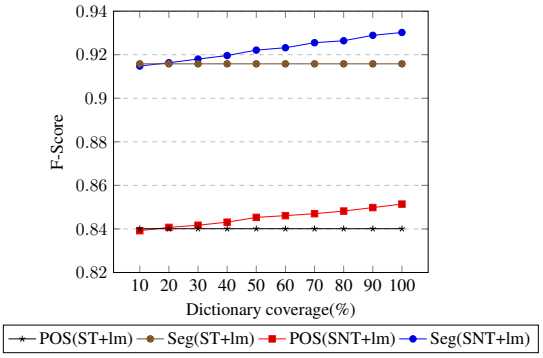

Figure 3: Results of SNT+lm and ST+lm based on different dictionaries for test set.

	Seg-F	POS-F	Nor-F
Stanford	**0.9058**	0.8163	
ST	0.8934	0.8263	
S;N;T	0.8885	0.8197	0.4058
SN;T	0.8945	0.8287	0.4207
SNT	0.8995	**0.8296**	**0.4391**
ST+lm	0.9162	0.8401	
S;N;T+lm	0.9132	0.8341	0.6276
SN;T+lm	0.9240	0.8439	0.6392
SNT+lm	**0.9261**	**0.8459**	**0.6413**

Table 6: Results on the test set. ST denotes the joint segmentation and POS tagging model. S;N;T denotes the pipeline model. SN denotes the joint segmentation and normalization model. SNT denotes the joint segmentatin. normalization and POS tagging model. lm denotes language model features. Seg-F denotes the F-Score of segmentation. POS-F denotes the F-Score of POS tagging. Nor-F denotes the F-Score of normalization.

Another type of error is phonetic substitutions of numbers, which are sometimes identified incorrectly. For example. “7456” is identified as a number in the experiments, but it means “气死我了” (I’m so angry). To settle this problem, it needs more context information.

6.5 Results of Lexical Normalization

It is interesting to explore how well the joint model can normalize informal words. We compare our results with two existing systems on text normalization based on our annotated microblog corpus.

(1) **WangDT** We re-implement Wang et al. (2013), which formalized the task as a classification problem and proposed rule-based and statistical features to model three plausible channels that explain the connection between formal and informal pairs. We use a single decision tree classifier

	P	R	F
SNT+lm	**0.9027**	0.4920	**0.6413**
WangDT	0.6214	**0.5543**	0.5859
LYTop1	0.6338	0.4920	0.5540

Table 7: Results of lexical normalization.

in the experiment.

(2) **LYTop1** Li and Yarowsky (2008) formalized the task as a ranking problem and proposed a conditional log-linear model to normalization. In the experiment, we select top 1 as the standard form of informal word.

We use the same division with 1000 sentences for training and 1000 for test. The training data is used for both the WangDT and LY. We re-segment the corpus using Stanford tools for the two baselines. WangDT uses CRF to detection informal words and LYTop1 uses the informal words detected using our joint model.

Although it is a little unfair for the two baselines compared with our joint model, which uses the external knowledge - normalization dictionary. The experiments can partly reflect some conclusions. Table 7 shows the results of normalization by different systems. The performance of our model is the best among the three systems. In particular, the precision in our SNT model improves upon the baselines significantly. The main reason is that our model is based on global features over whole sentences, while the two baselines based on local windows features.

7 Related Work

There has much work on text normalization. The task is generally treated as a noisy channel problem (Pennell and Liu, 2014; Cook and Stevenson, 2009; Yang and Eisenstein, 2013; Sonmez and Ozgur, 2014) or a translation problem (Aw et al., 2006; Contractor et al., 2010; Li and Liu, 2012; Zhang et al., 2014c). For English, most recent work (Han and Baldwin, 2011; Gouws et al., 2011; Han et al., 2012) uses two-step unsupervised approaches to first detect and then normalize informal words. They aim to produce and use informal/formal word lexicons and mappings.

In processing Chinese informal text, Wong and Xia (2008) address the problem of informal words in bulletin board system (BBS) chats by employing pattern matching. Xia et al. (2005) also use SVM-based classification to recognize Chinese informal sentences chats. Both methods have their advantages: the learning-based method does better on recall, while the pattern matching performs better on precision.

Li and Yarowsky (2008) tackle the problem of identifying informal/formal Chinese word pairs by generating candidates from Baidu search engine and ranking using a conditional log-linear model. Zhang et al. (2014c) analyze the phenomena of mixed text in Chinese microblogs, proposing a two-stage method to normalise mixed texts. However, their models employ pipelined words segmentation, resulting in reduced performance.

Wang and Kan (2013) propose a joint model to process word segmentation and informal word detection. However, text normalization is split to another task (Wang et al., 2013). Our joint model process word segmentation, POS tagging and normalization simultaneously. Kaji et al. (2014) propose a joint model for word segmentation, POS tagging and normalization for Japanese Microblogs. Their model is trained on a partially annotated microblog corpus. In contrast, our model can be trained on existing annotated corpora in standard text.

Researchers have recently developed various microblog corpora annotated with rich linguistic information. Gimpel et al. (2011) and Foster et al. (2011) annotate English microblog posts with POS tags. Han and Baldwin (2011) release a microblog corpus annotated with normalized words. Duan et al. (2012) develop a Chinese microblog corpus annotated with segmentation for SIGHAN bakeoff. Wang et al. (2013) release a Chinese microblog corpus for word segmentation and informal word detection. However, there are no microblog corpora annotated Chinese word segmentation, POS tags, and normalized sentences.

Our work is alse related to the work of word segmentation (Zhang and Clark, 2007; Zhang et al., 2013; Chen et al., 2015) and joint word segmentation and POS-tagging (Jiang et al., 2008; Zhang and Clark, 2010). A comprehensive survey is out of the scope of this paper, but interested readers can refer to Pei et al. (Pei et al., 2014) for a recent literature review of the fields.

To evaluate our model, we develop an annotated microblog corpus with word segmentation, POS tags, and normalization. Furthermore, we train our model by using a standard segmented and POS tagged corpus. We also present a comprehensive evaluation in terms of precision and recall on our

microblog test corpus. Such an evaluation has not been conducted in previous work due to the lack of annotated corpora for Chinese microblogs.

8 Conclusion

We proposed a joint model of word segmentation, POS tagging and normalization, in which the three tasks benefit from each other. The model is trained on standard corpora, hence there is no need to retrain it for new microblog corpora. The results demonstrated that the model can improve the performance of word segmentation and POS tagging with text normalization on microblogs, and our model can benefit from the language statistical information, which is not suitable to segment word and tag POS directly for microblogs because of the relatively low frequency of informal words.

In our model, lexical substitution is based on a normalization dictionary, which avoids the diversity of informal words, simplifying this problem for real world applications. The codes of the joint model and data set are published at the website: `https://github.com/qtxcm/JointModelNSP`.

Multilingual discriminative lexicalized phrase structure parsing

Place Paul Ricoeur 75013 Paris
benoit.crabbe@univ-paris-diderot.fr

Abstract

We provide a generalization of discriminative lexicalized shift reduce parsing techniques for phrase structure grammar to a wide range of morphologically rich languages. The model is efficient and outperforms recent strong baselines on almost all languages considered. It takes advantage of a dependency based modelling of morphology and a shallow modelling of constituency boundaries.

1 Introduction

Lexicalized phrase structure parsing techniques were first introduced by Charniak (2000) and Collins (2003) as generative probabilistic models. Nowadays most statistical models used in natural language processing are discriminative: discriminative models provide more flexibility for modelling a large number of variables and conveniently expressing their interactions. This trend is particularly striking if we consider the literature in dependency parsing. Most state of the art multilingual parsers are actually weighted by discriminative models (Nivre and Scholz, 2004; McDonald et al., 2005; Fernández-González and Martins, 2015).

With respect to multilingual phrase structure parsing, the situation is quite different. Most parsers focus on fixed word order languages like English or Chinese as exemplified by Zhu et al. (2013). Despite a few exceptions (Collins et al., 1999), multilingual state of the art results are generally derived from the generative model of Petrov et al. (2006). Although more recently Hall et al. (2014) introduced a conditional random field parser that clearly improved the state of the art in the multilingual setting.

Both Petrov et al. (2006) and Hall et al. (2014) frame their parsing model to model in priority regular surfacic patterns and word order: Petrov et al. (2006) crucially infers category refinements (called category 'splits') in order to specialize the grammar on recurrent informative patterns observed on input spans. Hall et al. (2014) relies on a similar intuition : the model essentially aims to capture regularities on the spans of constituents and their immediate neighbourhood, following earlier intuitions of Klein and Manning (2004). This modelling strategy has two main motivations. First it reduces the burden of feature engineering, making it easier to generalize to multiple languages. Second it avoids modeling explicitly bilexical dependencies for which parameters are notoriously hard to estimate from small data sets such as existing treebanks.

On the other hand this strategy becomes less intuitive when it comes to modeling free word order languages where word order and constituency should in principle be less informative. As such, the good results reported by Hall et al. (2014) are surprising. It suggests that word order and constituency might be more relevant than often thought for modelling free word order languages.

Nevertheless, free word order languages also tend to be morphologically rich languages. This paper shows that a parsing model that can effectively take morphology into account is key for parsing these languages. More specifically, we show that an efficient lexicalized phrase structure parser - modelling both dependencies and morphology - already significantly improves parsing accuracy. But we also show that an additional modelling of spans and constituency provides additional robustness that contributes to yield state of the art results on almost all languages considered, while remaining quite efficient. Moreover, given the availability of existing multi-view treebanks (Bhatt et al., 2009; Seddah et al., 2013; Qiu et al., 2014), our proposed solution only requires a lightweight infrastructure to achieve multilin-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1847–1856,
Lisbon, Portugal, 17-21 September 2015.

gual parsing without requiring costly language-dependent modifications such as feature engineering.

The paper is organized as follows. We first review the properties of multiview treebanks (Section 2). As these treebanks typically do not provide directly head annotation, an information required for lexicalized parsing, we provide an automated multilingual head annotation procedure (Section 3). We then describe in section 4 a variant of lexicalized shift reduce parsing that we use for the multilingual setting. It provides a way to integrate morphology in the model. Section 5 finally describes a set of experiments designed to test our main hypothesis and to point out the improvements over state of the art in multilingual parsing.

2 Multi-view treebanks

Multi-view treebanks are treebanks annotated both for constituents and dependencies that have the property to be token-wise aligned (Bhatt et al., 2009; Seddah et al., 2013; Qiu et al., 2014) . These double annotations are typically obtained by converting a constituency or dependency annotation into the other annotation type. This method was used for the construction of the dataset for the SPMRL 2013 shared task (Seddah et al., 2013), which contains multi-view treebanks for a number of morphologically rich languages, for which either constituency or dependency treebanks were available. The same kind of process was applied to the Penn TreeBank using the Stanford conversion system to produce dependency annotations (de Marneffe et al., 2006). In this paper, we use both of these datasets.

Although in multi-view treebanks each sentence is annotated both for constituency and dependency, they are not normalized for categories nor lexical features accross languages such as dependencies in the Google Universal Treebank (McDonald et al., 2013). What is more, the dependency and constituency structures may sometimes strongly differ. For some languages, like Hungarian, the conversion has involved some manual reannotation (Vincze et al., 2010).

3 Head annotation procedure

Lexicalized phrase structure parsers traditionally use hand-crafted heuristics for head annotation (Collins, 2003). Although these heuristics are available for some languages, for others they are non existent or non explicit and typically hidden in conversion procedures. In order to leverage the burden of managing language specific heuristics, we first automate head annotation by taking advantage of the multi-view annotation.

We begin by introducing some notation. Assuming a sentence $W = w_1 \dots w_n$, the dependency annotation of this sentence is assumed to be a dependency forest (Kuhlmann and Nivre, 2006). A dependency graph $G = \langle V, E \rangle$ where $V = \{1 \dots n\}$ is the set of word indexes or vertices and $E \subseteq V \times V$ is a set of dependency links. By convention, a dependency (i, j) means that i governs j. A dependency forest is a dependency graph such that a node has at most a single incoming edge and where there is no cycle. A node with no incoming edge is a root of the dependency forest and a dependency tree is a dependency forest with a single root. For some languages, such as German or Basque, the dependency structures found in the data set are actually dependency forests.

Lexicalized parsing relies on head annotation, in other words each node in a constituency tree is associated with the word index of its head. More formally, let A be the set of nodes in the c-tree, head annotation can be represented as a function $h : A \mapsto \{1 \dots n\}$ which maps each node $a \in A$ to the index of its head in the input sentence. h is obtained by leveraging head-related information associated with each rule in the grammar. More precisely, each rule $\tau \rightarrow \gamma$, with $\gamma = a_1 \dots a_k$, is associated with a head index i ($1 \leq i \leq k$) that states that the head $h(\tau)$ of any node labeled τ in a constituency tree that is built using this rule is the same as the head of the right-hand side symbol a_i.

A **Naive** h function is straightforwardly defined as the annotation of each local rule part of the tree in a bottom-up fashion:[1]

Base: $h(w_i) = i \qquad \forall w_i \in W$
Recurrence:

$$h(\tau) = \begin{cases} h(a_i) & \text{if } \forall_{a_j : a_j \in \gamma, i \neq j} \, (h(a_i), h(a_j)) \in E \\ \perp & \text{otherwise} \end{cases}$$

When $\exists a \in A$ such that $h(a) = \perp$ we say that the annotation has failed.

However the naive procedure fails in a large number of cases. Failures fall into the four patterns that are illustrated in Figure 1. For each of

[1] The additional case of unary rules is straightforward and left to the reader.

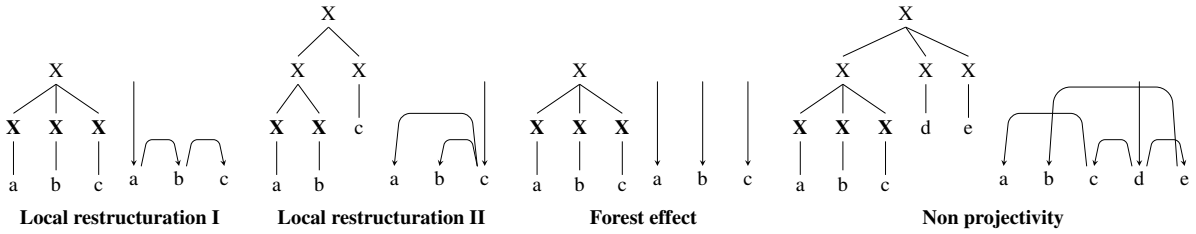

Figure 1: Patterns of the causes of problems taking place during head annotation

the patterns we have highlighted in bold the symbols for which the **Naive** procedure currently fails. *Local Restructuration I* is where the c-structure is flatter than the d-structure. Here the **Naive** procedure fails because $(a, c) \notin E$. *Local Restructuration II* is where the d-structure is flatter than the c-structure. The procedure fails because neither $(a, b) \in E$ nor $(b, a) \in E$. *Forest Effect* is where the d-structure is a dependency forest (here $E = \emptyset$). And finally *Non Projectivity* is where the d-tree is non projective.

We can easily correct the naive procedure for *Local Restructuration I* by taking advantage of $E+$, the non reflexive transitive closure of E, thus yielding the following **Corrected** procedure:

Base: $h(w_i) = i \qquad \forall w_i \in W$
Recurrence:

$$h(\tau) = \begin{cases} h(a_i) & \text{if } \forall_{a_j : a_j \in \gamma, i \neq j} (h(a_i), h(a_j)) \in E^+ \\ \perp & \text{otherwise} \end{cases}$$

The three other cases are more problematic, since their correction would somehow require altering the structure of either the c-tree or the d-tree. Refraining from altering the constituency data set we instead use a catch-all procedure that essentially creates the problematic head annotation by analogy with the rest of the data, yielding a fully **Robust** procedure that is guaranteed to succeed in any case:

Base: $h(w_i) = i \qquad \forall w_i \in W$
Recurrence:

$$h(\tau) = \begin{cases} h(a_i) & \text{if } \forall_{a_j : a_j \in \gamma, i \neq j} (h(a_i), h(a_j)) \in E^+ \\ h(a_{\text{KNN}(\tau \rightarrow \gamma)}) & \text{otherwise} \end{cases}$$

where KNN($\tau \rightarrow \gamma$) is a function returning a guess for the position of the head in γ, the right hand side of the rule, based on similarity to successfully head annotated rules.

The details are as follows. KNN($\tau \rightarrow \gamma$) supposes a dataset $D = (R_i, \mathcal{H}_i)_{i=1}^N$ of successfully head annotated rules. In this dataset, each rule $R_i = \tau \rightarrow \gamma$ is associated with $\mathcal{H}_i$ the position of the head in γ. We define the similarity between two rules $R_1 = \tau^{(1)} \rightarrow a_1^{(1)} \dots a_k^{(1)}$ and $R_2 = \tau^{(2)} \rightarrow a_1^{(2)} \dots a_{k'}^{(2)}$ to be the Levenshtein distance between $\tau^{(1)}, a_1^{(1)} \dots a_k^{(1)}$ and $\tau^{(2)}, a_1^{(2)} \dots a_{k'}^{(2)}$. In practice for a given rule R the function returns the most frequent $\mathcal{H}$ among the 5 most similar rules in the data set.

The full head annotated data set D is built by reading off the rules from the trees successfully annotated in the treebank by the **Corrected** procedure in a first pass. A second pass yields the final annotation by running the **Robust** procedure.

Analysis of the conversion We report in Table 1 an overall quantification of the conversion procedure: % Success (**Corrected**) reports the number of trees succesfully annotated by the **Corrected** procedure and Silver UAS reports an UAS score obtained by comparing the reference dependency trees to the conversion of those obtained from the Robust conversion of the head-annotated phrase structure trees back to dependency structures. The conversion works well apart from four languages (Arabic, Basque, German and Hungarian) which cause more difficulties.

Language	% Success (**Corrected**)	Silver UAS
ARABIC	61.7	92.0
BASQUE	54.2	82.7
ENGLISH	99.9	98.8
FRENCH	99.9	99.3
GERMAN	98.4	72.1
HEBREW	98.2	99.0
HUNGARIAN	85.9	80.1
KOREAN	100.0	100.0
POLISH	98.6	98.8
SWEDISH	99.6	98.8

Table 1: Quantification of the conversion

In order to better understand the problems faced by the conversion procedure, we manually inspected the errors returned by the **Corrected** pro-

cedure. For each language, we sampled 20 examples of failures encountered and we manually categorized the errors using the four patterns illustrated in Figure 1. Across languages, 49.9% of the errors come from the pattern *Local Restructuration II* and 50% from the pattern *Forest effect* and more suprisingly, we found only one example in our sample from the pattern *Non projectivity* in the Hungarian treebank. This overall average hides however an important variation across treebanks. The *Forest effect* is indeed massively found in the Basque[2] (100%) and German treebanks and more marginally in the Hungarian data set. Most of the time, these are cases of short word sequences (2 to 5 tokens) where all nodes are annoted as roots of the dependency trees. The *Local restructuration II* is mostly found in the Arabic, Hebrew and Polish treebanks and less frequently in Hungarian. Arabic and Hebrew tend to follow a binary annotation scheme partially inspired by X-Bar, hence creating additional constituent structures that are not directly inferrable from the dependency annotation. Polish uses this restructuration in patterns involving coordination. More surprisingly, non projective patterns, which we expected to be a significant feature of these languages, remain marginal in comparison to annotation related idiosyncrasic problems.

4 Parsing algorithm

This section provides an overview of the design of the constituent parsing system. There are three recent proposals for beam-based discriminative shift reduce parsing for phrase structure grammar with a structured perceptron and beam search (Zhu et al., 2013; Crabbé, 2014; Mi and Huang, 2015). All three proposals point out that for weighted phrase structure parsing, the shift reduce algorithm requires a special treatment of unary rules in order to compare derivations of the same length. They all provide different management schemes for these unaries.

The work described here draws on the LR algorithm introduced by Crabbé (2014), but provides a simpler algorithm, it precisely describes the management of unary rules and clarifies how spans and morphological information is represented (see section 5).

[2]The constituency conversion of the Basque treebank also contains a recurrent attachment error of the punctuations which we ignored when computing this statistic.

For each language, the grammar is induced from a treebank using the following preprocessing steps. The corpus is first head-annotated with the **Robust** head annotation procedure. Second, the treebank is head-markovized (order 0) and unary productions that do not emit tokens[3] are collapsed into unique symbols. Once this has been done we assume that tokens to be parsed are a list of couples (tag, wordform). The preprocessing steps ensure the binarized treebank implicitly encodes a binary lexicalized grammar whose rules are either in Chomsky Normal Form (CNF) like in (a) $X[h] \rightarrow A[x]\,B[h]$, $X[h] \rightarrow A[h]\,B[x]$, $X[t] \rightarrow t$ or are also of the form (b) $X[h] \rightarrow A[h]\,t$, $X[t] \rightarrow A[h]\,t$, $X[h] \rightarrow t\,B[h]$, $X[t] \rightarrow t\,B[h]$ where A, B, X are delexicalized non-terminals, h, x, t are tokens (terminals) and $A[h], A[x] \ldots X[t]$ are lexicalized non-terminals. Given a grammar in CNF, we can prove that for a sentence of length n, the number of derivation steps for a shift reduce parser is $3n - 1$. However our tagset-preserving transformation also introduces rules of the form (b), which explains why the number of derivation steps may vary from $2n - 1$ to $3n - 1$.

To ensure that a derivation is of length $3n - 1$, the parser forces each shift to be followed by either a unary reduction or an alternative dummy Ghost Reduction (GR). Given the pre-processed treebank we infer the set A of actions used by the parser. Let Σ be the set of non-terminal symbols (including temporary symbols) read off from the binary treebank. The set of actions contains one Shift (S), one Ghost Reduction (GR) a set of $|\Sigma|$ unary reductions (RU-X), one for each symbol, a set of $|\Sigma|$ binary left reductions (RL-X) and a set of $|\Sigma|$ binary right reductions (RR-X) (see also Sagae and Lavie (2006) and Figure 3 for details).

The parser itself is organized around two data structures: a stack of symbols, $\mathbf{S} = \ldots|s_2|s_1|s_0$, whose topmost element is s_0. Symbols are lexicalized non terminals or tokens of the form $A[x]$. The second structure is a queue statically filled with tokens $T = t_1 \ldots t_n$. Parsing is performed by sequentially generating configurations C of the form $\langle j, \mathbf{S}, \cdot \rangle$ where $\mathbf{S}$ is a stack and j is the index of the first element of the queue. Given an initial configuration $C_0 = \langle 1, \epsilon, \perp \rangle$, a derivation step $C_{t-1} \overset{a_{t-1}}{\Rightarrow} C_t$ generates a new configuration C_t by applying an action $a_{t-1} \in A$ as defined in Figure 3. The derivation is complete and successful

[3]In order not to alter the tagset of the treebank.

Figure 2: Features available for scoring. $\mathbf{s_x}$ denote a position in the stack. Stack positions are local trees of depth 1, features can access its **t**op, **l**eft and **r**ight nodes. The suffixes $\mathbf{c_p}, \mathbf{w_p}, \mathbf{lc}, \mathbf{rc}$ denote respectively the delexicalized category, the head token, the left corner token, the right corner token of a stack position. For tokens elements accessible from the stack ($\mathbf{s_x.w_x}$) and from the queue ($\mathbf{q_x}$), features can access the **word** form, pos **tag** or any morphological feature **m** available for that language as described in the table at the right

$$\textsc{Init} \quad \langle 1, \epsilon, \bot \rangle : 0$$
$$\textsc{Goal} \quad \langle n+1, \tau, \bot \rangle : w$$

$$\textsc{Shift} \quad \frac{\langle j, \mathbf{S}, \bot \rangle : w}{\langle j+1, \mathbf{S} \mid t_j.tag[t_j.word]), \top \rangle : w + F(S, \langle j, \mathbf{S} \rangle)}$$

$$\text{RL(X)} \quad \frac{\langle j, \mathbf{S}_\ominus \mid c_1[t_1]\ c_0[t_0], \bot \rangle : w}{\langle j, \mathbf{S}_\ominus \mid X[t_1], \bot \rangle : w + F(RL(X), \langle j, \mathbf{S} \rangle)}$$

$$\text{RR(X)} \quad \frac{\langle j, \mathbf{S}_\ominus \mid c_1[t_1]\ c_0[t_0], \bot \rangle : w}{\langle j, \mathbf{S}_\ominus \mid X[t_0], \bot \rangle : w + F(RR(X), \langle j, \mathbf{S} \rangle)}$$

$$\text{RU(X)} \quad \frac{\langle j, \mathbf{S}_\ominus \mid c_0[t_0], \top \rangle : w}{\langle j, \mathbf{S}_\ominus \mid X[t_0], \bot \rangle : w + F(RU(X), \langle j, \mathbf{S} \rangle)}$$

$$\text{GR(X)} \quad \frac{\langle j, \mathbf{S}_\ominus \mid c_0[t_0], \top \rangle : w}{\langle j, \mathbf{S}_\ominus \mid c_0[t_0], \bot \rangle : w + F(GR, \langle j, \mathbf{S} \rangle)}$$

Figure 3: Weighted inference rules

once the action C_{3n-1} is generated. A derivation sequence $C_{0 \Rightarrow \tau}$ is a sequence of derivation steps $C_0 \overset{a_0}{\Rightarrow} \dots \overset{a_{\tau-1}}{\Rightarrow} C_\tau$

Weighted prediction The choice of the action $a \in A$ at each derivation step is naturally non-deterministic. Determinism is provided by a weighting function based on a linear model of the form:

$$W(C_{0 \Rightarrow \tau}) = \sum_{i=0}^{\tau-1} \mathbf{w} \cdot \mathbf{\Phi}(a_i, C_i) = \sum_{i=0}^{\tau-1} F(a_i, C_i)$$

where $\mathbf{w} \in \mathbb{R}^d$ is a weight vector and $\mathbf{\Phi}(a_i, C_i) \in \{0,1\}^d$ is a feature vector. The best parse is then the successful derivation with the maximum score:

$$\hat{C}_{0 \Rightarrow 3n-1} = \underset{C_{0 \Rightarrow 3n-1} \in \text{GEN}_{3n-1}}{\text{argmax}} \quad W(C_{0 \Rightarrow 3n-1})$$

In practice, we use a beam of size K at each time step and lossy feature hashing, which makes the inference approximative.

For the purpose of computing weights, we extend the representation of the stack and queue elements such that the feature functions have access to a richer context than just simple lexicalized symbols of the form $A[x]$. As described in Figure 2 (left), features can also access the immediate left and right children of s_0 and s_1 as well as their left and right corner tokens. This allows us to encode the span models described in Section 5. We also use tuple-structured tokens encoding not only the word-form and the tag but also additional custom lexical features such as those enumerated in Figure 2 (right). This allows us to express the morphological models described in Section 5.

Finally, the parameters $\mathbf{w}$ are estimated with a parallel averaged structured perceptron designed to cope with inexact inference (beam search): we specifically rely on max-violation updates of Huang et al. (2012) and on minibatches to accelerate and parallelize training (Shalev-Shwartz et al., 2007; Zhao and Huang, 2013).

5 Experiments

The experiments aim to compare the contribution of span based features approximating some intuitions of Hall et al. (2014) for shift reduce parsing and morphological features for parsing free word order languages. We start by describing the evaluation protocol and by defining the models used.

We use the standard SPMRL data set (Seddah et al., 2013). Part of speech tags are generated with Marmot (Müller et al., 2013), a CRF tagger specifically designed to provide tuple-structured tags. The training and development sets are tagged by 10-fold jackknifing. Head annotation is supplied by the **Robust** procedure described in Section 3. The parser is systematically trained for 25 epochs with a max violation update perceptron, a beam of size 8 and a minibatch size of 24.

To enable a comparison with other published results, the evaluation is performed with a version of `evalb` provided by the SPMRL organizers (Seddah et al., 2013) which takes punctuation into account.

Baseline model (B) The baseline model uses a set of templates identical to those of Zhu et al. (2013) for parsing English and Chinese except that we have no specific templates for unary reductions.

Span-based model (B+S) This model extends the **B** model by modeling spans. The span model approximates an intuition underlying Hall et al. (2014): constituent boundaries contain very informative tokens (typically function words). These tokens together with the pattern of their neighborhood provide key clues for detecting and (sub-)typing constituents. Moreover, parameter estimation for frequent functional words should suffer less from data sparseness issues than the estimation of bilexical dependencies on lexical head words. The model includes conjunctions of nonterminal symbols on the stack with their left and right corners (words or tags) and also their immediately adjacent tokens across constituents. Using the notation given in Figure 2 we specifically included the following matrix templates :

$$\mathbf{s_0.c_t\&s_0.lc.word\&s_0.rc.word}$$
$$\mathbf{s_1.c_t\&s_1.lc.word\&s_1.rc.word}$$
$$\mathbf{s_0.c_t\&s_0.lc.word\&s_1.rc.word}$$
$$\mathbf{q_1.word\&s_0.lc.word\&s_0.rc.word}$$
$$\mathbf{q_2.word\&s_0.lc.word\&s_0.rc.word}$$

from which we derived additional backoff templates where only a single corner condition is expressed and/or words are replaced by tags.

Morphological model (B+M) This model extends the **B** model by adding morphological features. This model aims to approximate the intuition that morphological features such as case are key for identifying the structure of free word order languages. As feature engineering may become in principle quite complex once it comes to morphology, we targeted fairly crude models with the goal of providing a proof of concept. Therefore the morphologically informed models use as input a rich set of morphological features specified in Figure 2 (right) predicted by the CRF tagger (Müller et al., 2013) with the same jackkniffing as before. The content of Figure 2 provides an explicit indication of the actual features defined in the original treebanks (see Seddah et al. (2013) and references therein for details), while the columns are indicative normalized names. For Basque most of the additional morphological features further encode case and verbal subcategorization. For French the *mwe* field abbreviates IOB predicted tags derived from multi-word expression annotations found in the original dataset.

Now let M be the set of values enumerated for a language in Figure 2 (right), we systematically added the following templates to model **B**:

$$\begin{array}{ll}
\mathbf{s_0.w_t.m\&s_1.w_t.m\&q_1.tag} & \forall \mathbf{m} \in M \\
\mathbf{s_0.w_t.m\&s_1.c_t\&q_1.m} & \forall \mathbf{m} \in M \\
\mathbf{s_0.c_t.m\&s_1.w_t.m\&q_1.m} & \forall \mathbf{m} \in M \\
\mathbf{s_0.w_t.m\&q_1.m\&q_2.tag} & \forall \mathbf{m} \in M \\
\mathbf{s_0.w_t.m\&q_1.tag\&q_2.m} & \forall \mathbf{m} \in M \\
\mathbf{s_0.c_t\&q_1.m\&q_2.m} & \forall \mathbf{m} \in M
\end{array}$$

Essentially the model expresses interactions between morphological features from the constituent heads on the top of the stack and the morphological features from the tokens at the beginning of the queue.

Mixed model (B+S+M) Our last model is the union of the span model (**B+S**) and the morphological model (**B+M**).

Results (development) We measured the impact of the model variations on the development set for c-parsing on the SPMRL data sets (Table 2). We immediately observe that modelling spans tends to improve the results, in particular for languages where the head annotation is more problematic: Arabic[4], Basque, German and Hungarian and also Swedish however. So the span-based model seems to improve the parser's robustness in cases when dependencies lack precision. For this model, the average behaviour is similar to that of Hall et al. (2014) although the variance is high.

On the other hand, the morphological model tends to be most important for languages where head annotation is easier: French, Korean, Polish and Swedish. It is key for very richly inflected languages such as Basque and Hungarian even though our head annotation is more approximative[5]. A

[4] Although not detailed in the paper, we also observe that for Arabic, the morphological features are generally predicted with a lower accurracy by the tagger than for other languages.

[5] As annotation schemes are not normalized across languages, it is important to stress that these observations are very unlikely to be representative of the linguistic properties of these languages.They are more likely to be a result of annotation choices. For example Korean is a strongly agglutinative language for which much of the morphology is already encoded in the tag set.

	Model	Arabic	Basque	French	German	Hebrew	Hungarian	Korean	Polish	Swedish	Avg
1	Base	79.46	74.67	79.66	82.61	90.43	84.34	81.96	91.68	75.60	82.26

F1-scores provided by `evalb-spmrl` (Seddah et al., 2013). Takes punctuation into account and penalizes unparsed sentences.

Table 2: Development F-scores

comparison with Hall et al. (2014) also reveals that for Basque, Hungarian and Swedish, taking into account morphological information largely explains our improved results.

Results (test) We observe in Table 3 that our joint B+S+M model yields a state of the art c-parser on almost all languages considered[6]. It is quite clear that both our span and morphology enhanced models could be dramatically improved, but it shows that with reasonable feature engineering, these two sub-models are largely sufficient to improve the state of the art in c-parsing for these languages over strong baselines. Although in principle the Berkeley parsers (Petrov et al., 2006; Hall et al., 2014) are designed to be language-generic with an underlying design that is surprisingly accurate for free word order languages end up suffering from a lack of sensitivity to morphological information. Finally we also observe that our phrase structure parser clearly outperforms the TurboParser setup described by Fernández-González and Martins (2015) in which an elaborate output conversion procedure generates c-parses from d-parses.

Comparison with related work We conclude with a few comparisons with related work. This will enable us to show that our approach is not only accurate but also efficient. A comparison with dependency parsers will also allow us to better identify the properties of our proposal.

In order to test efficiency, we compared our parser to c-parsers trained on Penn Treebank (PTB) for which we have running times reported by Fernández-González and Martins (2015). This required first assigning heads, for which we used the Stanford tool for converting PTB to Basic Dependencies, and then used our **Robust** conversion method. We performed a simple test using the PTB standard split with the same experimental setting as before, except that we use the standard `evalb` scorer (Table 5). Although the time comparison remains indicative, it is clear that the parsing framework described in this paper is not only reasonably accurate on a fixed word order language such as English but it is also quite efficient. Parsing accuracies might be different with other head annotation schemes (See e.g. Elming et al. (2013) for illustrations). In our case, we compare the (B+S) model with automated head annotation to the Collins head annotation as implemented in the Standord CORE NLP library (Manning et al., 2014), where we can see that the Collins handcrafted head annotation yields better results than the automated one on English[7].

Table 5: Penn treebank test (WSJ 23)

The question is now to which extend c-trees encode meaningful dependencies? As lexicalized c-trees encode unlabeled dependency trees, our parser also directly outputs unlabeled d-trees by

[6]For Basque, our problem comes from a recurrent inconsistency in the SPMRL data set. As annotated in the c-trees, the punctuation induces a modification of the d-structure: c-trees encode a different governor for punctuation marks than d-trees. This not only causes problem to our head annotation procedure but also for the parser to solving these attachments. A simple correction results in a significant improvement of these parsing results. However we decided to leave the data untouched in order to preserve fair comparisons with other systems.

[7]This pattern does not seem to be systematic: on French we could also compare with head annotations described in (Arun and Keller, 2005) and we observed a slight improvement when using the automated procedure.

Parser (single)	Arabic	Basque	French	German	Hebrew	Hungarian	Korean	Polish	Swedish	Avg

Unlabeled Accuracy Scores. Best other is the best single parser UAS result reported either in SPMRL 13 or SPMRL 14 shared tasks.
Best ensemble is the best semi-supervised or ensemble system from either SPMRL 13 or SPMRL 14 (Björkelund et al., 2013; Björkelund et al., 2014).

Table 4: Multilingual test (UAS, dependency parsing)

simply reading them off from the lexicalized c-structure. We report in Table 4 the UAS evaluation of those dependencies and we compare them to the best results obtained by dependency parsers in both SPMRL13 and SPMRL14 shared tasks. For each language, the comparison is made with the best single dependency parsing system[8]. For English we compare against Standard TurboParser - which seems to be the most similar to our system- when parsing to Basic Stanford dependencies. The comparison with semi-supervised and ensemble parsers still provides a reasonable upperline (Björkelund et al., 2013).

As can be seen in Table 4, our results partly generalize the observation summarized by Cer et al. (2010) and Kong and Smith (2014) that phrase structure parsers tend to provide better dependencies than genuine dependency parsers for parsing to Stanford Dependencies. For English, our UAS is similar to that of TurboParser, but in a broader multilingual framework, the left side of the table shows that the unlabeled dependencies are clearly better than those of genuine dependency parsers. On the right side of the table are languages for which our dependencies are actually worse. This is not a surprise, since these are also the languages for which head annotation was more problematic in the first place. This last observation suggests that a lexicalized c-parser can also provide very accurate dependencies. A way to further generalize this observation to problematic languages would be either to design a less immediate post-processing conversion scheme or to further normalize the data set to obtain the correct heads from the outset.

[8]In practice it turns out that these are either DYALOG-SR (de La Clergerie, 2013) or sometimes MALTOPTIMIZER (Ballesteros and Nivre, 2012)

6 Conclusion

Lexicalized phrase structure parsing of morphologically rich languages used to be difficult since existing implementations targeting essentially English or Chinese do not allow a straightforward integration of morphology. Given multi-view treebanks, we achieve multilingual parsing with a language-agnostic head annotation procedure. Once this procedure has created the required data representation for lexicalized parsing, only modest and weakly language dependent feature engineering is required to achieve state-of-the-art accuracies on all languages considered: a minimal interface with morphology already contributes to improving accuracy, and this is specifically the case when heads are accurately identified. When heads are only approximatively identified, span-based configurational modelling tends to correct the approximation.

Leaving aside details concerning conversion and data normalization, we generally found that the unlabeled dependencies modelled by the lexicalized c-parser also tend to be highly accurate. For languages where c-annotations and d-annotations are less compatible, additional language renormalizations would help to get better comparisons.

As suggested in this paper, future work for parsing morphologically rich languages will require to focus both on feature selection and on the interface between syntax and morphology, which means in our case the interface between the segmenter, the tagger and the parser.

Hierarchical Low-Rank Tensors for Multilingual Transfer Parsing

Abstract

Accurate multilingual transfer parsing typically relies on careful feature engineering. In this paper, we propose a hierarchical tensor-based approach for this task. This approach induces a compact feature representation by combining atomic features. However, unlike traditional tensor models, it enables us to incorporate prior knowledge about desired feature interactions, eliminating invalid feature combinations. To this end, we use a hierarchical structure that uses intermediate embeddings to capture desired feature combinations. Algebraically, this hierarchical tensor is equivalent to the sum of traditional tensors with shared components, and thus can be effectively trained with standard online algorithms. In both unsupervised and semi-supervised transfer scenarios, our hierarchical tensor consistently improves UAS and LAS over state-of-the-art multilingual transfer parsers and the traditional tensor model across 10 different languages.[1]

1 Introduction

The goal of multilingual syntactic transfer is to parse a resource lean target language utilizing annotations available in other languages. Recent approaches have demonstrated that such transfer is possible, even in the absence of parallel data. As a main source of guidance, these methods rely on the commonalities in dependency structures across languages. These commonalities manifest themselves through a broad and diverse set of indicators, ranging from standard arc features used in monolingual parsers to typological properties needed to guide cross-lingual sharing (e.g., verb-subject ordering preference). In fact, careful feature engineering has been shown to play a crucial role in state-of-the-art multilingual transfer parsers (Täckström et al., 2013).

Verb-subject: {head POS=VERB} ∧ {modifier POS=NOUN} ∧{label=subj} ∧ {direction=LEFT}∧ {82A=SV}
Noun-adjective: {head POS=NOUN} ∧ {modifier POS=ADJ}∧ {direction=LEFT} ∧ {87A=Adj-Noun}

Table 1: Example verb-subject and noun-adjective typological features. 82A and 87A denote the WALS (Dryer et al., 2005) feature codes for verb-subject and noun-adjective ordering preferences.

Tensor-based models are an appealing alternative to manual feature design. These models automatically induce a compact feature representation by factorizing a tensor constructed from atomic features (e.g., the head POS). No prior knowledge about feature interactions is assumed. As a result, the model considers all possible combinations of atomic features, and addresses the parameter explosion problem via a low-rank assumption.

In the multilingual transfer setting, however, we have some prior knowledge about legitimate feature combinations. Consider for instance a typological feature that encodes verb-subject preferences. As Table 1 shows, it is expressed as a conjunction of five atomic features. Ideally, we would like to treat this composition as a single non-decomposable feature. However, the traditional tensor model decomposes this feature into multiple dimensions, and considers various combinations of these features as well as their individual interactions with other features. Moreover, we want to avoid invalid combinations that con-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1857–1867,
Lisbon, Portugal, 17-21 September 2015.

join the above feature with unrelated atomic features. For instance, there is no point to constructing features of the form {head POS=ADJ} ∧ {head POS=VERB} ∧ ··· ∧ {82A=SV} as the head *POS* takes a single value. However, the traditional tensor technique still considers these unobserved feature combinations, and assigns them non-zero weights (see Section 7). This inconsistency between prior knowledge and the low-rank assumption results in a sub-optimal parameter estimation.

To address this issue, we introduce a hierarchical tensor model that constrains parameter representation. The model encodes prior knowledge by explicitly excluding undesired feature combinations over the same atomic features. At the bottom level of the hierarchy, the model constructs combinations of atomic features, generating intermediate embeddings that represent the legitimate feature groupings. For instance, these groupings will not combine the verb-subject ordering feature and the POS head feature. At higher levels of the hierarchy, the model combines these embeddings as well as the expert-defined typological features over the same atomic features. The hierarchical tensor is thereby able to capture the interaction between features at various subsets of atomic features. Algebraically, the hierarchical tensor is equivalent to the sum of traditional tensors with shared components. Thus, we can use standard online algorithms for optimizing the low-rank hierarchical tensor.

We evaluate our model on labeled dependency transfer parsing using the newly released multilingual universal dependency treebank (McDonald et al., 2013). We compare our model against the state-of-the-art multilingual transfer dependency parser (Täckström et al., 2013) and the direct transfer model (McDonald et al., 2011). All the parsers utilize the same training resources but with different feature representations. When trained on source languages alone, our model outperforms the baselines for 7 out of 10 languages on both unlabeled attachment score (UAS) and labeled attachment score (LAS). On average, it achieves 1.1% UAS improvement over Täckström et al. (2013)'s model and 4.8% UAS over the direct transfer. We also consider a semi-supervised setting where multilingual data is augmented with 50 annotated sentences in the target language. In this case, our model achieves improvement of 1.7% UAS over Täckström et al. (2013)'s model and 4.5% UAS over the direct transfer.

2 Related Work

Multilingual Parsing The lack of annotated parsing resources for the vast majority of world languages has kindled significant interest in multi-source parsing transfer (Hwa et al., 2005; Durrett et al., 2012; Zeman and Resnik, 2008; Yu et al., 2013b; Cohen et al., 2011; Rasooli and Collins, 2015). Recent research has focused on the non-parallel setting, where transfer is driven by cross-lingual commonalities in syntactic structure (Naseem et al., 2010; Täckström et al., 2013; Berg-Kirkpatrick and Klein, 2010; Cohen and Smith, 2009; Duong et al., 2015).

Our work is closely related to the selective-sharing approaches (Naseem et al., 2012; Täckström et al., 2013). The core of these methods is the assumption that head-modifier attachment preferences are universal across different languages. However, the sharing of arc direction is selective and is based on typological features. While this selective sharing idea was first realized in the generative model (Naseem et al., 2012), higher performance was achieved in a discriminative arc-factored model (Täckström et al., 2013). These gains were obtained by a careful construction of features templates that combine standard dependency parsing features and typological features. In contrast, we propose an automated, tensor-based approach that can effectively capture the interaction between these features, yielding a richer representation for cross-lingual transfer. Moreover, our model handles labeled dependency parsing while previous work only focused on the unlabeled dependency parsing task.

Tensor-based Models Our approach also relates to prior work on tensor-based modeling. Lei et al. (2014) employ three-way tensors to obtain a low-dimensional input representation optimized for parsing performance. Srikumar and Manning (2014) learn a multi-class label embedding tailored for document classification and POS tagging in the tensor framework. Yu and Dredze (2015), Fried et al. (2015) apply low-rank tensor decompositions to learn task-specific word and phrase embeddings. Other applications of tensor framework include low-rank regularization (Primadhanty et al., 2015; Quattoni et al., 2014; Singh et al., 2015) and neural tensor networks (Socher et

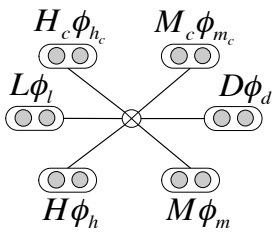

Figure 1: Visual representation for traditional multiway tensor.

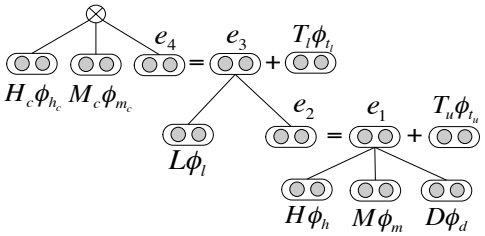

Figure 2: Visual representation for hierarchical tensor, represented as a tree structure. The tensor first captures the low-level interaction ($H\phi_h$, $M\phi_m$ and $D\phi_d$) by an element-wise product, and then combines the intermediate embedding with other components higher in the hierarchy, e.g. e_2 and $L\phi_l$. The equations show that we composite two representations by an element-wise sum.

al., 2013; Yu et al., 2013a). While these methods can automatically combine atomic features into a compact composite representation, they cannot take into account constraints on feature combination. In contrast, our method can capture features at different composition levels, and more generally can incorporate structural constraints based on prior knowledge. As our experiments show, this approach delivers higher transfer accuracy.

3 Hierarchical Low-rank Scoring for Transfer Parsing

3.1 Background

We start by briefly reviewing the traditional three-way tensor scoring function (Lei et al., 2014). The three-way tensor characterizes each arc $h \rightarrow m$ using the tensor-product over three feature vectors: the head vector ($\phi_h \in \mathbb{R}^n$), the modifier vector ($\phi_m \in \mathbb{R}^n$) and the arc vector ($\phi_{h\rightarrow m} \in \mathbb{R}^l$). ϕ_h captures atomic features associated with the head, such as its POS tag and its word form. Similarly, ϕ_m and $\phi_{h\rightarrow m}$ capture atomic features associated with the modifier and the arc respectively. The tensor-product of these three vectors is a rank-1 tensor:

$$\phi_h \otimes \phi_m \otimes \phi_{h\rightarrow m} \in \mathbb{R}^{n\times n\times l}$$

This rank-1 tensor captures all possible combinations of the atomic features in each vector, and therefore significantly expands the feature set. The tensor score is the inner product between a three-way parameter tensor $A \in \mathbb{R}^{n\times n\times l}$ and this rank-1 feature tensor:

$$vec(A) \cdot vec(\phi_h \otimes \phi_m \otimes \phi_{h\rightarrow m})$$

where $vec(\cdot)$ denotes the vector representation of a tensor. This tensor scoring method avoids the parameter explosion and overfitting problem by assuming a low-rank factorization of the parameters A. Specifically, A is decomposed into the sum of r rank-1 components:

$$A = \sum_{i=1}^{r} U(i) \otimes V(i) \otimes W(i)$$

where r is the rank of the tensor, $U, V \in \mathbb{R}^{r\times n}$ and $W \in \mathbb{R}^{r\times l}$ are parameter matrices. $U(i)$ denotes the i-th row of matrix U and similarly for $V(i)$ and $W(i)$. Figure 1 shows the representation of a more general multiway factorization. With this factorization, the model effectively alleviates the feature explosion problem by projecting sparse feature vectors into dense r-dimensional embeddings via U, V and W. Subsequently, the score is computed as follows:

$$S_{tensor}(h \rightarrow m) = \sum_{i=1}^{r} [U\phi_h]_i [V\phi_m]_i [W\phi_{h\rightarrow m}]_i$$

where $[\cdot]_i$ denotes the i-th element of the matrix.

In multilingual transfer, however, we want to incorporate typological features that do not fit in any of the components. For example, if we add the verb-subject ordering preference into $\phi_{h\rightarrow m}$, the tensor will represent the concatenation of this preference with a noun-adjective arc, even though this feature should never trigger.

3.2 Hierarchical Low-rank Tensor

To address this issue, we propose the hierarchical factorization of tensor parameters.[2] The key idea is to generate intermediate embeddings that capture the interaction of the same set of atomic

[2] In this section we focus on delexicalized transfer, and describe the lexicalization process in Section 3.3.

features as other expert-defined features. As Figure 2 shows, this design enables the model to handle expert-defined features over various subsets of the atomic features.

Now, we will illustrate this idea in the context of multilingual parsing. Table 2 summarizes the notations of the feature vectors and the corresponding parameters. Specifically, for each arc $h \rightarrow m$ with label l, we first compute the intermediate feature embedding e_1 that captures the interaction between the head ϕ_h, the modifier ϕ_m and the arc direction and length ϕ_d, by an element-wise product.

$$[e_1]_i = [H\phi_h]_i[M\phi_m]_i[D\phi_d]_i \quad (1)$$

where $[\cdot]_i$ denotes the i-th value of the feature embedding, and H, M and D are the parameter matrices as in Table 2. The embedding e_1 captures the unconstrained interaction over the *head*, the *modifier* and the *arc*. Note that ϕ_{t_u} includes expert-defined typological features that rely on the specific values of the head POS, the modifier POS and the arc direction, such as the example noun-adjective feature in Table 1. Therefore, the embedding $T_u\phi_{t_u}$ captures an expert-defined interaction over the *head*, the *modifier* and the *arc*. Thus e_1 and $T_u\phi_{t_u}$ provide two different representations of the same set of atomic features (e.g. the *head*) and our prior knowledge motivates us to exclude the interaction between them since the low-rank assumption would not apply. Thus, we combine e_1 and $T_u\phi_{t_u}$ as e_2 using an element-wise sum

$$[e_2]_i = [e_1]_i + [T_u\phi_{t_u}]_i \quad (2)$$

and thereby avoid such combinations. As Figure 2 shows, e_2 in turn is used to capture the higher level interaction with arc label features ϕ_l,

$$[e_3]_i = [L\phi_l]_i[e_2]_i \quad (3)$$

Now e_3 captures the interaction between head, modifier, arc direction, length and label. It is over the same set of atomic features as the typological features that depend on arc labels ϕ_{t_l}, such as the example verb-subject ordering feature in Table 1. Therefore, we sum over these embeddings as

$$[e_4]_i = [e_3]_i + [T_l\phi_{t_l}]_i \quad (4)$$

Finally, we capture the interaction between e_4 and context feature embeddings $H_c\phi_{h_c}$ and $M_c\phi_{m_c}$ and compute the tensor score as

Notation	Description
H, ϕ_h M, ϕ_m	Head/modifier POS tag
D, ϕ_d	Arc length and direction
L, ϕ_l	Arc label
T_u, ϕ_{t_u}	Typological features that depend on head/modifier POS but not arc label
T_l, ϕ_{t_l}	Typological features that depend on arc label
H_c, ϕ_{h_c} M_c, ϕ_{m_c}	POS tags of head/modifier neighboring words

Table 2: Notations and descriptions of parameter matrices and feature vectors in our hierarchical tensor model.

$$S_{tensor}(h \xrightarrow{l} m) = \sum_{i=1}^{r} [H_c\phi_{h_c}]_i[M_c\phi_{m_c}][e_4]_i \quad (5)$$

By combining Equation 1 to 5, we observe that our hierarchical tensor score decomposes into three multiway tensor scoring functions.

$$\begin{aligned} S_{tensor}(h \xrightarrow{l} m) &= \sum_{i=1}^{r} [H_c\phi_{h_c}]_i[M_c\phi_{m_c}]_i \\ &\quad \Big\{[T_l\phi_{t_l}]_i + [L\phi_l]_i \\ &\quad \Big([T_u\phi_{t_u}]_i + [H\phi_h]_i[M\phi_m]_i[D\phi_d]_i\Big)\Big\} \\ &= \sum_{i=1}^{r} \Big\{[H_c\phi_{h_c}]_i[M_c\phi_{m_c}]_i[T_l\phi_{t_l}]_i \\ &+ [H_c\phi_{h_c}]_i[M_c\phi_{m_c}]_i[L\phi_l]_i[T_u\phi_{t_u}]_i \\ &+ [H_c\phi_{h_c}]_i[M_c\phi_{m_c}]_i[L\phi_l]_i[H\phi_h]_i[M\phi_m]_i[D\phi_d]_i\Big\} \end{aligned} \quad (6)$$

This decomposition provides another view of our tensor model. That is, our hierarchical tensor is algebraically equivalent to the sum of three multiway tensors, where H_c, M_c and L are shared.[3] From this perspective, we can see that our tensor model effectively captures the following three sets of combinations over atomic features:

f_1: $\phi_{h_c} \otimes \phi_{m_c} \otimes \phi_{t_l}$
f_2: $\phi_{h_c} \otimes \phi_{m_c} \otimes \phi_l \otimes \phi_{t_u}$
f_3: $\phi_{h_c} \otimes \phi_{m_c} \otimes \phi_l \otimes \phi_h \otimes \phi_m \otimes \phi_d$

[3] We could also associate each multiway tensor with a different weight. In our work, we keep them weighted equally.

The last set of features f_3 captures the interaction across standard atomic features. The other two sets of features f_1 and f_2 focus on combining atomic typological features with atomic label and context features. Consequently, we explicitly assign zero weights for invalid assignments, by excluding the combination of ϕ_{t_u} with ϕ_h and ϕ_m.

3.3 Lexicalization Components

In order to encode lexical information in our tensor-based model, we add two additional components, $H_w\phi_{h_w}$ and $M_w\phi_{m_w}$, for head and modifier lexicalization respectively. We compute the final score as the interaction between the delexicalized feature embedding in Equation 5 and the lexical components. Specifically:

$$[e_5]_i = [H_c\phi_{h_c}]_i[M_c\phi_{m_c}]_i[e_4]_i$$
$$S_{tensor}(h \xrightarrow{l} m) = \sum_{i=1}^{r}[H_w\phi_{h_w}]_i[M_w\phi_{m_w}]_i[e_5]_i \quad (7)$$

where e_5 is the embedding that represents the delexicalized transfer results. We describe the features in ϕ_{h_w} and ϕ_{m_w} in Section 5.

3.4 Combined Scoring

Similar to previous work on low-rank tensor scoring models (Lei et al., 2014; Lei et al., 2015), we combine the traditional scoring and the low-rank tensor scoring. More formally, for a sentence $\mathbf{x}$ and a dependency tree $\mathbf{y}$, our final scoring function has the form

$$S(\mathbf{x},\mathbf{y}) = \gamma \sum_{h \xrightarrow{l} m \in \mathbf{y}} \mathbf{w}\cdot\phi(h \xrightarrow{l} m) + (1-\gamma)\sum_{h \xrightarrow{l} m \in \mathbf{y}} S_{tensor}(h \xrightarrow{l} m) \quad (8)$$

where $\phi(h \xrightarrow{l} m)$ is the traditional features for arc $h \rightarrow m$ with label l and $\mathbf{w}$ is the corresponding parameter vector. $\gamma \in [0,1]$ is the balancing hyper-parameter and we tune the value on the development set. The parameters in our model are $\theta = (\mathbf{w}, H, M, D, L, T_u, T_l, H_c, M_c)$, and our goal is to optimize all parameters given the training set.

4 Learning

In this section, we describe our learning method.[4] Following standard practice, we optimize the parameters $\theta = (\mathbf{w}, H, M, D, L, T_u, T_l, H_c, M_c)$ in a maximum soft-margin framework, using online passive-aggressive (PA) updates (Crammer et al., 2006).

For tensor parameter update, we employ the joint update method originally used by Lei et al. (2015) in the context of four-way tensors. While our tensor has a very high order (8 components for the delexicalized parser and 10 for the lexicalized parser) and is hierarchical, the gradient computation is nevertheless similar to that of traditional tensors. As described in Section 3.2, we can view our hierarchical tensor as the combination of three multiway tensors with parameter sharing. Therefore, we can compute the gradient of each multiway tensor and take the sum accordingly. For example, the gradient of the label component is

$$\partial L = \sum_{h \xrightarrow{l} m \in \mathbf{y}^*} \Big((H_c\phi_{h_c}) \odot (M_c\phi_{m_c}) \odot [(T_u\phi_{t_u}) + (H\phi_h) \odot (M\phi_m) \odot (D\phi_d)]\Big) \otimes \phi_l - \sum_{h \xrightarrow{l} m \in \tilde{\mathbf{y}}} \Big((H_c\phi_{h_c}) \odot (M_c\phi_{m_c}) \odot [(T_u\phi_{t_u}) + (H\phi_h) \odot (M\phi_m) \odot (D\phi_d)]\Big) \otimes \phi_l \quad (9)$$

where $\odot$ is the element-wise product and $+$ denotes the element-wise addition. $\mathbf{y}^*$ and $\tilde{\mathbf{y}}$ are the gold tree and the maximum violated tree respectively. For each sentence $\mathbf{x}$, we find $\tilde{\mathbf{y}}$ via cost-augmented decoding.

Tensor Initialization Given the high tensor order, initialization has a significant impact on the learning quality. We extend the previous power method for high-order tensor initialization (Lei et al., 2015) to the hierarchical structure using the algebraic view as in computing the gradient.

Briefly, the power method incrementally computes the most important rank-1 component for $H(i)$, $M(i)$ etc, for $i = 1 \ldots r$. In each iteration, the algorithm updates each component by taking the multiplication between the tensor T and the rest of the components. When we update the label component l, we do the multiplication for different

[4] Our description focuses on delexicalized transfer, and we can easily extend the method to the lexicalized case.

Feature	Description
82A	Order of Subject and Verb
83A	Order of Object and Verb
85A	Order of Adposition and Noun Phrase
86A	Order of Genitive and Noun
87A	Order of Adjective and Noun

Table 3: Typological features from WALS (Dryer et al., 2005) used to build the feature templates in our work, inspired by Naseem et al. (2012). Unlike previous work (Naseem et al., 2012; Täckström et al., 2013), we use 82A and 83A instead of 81A (order of subject, object and verb) because we can distinguish between subject and object relations based on dependency labels.

multiway tensors and then take the sum.

$$l = \langle T_0, h_c, m_c, -, t_u \rangle + \langle T_1, h_c, m_c, -, h, m, d \rangle$$

where the operator $\langle T_0, h_c, m_c, -, t_u \rangle$ returns a vector in which the i-th element is computed as $\sum_{uvw} T_0(i, u, v, w) h_c(u) m_c(v) t_u(w)$. The algorithm updates other components in a similar fashion until convergence.

5 Features

Linear Scoring Features Our traditional linear scoring features in $\phi(h \xrightarrow{l} m)$ are mainly drawn from previous work (Täckström et al., 2013). Table 3 lists the typological features from "The World Atlas of Language Structure (WALS)" (Dryer et al., 2005) used to build the feature templates in our work. We use 82A and 83A for verb-subject and verb-object order respectively because we can distinguish between these two relations based on dependency labels. Table 4 summarizes the typological feature templates we use. In addition, we expand features with dependency labels to enable labeled dependency parsing.

Tensor Scoring Features For our tensor model, feature vectors listed in Table 2 capture the five types of atomic features as follows:

(a) ϕ_h, ϕ_m: POS tags of the head or the modifier.
(b) ϕ_{h_c}, ϕ_{m_c}: POS tags of the left/right neighboring words.
(c) ϕ_l: dependency labels.
(d) ϕ_d: dependency length conjoined with direction.
(e) ϕ_{t_u}, ϕ_{t_l}: selectively shared typological features, as described in Table 4.

ϕ_{t_l}	$dir \cdot$82A$\cdot\delta(hp$=VERB$\wedge mp$=NOUN$\wedge$subj$\in l)$
	$dir \cdot$82A$\cdot\delta(hp$=VERB$\wedge mp$=PRON$\wedge$subj$\in l)$
	$dir \cdot$83A$\cdot\delta(hp$=VERB$\wedge mp$=NOUN$\wedge$obj$\in l)$
	$dir \cdot$83A$\cdot\delta(hp$=VERB$\wedge mp$=PRON$\wedge$obj$\in l)$
ϕ_{t_u}	$dir \cdot$85A$\cdot\delta(hp$=ADP$\wedge mp$=NOUN$)$
	$dir \cdot$85A$\cdot\delta(hp$=ADP$\wedge mp$=PRON$)$
	$dir \cdot$86A$\cdot\delta(hp$=NOUN$\wedge mp$=NOUN$)$
	$dir \cdot$87A$\cdot\delta(hp$=ADJ$\wedge mp$=NOUN$)$

Table 4: Typological feature templates used in our work. hp/mp are POS tags of the head/modifier. $dir \in \{$LEFT, RIGHT$\}$ denotes the arc direction. 82A-87A denote the WALS typological feature value. $\delta(\cdot)$ is the indicator function. subj $\in l$ denotes that the arc label l indicates a subject relation, and similarly for obj $\in l$.

We further conjoin atomic features (b) and (d) with the family and the typological class of the language, because the arc direction and the word order distribution depends on the typological property of languages (Täckström et al., 2013). We also add a bias term into each feature vector.

Partial Lexicalization We utilize multilingual word embeddings to incorporate partial lexical information in our model. We use the CCA method (Faruqui and Dyer, 2014) to generate multilingual word embeddings. Specifically, we project word vectors in each non-English language to the English embedding space. To reduce the noise from the automatic projection process, we only incorporate lexical information for the top-100 most frequent words in the following closed classes: pronoun, determiner, adposition, conjunction, particle and punctuation mark. Therefore, we call this feature extension partial lexicalization.[5]

We follow previous work (Lei et al., 2014) for adding embedding features. For the linear scoring model, we simply append the head and the modifier word embeddings after the feature vector. For the tensor-based model, we add each entry of the word embedding as a feature value into ϕ_{h_w} and ϕ_{m_w}. In addition, we add indicator features for the English translation of words because this improves performance in preliminary experiments. For example, for the German word und, we add the word and as a feature.

[5] In our preliminary experiments, we observe that our lexicalized model usually outperforms the unlexicalized counterparts by about 2%.

6 Experimental Setup

Dataset We evaluate our model on the newly released multilingual universal dependency treebank v2.0 (McDonald et al., 2013) that consists of 10 languages: English (EN), French (FR), German (DE), Indonesian (ID), Italian (IT), Japanese (JA), Korean (KO), Brazilian-Portuguese (PT), Spanish (ES) and Swedish (SV). This multilingual treebank is annotated with a universal POS tagset and a universal dependency label set. Therefore, this dataset is an excellent benchmark for cross-lingual transfer evaluation. For POS tags, the gold universal annotation used the coarse tagset (Petrov et al., 2011) that consists of 12 tags: noun, verb, adjective, adverb, pronoun, determiner, adposition, numeral, conjunction, particle, punctuation mark, and a catch-all tag X. For dependency labels, the universal annotation developed the Stanford dependencies (De Marneffe and Manning, 2008) into a rich set of 40 labels. This universal annotation enables labeled dependency parsing in cross-lingual transfer.

Evaluation Scenarios We first consider the unsupervised transfer scenario, in which we assume no target language annotations are available. Following the standard setup, for each target language evaluated, we train our model on the concatenation of the training data in all other source languages.

In addition, we consider the semi-supervised transfer scenario, in which we assume 50 sentences in the target language are available with annotation. However, we observe that random sentence selection of the supervised sample results in a big performance variance. Instead, we select sentences that contain patterns that are absent or rare in source language treebanks. To this end, each time we greedily select the sentence that minimizes the KL divergence between the trigram distribution of the target language and the trigram distribution of the training data after adding this sentence. The training data includes both the target and the source languages. The trigrams are based on universal POS tags. Note that our method does not require any dependency annotations. To incorporate the new supervision, we simply add the new sentences into the original training set, weighing their impact by a factor of 10.

Baselines We compare against different variants of our model.

- **Direct**: a direct transfer baseline (McDonald et al., 2011) that uses only delexicalized features in the MSTParser (McDonald et al., 2005).
- **NT-Select**: our model without the tensor component. This baseline corresponds to the prior feature-based transfer method (Täckström et al., 2013) with extensions to labeled parsing, lexicalization and semi-supervised parsing.[6]
- **Multiway**: tensor-based model where typological features are added as an additional component and parameters are factorized in the multiway structure similarly as in Figure 1.
- **Sup50**: our model trained only on the 50 sentences in the target language in the semi-supervised scenario.

In all the experiments we incorporate partial lexicalization for all variants of our model and we focus on labeled dependency parsing.

Supervised Upper Bound As a performance upper bound, we train the RBGParser (Lei et al., 2014), the state-of-the-art tensor-based parser, on the full target language training set. We train the first-order model[7] with default parameter settings, using the current version of the code.[8]

Evaluation Measures Following standard practices, we report unlabeled attachment score (UAS) and labeled attachment score (LAS), excluding punctuation. For all experiments, we report results on the test set and omit the development results because of space.

Experimental Details For all experiments, we use the arc-factored model and use Eisner's algorithm (Eisner, 1996) to infer the projective Viterbi parse. We train our model and the baselines for 10 epochs. We set a strong regularization $C = 0.001$ during learning because cross-lingual transfer contains noise and the models can easily overfit. Other hyper-parameters are set as $\gamma = 0.3$ and $r = 200$ (rank of the tensor). For partial lexicalization, we set the embedding dimension to 50.

7 Results

Table 5 and 7 summarize the results for the unsupervised and the semi-supervised scenarios. Averaged across languages, our model outperforms all

[6] We use this as a re-implementation of Täckström et al. (2013)'s model because their code is not publicly available.

[7] All multilingual transfer models in our work and in Täckström et al. (2013)'s work are first-order. Therefore, we train first-order RBGParser for consistency.

Table 5: **Unsupervised:** Unlabeled attachment scores (UAS) and Labeled attachment scores (LAS) of different variants of our model with partial lexicalization in unsupervised scenario. "Direct" and "Multiway" indicate the direct transfer and the multiway variants of our model. "NT-Select" indicates our model without tensor component, corresponding to a re-implementation of previous transfer model (Täckström et al., 2013) with extensions to partial lexicalization and labeled parsing. The last column shows the results by our hierarchical tensor-based model. Boldface numbers indicate the best UAS or LAS.

Feature	Weight
87A$\wedge hp$=NOUN$\wedge mp$=ADJ	2.24×10^{-3}
87A$\wedge hp$=VERB$\wedge mp$=NOUN	8.88×10^{-4}
87A$\wedge hp$=VERB$\wedge mp$=PRON	1.21×10^{-4}
87A$\wedge hp$=NOUN$\wedge mp$=NOUN	9.48×10^{-4}
87A$\wedge hp$=ADP$\wedge mp$=NOUN	3.87×10^{-4}

Table 6: Examples of weights for feature combinations between the typological feature 87A=Adj-Noun and different types of arcs. The first row shows the weight for the valid feature (conjoined with noun→adjective arcs) and the rest show weights for the invalid features (conjoined with other types of arcs).

the baselines in both cases. Moreover, it achieves best UAS and LAS on 7 out of 10 languages. The difference is more pronounced in the semi-supervised case. Below, we summarize our findings when comparing the model with the baselines.

Impact of Hierarchical Tensors We first analyze the impact of using a hierarchical tensor by comparing against the Multiway baseline that implements traditional tensor model. As Table 6 shows, this model learns non-zero weights even for invalid feature combinations.

This disregard to known constraints impacts the resulting performance. In the unsupervised scenario, our hierarchical tensor achieves an average improvement of 0.5% on UAS and 1.3% on LAS. Moreover, our model obtains better UAS on all languages and better LAS on 9 out of 10 languages. This observation shows that the multilingual transfer consistently benefits more from a hierarchical tensor structure. In addition, we observe a similar gain over this baseline in the semi-supervised scenario.

Impact of Tensor Models To evaluate the effectiveness of tensor modeling in multilingual transfer, we compare our model against the NT-Select baseline. In the unsupervised scenario, our tensor model yields a 1.1% gain on UAS and a 1.5% on LAS. In the semi-supervised scenario, the improvement is more pronounced, reaching 1.7% on UAS and 1.9% on LAS. The relative error reduction almost doubles, e.g. 7.1% vs. 3.8% on UAS.

While both our model and NT-Select outperform Direct baseline by a large margin on UAS, we observe that NT-Select achieves a slightly worse LAS than Direct. By adding a tensor component, our model outperforms both baselines on LAS, demonstrating that tensor scoring function is able to capture better labeled features for transfer comparing to Direct and NT-Select baselines.

Transfer Performance in the Context of Supervised Results To assess the contribution of multilingual transfer, we compare against the Sup50 results in which we train our model only on 50 target language sentences. As Table 7 shows, our model improves UAS by 2.3% and LAS by 2.7%. We also provide a performance upper bound

Table 7: **Semi-supervised and Supervised:** UAS and LAS of different variants of our model when 50 annotated sentences in the target language are available. "Sup50" columns show the results of our model when only supervised data in the target language is available. We also include in the last two columns the supervised training results with partial or full lexicalization as the performance upper bound. Other columns have the same meaning as in Table 5. Boldface numbers indicate the best UAS or LAS.

by training RBGParser on the full training set.[9] When trained with partial lexical information as in our model, RBGParser gives 82.9% on UAS and 74.5% on LAS with partial lexical information. By utilizing source language annotations, our model closes the performance gap between training on the 50 sentences and on the full training set by about 30% on both UAS and LAS. We further compare to the performance upper bound with full lexical information (87.3% UAS and 83.5% LAS). In this case, our model still closes the performance gap by 21% on UAS and 15% on LAS.

Time Efficiency of Hierarchical Tensors We observe that our hierarchical structure retains the time efficiency of tensor models. On the English test set, the decoding speed of our hierarchical tensor is close to the multiway counterpart (58.6 vs. 61.2 sentences per second), and is lower than the three-way tensor by a factor of 3.1 (184.4 sentences per second). The time complexity of tensors is linear to the number of low-rank components, and is independent of the factorization structure.

8 Conclusions

In this paper, we introduce a hierarchical tensor based-model which enables us to constrain learned representation based on desired feature interactions. We demonstrate that our model outperforms state-of-the-art multilingual transfer parsers and traditional tensors. These observations, taken together with the fact that hierarchical tensors are efficiently learnable, suggest that the approach can be useful in a broader range of parsing applications; exploring the options is an appealing line of future research.

[9] On average, each language has more than 10,000 training sentences.

Diversity in Spectral Learning for Natural Language Parsing

Shashi Narayan and Shay B. Cohen

Abstract

We describe an approach to create a diverse set of predictions with spectral learning of latent-variable PCFGs (L-PCFGs). Our approach works by creating multiple spectral models where noise is added to the underlying features in the training set before the estimation of each model. We describe three ways to decode with multiple models. In addition, we describe a simple variant of the spectral algorithm for L-PCFGs that is fast and leads to compact models. Our experiments for natural language parsing, for English and German, show that we get a significant improvement over baselines comparable to state of the art. For English, we achieve the F_1 score of 90.18, and for German we achieve the F_1 score of 83.38.

1 Introduction

It has been long identified in NLP that a diverse set of solutions from a decoder can be reranked or recombined in order to improve the accuracy in various problems (Henderson and Brill, 1999). Such problems include machine translation (Macherey and Och, 2007), syntactic parsing (Charniak and Johnson, 2005; Sagae and Lavie, 2006; Fossum and Knight, 2009; Zhang et al., 2009; Petrov, 2010; Choe et al., 2015) and others (Van Halteren et al., 2001).

The main argument behind the use of such a diverse set of solutions (such as k-best list of parses for a natural language sentence) is the hope that each solution in the set is mostly correct. Therefore, recombination or reranking of solutions in that set will further optimize the choice of a solution, combining together the information from all solutions.

In this paper, we explore another angle for the use of a set of parse tree predictions, where all predictions are made for the same sentence. More specifically, we describe techniques to exploit diversity with spectral learning algorithms for natural language parsing. Spectral techniques and the method of moments have been recently used for various problems in natural language processing, including parsing, topic modeling and the derivation of word embeddings (Luque et al., 2012; Cohen et al., 2013; Stratos et al., 2014; Dhillon et al., 2015; Rastogi et al., 2015; Nguyen et al., 2015; Lu et al., 2015).

Cohen et al. (2013) showed how to estimate an L-PCFG using spectral techniques, and showed that such estimation outperforms the expectation-maximization algorithm (Matsuzaki et al., 2005). Their result still lags behind state of the art in natural language parsing, with methods such as coarse-to-fine (Petrov et al., 2006).

We further advance the accuracy of natural language parsing with spectral techniques and L-PCFGs, yielding a result that outperforms the original Berkeley parser from Petrov and Klein (2007). Instead of exploiting diversity from a k-best list from a single model, we estimate multiple models, where the underlying features are perturbed with several perturbation schemes. Each such model, during test time, yields a single parse, and all parses are then used together in several ways to select a single best parse.

The main contributions of this paper are two-fold. First, we present an algorithm for estimating L-PCFGs, akin to the spectral algorithm of Cohen et al. (2012), but simpler to understand and implement. This algorithm has value for readers who are interested in learning more about spectral algorithms – it demonstrates some of the core ideas in spectral learning in a rather intuitive way. In addition, this algorithm leads to sparse grammar estimates and compact models.

Second, we describe how a diverse set of predictors can be used with spectral learning techniques.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1868–1878,
Lisbon, Portugal, 17-21 September 2015.

Our approach relies on adding noise to the feature functions that help the spectral algorithm compute the latent states. Our noise schemes are similar to those described by Wang et al. (2013). We add noise to the whole training data, then train a model using our algorithm (or other spectral algorithms; Cohen et al., 2013), and repeat this process multiple times. We then use the set of parses we get from all models in a recombination step.

The rest of the paper is organized as follows. In §2 we describe notation and background about L-PCFG parsing. In §3 we describe our new spectral algorithm for estimating L-PCFGs. It is based on similar intuitions as older spectral algorithms for L-PCFGs. In §4 we describe the various noise schemes we use with our spectral algorithm and the spectral algorithm of Cohen et al. (2013). In §5 we describe how to decode with multiple models, each arising from a different noise setting. In §6 we describe our experiments with natural language parsing for English and German.

2 Background and Notation

We denote by $[n]$ the set of integers $\{1, \ldots, n\}$. For a statement Γ, we denote by $[[\Gamma]]$ its indicator function, with values 0 when the assertion is false and 1 when it is true.

An L-PCFG is a 5-tuple $(\mathcal{N}, \mathcal{I}, \mathcal{P}, m, n)$ where:

- $\mathcal{N}$ is the set of nonterminal symbols in the grammar. $\mathcal{I} \subset \mathcal{N}$ is a finite set of *interminals*. $\mathcal{P} \subset \mathcal{N}$ is a finite set of *preterminals*. We assume that $\mathcal{N} = \mathcal{I} \cup \mathcal{P}$, and $\mathcal{I} \cap \mathcal{P} = \emptyset$. Hence we have partitioned the set of nonterminals into two subsets.
- $[m]$ is the set of possible hidden states.
- $[n]$ is the set of possible words.
- For all $a \in \mathcal{I}$, $b \in \mathcal{N}$, $c \in \mathcal{N}$, $h_1, h_2, h_3 \in [m]$, we have a binary context-free rule $a(h_1) \rightarrow b(h_2)\ \ c(h_3)$.
- For all $a \in \mathcal{P}$, $h \in [m]$, $x \in [n]$, we have a lexical context-free rule $a(h) \rightarrow x$.

Latent-variable PCFGs are essentially equivalent to probabilistic regular tree grammars (PRTGs; Knight and Graehl, 2005) where the righthand side trees are of depth 1. With general PRTGs, the righthand side can be of arbitrary depth, where the leaf nodes of these trees correspond to latent states in the L-PCFG formulation

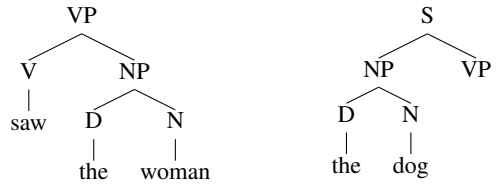

Figure 1: The inside tree (left) and outside tree (right) for the nonterminal `VP` in the parse tree `(S (NP (D the) (N dog)) (VP (V saw) (NP (D the) (N woman))))`.

above and the internal nodes of these trees correspond to interminal symbols in the L-PCFG formulation.

Two important concepts that will be used throughout of the paper are that of an "inside tree" and an "outside tree." Given a tree, the inside tree for a node contains the entire subtree below that node; the outside tree contains everything in the tree excluding the inside tree. See Figure 1 for an example. Given a grammar, we denote the space of inside trees by T and the space of outside trees by O.

3 Clustering Algorithm for Estimating L-PCFGs

We assume two feature functions, $\phi: T \rightarrow \mathbb{R}^d$ and $\psi: O \rightarrow \mathbb{R}^{d'}$, mapping inside and outside trees, respectively, to a real vector. Our training data consist of examples $(a^{(i)}, t^{(i)}, o^{(i)}, b^{(i)})$ for $i \in \{1 \ldots M\}$, where $a^{(i)} \in \mathcal{N}$; $t^{(i)}$ is an inside tree; $o^{(i)}$ is an outside tree; and $b^{(i)} = 1$ if $a^{(i)}$ is the root of tree, 0 otherwise. These are obtained by splitting all trees in the training set into inside and outside trees at each node in each tree. We then define $\Omega^a \in \mathbb{R}^{d \times d'}$:

$$\Omega^a = \frac{\sum_{i=1}^{M} [[a^{(i)} = a]] \phi(t^{(i)}) (\psi(o^{(i)}))^\top}{\sum_{i=1}^{M} [[a^{(i)} = a]]} \quad (1)$$

This matrix is an empirical estimate for the cross-covariance matrix between the inside trees and the outside trees of a given nonterminal a. An inside tree and an outside tree are conditionally independent according to the L-PCFG model, when the latent state at their connecting point is known. This means that the latent state can be identified by finding patterns that co-occur together in inside and outside trees – it is the only random variable that can explain such correlations. As such,

Inputs: An input treebank with the following additional information: training examples $(a^{(i)}, t^{(i)}, o^{(i)}, b^{(i)})$ for $i \in \{1 \dots M\}$, where $a^{(i)} \in \mathcal{N}$; $t^{(i)}$ is an inside tree; $o^{(i)}$ is an outside tree; and $b^{(i)} = 1$ if the rule is at the root of tree, 0 otherwise. A function ϕ that maps inside trees t to feature-vectors $\phi(t) \in \mathbb{R}^d$. A function ψ that maps outside trees o to feature-vectors $\psi(o) \in \mathbb{R}^{d'}$. An integer k denoting the thin-SVD rank. An integer m denoting the number of latent states.

Algorithm:
(Step 1: Singular Value Decompositions)

- Calculate SVD on Ω^a to get $\hat{U}^a \in \mathbb{R}^{(d \times k)}$ and $\hat{V}^a \in \mathbb{R}^{(d' \times k)}$ for each $a \in \mathcal{N}$.

(Step 1: Projection)

- For all $i \in [M]$, compute $y^{(i)} = (\hat{U}^{a_i})^\top \phi(t^{(i)})$ and $z^{(i)} = (\hat{V}^{a_i})^\top \psi(o^{(i)})$.
- For all $i \in [M]$, set $x^{(i)}$ to be the concatenation of $y^{(i)}$ and $z^{(i)}$.

(Step 2: Cluster Projections)

- For all $a \in \mathcal{N}$, cluster the set $\{x^{(i)} \mid a^{(i)} = a\}$ to get a clustering function $\gamma \colon \mathbb{R}^{2k} \to [m]$ that maps a projected vector $x^{(i)}$ to a cluster in $[m]$.

(Step 3: Compute Final Parameters)

- Annotate each node in the treebank with $\gamma(x^{(i)})$.
- Compute the probability of a rule $p(a[h_1] \to b[h_2]\, c[h_3] \mid a[h_1])$ as the relative frequency of its appearance in the cluster-annotated treebank.
- Similarly, compute the root probabilities $\pi(a[h])$ and preterminal rules $p(a[h] \to x \mid a[h])$.

Figure 2: The clustering estimation algorithm for L-PCFGs.

if we reduce the dimensions of Ω^a using singular value decomposition (SVD), we essentially get representations for the inside trees and the outside trees that correspond to the latent states.

This intuition leads to the algorithm that appears in Figure 2. The algorithm we describe takes as input training data, in the form of a treebank, decomposed into inside and outside trees at each node in each tree in the training set.

The algorithm first performs SVD for each of the set of inside and outside trees for all nonterminals.[1] This step is akin to CCA, which has been used in various contexts in NLP, mostly to derive representations for words (Dhillon et al., 2015; Rastogi et al., 2015). The algorithm then takes the representations induced by the SVD step, and clusters them – we use k-means to do the clustering. Finally, it maps each SVD representation to a cluster, and as a result, gets a cluster identifier for each node in each tree in the training data. These clusters are now treated as latent states that are "observed." We subsequently follow up with frequency count maximum likelihood estimate to estimate the probabilities of each parameter in the L-PCFG.

Consider for example the estimation of rules of the form $a \to x$. Following the clustering step we obtain for each nonterminal a and latent state h a set of rules of the form $a[h] \to x$. Each such instance comes from a single training example of a lexical rule. Next, we compute the probability of the rule $a[h] \to x$ by counting how many times that rule appears in the training instances, and normalize by the total count of $a[h]$ in the training instances. Similarly, we compute probabilities for binary rules of the form $a \to b\, c$.

The features that we use for ϕ and ψ are similar to those used in Cohen et al. (2013). These features look at the local neighborhood surrounding a given node. More specifically, we indicate the following information with the inside features (throughout these definitions assume that $a \to b\, c$ is at the root of the inside tree t):

- The pair of nonterminals (a, b). E.g., for the inside tree in Figure 1 this would be the pair (VP, V).
- The pair (a, c). E.g., (VP, NP).
- The rule $a \to b\, c$. E.g., VP $\to$ V NP.
- The rule $a \to b\, c$ paired with the rule at the node b. E.g., for the inside tree in Figure 1 this would correspond to the tree fragment (VP (V saw) NP).
- The rule $a \to b\, c$ paired with the rule at the node c. E.g., the tree fragment (VP V (NP D N)).
- The head part-of-speech of t paired with a. E.g., the pair (VP, V).
- The number of words dominated by t paired with a. E.g., the pair (VP, 3).

In the case of an inside tree consisting of a single rule $a \to x$ the feature vector simply indicates the identity of that rule.

For the outside features, we use:

[1] We normalize features by their variance.

- The rule above the foot node. E.g., for the outside tree in Figure 1 this would be the rule S $\rightarrow$ NP VP* (the foot nonterminal is marked with $*$).
- The two-level and three-level rule fragments above the foot node. These features are absent in the outside tree in Figure 1.
- The label of the foot node, together with the label of its parent. E.g., the pair (VP, S).
- The label of the foot node, together with the label of its parent and grandparent.
- The part-of-speech of the first head word along the path from the foot of the outside tree to the root of the tree which is different from the head node of the foot node.
- The width of the spans to the left and to the right of the foot node, paired with the label of the foot node.

Other Spectral Algorithms The SVD step on the Ω^a matrix is pivotal to many algorithms, and has been used in the past for other L-PCFG estimation algorithms. Cohen et al. (2012) used it for developing a spectral algorithm that identifies the parameters of the L-PCFG up to a linear transformation. Their algorithm generalizes the work of Hsu et al. (2009) and Bailly et al. (2010).

Cohen and Collins (2014) also developed an algorithm that makes use of an SVD step on the inside-outside. It relies on the idea of "pivot features" – features that uniquely identify latent states.

Louis and Cohen (2015) used a clustering algorithm that resembles ours but does not separate inside trees from outside trees or follows up with a singular value decomposition step. Their algorithm was applied to both L-PCFGs and linear context-free rewriting systems. Their application was the analysis of hierarchical structure of conversations in online forums.

In our preliminary experiments, we found out that the clustering algorithm by itself performs worse than the spectral algorithm of Cohen et al. (2013). We believe that the reason is two-fold: (a) k-means finds a local maximum during clustering; (b) we do hard clustering instead of soft clustering. However, we detected that the clustering algorithm gives a more diverse set of solutions, when the features are perturbed. As such, in the next sections, we explain how to perturb the models we get from the clustering algorithm (and the spectral algorithm) in order to improve the accuracy of the clustering and spectral algorithms.

4 Spectral Estimation with Noise

It has been shown that a diverse set of predictions can be used to help improve decoder accuracy for various problems in NLP (Henderson and Brill, 1999). Usually a k-best list from a single model is used to exploit model diversity. Instead, we estimate multiple models, where the underlying features are filtered with various noising schemes.

We try three different types of noise schemes for the algorithm in Figure 2:

Dropout noise: Let $\sigma \in [0, 1]$. We set each element in the feature vectors $\phi(t)$ and $\psi(o)$ to 0 with probability σ.

Gaussian (additive): Let $\sigma > 0$. For each $x^{(i)}$, we draw a vector $\varepsilon \in \mathbb{R}^{2k}$ of Gaussians with mean 0 and variance σ^2, and then set $x^{(i)} \leftarrow x^{(i)} + \varepsilon$.

Gaussian (multiplicative): Let $\sigma > 0$. For each $x^{(i)}$, we draw a vector $\varepsilon \in \mathbb{R}^{2k}$ of Gaussians with mean 0 and variance σ^2, and then set $x^{(i)} \leftarrow x^{(i)} \otimes (1 + \varepsilon)$, where $\otimes$ is coordinate-wise multiplication.

Note the distinction between the dropout noise and the Gaussian noise schemes: the first is performed on the feature vectors before the SVD step, and the second is performed after the SVD step. It is not feasible to add Gaussian noise prior to the SVD step, since the matrix Ω^a will no longer be sparse, and its SVD computation will be computationally demanding.

Our use of dropout noise here is inspired by "dropout" as is used in neural network training, where various connections between units in the neural network are dropped during training in order to avoid overfitting of these units to the data (Srivastava et al., 2014).

The three schemes we described were also used by Wang et al. (2013) to train log-linear models. Wang et al.'s goal was to prevent overfitting by introducing this noise schemes as additional regularizer terms, but without explicitly changing the training data. We do filter the data through these noise schemes, and show in §6 that all of these noise schemes do not improve the performance of our estimation on their own. However, when multiple models are created with these noise schemes,

and then combined together, we get an improved performance. As such, our approach is related to the one of Petrov (2010), who builds a committee of latent-variable PCFGs in order to improve a natural language parser.

We also use these perturbation schemes to create multiple models for the algorithm of Cohen et al. (2012). The dropout scheme stays the same, but for the Gaussian noising schemes, we follow a slightly different procedure. After noising the projections of the inside and outside feature functions we get from the SVD step, we use these projected noised features as a new set of inside and outside feature functions, and re-run the spectral algorithm of Cohen et al. (2012) on them.

We are required to add this extra SVD step because the spectral algorithm of Cohen et al. assumes the existence of linearly transformed parameter estimates, where the parameters of each nonterminal a is linearly transformed by unknown invertible matrices. These matrices cancel out when the inside-outside algorithm is run with the spectral estimate output. In order to ensure that these matrices still exactly cancel out, we have to follow with another SVD step as described above. The latter SVD step is performed on a dense $\Omega^a \in \mathbb{R}^{m \times m}$ but this is not an issue considering m (the number of latent states) is much smaller than d or d'.

5 Decoding with Multiple Models

Let $G_1, \ldots, G_p$ be a set of L-PCFG grammars. In §6, we create such models using the noising techniques described above. The question that remains is how to combine these models together to get a single best output parse tree given an input sentence.

With L-PCFGs, decoding a single sentence requires marginalizing out the latent states to find the best skeletal tree[2] for a given string. Let s be a sentence. We define $t(G_i, s)$ to be the output tree according to minimum Bayes risk decoding. This means we follow Goodman (1996), who uses dynamic programming to compute the tree that maximizes the sum of all marginals of all nonterminals in the output tree. Each marginal, for each span $\langle a, i, j \rangle$ (where a is a nonterminal and i and j are endpoints in the sentence), is computed by using the inside-outside algorithm.

[2]A skeletal tree is a derivation tree without latent states decorating the nonterminals.

In addition, let $\mu(a, i, j | G_k, s)$ be the marginal, as computed by the inside-outside algorithm, for the span $\langle a, i, j \rangle$ with grammar G_k for string s. We use the notation $\langle a, i, j \rangle \in t$ to denote that a span $\langle a, i, j \rangle$ is in a tree t.

We suggest the following three ways for decoding with multiple models $G_1, \ldots, G_p$:

Maximal tree coverage: Using dynamic programming, we return the tree that is the solution to:

$$t^* = \arg\max_t \sum_{\langle a,i,j \rangle \in t} \sum_{k=1}^{p} [[\langle a, i, j \rangle \in t(G_k, s)]].$$

This implies that we find the tree that maximizes its coverage with respect to all other trees that are decoded using $G_1, \ldots, G_p$.

Maximal marginal coverage: Using dynamic programming, we return the tree that is the solution to:

$$t^* = \arg\max_t \sum_{\langle a,i,j \rangle \in t} \sum_{k=1}^{p} \mu(a, i, j | G_k, s).$$

This is similar to maximal tree coverage, only instead of considering just the single decoded tree for each model among $G_1, \ldots, G_p$, we make our decoding "softer," and rely on the marginals that each model gives.

MaxEnt reranking: We train a MaxEnt reranker on a training set that includes outputs from multiple models, and then, during testing time, decode with each of the models, and use the trained reranker to select one of the parses. We use the reranker of Charniak and Johnson (2005).[3]

As we see later in §6, it is sometimes possible to extract more information from the training data by using a network, or a hierarchy of the above tree combination methods. For example, we get our best result for parsing by first using MaxEnt with several subsets of the models, and then combining the output of these MaxEnt models using maximal tree coverage.

[3]Implementation: `https://github.com/BLLIP/bllip-parser`. More specifically, we used the programs `extract-spfeatures`, `cvlm-lbfgs` and `best-indices`. `cvlm-lbfgs` was used with the default hyperparameters from the Makefile.

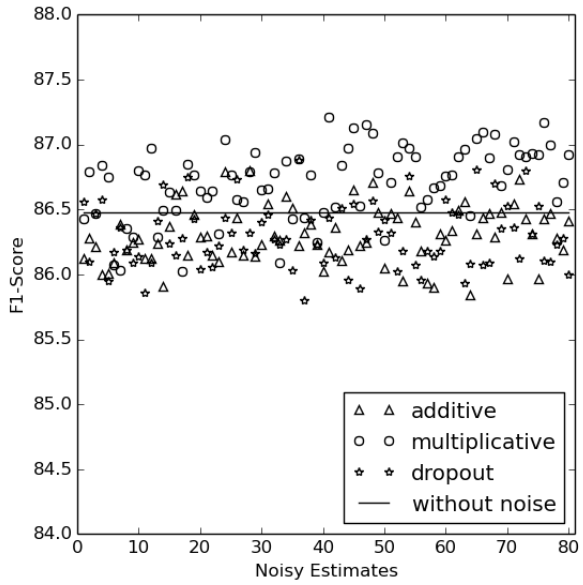

Figure 3: F_1 scores of noisy models. Each data point gives the F_1 accuracy of a single model on the development set, based on the legend. The x-axis enumerates the models (80 in total for each noise scheme).

6 Experiments

In this section, we describe parsing experiments with two languages: English and German.

6.1 Results for English

For our English parsing experiments, we use a standard setup. More specifically, we use the Penn WSJ treebank (Marcus et al., 1993) for our experiments, with sections 2–21 as the training data, and section 22 used as the development data. Section 23 is used as the final test set. We binarize the trees in training data, but transform them back before evaluating them.

For efficiency, we use a base PCFG without latent states to prune marginals which receive a value less than 0.00005 in the dynamic programming chart. The parser takes part-of-speech tagged sentences as input. We tag all datasets using Turbo Tagger (Martins et al., 2010), trained on sections 2–21. We use the F_1 measure according to the PARSEVAL metric (Black et al., 1991) for the evaluation.

Preliminary experiments We first experiment with the number of latent states for the clustering algorithm without perturbations. We use $k = 100$ for the SVD step. Whenever we need to cluster a set of points, we run the k-means algorithm 10 times with random restarts and choose the clustering result with the lowest objective value. On section 22, the clustering algorithm achieves the following results (F_1 measure): $m = 8$: 84.30%, $m = 16$: 85.98%, $m = 24$: 86.48%, $m = 32$: 85.84%, $m = 36$: 86.05%, $m = 40$: 85.43%. As we increase the number of states, performance improves, but plateaus at $m = 24$. For the rest of our experiments, both with the spectral algorithm of Cohen et al. (2012) and the clustering algorithm presented in this paper, we use $m = 24$.

Compact models One of the advantage of the clustering algorithm is that it leads to much more compact models. The number of nonzero parameters with $m = 24$ for the clustering algorithm is approximately 97K, while the spectral algorithms lead to a significantly larger number of nonzero parameters with the same number of latent states: approximately 54 million.

Oracle experiments To what extent do we get a diverse set of solutions from the different models we estimate? This question can be answered by testing the oracle accuracy in the different settings. For each type of noising scheme, we generated 80 models, 20 for each $\sigma \in \{0.05, 0.1, 0.15, 0.2\}$. Each noisy model by itself lags behind the best model (see Figure 3). However, when choosing the best tree among these models, the additively-noised models get an oracle accuracy of 95.91% on section 22; the multiplicatively-noised models get an oracle accuracy of 95.81%; and the dropout-noised models get an oracle accuracy of 96.03%. Finally all models combined get an oracle accuracy of 96.67%. We found out that these oracle scores are comparable to the one Charniak and Johnson (2005) report.

We also tested our oracle results, comparing the spectral algorithm of Cohen et al. (2013) to the clustering algorithm. We generated 20 models for each type of noising scheme, 5 for each $\sigma \in \{0.05, 0.1, 0.15, 0.2\}$) for the spectral algorithm.[4] Surprisingly, even though the spectral models were smoothed, their oracle accuracy was lower than the accuracy of the clustering algo-

[4]There are two reasons we use a smaller number of models with the spectral algorithm: (a) models are not compact (see text) and (b) as such, parsing takes comparatively longer. However, in the above comparison, we use 20 models for the clustering algorithm as well.

	Clustering			Spectral (smoothing)			Spectral (no smoothing)		
	MaxTre	MaxMrg	MaxEnt	MaxTre	MaxMrg	MaxEnt	MaxTre	MaxMrg	MaxEnt
Add	88.68	88.64	89.50	88.20	88.28	88.59	86.72	86.85	87.94
Mul	88.74	88.66	89.89	88.48	88.70	89.46	86.97	86.53	89.04
Dropout	88.68	88.56	89.80	88.64	88.71	**89.47**	88.37	88.06	89.52
All	88.84	88.75	**89.95**	88.38	88.75	89.45	87.49	87.00	**89.85**
No noise	86.48			88.53 (Cohen et al., 2013)			86.47 (Cohen et al., 2013)		

Table 1: Results on section 22 (WSJ). MaxTre denotes decoding using maximal tree coverage, MaxMrg denotes decoding using maximal marginal coverage, and MaxEnt denotes the use of a discriminative reranker. Add, Mul and Dropout denote the use of additive Gaussian noise, multiplicative Gaussian noise and dropout noise, respectively. The number of models used in the first three rows for the clustering algorithm is 80: 20 for each $\sigma \in \{0.05, 0.1, 0.15, 0.2\}$. For the spectral algorithm, it is 20, 5 for each σ (see footnotes). The number of latent states is $m = 24$. For All, we use all models combined from the first three rows. The "No noise" baseline for the spectral algorithm is taken from Cohen et al. (2013). The best figure in each algorithm block is in boldface.

rithm: 92.81% vs. 95.73%.[5] This reinforces two ideas: (i) that noising acts as a regularizer, and has a similar role to backoff smoothing, as we see below; and (ii) the noisy estimation for the clustering algorithm produces a more diverse set of parses than that produced with the spectral algorithm.

	Method	F_1
Best	Spectral (unsmoothed)	89.21
	Spectral (smoothed)	88.87
	Clustering	89.25
Hier	Spectral (unsmoothed)	89.09
	Spectral (smoothed)	89.06
	Clustering	**90.18**

Table 2: Results on section 23 (English). The first three results (Best) are taken with the best model in each corresponding block in Table 1. The last three results (Hier) use a hierarchy of the above tree combination methods in each block. It combines all MaxEnt results using the maximal tree coverage (see text).

It is also important to note that the high oracle accuracy is not just the result of k-means not finding the global maximum for the clustering objective. If we just run the clustering algorithms with 80 models as before, without perturbing the features, the oracle accuracy is 95.82%, which is lower than the oracle accuracy with the additive and dropout perturbed models. To add to this, we see below that perturbing the training set with the spectral algorithm of Cohen et al. improves the accuracy of the spectral algorithm. Since the spectral algorithm of Cohen et al. does not maximize any objective locally, it shows that the role of the perturbations we use is important.

Results Results on the development set are given in Table 1 with our three decoding methods. We present the results from three algorithms: the clustering algorithm and the spectral algorithms (smoothed and unsmoothed).[6]

It seems that dropout noise for the spectral algorithm acts as a regularizer, similarly to the backoff smoothing techniques that are used in Cohen et al. (2013). This is evident from the two spectral algorithm blocks in Table 1, where dropout noise does not substantially improve the smoothed spectral model (Cohen et al. report accuracy of 88.53% with smoothed spectral model for $m = 24$ without noise) – the accuracy is 88.64%–88.71%–89.47%, but the accuracy substantially improves for the unsmoothed spectral model, where dropout brings an accuracy of 86.47% up to 89.52%.

All three blocks in Table 1 demonstrate that decoding with the MaxEnt reranker performs the best. Also it is interesting to note that our results continue to improve when combining the output of previous combination steps further. The best result on section 22 is achieved when we combine, using maximal tree coverage, all MaxEnt outputs of the clustering algorithm (the first block in Ta-

[5] Oracle scores for the clustering algorithm: 95.73% (20 models for each noising scheme) and 96.67% (80 models for each noising scheme).

[6] Cohen et al. (2013) propose two variants of spectral estimation for L-PCFGs: smoothed and unsmoothed. The smoothed model uses a simple backedoff smoothing method which leads to significant improvements over the unsmoothed one. Here we compare our clustering algorithm against both of these models. However unless specified otherwise, the spectral algorithm of Cohen et al. (2013) refers to their best model, i.e. the smoothed model.

	Clustering			Spectral (smoothing)			Spectral (no smoothing)		
	MaxTre	MaxMrg	MaxEnt	MaxTre	MaxMrg	MaxEnt	MaxTre	MaxMrg	MaxEnt
Add	77.34	76.87	80.01	77.76	77.85	78.09	77.44	77.56	77.91

No noise	75.04			77.71			77.07		

Table 3: Results on the development set for German. See Table 1 for interpretation of MaxTre, MaxMrg, MaxEnt and Add, Mul and Dropout. The number of models used in the first three rows for the clustering algorithm is 80: 20 for each $\sigma \in \{0.05, 0.1, 0.15, 0.2\}$. For the spectral algorithm, it is 20, 5 for each σ. The number of latent states is $m = 8$. For All, we use all models combined from the first three rows. The best figure in each algorithm block is in boldface.

ble 1). This yields a 90.68% F_1 accuracy. This is also the best result we get on the test set (section 23), 90.18%. See Table 2 for results on section 23.

Our results are comparable to state-of-the-art results for parsing. For example, Sagae and Lavie (2006), Fossum and Knight (2009) and Zhang et al. (2009) report an accuracy of 93.2%-93.3% using parsing recombination; Shindo et al. (2012) report an accuracy of 92.4 F_1 using a Bayesian tree substitution grammar; Petrov (2010) reports an accuracy of 92.0% using product of L-PCFGs; Charniak and Johnson (2005) report accuracy of 91.4 using a discriminative reranking model; Carreras et al. (2008) report 91.1 F_1 accuracy for a discriminative, perceptron-trained model; Petrov and Klein (2007) report an accuracy of 90.1 F_1. Collins (2003) reports an accuracy of 88.2 F_1.

6.2 Results for German

For the German experiments, we used the NEGRA corpus (Skut et al., 1997). We use the same setup as in Petrov (2010), and use the first 18,602 sentences as a training set, the next 1,000 sentences as a development set and the last 1,000 sentences as a test set. This corresponds to an 80%-10%-10% split of the treebank.

Our German experiments follow the same setting as in our English experiments. For the clustering algorithm we generated 80 models, 20 for each $\sigma \in \{0.05, 0.1, 0.15, 0.2\}$. For the spectral algorithm, we generate 20 models, 5 for each σ.

For the reranking experiment, we had to modify the BLLIP parser (Charniak and Johnson, 2005) to use the head features from the German treebank. We based our modifications on the documentation for the NEGRA corpus (our modifications are based mostly on mapping of nonterminals to coarse syntactic categories).

Preliminary experiments For German, we also experiment with the number of latent states. On the development set, we observe that the F_1 measure is: 75.04% for $m = 8$, 73.44% for $m = 16$ and 70.84% for $m = 24$. For the rest of our experiments, we fix the number of latent states at $m = 8$.

	Spectral (smoothed)	79.96
	Clustering	**83.38**

Table 4: Results on the test set for the German data. The first three results (Best) are taken with the best model in each corresponding block in Table 3. The last three results (Hier) use a hierarchy of the above tree combination methods.

Oracle experiments The additively-noised models get an oracle accuracy of 90.58% on the development set; the multiplicatively-noised models get an oracle accuracy of 90.47%; and the dropout-noised models get an oracle accuracy of 90.69%. Finally all models combined get an oracle accuracy of 92.38%.

We compared our oracle results to those given by the spectral algorithm of Cohen et al. (2013). With 20 models for each type of noising scheme, all spectral models combined achieve an oracle accuracy of 83.45%. The clustering algorithm gets the oracle score of 90.12% when using the same number of models.

Results Results on the development set and on the test set are given in Table 3 and Table 4 respectively.

Like English, in all three blocks in Table 3, decoding with the MaxEnt reranking performs the best. Our results continue to improve when further combining the output of previous combination steps. The best result of 82.04% on the development set is achieved when we combine, using maximal tree coverage, all MaxEnt outputs of the clustering algorithm (the first block in Table 3). This also leads to the best result of 83.38% on the test set. See Table 4 for results on the test set.

Our results are comparable to state-of-the-art results for German parsing. For example, Petrov (2010) reports an accuracy of 84.5% using product of L-PCFGs; Petrov and Klein (2007) report an accuracy of 80.1 F_1; and Dubey (2005) reports an accuracy of 76.3 F_1.

7 Discussion

From a theoretical point of view, one of the great advantages of spectral learning techniques for latent-variable models is that they yield consistent parameter estimates. Our clustering algorithm for L-PCFG estimation breaks this, but there is a work-around to obtain an algorithm which would be statistically consistent.

The main reason that our algorithm is not a consistent estimator is that it relies on k-means clustering, which maximizes a non-convex objective using hard clustering steps. The k-means algorithm can be viewed as "hard EM" for a Gaussian mixture model (GMM), where each latent state is associated with one of the mixture components in the GMM. This means that instead of following up with k-means, we could have identified the parameters and the posteriors for a GMM, where the observations correspond to the vectors that we cluster. There are now algorithms, some of which are spectral, that aim to solve this estimation problem with theoretical guarantees (Vempala and Wang, 2004; Kannan et al., 2005; Moitra and Valiant, 2010).

With theoretical guarantees on the correctness of the posteriors from this step, the subsequent use of maximum likelihood estimation step could yield consistent parameter estimates. The consistency guarantees will largely depend on the amount of information that exists in the base feature functions about the latent states according to the L-PCFG model.

8 Conclusion

We presented a novel estimation algorithm for latent-variable PCFGs. This algorithm is based on clustering of continuous tree representations, and it also leads to sparse grammar estimates and compact models. We also showed how to get a diverse set of parse tree predictions with this algorithm and also older spectral algorithms. Each prediction in the set is made by training an L-PCFG model after perturbing the underlying features that estimation algorithm uses from the training data. We showed that such a diverse set of predictions can be used to improve the parsing accuracy of English and German.

Abstract

Recently, neural network based dependency parsing has attracted much interest, which can effectively alleviate the problems of data sparsity and feature engineering by using the dense features. However, it is still a challenge problem to sufficiently model the complicated syntactic and semantic compositions of the dense features in neural network based methods. In this paper, we propose two heterogeneous gated recursive neural networks: tree structured gated recursive neural network (Tree-GRNN) and directed acyclic graph structured gated recursive neural network (DAG-GRNN). Then we integrate them to automatically learn the compositions of the dense features for transition-based dependency parsing. Specifically, Tree-GRNN models the feature combinations for the trees in stack, which already have partial dependency structures. DAG-GRNN models the feature combinations of the nodes whose dependency relations have not been built yet. Experiment results on two prevalent benchmark datasets (PTB3 and CTB5) show the effectiveness of our proposed model.

1 Introduction

Transition-based dependency parsing is a core task in natural language processing, which has been studied with considerable efforts in the NLP community. The traditional discriminative dependency parsing methods have achieved great success (Koo et al., 2008; He et al., 2013; Bohnet, 2010; Huang and Sagae, 2010; Zhang and Nivre, 2011; Martins et al., 2009; McDonald et al., 2005; Nivre et al., 2006; Kübler et al., 2009; Goldberg and Nivre, 2013; Choi and McCallum, 2013; Ballesteros and Bohnet, 2014). However, these methods are based on discrete features and suffer from the problems of data sparsity and feature engineering (Chen and Manning, 2014).

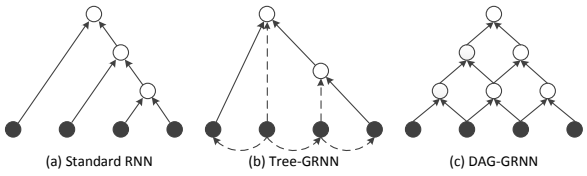

Figure 1: Sketch of three recursive neural networks (RNN). (a) is the standard RNN for constituent tree; (b) is Tree-GRNN for dependency tree, in which the dashed arcs indicate the dependency relations between the nodes; (c) is DAG-GRNN for the nodes without given topological structure.

Recently, distributed representations have been widely used in a variety of natural language processing (NLP) tasks (Collobert et al., 2011; Devlin et al., 2014; Socher et al., 2013; Turian et al., 2010; Mikolov et al., 2013b; Bengio et al., 2003). Specific to the transition-based parsing, the neural network based methods have also been increasingly focused on due to their ability to minimize the efforts in feature engineering and the boosted performance (Le and Zuidema, 2014; Stenetorp, 2013; Bansal et al., 2014; Chen and Manning, 2014; Zhu et al., 2015).

However, most of the existing neural network based methods still need some efforts in feature engineering. For example, most methods often select the first and second leftmost/rightmost children of the top nodes in stack, which could miss some valuable information hidden in the unchosen nodes. Besides, the features of the selected nodes are just simply concatenated and then fed into neural network. Since the concatenation operation is relatively simple, it is difficult to model the com-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1879–1889,
Lisbon, Portugal, 17-21 September 2015.

plicated feature combinations which can be manually designed in the traditional discrete feature based methods.

To tackle these problems, we use two heterogeneous gated recursive neural networks, tree structured gated recursive neural network (Tree-GRNN) and directed acyclic graph gated structured recursive neural network (DAG-GRNN), to model each configuration during transition based dependency parsing. The two proposed GRNNs introduce the gate mechanism (Chung et al., 2014) to improve the standard recursive neural network (RNN) (Socher et al., 2013; Socher et al., 2014), and can model the syntactic and semantic compositions of the nodes during parsing.

Figure 1 gives a rough sketch for the standard RNN, Tree-GRNN and DAG-GRNN. Tree-GRNN is applied to the partial-constructed trees in stack, which have already been constructed according to the previous transition actions. DAG-GRNN is applied to model the feature composition of nodes in stack and buffer which have not been labeled their dependency relations yet. Intuitively, Tree-GRNN selects and merges features recursively from children nodes into their parent according to their dependency structures, while DAG-GRNN further models the complicated combinations of extracted features and explicitly exploits features in different levels of granularity.

To evaluate our approach, we experiment on two prevalent benchmark datasets: English Penn Treebank 3 (PTB3) and Chinese Penn Treebank 5 (CTB5) datasets. Experiment results show the effectiveness of our proposed method. Compared to the parser of Chen and Manning (2014), we receive 0.6% (UAS) and 0.9% (LAS) improvement on PTB3 test set, while we receive 0.8% (UAS) and 1.3% (LAS) improvement on CTB5 test set.

2 Neural Network Based Transition Dependency Parsing

2.1 Transition Dependency Parsing

In this paper, we employ the arc-standard transition systems (Nivre, 2004) and examine only greedy parsing for its efficiency. Figure 2 gives an example of arc-standard transition dependency parsing.

In transition-based dependency parsing, the consecutive configurations of parsing process can be defined as $c^{(i)} = (s^{(i)}, b^{(i)}, A^{(i)})$ which consists of a stack s, a buffer b, and a set of dependency arcs A. Then, the greedy parsing process consecutively predicts the actions based on the features extracted from the corresponding configurations. For a given sentence $w_1, \dots, w_n$, parsing process starts from a initial configuration $c^{(0)} = ([ROOT], [w_1, \dots, w_n], \emptyset)$, and terminates at some configuration $c^{(2n)} = ([ROOT], \emptyset, A^{(2n)}]$, where n is the length of the given sentence $w_{1:n}$. As a result, we derive the parse tree of the sentence $w_{1:n}$ according to the arcs set $A^{(2n)}$.

In arc-standard system, there are three types of actions: **Left-Arc**, **Right-Arc** and **Shift**. Denoting $s_j(j = 1, 2, \dots)$ as the j^{th} top element of the stack, and $b_j(j = 1, 2, \dots)$ as the j^{th} front element of the buffer, we can formalize the three actions of arc-standard system as:

- **Left-Arc**(l) adds an arc $s_2 \leftarrow s_1$ with label l and removes s_2 from the stack, resulting a new arc $l(s_1, s_2)$. Precondition: $|s| \geq 3$ (The ROOT node cannot be child node).
- **Right-Arc**(l) adds an arc $s_2 \rightarrow s_1$ with label l and removes s_1 from the stack, resulting a new arc $l(s_2, s_1)$. Precondition: $|s| \geq 2$.
- **Shift** removes b_1 from the buffer, and adds it to the stack. Precondition: $|b| \geq 1$.

The greedy parser aims to predict the correct transition action for a given configuration. There are two versions of parsing: unlabeled and labeled versions. The set of possible action candidates $\mathcal{T} = 2n_l + 1$ in the labeled version of parsing, and $\mathcal{T} = 3$ in the unlabeled version, where n_l is number of different types of arc labels.

2.2 Neural Network Based Parser

In neural network architecture, the words, POS tags and arc labels are mapped into distributed vectors (embeddings). Specifically, given the word embedding matrix $\mathbf{E}^w \in \mathbb{R}^{d_e \times n_w}$, each word w_i is mapped into its corresponding column $\mathbf{e}^w_{w_i} \in \mathbb{R}^{d_e}$ of $\mathbf{E}^w$ according to its index in the dictionary, where d_e is the dimensionality of embeddings and n_w is the dictionary size. Likewise, The POS and arc labels are also mapped into embeddings by the POS embedding matrix $\mathbf{E}^t \in \mathbb{R}^{d_e \times n_t}$ and arc label embedding matrix $\mathbf{E}^l \in \mathbb{R}^{d_e \times n_l}$ respectively, where n_t and n_l are the numbers of distinct POS tags and arc labels respectively. Correspondingly, embeddings of each POS tag t_i and each arc label l_i are $\mathbf{e}^t_{t_i} \in \mathbb{R}^{d_e}$ and $\mathbf{e}^l_{l_i} \in \mathbb{R}^{d_e}$ extracted from $\mathbf{E}^t$ and $\mathbf{E}^l$ respectively.

Configurations				Gold Actions

10	[ROOT]	$\emptyset$	A$\cup$ROOT(ROOT,likes)	Right_Arc(ROOT)

Figure 2: An example of arc-standard transition dependency parsing.

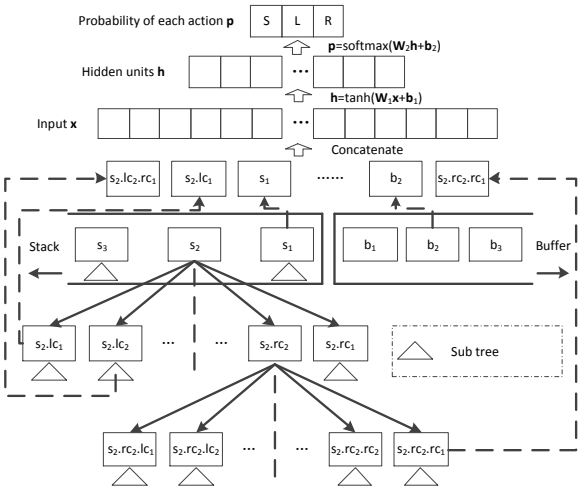

Figure 3: Architecture of neural network based transition dependency parsing.

Figure 3 gives the architecture of neural network based parser. Following Chen and Manning (2014), a set of elements S from stack and buffer (e.g. $S = \{s_2.lc_2.rc_1, s_2.lc_1, s_1, b_2, s_2.rc_2.rc_1, \dots\}$) is chosen as input. Specifically, the information (word, POS or label) of each element in the set S (e.g. $\{s_2.lc_2.rc_1.t, s_2.lc_1.l, s_1.w, s_1.t, b_2.w, \dots\}$) are extracted and mapped into their corresponding embeddings. Then these embeddings are concatenated as the input vector $\mathbf{x} \in \mathbb{R}^{\hat{d}}$. A special token NULL is used to represent a non-existent element.

We perform a standard neural network using one hidden layer with d_h hidden units followed by a softmax layer as:

$$\mathbf{h} = g(\mathbf{W}_1\mathbf{x} + \mathbf{b}_1), \quad (1)$$

$$\mathbf{p} = \text{softmax}(\mathbf{W}_2\mathbf{h} + \mathbf{b}_2), \quad (2)$$

where $\mathbf{W}_1 \in \mathbb{R}^{d_h \times \hat{d}}$, $\mathbf{b}_1 \in \mathbb{R}^{d_h}$, $\mathbf{W}_2 \in \mathbb{R}^{|\mathcal{T}| \times d_h}$, $\mathbf{b}_2 \in \mathbb{R}^{|\mathcal{T}|}$.Here, g is a non-linear function which can be hyperbolic tangent, sigmoid, cube (Chen and Manning, 2014), etc.

3 Recursive Neural Network

Recursive neural network (RNN) is one of classical neural networks, which performs the same set of parameters recursively on a given structure (e.g. syntactic tree) in topological order (Pollack, 1990; Socher et al., 2013).

In the simplest case, children nodes are combined into their parent node using a weight matrix $\mathbf{W}$ which is shared across the whole network, followed by a non-linear function $g(\cdot)$. Specifically, given the left child node vector $\mathbf{h}_L \in \mathbb{R}^d$ and right child node vector $\mathbf{h}_R \in \mathbb{R}^d$, their parent node vector $\mathbf{h}_P \in \mathbb{R}^d$ will be formalized as:

$$\mathbf{h}_P = g\left(\mathbf{W}\begin{bmatrix}\mathbf{h}_L \\ \mathbf{h}_R\end{bmatrix}\right), \quad (3)$$

where $\mathbf{W} \in \mathbb{R}^{d \times 2d}$ and g is a non-linear function as mentioned above.

4 Architecture of Two Heterogeneous Gated Recursive Neural Networks for Transition-based Dependency Parsing

In this paper, we apply the idea of recursive neural network (RNN) to dependency parsing task. RNN needs a pre-defined topological structure. However, in each configuration during parsing, just partial dependency relations have been constructed, while the remains are still unknown. Besides, the standard RNN can just deal with the binary tree. Therefore we cannot apply the standard RNN directly.

Here, we propose two heterogeneous recursive neural networks: tree structured gated recursive neural network (Tree-GRNN) and directed acyclic graph structured gated recursive neural network

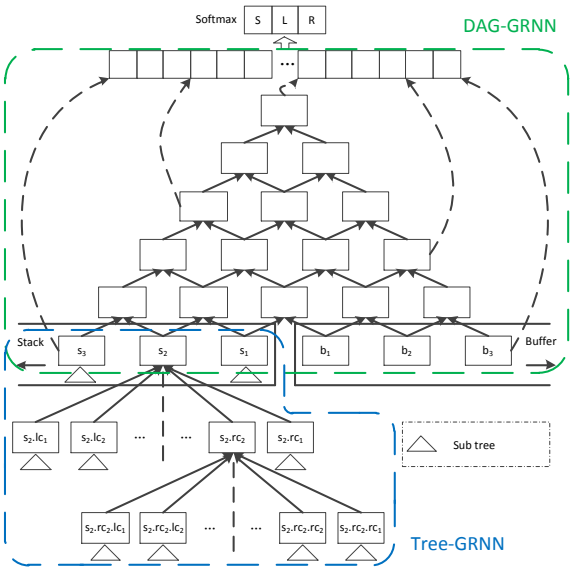

Figure 4: Architecture of our proposed dependency parser using two heterogeneous gated recursive neural networks.

(DAG-GRNN). Tree-GRNN is applied to the subtrees with partial dependency relations in stack which have already been constructed according to the previous transition actions. DAG-GRNN is employed to model the feature composition of nodes in stack and buffer which have not been labeled their dependency relations yet.

Figure 4 shows the whole architecture of our model, which integrates two different GRNNs to predict the action for each parsing configuration. The detailed descriptions of two GRNNs will be discussed in the following two subsections.

4.1 Tree Structured Gated Recursive Neural Network

It is a natural way to merge the information from children nodes into their parent node recursively according to the given tree structures in stack. Although the dependency relations have been built, it is still hard to apply the recursive neural network (as Eq. 3) directly for the uncertain number of children of each node in stack. By averaging operation on children nodes (Socher et al., 2014), the parent node cannot well capture the crucial features from the mixed information of its children nodes. Here, we propose tree structured gated recursive neural network (Tree-GRNN) incorporating the gate mechanism (Cho et al., 2014; Chung et al., 2014; Chen et al., 2015a; Chen et al., 2015b), which can selectively choose the

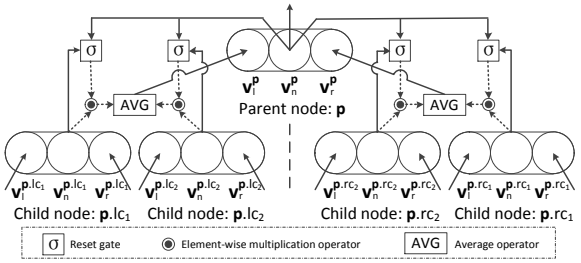

Figure 5: Minimal structure of tree structured gated recursive neural network (Tree-GRNN). The solid arrow denotes that there is a weight matrix on the link, while the dashed one denotes none.

crucial features according to the gate state. Figure 5 shows the minimal structure of Tree-GRNN model.

In Tree-GRNN, each node $\mathbf{p}$ of trees in stack is composed of three components: state vector of left children nodes $\mathbf{v}_l^{\mathbf{p}} \in \mathbb{R}^{d_c}$, state vector of current node $\mathbf{v}_n^{\mathbf{p}} \in \mathbb{R}^{d_n}$ and state vector of right children nodes $\mathbf{v}_r^{\mathbf{p}} \in \mathbb{R}^{d_c}$, where d_n and d_c indicate the corresponding vector dimensionalities. Particularly, we represent information of node $\mathbf{p}$ as a vector

$$\mathbf{v}^{\mathbf{p}} = \begin{bmatrix} \mathbf{v}_l^{\mathbf{p}} \\ \mathbf{v}_n^{\mathbf{p}} \\ \mathbf{v}_r^{\mathbf{p}} \end{bmatrix}, \tag{4}$$

where $\mathbf{v}^{\mathbf{p}} \in \mathbb{R}^q$ and $q = 2d_c + d_n$. Specifically, $\mathbf{v}_n^{\mathbf{p}}$ contains the information of current node including its word form $\mathbf{p}.w$, pos tag $\mathbf{p}.t$ and label type $\mathbf{p}.l$ as shown in Eq. 5, and $\mathbf{v}_l^{\mathbf{p}}$ and $\mathbf{v}_r^{\mathbf{p}}$ are initialized by zero vectors $\mathbf{0} \in \mathbb{R}^{d_c}$, then update as Eq. 6.

$$\mathbf{v}_n^{\mathbf{p}} = \tanh\left(\begin{bmatrix} \mathbf{e}^w_{\mathbf{p}.w} \\ \mathbf{e}^t_{\mathbf{p}.t} \\ \mathbf{e}^l_{\mathbf{p}.l} \end{bmatrix}\right), \tag{5}$$

where word embedding $\mathbf{e}^w_{\mathbf{p}.w} \in \mathbb{R}^{d_e}$, pos embedding $\mathbf{e}^t_{\mathbf{p}.t} \in \mathbb{R}^{d_e}$ and label embedding $\mathbf{e}^l_{\mathbf{p}.l} \in \mathbb{R}^{d_e}$ are extracted from embedding matrices $\mathbf{E}^w$, $\mathbf{E}^t$ and $\mathbf{E}^l$ according to the indices of the corresponding word $\mathbf{p}.w$, pos $\mathbf{p}.t$ and label $\mathbf{p}.l$ respectively. Specifically, in the case of unlabeled attachment parsing, we ignore the last term $\mathbf{e}^l_{\mathbf{p}.l}$ in Eq. 5. Thus, the dimensionality d_n of $\mathbf{v}_n^{\mathbf{p}}$ varies. In labeled attachment parsing case, we set a special token NULL to represent label $\mathbf{p}.l$ if not available (e.g. $\mathbf{p}$ is the node in stack or buffer).

By given node $\mathbf{p}$ and its left children nodes $\mathbf{p}.lc_i$ and right children nodes $\mathbf{p}.rc_i$, we update the left

children information $\mathbf{v}_l^{\mathbf{p}}$ and right children information $\mathbf{v}_r^{\mathbf{p}}$ as

$$\begin{aligned}\mathbf{v}_l^{\mathbf{p}} &= \tanh(\mathbf{W}_l \frac{1}{N_L(\mathbf{p})} \sum_i \mathbf{o}^{\mathbf{p}.lc_i} \odot \mathbf{v}^{\mathbf{p}.lc_i} + \mathbf{b}_l), \\ \mathbf{v}_r^{\mathbf{p}} &= \tanh(\mathbf{W}_r \frac{1}{N_R(\mathbf{p})} \sum_i \mathbf{o}^{\mathbf{p}.rc_i} \odot \mathbf{v}^{\mathbf{p}.rc_i} + \mathbf{b}_r),\end{aligned} \tag{6}$$

where $\mathbf{o}^{\mathbf{p}.lc_i}$ and $\mathbf{o}^{\mathbf{p}.rc_i}$ are the reset gates of the nodes $\mathbf{p}.lc_i$ and $\mathbf{p}.rc_i$ respectively as shown in Eq. 7. In addition, functions $N_L(\mathbf{p})$ and $N_R(\mathbf{p})$ result the numbers of left and right children nodes of node $\mathbf{p}$ respectively. The operator $\odot$ indicates element multiplication here. $\mathbf{W}_l \in \mathbb{R}^{d_c \times q}$ and $\mathbf{W}_r \in \mathbb{R}^{d_c \times q}$ are weight matrices. $\mathbf{b}_l \in \mathbb{R}^{d_c}$ and $\mathbf{b}_r \in \mathbb{R}^{d_c}$ are bias terms.

The reset gates $\mathbf{o}^{\mathbf{p}.lc_i}$ and $\mathbf{o}^{\mathbf{p}.rc_i}$ can be formalized as

$$\begin{aligned}\mathbf{o}^{\mathbf{p}.lc_i} &= \sigma(\mathbf{W}_o \begin{bmatrix} \mathbf{v}^{\mathbf{p}.lc_i} \\ \mathbf{v}_n^{\mathbf{p}} \end{bmatrix} + \mathbf{b}_o), \\ \mathbf{o}^{\mathbf{p}.rc_i} &= \sigma(\mathbf{W}_o \begin{bmatrix} \mathbf{v}^{\mathbf{p}.rc_i} \\ \mathbf{v}_n^{\mathbf{p}} \end{bmatrix} + \mathbf{b}_o),\end{aligned} \tag{7}$$

where σ indicates the sigmoid function, $\mathbf{W}_o \in \mathbb{R}^{q \times (q+d_n)}$ and $\mathbf{b}_o \in \mathbb{R}^q$.

By the mechanism above, we can summarize the whole information into the stack recursively from children nodes to their parent using the partial-built tree structure. Intuitively, the gate mechanism can selectively choose the crucial features of a child node according to the gate state which is derived from the current child node and its parent.

4.2 Directed Acyclic Graph Structured Gated Recursive Neural Network

Previous neural based parsing works feed the extracted features into a standard neural network with one hidden layer. Then, the hidden units are fed into a softmax layer, outputting the probability vector of available actions. Actually, it cannot well model the complicated combinations of extracted features. As for the nodes, whose dependency relations are still unknown, we propose another recursive neural network namely directed acyclic graph structured gated recursive neural network (DAG-GRNN) to better model the interactions of features.

Intuitively, the DAG structure models the combinations of features by recursively mixing the information from the bottom layer to the top layer as shown in Figure 4. The concatenation operation can be regraded as a mix of features in different levels of granularity. Each node in the directed acyclic graph can be seen as a complicated feature composition of its governed nodes.

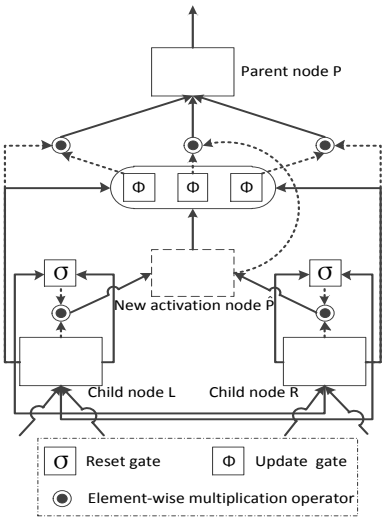

Figure 6: Minimal structure of directed acyclic graph structured gated recursive neural network (DAG-GRNN). The solid arrow denotes that there is a weight matrix on the link, while the dashed one denotes none.

Moreover, we also use the gate mechanism to better model the feature combinations by introducing two kinds of gates, namely "reset gate" and "update gate". Intuitively, each node in the network seems to preserve all the information of its governed notes without gates, and the gate mechanism similarly plays a role of filter which decides how to selectively exploit the information of its children nodes, discovering and preserving the crucial features.

DAG-GRNN structure consists of minimal structures as shown in Figure 6. Vectors $\mathbf{h}^P$, $\mathbf{h}^L$, $\mathbf{h}^R$ and $\mathbf{h}^{\hat{P}} \in \mathbb{R}^q$ denote the value of the parent node P, left child node L, right child node R and new activation node $\hat{P}$ respectively. The value of parent node $\mathbf{h}^P \in \mathbb{R}^q$ is computed as:

$$\mathbf{h}^P = \mathbf{z}_{\hat{P}} \odot \mathbf{h}^{\hat{P}} + \mathbf{z}_L \odot \mathbf{h}^L + \mathbf{z}_R \odot \mathbf{h}^R, \tag{8}$$

where $\mathbf{z}_{\hat{P}}$, $\mathbf{z}_L$ and $\mathbf{z}_R \in \mathbb{R}^q$ are update gates for new activation node $\hat{P}$, left child node L and right child node R respectively. Operator $\odot$ indicates element-wise multiplication.

The update gates $\mathbf{z}$ can be formalized as:

$$\mathbf{z} = \begin{bmatrix} \mathbf{z}_{\hat{P}} \\ \mathbf{z}_L \\ \mathbf{z}_R \end{bmatrix} \propto \exp(\mathbf{W}_z \begin{bmatrix} \mathbf{h}^{\hat{P}} \\ \mathbf{h}^L \\ \mathbf{h}^R \end{bmatrix}), \quad (9)$$

which are constrained by:

$$\begin{cases} [\mathbf{z}_{\hat{P}}]_k + [\mathbf{z}_L]_k + [\mathbf{z}_R]_k = 1, & 1 \le k \le q, \\ [\mathbf{z}_{\hat{P}}]_k \ge 0, & 1 \le k \le q, \\ [\mathbf{z}_L]_k \ge 0, & 1 \le k \le q, \\ [\mathbf{z}_R]_k \ge 0, & 1 \le k \le q, \end{cases} \quad (10)$$

where $\mathbf{W}_z \in \mathbb{R}^{3q \times 3q}$ is the coefficient of update gates.

The value of new activation node $\mathbf{h}_{\hat{P}}$ is computed as:

$$\mathbf{h}_{\hat{P}} = \tanh(\mathbf{W}_{\hat{P}} \begin{bmatrix} \mathbf{r}_L \odot \mathbf{h}_L \\ \mathbf{r}_R \odot \mathbf{h}_R \end{bmatrix}), \quad (11)$$

where $\mathbf{W}_{\hat{P}} \in \mathbb{R}^{q \times 2q}$, $\mathbf{r}_L \in \mathbb{R}^q$, $\mathbf{r}_R \in \mathbb{R}^q$. $\mathbf{r}_L$ and $\mathbf{r}_R$ are the reset gates for left child node L and right child node R respectively, which can be formalized as:

$$\mathbf{r} = \begin{bmatrix} \mathbf{r}_L \\ \mathbf{r}_R \end{bmatrix} = \sigma(\mathbf{W}_r \begin{bmatrix} \mathbf{h}_L \\ \mathbf{h}_R \end{bmatrix}), \quad (12)$$

where $\mathbf{W}_r \in \mathbb{R}^{2q \times 2q}$ is the coefficient of two reset gates and σ indicates the sigmoid function.

Intuitively, the reset gates $\mathbf{r}$ partially read the information from the left and right children, outputting a new activation node $\mathbf{h}_{\hat{P}}$, while the update gates $\mathbf{z}$ selectively choosing the information among the the new activation node $\hat{P}$, the left child node L and the right child node R. This gate mechanism is effective to model the combinations of features.

Finally, we concatenate all the nodes in the DAG-GRNN structure as input $\mathbf{x}$ of the architecture described in Section 2.2, resulting the probability vector for all available actions.

4.3 Inference

We use greedy decoding in parsing. At each step, we apply our two GRNNs on the current configuration to extract the features. After softmax operation, we choose the feasible transition with the highest possibility, and perform the chosen transition on the current configuration to get the next configuration state.

In practice, we do not need calculate the Tree-GRNN over the all trees in the stack on the current configuration. Instead, we preserve the representations of trees in the stack. When we need apply a new transition on the configuration, we update the relative representations using Tree-GRNN.

5 Training

We use the maximum likelihood (ML) criterion to train our model. By extracting training set (x_i, y_i) from gold parse trees using a shortest stack oracle which always prefers Left-Arc(l) or Right-Arc(l) action over Shift, the goal of our model is to minimize the loss function with the parameter set θ:

$$J(\theta) = -\frac{1}{m}\sum_{i=1}^{m} \log \mathbf{p}(y_i|x_i;\theta) + \frac{\lambda}{2m}\|\theta\|_2^2, \quad (13)$$

where m is number of extracted training examples which is as same as the number of all configurations.

Following Socher et al. (2013), we use the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatch strategy to minimize the objective. We also employ dropout strategy to avoid overfitting.

In practice, we perform DAG-GRNN with two hidden layers, which gets the best performance. We use the approximated gradient for Tree-GRNN, which only performs gradient back propagation on the first two layers.

6 Experiments

6.1 Datasets

To evaluate our proposed model, we experiment on two prevalent datasets: English Penn Treebank 3 (PTB3) and Chinese Penn Treebank 5 (CTB5) datasets.

- **English** For English Penn Treebank 3 (PTB3) dataset, we use sections 2-21 for training, section 22 and section 23 as development set and test set respectively. We adopt CoNLL Syntactic Dependencies (CD) (Johansson and Nugues, 2007) using the LTH Constituent-to-Dependency Conversion Tool.
- **Chinese** For Chinese Penn Treebank 5 (CTB5) dataset, we follow the same split as described in (Zhang and Clark, 2008). Dependencies are converted by the Penn2Malt tool with the head-finding rules of (Zhang and Clark, 2008).

Embedding size	$d_e = 50$
Dimensionality of child node vector	$d_c = 50$
Initial learning rate	$\alpha = 0.05$
Regularization	$\lambda = 10^{-8}$
Dropout rate	$p = 20\%$

Table 1: Hyper-parameter settings.

6.2 Experimental Settings

For parameter initialization, we use random initialization within (-0.01, 0.01) for all parameters except the word embedding matrix $\mathbf{E}^w$. Specifically, we adopt pre-trained English word embeddings from (Collobert et al., 2011). And we pre-train the Chinese word embeddings on a huge unlabeled data, the Chinese Wikipedia corpus, with word2vec toolkit (Mikolov et al., 2013a).

Table 1 gives the details of hyper-parameter settings of our approach. In addition, we set mini-batch size to 20. In all experiments, we only take s_1, s_2, s_3 nodes in stack and b_1, b_2, b_3 nodes in buffer into account. We also apply dropout strategy here, and only dropout at the nodes in stack and buffer with probability $p = 20\%$.

6.3 Results

The experiment results on PTB3 and CTB5 datasets are list in Table 2 and 3 respectively. On all datasets, we report unlabeled attachment scores (UAS) and labeled attachment scores (LAS). Conventionally, punctuations are excluded in all evaluation metrics.

To evaluate the effectiveness of our approach, we compare our parsers with feature-based parser and neural-based parser. For feature-based parser, we compare our models with two prevalent parsers: MaltParser (Nivre et al., 2006) and MSTParser (McDonald and Pereira, 2006). For neural-based parser, we compare our results with parser of Chen and Manning (2014). Compared with parser of Chen and Manning (2014), our parser with two heterogeneous gated recursive neural networks (Tree-GRNN+DAG-GRNN) receives 0.6% (UAS) and 0.9% (LAS) improvement on PTB3 test set, and receives 0.8% (UAS) and 1.3% (LAS) improvement on CTB5 test set.

Since that speed of algorithm is not the focus of our paper, we do not optimize the speed a lot. On CTB (UAS), it takes about 2 days to train Tree-GRNN+DAG-GRNN model with CPU only. The testing speed is about 2.7 sentences per second. All implementation is based on Python.

6.4 Effects of Gate Mechanisms

We adopt five different models: plain parser, Tree-RNN parser, Tree-GRNN parser, Tree-RNN+DAG-GRNN parser, and Tree-GRNN+DAG-GRNN parser. The experiment results show the effectiveness of our proposed two heterogeneous gated recursive neural networks.

Specifically, plain parser is as same as parser of Chen and Manning (2014). The difference between them is that plain parser only takes the nodes in stack and buffer into account, which uses a simpler feature template than parser of Chen and Manning (2014). As plain parser omits all children nodes of trees in stack, it performs poorly compared with parser of Chen and Manning (2014). In addition, we find plain parser outperforms MaltParser (standard) on PTB3 dataset making about 1% progress, while it performs poorer than MaltParser (standard) on CTB5 dataset. It shows that the children nodes of trees in stack is of great importance, especially for Chinese. Moreover, it also shows the effectiveness of neural network based model which could represent complicated features as compacted embeddings. Tree-RNN parser additionally exploits all the children nodes of trees in stack, which is a simplified version of Tree-GRNN without incorporating the gate mechanism described in Section 4.1. In anther word, Tree-RNN omits the gate terms $\mathbf{o}^{\mathbf{p}.lc_i}$ and $\mathbf{o}^{\mathbf{p}.rc_i}$ in Eq. 6. As we can see, the results are significantly boosted by utilizing the all information in stack, which again shows the importance of children nodes of trees in stack. Although the results of Tree-RNN are comparable to results of Chen and Manning (2014), it not outperforms parser of Chen and Manning (2014) in all cases (e.g. UAS on CTB5), which implies that exploiting all information without selection might lead to incorporate noise features. Moreover, Tree-GRNN parser further boosts the performance by incorporating the gate mechanism. Intuitively, Tree-RNN who exploits all the information of stack without selection cannot well capture the crucial features, while Tree-GRNN with gate mechanism could selectively choose and preserve the effective features by adapting the current gate state.

We also experiment on parsers using two heterogeneous gated recursive neural networks: Tree-RNN+DAG-GRNN parser and Tree-GRNN+DAG-GRNN parser. The similarity of

Tree-GRNN+DAG-GRNN	**84.6**	**83.6**	**84.7**	**83.7**

Table 3: Performance of different models on CTB5 dataset. UAS: unlabeled attachment score. LAS: labeled attachment score.

two parsers is that they all employ the DAG structured recursive neural network with gate mechanism to model the combination of features extracted from stack and buffer. The difference between them is the former one employs the Tree-RNN without gate mechanism to model the features of stack, while the later one employs the gated version (Tree-GRNN). Again, the performance of these two parsers is further boosted, which shows DAG-GRNN can well model the combinations of features which is summarized by Tree-(G)RNN structure. In addition, we find the performance does not drop a lot in almost cases by turning off the gate mechanism of Tree-GRNN, which implies that the DAG-GRNN can help selecting the information from trees in stack, even it has not been selected by gate mechanism of Tree-GRNN yet.

6.5 Convergency Speed

To further analyze the convergency speed of our approach, we compare the UAS results on development sets of two datasets for first ten epoches as shown in Figure 7 and 8. As plain parser only take the nodes in stack and buffer into account, the performance is much poorer than the rest parsers. Moreover, Tree-GRNN converges slower than Tree-RNN, which shows that it might be more difficult to learn this gate mechanism. By introducing the DAG-GRNN, both Tree-RNN and Tree-GRNN parsers become faster to converge, which shows that the DAG-GRNN is of great help in boosting the convergency speed.

7 Related Work

Many neural network based methods have been used for transition based dependency parsing.

Chen et al. (2014) and Bansal et al. (2014) used the dense vectors (embeddings) to represent words or features and found these representations are

complementary to the traditional discrete feature representation. However, these two methods only focus on the dense representations (embeddings) of words or features.

Stenetorp (2013) first used RNN for transition based dependency parsing. He followed the standard RNN and used the binary combination to model the representation of two linked words. But his model does not achieve the performance of the traditional method.

Le and Zuidema (2014) proposed a generative re-ranking model with Inside-Outside Recursive Neural Network (IORNN), which can process trees both bottom-up and top-down. However, IORNN works in generative way and just estimates the probability of a given tree, so IORNN cannot fully utilize the incorrect trees in k-best candidate results. Besides, IORNN treats dependency tree as a sequence, which can be regarded as a generalization of simple recurrent neural network (SRNN) (Elman, 1990).

Although the two methods also used RNN, they just deal with the binary combination, which is unnatural for dependency tree.

Zhu et al. (2015) proposed a recursive convolutional neural network (RCNN) architecture to capture syntactic and compositional-semantic representations of phrases and words in a dependency tree. Different with the original recursive neural network, they introduced the convolution and pooling layers, which can model a variety of compositions by the feature maps and choose the most informative compositions by the pooling layers.

Chen and Manning (2014) improved the transition-based dependency parsing by representing all words, POS tags and arc labels as dense vectors, and modeled their interactions with neural network to make predictions of actions. Their method only relies on dense features, and is not able to automatically learn the most useful feature conjunctions to predict the transition action.

Compared with (Chen and Manning, 2014), our method can fully exploit the information of all the descendants of a node in stack with Tree-GRNN. Then DAG-GRNN automatically learns the complicated combination of all the features, while the traditional discrete feature based methods need manually design them.

Dyer et al. (2015) improved the transition-based dependency parsing using stack long short term memory neural network and received significant improvement on performance. They focused on exploiting the long distance dependencies and information, while we aims to automatically model the complicated feature combination.

8 Conclusion

In this paper, we pay attention to the syntactic and semantic composition of the dense features for transition-based dependency parsing. We propose two heterogeneous gated recursive neural networks, Tree-GRNN and DAG-GRNN. Each hidden neuron in two proposed GRNNs can be regarded as a different combination of the input features. Thus, the whole model has an ability to simulate the design of the sophisticated feature combinations in the traditional discrete feature based methods.

Although the two proposed GRNNs are only used for the greedy parsing based on arc-standard transition system in this paper, it is easy to generalize them to other transition systems and graph based parsing. In future work, we would also like to extend our GRNNs for the other NLP tasks.

Abstract

In this paper, a turn-taking phenomenon taxonomy is introduced, organised according to the level of information conveyed. It is aimed to provide a better grasp of the behaviours used by humans while talking to each other, so that they can be methodically replicated in spoken dialogue systems. Five interesting phenomena have been implemented in a simulated environment: the system barge-in with three variants (resulting from either an unclear, an incoherent or a sufficient user message), the feedback and the user barge-in. The experiments reported in the paper illustrate that how such phenomena are implemented is a delicate choice as their impact on the system's performance is variable.

1 Introduction

A spoken dialogue system is said to be incremental when it does not wait until the end of the user's utterance in order to process it (Dohsaka and Shimazu, 1997; Allen et al., 2001; Schlangen and Skantze, 2011). New audio information is captured by an incremental Automatic Speech Recognition (ASR) at a certain frequency (Breslin et al., 2013) and at each new step, the partial available information is processed immediately. Therefore, the system is able to replicate a rich set of **turn-taking phenomena** (TTP) that are performed by human beings when talking to each other (Sacks et al., 1974; Clark, 1996). Replicating these TTP in dialogue systems can help to make them more efficient (e.g. (El Asri et al., 2014)) and enhance their ability to recover from misunderstandings (Skantze and Schlangen, 2009).

Several contributions already explored different TTP like end-point detection (Raux and Eskenazi, 2008), backchannels (Meena et al., 2014; Visser et al., 2014), feedback (Skantze and Schlangen, 2009) or barge-in (Selfridge et al., 2013; Ghigi et al., 2014). However, these studies have been performed separately with no unified view and no comparison of respective merits, importance and co-influence of the different TTP. In order to have a better grasp on the concept of turn-taking in a dialogue and a guideline for the implementation, we felt the need to introduce a *taxonomy* of these TTP. Our motivation is to clarify which TTP are interesting to implement given the task at hand. As an illustration, five TTP (which we assume have the best properties to improve the dialogue efficiency) have been implemented and compared in a slot-filling simulated environment.

Section 2 introduces the TTP taxonomy and Section 3 describes the simulated environment, the experimental setup and the results. We then conclude in Section 4.

2 Turn-taking phenomena taxonomy

In linguistics and philosophy of language, a distinction is made between two different levels of a speech act analysis: *locutionary acts* and *illocutionary acts* (Austin, 1962; Searle, 1969). Loosely speaking, a *locutionary act* refers to the act of uttering sounds without taking their meaning into account. When the semantic information is the object of interest, it is an *illocutionary act*. In (Raux and Eskenazi, 2009), four basic turn-taking transitions are presented: *the turn transitions with gap*, *the turn transitions with overlap*, *the failed interruptions* and *the time outs* where only the mechanics of turn-taking are studied at a locutionary level. In (Gravano and Hirschberg, 2011), the authors propose a *turn-taking labeling scheme*, which is a modified version of the original *classification of interruptions and smooth speaker-switches* introduced in (Beattie, 1982). This classification is richer than the one in (Raux and Eskenazi, 2009) as the meaning of the turn-taker utterance

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1890–1895,
Lisbon, Portugal, 17-21 September 2015.

Table 1: *Turn-taking phenomena taxonomy. The rows/columns correspond to the levels of information added by the floor giver/taker. The phenomena in black have been implemented in the simulator.*

	T_REF_IMPL	**T_REF_RAW**	**T_REF_INTERP**	**T_MOVE**
G_NONE	FLOOR_TAKING_IMPL			INIT_DIALOGUE
G_FAIL	FAIL_IMPL	FAIL_RAW	FAIL_INTERP	
G_INCOHERENCE	INCOHERENCE_IMPL	INCOHERENCE_RAW	INCOHERENCE_INTERP	
G_INCOMPLETE	BACKCHANNEL	FEEDBACK_RAW	FEEDBACK_INTERP	
G_SUFFICIENT	REF_IMPL	REF_RAW	REF_INTERP	BARGE_IN_RESP
G_COMPLETE	REKINDLE			END_POINT

is taken into account. From a computational point of view, it is more interesting to add high-level information to classify these behaviours as semantics clearly influence turn-taking decisions (Duncan, 1972; Gravano and Hirschberg, 2011). In this paper, a more fine-grained taxonomy of TTP is introduced where utterances are considered both at locutionary and illocutionary levels.

During a floor transition, the person who starts speaking will be called T (Taker) whereas the person that was speaking just before will be called G (Giver). At the beginning of the dialogue, the person that initiates the dialogue will be called T and the other G by convention. We classify TTP given two criteria: the *quantity of information that has been injected by G* before the floor transition (rows in Table 1) and the *quantity of information that T tries to add by taking the floor* (columns in Table 1). Table 2 gives the meaning of the different criteria's labels.

Table 2: *Taxonomy labels*

G_NONE	No information given

G_INCOHERENT	Incoherent information
G_INCOMPLETE	Incomplete information
G_INSUFFICIENT	Insufficient information
G_SUFFICIENT	Sufficient information
G_COMPLETE	Complete utterance
T_REF_IMPL	Implicit ref. to G's utterance
T_REF_RAW	Raw ref. to G's utterance
T_REF_INTERP	Reference with interpretation
T_MOVE	Dialogue move (with improvement)

At the beginning of the dialogue (G_NONE), T can implicitly announce that she wants to take the floor by using hand gestures or by clearing her throat for instance (FLOOR_TAKING_IMPL), or she can directly initiate the dialogue (INIT_DIALOGUE). If G is already speaking, her message can be not understandable by T (G_FAIL). T can warn G implicitly by frowning for example (FAIL_IMPL) or explicitly, in a raw manner by saying *Sorry?* (FAIL_RAW) or by pointing out what has not been understood (FAIL_INTERP). In addition, even if the meaning of the message has been understood, it can be incoherent with the interaction context (G_INCOHERENT, e.g. trying to book a flight from a city with no airport). Again, T can warn G implicitly (INCOHERENCE_IMPL) or explicitly, either by explaining the reason of the problem (INCOHERENCE_INTERP) or not (INCOHERENCE_RAW).

In the case G's utterance is not problematic but yet incomplete (G_INCOMPLETE), T can let her understand that she understands what has been said so far by performing a BACKCHANNEL (*Yes*, *uhum* etc.), by repeating his words exactly (FEEDBACK_RAW) or by commenting them (FEEDBACK_INTERP), for example: *Yesterday I went to this new Chinese restaurant in town... / Yeah Fing Shui / ...and it was a pretty good deal*). If G utters enough information to move the dialogue forward (G_SUFFICIENT), T can refer to an element in G's utterance implicitly (*Aha*) by reacting at the proper timing (REF_IMPL), or explicitly in a raw (REF_RAW, for example *Ok, Sunday*) or interpreted manner (REF_INTERP, for example *Yeah, Sunday is the only day when I am free*). T can also interrupt G to add some information that is relevant to the course of the dialogue (BARGE_IN_RESP). Finally, she can wait until G has finished his utterance (G_COMPLETE) and warn him that he should add more information (REKINDLE, for example: *And?*) or start a new dialogue turn (END_POINT).

In the rest of this paper, five incremental TTP that are the more used in general, and therefore studied, have been tested in a simulated environment: FAIL_RAW (Ghigi et al., 2014), INCOHERENCE_INTERP (DeVault et al., 2011), FEEDBACK_RAW (Skantze and Schlangen, 2009) and BARGE_IN_RESP from both sides, user (Selfridge et al., 2013) and system interruptions (DeVault et al., 2011), along with

INIT_DIALOGUE and END_POINT that already exist in traditional systems.

3 Simulation

3.1 Service task

A personal agenda assistant task has been implemented in the simulated dialogue system (referred to as the *service* hereafter). The user can add events to her agenda as long as they do not overlap with existing events. She can also move events in the agenda or delete them (ADD, MODIFY and DELETE actions). An event corresponds to a title, a date, a time slot, a priority, and the list of alternative dates and time slots where the event can fit, in the case the main date and slot are not available. For example: {**title:** *house cleaning*, **date:** *January* 6^{th}, **slot:** *from 18 to 20*, **priority:** *3*, **alternative 1:** *January* 7^{th}*, from 18 to 20*, **alternative 2:** *January* 9^{th}*, from 10 to 12*}.

3.2 User simulator

3.2.1 Overview

The architecture of the User Simulator (US) is built around five modules: the Natural Language Understanding (NLU) module, the Intent Manager, the Natural Language Generator (NLG), the Verbosity Manager, the ASR Output Simulator, and the Patience Manager. These modules are described in the following.

NLU module: The NLU module is very simple as the service's utterances are totally known by the US and no parsing is involved. Each one of them is associated with a specific dialogue act.

Intent Manager: The Intent Manager is somehow the brain of the US, as it determines its next intent given the general goal and the last NLU result. The general goal depends on the scenario at hand, which is in turn determined by two lists of events: the initial list (*InitList*) and the list of events to add to the agenda during the dialogue (*ToAddList*). The Intent Manager tries to add each event from the latter given the constraints imposed by the former. If the events of both lists cannot be kept, those with lower priorities are abandoned or deleted until a solution is reached.

The service asks for the different slot values in a mixed initiative way. At first, the user has the initiative in the sense that she is asked to provide all the slot values in the same utterance. If there is still missing information (because the user did not provide all the slot values or because of ASR noise), the remaining slot values are asked for one by one (system initiative).

NLG module: The NLG figures out the next sentence to utter given the current Intent Manager's output. A straightforward sentence is computed, for example, *Add the event meeting Mary on July* 6^{th} *from 18:00 until 20:00*.

Verbosity Manager: The Verbosity Manager randomly expands the NLG output with some usual prefixes (like *I would like to...*) and suffixes (like *please*, *if possible*...). Also, a few sentences are replaced with off-domain words or repeated twice as it is the case in real dialogues (Ghigi et al., 2014). For questions concerning a specific slot, neither prefixes nor suffixes are added.

Patience Manager: When the dialogue lasts too long, the US can get impatient and hang up. The US patience corresponds to a threshold on each task duration. It is randomly sampled around a mean of 180 seconds for the experiments. A speech rate of 200 words per minute is assumed for the dialogue duration estimation (Yuan et al., 2006). Moreover, a silence of one second is assumed at each regular system/user transition and a two second silence is assumed the other way round. For interruptions and accurate end-point detection, no silence is taken into account.

3.3 ASR Output Simulator

The US can run either in a *traditional mode* in the sense that it provides a complete utterance to the system then it waits for a response, or in an *incremental mode* where a growing utterance is outputted at each new word. For example: *I*, *I want*, *I want to*, *I want to add*...etc. In incremental dialogue systems, the turn increment (called the *micro-turn* in this case) could be different than the word (a small duration for example).

The ASR output simulator can be used in both modes, but as the traditional mode is a special case of the incremental one, we describe the latter only. This module computes a noisy version of each word (substitution, deletion, or insertion). It also associates a confidence score with each new partial utterance. Moreover, a word in the ASR output can change later as new words pop in (Selfridge et al., 2011; McGraw and Gruenstein, 2012). In the following, this mechanism is referred to as the *ASR instability*. At each micro-turn, the sys-

tem can keep listening to the US or decide to take the floor (see Section 3.4).

3.4 Scheduler

The same architecture as in (Khouzaimi et al., 2014) is used. A *Scheduler* module is inserted between the service and the user simulator. As the ASR output utterance grows, the partial utterances are sent, at each micro-turn, to the Scheduler. In turn, the latter transfers them to the service and waits for its responses.

The aim of this module is to make turn-taking decisions. Given the last system's response and some other features and rules determined by the designer, or learned from data, the Scheduler decides whether or not to convey that response to the client immediately or not.

3.5 Dialogue example

In the following example, the user has to delete an event, before adding another one (ASR noise is not introduced here):

SYSTEM: Hi. Welcome to your agenda management service. How can I help you?

USER: I would like to add the event birthday party on January 6^{th} from 6 pm to 11 pm if it is possible.

SYSTEM: The time slot from 6 pm to 11 pm on January 6^{th} overlaps with the event house cleaning on January 6^{th} from 7 pm to 9 pm. How can I help you?

USER: Delete the event house cleaning.

SYSTEM: Ok. So you want to delete the event house cleaning that takes place on January 6^{th} from 7 pm to 9 pm. Right?

USER: Yes.

SYSTEM: Got it. Do you want to perform some other action?

USER: Yes.

SYSTEM: Add the event birthday party on January 6^{th} from 6 pm to 11 pm.

USER: Ok. So you want to add the event birthday party on January 6^{th} from 6 pm to 11 pm. Right?

USER: Yes.

SYSTEM: Got it. Do you want to perform some other action?

SYSTEM: No.

USER: Thank you. Bye!

3.6 TTP implementation

Replicating some turn-taking phenomena like backchannels makes the system seems more realistic (Meena et al., 2014). In this work, the focus is on dialogue efficiency, therefore, the following TTP have been chosen for the implementation: FAIL_RAW, INCOHERENCE_INTERP, FEEDBACK_RAW and BARGE_IN_RESP from the user's and the system's point of view.

At each micro-turn, the system has to pick an action among three options: to wait (WAIT), to retrieve the last service's response to the client (SPEAK) or to repeat the word at position $n-2$ (if n is the current number of words, because of the ASR instability) in the current partial request (REPEAT). To replicate each selected TTP, a set of rules have been specified to make the proper decision. We review the triggering features related to each TTP accommodated to the task at hand (agenda filling).

FAIL_RAW: Depending on the last system's dialogue act, a threshold relative to the number of words without detecting a key concept in the utterance has been set. In the case of an open question (where the system waits for all the information needed in one request), if no action type has been detected after 6 words, a FAIL_RAW event is declared. The system waits for 3 words in the case of a yes/no question, for 4 words in the case of a date and for 6 words in the case of slots (some concepts need more words to be detected and the user may use additional off-domain words).

INCOHERENCE_INTERP: This event is useful to promptly react to partial requests that would eventually lead to an error, not because they were not correctly understood, but because they are in conflict with the current dialogue state. If such an inconsistency is detected, the system waits for two words (ASR instability) and if it is maintained, it takes the floor to warn the user.

FEEDBACK_RAW: If at time t, a new word is added to the partial utterance and the ratio between the last partial utterance's score and the one before last (which corresponds to the score of the last increment) is lower than 1/2, then the system waits for two words (because of the ASR instability), and if the word is still in the partial utterance, a REPEAT action is performed.

BARGE_IN_RESP (System): This TTP depends on the last system dialogue act as it determines which kind of NLU concept the system is

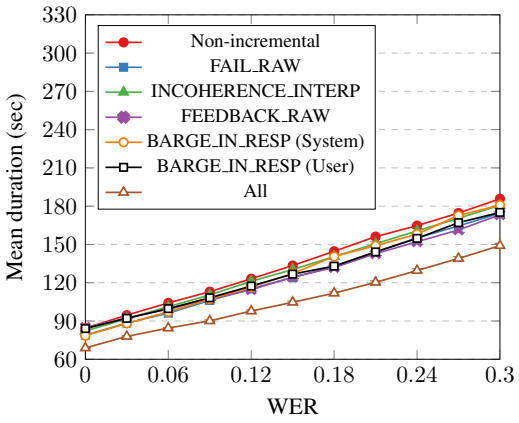

Figure 1: Simulated dialogue duration for different noise levels

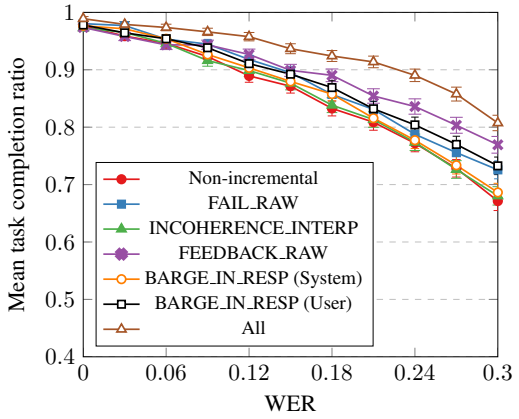

Figure 2: Simulated dialogue task completion for different noise levels

waiting for. Once it is detected, the system waits for two more words (ASR instability) and if the concept is maintained, it performs a SPEAK.

USER_BARGE_RESP (User): This event is triggered directly by the user (no system decision is involved). For each system dialogue act, the moment when a familiar user would barge-in is manually defined in the simulator.

Dialogue duration and task completion are used as evaluation criteria. The task completion rate is the ratio between the number of dialogues where the user did not hang up (because of her patience limit) and the total number of dialogues.

The five implemented TTP have been tested single-handled and in an aggregated manner (referred to as *All* strategy). They have also been been compared to a non-incremental baseline (see Figure 1 and 2). Three dialogue scenarios and different WER levels were tested. For each strategy and each WER, 1000 dialogues have been simulated for each scenario. Figure 1 (resp. Figure 2) represents the mean duration (resp. the mean task completion), with the corresponding 95% confidence intervals, for the different strategies and for WER varying between 0 and 0.3.

The FEEDBACK_RAW strategy performs best whereas INCOHERENCE_INTERP does not improve over the baseline. This is due to the fact that the system has to deal with an open slot (which set of possible values is not closed and known a priori): the event's description. The system mostly performs ADD actions, so the description slot can take any value and is never compared with existing data. This is the case of many application like message dictation for example. However, in the case of service at hand, an initial concept must be detected (the action), therefore, FAIL_RAW improves the performance. BARGE_IN_RESP from user's side is also useful here as dialogues can be long and may contain repetitive system dialogue acts. The users get familiar with the systems and may infer the end of the system's question before it ends. Obviously it is questionable that users may be patient enough (up to several minutes) to achieve such simple tasks in real life. But for the sake of the simulation it was necessary to generate dialogues long enough to have the studied TTP influence them. In a next step, increasing the service capacities (and complexity) will remedy that as a side effect. Finally, BARGE_IN_RESP from the system's side does not bring any improvement either which is due to the fact that in this task and because of input noise, in most cases, the response to the initial open question is not enough to fill all the slots. The responses to single-slot questions do not contain suffixes which explains the inefficiency of the last strategy (the US stops speaking as soon as the slot value is given).

4 Conclusion and future work

This paper introduces a new taxonomy of turn-taking phenomena in human dialogue. Then an experiment where five TTP are implemented has been run in a simulated environment. It illustrates the potentiality of the taxonomy and shows that some TTP are worth replicating in some situations but not all. In future work, we plan to perform TTP analysis in the case of real users and to optimise the hand-crafted rules introduced here to operate the floor management in the system (when to take/give the floor and according to which TTP scheme) by using reinforcement learning (Sutton and Barto, 1998; Lemon and Pietquin, 2012).

Abstract

This paper focuses on language modeling with adequate robustness to support different domain tasks. To this end, we propose a hierarchical latent word language model (h-LWLM). The proposed model can be regarded as a generalized form of the standard LWLMs. The key advance is introducing a multiple latent variable space with hierarchical structure. The structure can flexibly take account of linguistic phenomena not present in the training data. This paper details the definition as well as a training method based on layer-wise inference and a practical usage in natural language processing tasks with an approximation technique. Experiments on speech recognition show the effectiveness of h-LWLM in out-of domain tasks.

1 Introduction

Language models (LMs) are essential for automatic speech recognition or statistical machine translation (Rosenfeld, 2000). The performance of LMs strongly depends on quality and quantity of their training data. Superior performance is usually obtained by using enormous domain-matched training data sets to construct LMs (Brants et al., 2007). Unfortunately, in many cases, large amounts of domain-matched training data sets are not available. Therefore, LM technology that can robustly work for domains that differ from that of the training data is needed (Goodman, 2001).

For robust language modeling, several technologies have been proposed. Fundamental techniques are smoothing (Chen and Goodman, 1999) and clustering (Brown et al., 1992). Other solutions are Bayesian modeling (Teh, 2006) and ensemble modeling (Xu and Jelinek, 2004; Emami and Jelinek, 2005). Moreover, continuous representation of words in neural network LMs can also support robust modeling (Bengio et al., 2003; Mikolov et al., 2010). However, previous works are focused on maximizing performance in the same domain as that of the training data. In other words, it is uncertain that these technologies robustly support out-of domain tasks.

In contrast, latent words LMs (LWLMs) (Deschacht et al., 2012) are clearly effective for out-of domain tasks. We employed the LWLM to speech recognition and the resulting performance was significantly superior in out-of domain tasks while the performance was comparable in domain-matched task to conventional LMs (Masumura et al., 2013a; Masumura et al., 2013b). LWLMs are generative models that employ a latent word space. The latent space can flexibly take into account relationships between words and the modeling helps to efficiently increase the robustness to out-of domain tasks (Sec. 2).

In this paper, we focus on LWLMs and aim to make them more flexible for greater robustness to out-of domain tasks. To this end, this paper takes note of a fact that standard LWLM simply represents the latent space as n-gram model of latent words. However, function and meaning of words are essentially hierarchical and upper layers ought to be useful to increase the robustness to out-of domain tasks. The conventional LWLMs do not model the hierarchy, while the latent words are used to represent function and meaning of words. Thus, we tried to model the hierarchy in the latent space by estimating a latent word of a latent word recursively.

This paper proposes a novel LWLM with multiple latent word spaces that are hierarchically structured; we call it the hierarchical LWLM (h-LWLM). The proposed model can be regarded as a generalized form of the standard LWLMs. The hierarchical structure can take into account the abstraction process of function and meaning of words. Therefore, it can be expected that h-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1896–1901,
Lisbon, Portugal, 17-21 September 2015.

LWLMs flexibly calculate generative probability for unseen words unlike non-hierarchical LWLMs. To create the hierarchical latent word structure from training data sets, we also propose a layer-wise inference. The inference is inspired by a deep Boltzmann machine (Salakhutdinov and Hinton, 2009) that stacks up restricted Boltzmann machines (Hinton et al., 2006). In addition, we detail an n-gram approximation technique to apply the proposed model to practical natural language processing tasks (see Sec. 3).

In experiments, we construct LMs from spontaneous lecture task data and apply them to a contact center dialogue task and a voice mail task as out-of domain tasks. The effectiveness of the proposed method is shown by perplexity and speech recognition evaluation (Sec. 4).

2 Latent Words Language Models

LWLMs are generative models with single latent word space (Deschacht et al., 2012). The latent word is represented as a specific word that is selected from the entire vocabulary. Thus, the number of latent words equals the number of observed words.

Bayesian modeling of LWLM produces the generative probability of observed word sequence $\boldsymbol{w} = w_1, \cdots, w_K$ as:

$$P(\boldsymbol{w}) = \int_{\boldsymbol{\theta}} \prod_{k=1}^{K} \sum_{h_k} P(w_k|h_k, \boldsymbol{\theta}) P(h_k|\boldsymbol{l}_k, \boldsymbol{\theta}) P(\boldsymbol{\theta}) d\boldsymbol{\theta}, \quad (1)$$

where $\boldsymbol{\theta}$ indicates a model parameter of the LWLM, $\boldsymbol{h} = h_1, \cdots, h_K$ denotes a latent word sequence and $\boldsymbol{l}_k$ denotes context latent words $h_{k-n+1}, \cdots, h_{k-1}$. $P(h_k|\boldsymbol{l}_k, \boldsymbol{\theta})$ represents the transition probability which can be expressed by an n-gram model for latent words, and $P(w_k|h_k, \boldsymbol{\theta})$ represents the emission probability that models the dependency between the observed word and the latent word. More details are shown in previous works (Deschacht et al., 2012; Masumura et al., 2013a; Masumura et al., 2013b).

3 Hierarchical LWLMs

3.1 Definition

This paper introduces h-LWLM. The proposed model has multiple latent word spaces in a hierarchical structure. Thus, it assumes that there is a latent word behind a latent word. The proposed model can be regarded as a generalized form of the standard LWLM. Thus, standard LWLMs correspond to h-LWLMs with just one layer. The latent words in all layers are represented as a specific word that is selected from the entire vocabulary.

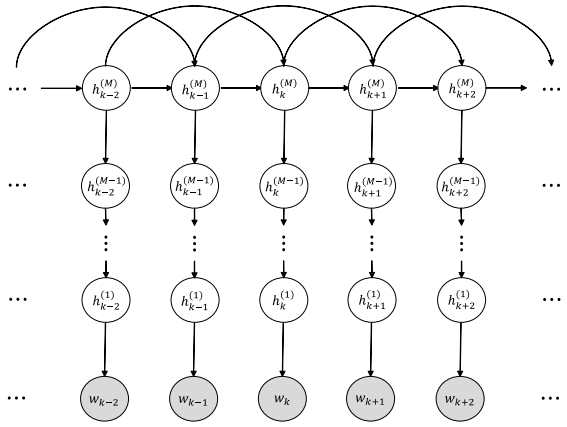

Figure 1: Graphical representation of h-LWLM.

A graphic rendering of h-LWLM is shown in Figure 1. In a generative process of the h-LWLM, a latent word in the highest layer is first generated depending on its context latent words. Next, a latent word in a lower layer is recursively generated depending on the latent word in the upper layer. Finally, an observed word is generated depending on the latent word in the lowest layer.

Bayesian modeling of h-LWLM produces the following generative probability:

$$P(\boldsymbol{w}) = \int_{\boldsymbol{\Theta}} \prod_{k=1}^{K} \sum_{h_k^{(1)}} \cdots \sum_{h_k^{(M)}} P(w_k|h_k^{(1)}, \boldsymbol{\Theta}) \cdots P(h_k^{(M-1)}|h_k^{(M)}, \boldsymbol{\Theta}) P(h_k^{(M)}|\boldsymbol{l}_k^{(M)}, \boldsymbol{\Theta}) P(\boldsymbol{\Theta}) d\boldsymbol{\Theta}, \quad (2)$$

where M is the number of layers and $\boldsymbol{\Theta}$ indicates a model parameter of h-LWLM. $\boldsymbol{h}^{(m)} = h_1^{(m)}, \cdots, h_K^{(m)}$ denotes a latent word sequence in the m-th layer. $P(h_k^{(M)}|\boldsymbol{l}_k^{(M)}, \boldsymbol{\Theta})$ represents the transition probability which is expressed by n-gram model for latent words in the highest layer. $P(h_k^{(m)}|h_k^{(m+1)}, \boldsymbol{\Theta})$ and $P(w_k|h_k^{(1)}, \boldsymbol{\Theta})$ represent the emission probabilities that respectively model the dependency between latent words in two layers and the dependency between the observed word and the latent word in the lowest layer.

As the integral with respect to $\boldsymbol{\Theta}$ is analytically

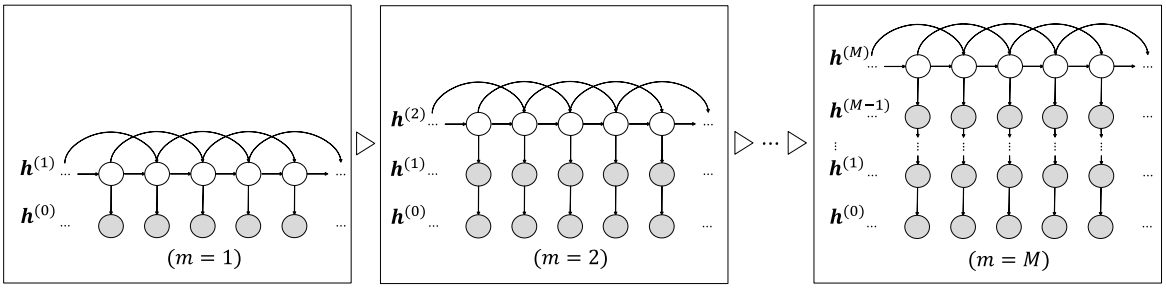

Figure 2: Layer-wise inference procedure.

Algorithm 1 :
Inference procedure for h-LWLM.

Input: Training data $\boldsymbol{w}$, number of instances T, number of layers M
Output: Model parameters $\boldsymbol{\Theta}_1, \cdots, \boldsymbol{\Theta}_T$

1: **for** $t = 1$ to T **do**
2: $\quad \boldsymbol{h}^{(0)} = \boldsymbol{w}$
3: $\quad$ **for** $m = 1$ to M **do**
4: $\quad\quad \boldsymbol{\theta}^{(m)}, \boldsymbol{h}^{(m)} \sim P(\boldsymbol{h}^{(m)} | \boldsymbol{h}^{(m-1)}, \boldsymbol{\theta}^{(m)})$
5: $\quad$ **end for**
6: $\quad \boldsymbol{\Theta}_t = \boldsymbol{\theta}^{(1)}, \cdots, \boldsymbol{\theta}^{(M)}$
7: **end for**
8: **return** $\boldsymbol{\Theta}_1, \cdots, \boldsymbol{\Theta}_T$

intractable, the equation can be approximated as:

$$P(\boldsymbol{w}) = \frac{1}{T} \prod_{k=1}^{K} \sum_{t=1}^{T} \sum_{h_k^{(1)}} \cdots \sum_{h_k^{(M)}} P(w_k | h_k^{(1)}, \boldsymbol{\Theta}_t) \cdots P(h_k^{(M-1)} | h_k^{(M)}, \boldsymbol{\Theta}_t) P(h_k^{(M)} | \boldsymbol{l}_k^{(M)}, \boldsymbol{\Theta}_t). \quad (3)$$

The probability distribution can be approximated using T instances of point estimated parameter; $\boldsymbol{\Theta}_t$ indicates the t-th point estimated parameter.

3.2 Parameter Inference

This paper proposes a layer-wise inference procedure for constructing h-LWLMs from training data. The detailed procedure is shown in **Algorithm 1**, and Figure 2 shows an image representation of the procedure as increased with the number of layers. In the procedure, LWLM structure is recursively accumulated by estimating a latent word sequence in an upper layer from a latent word sequence in the lower layer.

Line 4 in **Algorithm 1** denotes the key procedure of estimating a latent word sequence in an upper layer from a latent word sequence in the lower layer. $\boldsymbol{\theta}^{(m)}$ denotes model parameter of LWLM structure in m-th layer; it can be defined from both $\boldsymbol{h}^{(m)}$ and $\boldsymbol{h}^{(m-1)}$. For the inference of $\boldsymbol{h}^{(m)}$ from $\boldsymbol{h}^{(m-1)}$, Gibbs sampling is suitable (Casella and George, 1992; Robert et al., 1993; Scott, 2002). Gibbs sampling picks a new value for $h_k^{(m)}$ according to its probability distribution which is estimated from both $\boldsymbol{h}_{-k}^{(m)}$ and $\boldsymbol{h}^{(m-1)}$. $\boldsymbol{h}_{-k}^{(m)}$ represents all latent words in the m-th layer except for $h_k^{(m)}$. The probability distribution is given by:

$$P(h_k^{(m)} | \boldsymbol{h}_{-k}^{(m)}, \boldsymbol{h}^{(m-1)}, \boldsymbol{\theta}^{(m)}) \propto P(h_k^{(m-1)} | h_k^{(m)}, \boldsymbol{\theta}^{(m)}) \prod_{j=k}^{k+n-1} P(h_j^{(m)} | \boldsymbol{l}_j^{(m)}, \boldsymbol{\theta}^{(m)}). \quad (4)$$

For the inference, the prior distribution is necessary for each probability distribution. Usually, a hierarchical Pitman-Yor prior (Teh, 2006) is used for each transition probability and a Dirichlet prior (MacKay and Peto, 1994) is used for each emission probability.

As shown in line 6, t-th point estimated parameter $\boldsymbol{\Theta}_t$ indicates parameters of each LWLM for all layers in t-th iteration. The transition probabilities except for M-th layer are only used in the layer-wise inference procedure.

3.3 Usage

It is impractical to directly apply the h-LWLM to natural language processing tasks since the proposed model has multiple latent word spaces and we have to consider all possible latent word assignment for calculating generative probabilities. Therefore, this paper introduces an n-gram approximation technique as well as that for standard LWLM (Masumura et al., 2013a).

Algorithm 2 :
Random sampling for trained h-LWLM.

Input: Model parameters $\boldsymbol{\Theta}_1, \cdots, \boldsymbol{\Theta}_T$, number of sampled words K
Output: Sampled data $\boldsymbol{w}$

1: **for** $k = 1$ to K **do**
2: $\quad \boldsymbol{\Theta}_t \sim P(\boldsymbol{\Theta}_t) = \frac{1}{T}$
3: $\quad h_k^{(M)} \sim P(h_k^{(M)} | \boldsymbol{l}_k^{(M)}, \boldsymbol{\Theta}_t)$
4: $\quad$ **for** $m = M - 1$ to 1 **do**
5: $\quad\quad h_k^{(m)} \sim P(h_k^{(m)} | h_k^{(m+1)}, \boldsymbol{\Theta}_t)$
6: $\quad$ **end for**
7: $\quad w_k \sim P(w_k | h_k^{(1)}, \boldsymbol{\Theta}_t)$
8: **end for**
9: **return** $\boldsymbol{w} = w_1, \cdots, w_K$

The n-gram approximation is conducted as following steps. First, a lot of text data that permit h-LWLMs to be approximated by n-gram structure is generated by random sampling using trained h-LWLM. Next, an n-gram model is constructed from the generated data. The random sampling is based on **Algorithm 2**. The sampled data $\boldsymbol{w}$ in line 9 is only used for n-gram model estimation.

4 Experiments

4.1 Experimental Conditions

Our basic assumption is domain-matched training data is not available. Thus, for LM training, we used the Corpus of Spontaneous Japanese (CSJ) whose domain is a spontaneous lecture task (Maekawa et al., 2000). We divided CSJ into a training set and a small validation set (Valid). The validation set was used for optimizing several hyper parameters of LMs. For evaluation, a contact center dialogue task (Test 1) and a voice mail task (Test 2) were prepared. In contact center dialogue task, two speakers, an operator and a customer, talked to each other as in call center dialogues. 24 phone calls (24 operator channels and 24 customer channels) were used in the evaluation. In the voice mail task, a person spoke small voice messages using a smart phone. 237 messages are used in the evaluation. The training data had about 7M words, the vocabulary size was about 80K. The validation data size and test data size (both tasks) were about 20K words.

For speech recognition evaluation, we prepared an acoustic model based on hidden Markov models with deep neural networks (DNN-HMM) (Hinton et al., 2012). The DNN-HMM had 8 hidden layers with 2048 nodes. The speech recognizer was a weighted finite state transducer (WFST) decoder (Mohri et al., 2001; Hori et al., 2007).

As a baseline, 3-gram LM with interpolated Kneser-Ney smoothing (`MKN`) (Kneser and Ney, 1995) and 3-gram hierarchical Pitman-Yor LM (`HPY`) (Huang and Yor, 2007) were constructed from the training data. We also trained a class-based recurrent neural network LM with 500 hidden nodes and 500 classes (`RNN`) for comparison to state-of-the art language modeling (Mikolov et al., 2011). In addition, we constructed 3-gram standard LWLM and 3-gram h-LWLMs (`LW`). `LW` with 1 layer represents standard LWLM, and `LW` with 2-5 layers represent proposed h-LWLMs. The number of instances was set to 10 for each `LW`. For their n-gram approximation, we generated one billion words and approximated each as a 3-gram HPYLM. Moreover, we constructed interpolated model with `LW` and `HPY` (`LW+HPY`).

4.2 Results

Figure 3 shows the relation between number of layers in h-LWLM and perplexity (PPL) reduction for each condition. In addition, Table 1 shows speech recognition results in terms of word error rate (WER) for each condition. `RNN` was only tested in PPL evaluation as `RNN` cannot be converted into WFST format.

For the validation set (same domain as that of training set), PPL was not improved by the hierarchical structure in `LW`. `LW` is comparable to `MKN` and `HPY`, and inferior to `RNN` in terms of PPL. On the other hand, in test sets (out-of domain tasks), PPL improved with the increase in the number of layers in `LW`. `LW` with 5 layers was superior to 1 layer in terms of PPL and WER. The best results were obtained by `LW+HPY` with 5 layers. In fact, when we generated one billion words using a trained LWLM or trained h-LWLM, the number of observed trigrams in h-LWLM with 5 layers was 101M while the number of observed trigrams in non-hierarchical LWLM was 94M. Thus, h-LWLM can generate unseen words unlike non-hierarchical LWLM. Moreover, trigram coverage in each test data slightly increased with number of layers. These results show that h-LWLM with multiple layers offers robust performance not possible with other models while its performance in the same domain as that of training data was not improved. As a result, `LW+HPY` with 5 layers

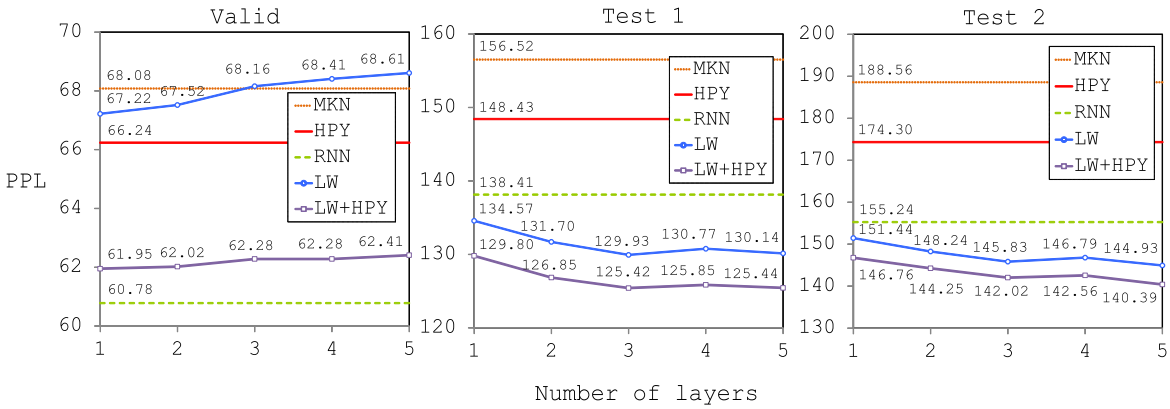

Figure 3: Perplexity (PPL) results.

Setup	Layer	Valid	Test 1	Test 2
MKN	-	24.79	38.67	32.31
HPY	-	24.67	38.29	32.00
LW	1	24.54	36.93	30.26
LW	5	24.60	36.49	29.57
LW+HPY	1	**23.62**	36.49	29.76
LW+HPY	5	23.68	**36.03**	**29.21**

Table 1: Word error rate (WER) results (%).

performed significantly better than MKN, HPY and RNN in the out-of domain tasks.

5 Conclusions

This paper proposed h-LWLM for robust modeling and detailed its definition, inference procedure, and approximation method. The proposed model has a hierarchical latent word space and it can flexibly handle linguistic phenomena not present in the training data. Our experiments showed that h-LWLM offers improved robustness to out-of domain tasks; h-LWLM is also superior to standard LWLM in terms of PPL and WER. Furthermore, our approach is significantly superior to the conventional n-gram models or the recurrent neural network LM in out-of domain tasks.

Abstract

Speech translation is conventionally carried out by cascading an automatic speech recognition (ASR) and a statistical machine translation (SMT) system. The hypotheses chosen for translation are based on the ASR system's acoustic and language model scores, and typically optimized for word error rate, ignoring the intended downstream use: automatic translation. In this paper, we present a *coarse-to-fine* model that uses features from the ASR and SMT systems to optimize this coupling. We demonstrate that several standard features utilized by ASR and SMT systems can be used in such a model at the speech-translation interface, and we provide empirical results on the Fisher Spanish-English speech translation corpus.

1 Introduction

Speech translation is the process of translating speech in the source language to text or speech in the target language. This process is typically structured as a three step pipeline. Step one involves training an Automatic Speech Recognition (ASR) system to transcribe speech to text in the source language. Step two involves extracting an appropriate form of the ASR output to translate. We will refer to this step as the Speech-Translation interface. In the simplest scenario, the ASR 1-best output can be used as the source text to translate. It may be useful to consider alternative ASR hypotheses and these take the form of an N-best list or a word-lattice. An N-best list can be included easily into the tuning and the decoding process of a statistical machine translation (SMT) system (Zhang et al., 2004). Several researchers have proposed solutions to incorporating lattices and confusion networks in this process (Saleem et al., 2004; Matusov et al., 2005; Bangalore and Riccardi, 2000; Dyer et al., 2008a; Bertoldi and Federico, 2005; Quan et al., 2005; Mathias and Byrne, 2006; Bertoldi et al., 2007). Word lattice input to SMT for tuning and decoding increases the complexity of the decoding process because of the exponential number of alternatives that are present. Finally, step three involves training and tuning a Statistical Machine Translation (SMT) system and decoding the output extracted through the speech translation interface.

This paper presents a featurized model which performs the job of hypothesis selection from the outputs of the ASR system for the input to the SMT system. Our motivation is as follows:

1. **Using downstream information** : Hypothesis selection for the input to the SMT system should be done jointly by the ASR and the SMT systems. That is, there may exist hypotheses that a trained SMT system may find easier to translate and produce better translations for than the ones that are deemed best based on the ASR acoustic and language model scores. Incorporation of knowledge from the downstream process (translation) is vital to selecting translation options, and subsequently producing better translations.

2. **Coarse-to-fine grained decoding** : An intermediate model which acts as an interface and is a weak (coarse) version of the downstream process may be able to select better hypotheses. In effect, a weak translation decoder can be used as the interface to estimate the expected translation quality of an ASR hypothesis. This method of hypothesis selection should be able to incorporate features from the ASR and the SMT system.

3. **Phrase units vs. word units** : When a phrase based SMT system is used for translation,

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1902–1907,
Lisbon, Portugal, 17-21 September 2015.

optimization for hypothesis selection at the Speech-Translation interface should be conducted using phrases as the basic unit instead of words.

2 Coarse-to-Fine Speech Translation

In this section, we describe the featurized model (coarse-grain MT decoder) for hypothesis selection that uses information from the ASR and SMT systems (impedance matching). We assume the presence of ASR and SMT systems that have been trained separately. In addition to creating almost no disruption in the traditional pipeline approach, this allows us to incorporate local gains from each system. To elaborate, our methods avoid joint optimization of the ASR and the SMT system with respect to a translation metric (Vidal, 1997; Ney, 1999), which is not feasible for larger datasets. Also, considering the dearth of speech translation training datasets, this method allows independent training of the ASR and SMT systems on data created only for ASR training and parallel data for SMT. We start by introducing the formal machinery that will be used and by presenting a simple example to motivate the model. The complete featurized model follows this exposition.

Let Σ and Γ be alphabets of words and phrases respectively in the source language. Using these, we can define the following finite state machines:

1. **Word Lattice** (L) : A finite state acceptor that accepts word-sequences in the source language ($L : \Sigma^* \rightarrow \Sigma^*$). This represents the unpruned ASR word lattice output in our model (Figure 1a).

2. **Phrase segmentation Transducer** (S) : A cyclic finite state transducer that transduces a sequence of words to phrases in the source language ($S : \Sigma^* \rightarrow \Gamma^*$). This is built from the source side of the phrase table. Each path represents one source side phrase in the phrase table. Traversing a path is equivalent to consuming the words in a phrase and producing the phrase as a token (Figure 1b).

3. **Weighted word lattice** ($\tilde{L}_{ASR}$) : A weighted version of L ($\tilde{L}_{ASR} : \Sigma^* \rightarrow \Sigma^*/\mathbb{R}^+$). We use the subscript to denote the nature/source of the weights.

4. **Phrase acceptor** ($\tilde{W}_{MT}$) : A finite state acceptor that accepts source phrases in the SMT system's phrase table ($\tilde{W}_{MT} : \Gamma \rightarrow \Gamma/\mathbb{R}$). It is weighted by features derived from the SMT system.

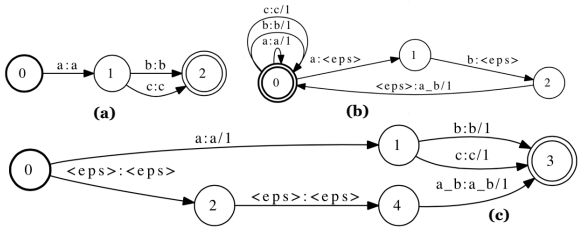

Figure 1: *A toy example for producing a phrase length weighted phrase lattice. (a) An unweighted word lattice. (b) A phrase segmentation transducer which transduces words to phrases and has a weight of one per path. Each path is a source phrase in the phrase table. (c) A phrase lattice produced by composing the word lattice and phrase segmentation transducer.*

5. **Phrase lattice** (P) : The result of the composition of a word lattice (acceptor) with the phrase segmentation transducer ($P : \Sigma^* \rightarrow \Gamma^*$). This represents all possible phrase segmentations of all the ASR hypotheses in the word lattice.

$$P = \det(\min(L \circ S))$$

We will represent weighted versions of P as $\tilde{P}_{ASR/MT}$ with subscripts to denote the origin of the weights (Figure 1c).

2.1 A simple model : Maximum Spanning Phrases

We motivate our model with this fairly simple scenario. Suppose that we believe that if our SMT input could be covered by longer source side phrases[1], we would produce better translations. This may be viewed as a tiling problem where the tiles are the source phrases in the phrase table and the goal is to select the ASR hypothesis that requires the least number of phrases to cover[2]. To achieve this using our existing machinery, we create $\tilde{S}$, a weighted version of S (Figure 1 (b)), such

[1] In phrase based translation, target translations are produced for each possible span of the input sentence allowed by the phrase table. Translation of a longer source side phrase produces fewer translation options and may be more reliable given sufficient occurrences in the training data.

[2] It may be useful to incorporate a brevity penalty here, since this approach has a strong bias towards selecting shorter hypotheses. We will use other features to counter this bias in the following sections.

that

$$w(\delta^{(\tilde{S})}) = \begin{cases} 0 & : \pi_1(\delta^{(S)}) \in \Sigma \text{ and } \pi_2(\delta^{(S)}) = \epsilon \\ 1 & : \pi_2(\delta^{(S)}) \in \Gamma \text{ and } \pi_1(\delta^{(S)}) = \epsilon \end{cases}$$

where $\delta^{(\tilde{S})}$ is an edge in $\tilde{S}$ and π_1 and π_2 are the input and output projections respectively. Using this segmentation transducer and an unweighted word lattice, L (Figure : 1 (a)), we produce a phrase lattice $\tilde{P}_{MT}$. Assuming the weights are in the log-semiring, the weight of a path $\delta^{(\tilde{P})*}$ in $\tilde{P}_{MT}$ is

$$w(\delta^{(\tilde{P})*}) = \sum_{\delta^{(\tilde{P})} \in \delta^{(\tilde{P})*}} w(\delta^{(\tilde{P})})$$

Figure 1(c) shows an example of this phrase lattice. Weights in the phrase lattice follow the same definition as the weights in the segmentation transducer. Hence, the weight of a path in the phrase lattice is simply the number of phrases used to cover this path. The shortest path [3] in the phrase lattice $\tilde{P}_{MT}$, corresponds to the hypothesis we were looking for. This simple example, demonstrates how we may be able to use SMT features (source phrase length in this case) to select hypotheses from the phrase lattice.

2.2 A general featurized model for hypothesis selection

We now present a general framework in which hypothesis selection can be carried out using knowledge (features) from the ASR and the SMT system. As described earlier, this form of 'impedance' matching allows us to select hypotheses from an unpruned ASR word lattice for which the SMT system is more likely to find good translations. Incorporating ASR weights also ensures that we take into account what the ASR system considers to be good hypotheses. We start with the previously discussed idea of a phrase lattice, using weights from the ASR system only. That is,

$$\tilde{P}_{ASR} = \det(\min(\tilde{L}_{ASR} \circ S))$$

Now, we use the weighted phrase acceptor $\tilde{W}_{MT}$ to bring in the SMT features [4]. Composing this with the weighted phrase lattice, we get

$$\tilde{P}_{ASR,MT} = \det(\min(\tilde{P}_{ASR} \circ (\tilde{W}_{MT})^*)$$

where $(\tilde{W}_{MT})^*$ is the Kleene closure of $(\tilde{W}_{MT})$. We assume that the edge weights are in the log-semiring. Hence, after these two compositions, the edge weights in $\tilde{P}_{ASR,MT}$ can be represented as

$$\begin{aligned} w(\delta^{(\tilde{P}_{ASR,MT})}) &= \sum_j \beta_j f_{j,ASR} + \sum_k \gamma_k f_{k,MT} \\ &= \sum_i \lambda_i f_i \end{aligned}$$

where $\delta^{(\tilde{P}_{ASR,MT})}$ is an edge in $\tilde{P}_{ASR,MT}$, β, γ are feature weights, f_{ASR} and f_{MT} are features from the ASR and SMT system respectively. This form represents a log-linear model (our features are already assumed to be in log-space). where f_i is any feature and λ_i is the corresponding feature weight. We may now extract the one-best, N-best or lattice input for the SMT system from $\tilde{P}_{ASR,MT}$.

2.2.1 A discussion about related techniques

1. Decoding (Translation) : Our model closely resembles a featurized finite-state transducer based translation model. If we replace the output alphabet of the acceptor $(\tilde{W}_{MT})^*$ with the target side phrases, we will actually get output in the target language. Even though this model does not explicity include reordering, the coarse-grained decoder has access to information that can enable better decisions about which hypotheses are better for the downstream process (translation).

2. Lattice Decoding : (Dyer et al., 2008b) suggests passing the entire word lattice to the SMT system. However, even if these lattices are not pruned, a beam based decoder might not consider hypotheses that our model may produce through coarse-grained decoding.

3. Language model re-scoring : One may use a bigger source language model to re-score the ASR lattice (or an N-best list). This however, does not consider any SMT features in re-scoring. With our model, we can simply use this as an additional feature.

2.2.2 Training

Training the hypothesis selection model can be carried out using standard methods for log linear models on a held-out set. This also requires decoding (translation) of a deep N-best list derived from the held-out set. The objective of training then simply becomes maximization of the translation

[3] To compute the shortest path, we switch from the log to the tropical semiring (A semiring with ordinary addition as the multiplication operator and $\max$ as the addition operator).

[4] Alternatively, we may have introduced the weights in the segmentation transducer itself. This separate machine is introduced for efficient training of this model.

quality given any metric that provides sentence level scores. Each time our model produces a hypothesis, its score can be looked up from the pre-translated N-best list. Also, whenever the weights are updated, the only structures that need to be rebuilt are $\tilde{W}^*_{MT}$ and $\tilde{P}_{ASR,MT}$ [5].

2.2.3 Features

We use the following features in our implementation of this model. However, any relevant ASR and SMT feature may be readily added to this model.

1. **ASR scores** : We incorporate the ASR acoustic (AM) and language (LM) model scores as one combined feature.

   $$f_{ASR} = LM + \alpha * AM$$

   Here, LM, AM are negative log-probabilities and α is the acoustic scaling parameter chosen to minimize ASR word error rate.

2. **Source phrase count** : As described in section 2.1, this feature may be used to capture the intuition that using a fewer number of phrases to cover the input sentence may produce better translations.

3. **Length normalized phrase unigram probability** : We may use a phrase LM feature by incorporating phrase n-gram probabilities (normalized) by length.

   $$f_{\text{uni}}(f_j) = \left[\frac{\text{freq}(f_j)}{\sum_k \text{freq}(f_k)} \right]^{\text{len}(f_j)}$$

   where f_j is a source side phrase in the phrase table.

4. **Phrase translation entropy** : For each source side phrase p_j, we may have multiple translations (e_i) in the phrase table with different translation probabilities ($p(e_i|f_j)$). A simple entropy measure can be used as a feature to estimate the confidence that the SMT system has in translating f_j.

   $$\begin{aligned} f_{\text{tr}}(p_j) &= H_{\text{tr}}(E|p_j) \\ &= -\sum_i p_{\text{tr}}(e_i|f_j) \log p_{\text{tr}}(e_i|f_j) \end{aligned}$$

5. **Lexical translation entropy** : Similarly, we can use an entropy measure based on the lexical translation probability as a feature.

   $$\begin{aligned} f_{\text{lex}}(p_j) &= H_{\text{lex}}(E|p_j) \\ &= -\sum_i p_{\text{lex}}(e_i|f_j) \log p_{\text{lex}}(e_i|f_j) \end{aligned}$$

3 Results

We use the Fisher and Callhome Spanish-English Speech Translation Corpus (Post et al., 2013) for our experiments. This Fisher dataset consists of 819 transcribed and translated telephone conversations. The corpus is split into a training, dev and two test sets (dev-2 and test). We use the dev set for training the feature weights of the proposed model.

We use the Kaldi speech recognition tools (Povey et al., 2011) to build our Spanish ASR systems. Our state-of-the-art ASR system is the p-norm DNN system of (Zhang et al., 2014). The word-error-rates on the dev and test sets of the Fisher dataset (dev, dev-2, test) are 29.80%, 29.79% and 25.30% respectively.

For the SMT system, we use the phrase based translation system of Moses (Koehn et al., 2007) with sparse features. The system is trained and tuned on the train and dev partitions of the Fisher dataset respectively. The BLEU scores of the MT output for the the dev-2 and the test partitions are 65.38% and 62.91% respectively. While decoding the ASR output, we tune on the 1-best ASR output for the dev partition. With this modified system, the BLEU scores for the ASR 1-best output of the dev2 and the test partitions are 40.06% and 40.4% respectively. We use this system as the baseline for our experiments (Table 1).

We note that if we were to use the lattice oracle[6] from our ASR system as input to the SMT system, we get a BLEU score of 46.59% for the dev2 partition of the Fisher dataset. This indicates that the best gain (+BLEU) that an oracle lattice reranker could get is only 6.53%.

To tune the weights of the coarse decoder, we decode 500-best ASR outputs for the tuning set with the SMT system. This maps each ASR hypothesis to a target language translation. An OOV feature was added to handle words that were not seen by the SMT system. The tuning process was then carried out so as to maximize the BLEU with

[5] This requires the use of one ASR feature, addressed in the "Features" section

[6] Path in the lattice that has the least word error rate.

Experiment	BLEU (dev2)	BLEU (test)
Transcripts	65.4%	62.9%
Lattice Oracle	46.59%	46.17%
ASR 1-best	40.06%	40.4%
Coarse decoder	**40.26%**	**40.46%**

Table 1: Performance when using the coarse decoder interface compared to the the decoding the human transcripts, the ASR 1-best or the lattice oracle (the path in the ASR lattice with the least WER : not available during test time.)

respect to the reference translation of the ASR hypothesis selected by the coarse grained decoder. We used ZMERT (Zaidan, 2009) for tuning which was configured to expect a 300-best list from the decoder at every iteration using the Fisher dev set. 15 iterations of tuning were carried out for each experiment. We then use the tuned weight vector to decode the Fisher-dev2 and the Fisher-test set using our coarse grained decoder. We extract the one-best output and use it as input to the pretrained SMT system (description in the preceding section). Table 1 reports the results achieved the featurized coarse grained decoder.

4 Conclusions

We present a *coarse-to-fine* featurized model which acts as the interface between ASR and SMT systems. By utilizing information from the upstream (ASR) and the downstream (SMT) systems, this model makes more informed decisions about which hypotheses from the ASR word lattice may result in better translation results. Moreover, the model takes the form of a coarse finite state transducer based translation decoder which imitates the downstream system. This enables it to estimate translation quality even before the complete SMT system is used for decoding. Finally, the proposed model is featurized and may accept any weight from the ASR and SMT system that are deemed useful for optimizing translation quality.

The Spanish Fisher corpus is one of a few conversational speech translation datasets available, and we start with a strong baseline system. We therefore persevere with the experimental setup described above, even though the maximum (oracle) improvement by any rescoring method is only 6.5% BLEU, as noted above. This partially explains the small gains reported here, and suggests that this method should be evaluated further on another corpus, e.g. the Egyptian Arabic translation dataset, with greater headroom for improvement.
